Various clinical and special tests have been used in the evaluation of patients with hand–arm vibration syndrome. These include digital blood pressure measurements, vibrotactile thresholds, sensory aesthesiometry, and cold provocation tests. The clinical and occupational history is of greater importance than the results of any of the various tests in the diagnosis of hand–arm vibration syndrome.

The differential diagnosis should include other causes for Raynaud's phenomenon (constitutional or secondary to rheumatoid arthritis, systemic lupus erythematosus, scleroderma, and other autoimmune disorders, cryoglobulinaemia, frostbite, and the thoracic outlet syndrome). Use of ergot, clonidine, and b-blockers, occupational exposure to vinyl chloride monomer, and heavy cigarette smoking may be contributory factors.

Management, treatment, and prevention

The severity of hand–arm vibration syndrome can be staged using the Stockholm Workshop Scale (Table 1). The grade of the disorder is indicated by the stage and the number of affected fingers on each hand; for example, '2L(2)/1R(3)' refers to two digits at stage 2 in the left hand; and three digits at stage 1 in the right hand.

Engineering controls can minimize the transmission of vibration from machinery to the body or hands. The patient may be able to continue in their job following such action. Where the condition is severe and the source of vibration cannot be eliminated, redeployment should be considered. In early cases redeployment may arrest or reverse the progression of symptoms. In severe cases the disease can progress regardless of removal from further exposure to vibration.

Advice to the patient includes avoidance or reduction of further exposure to vibration, use of appropriate gloves, keeping the body and hands warm, especially in cold weather, and cessation of cigarette smoking. Vasodilatory drugs such as tolazoline, inositol, and cyclandelate, and calcium antagonists such as verapamil and nifedipine, angiotensin-converting enzyme inhibitors, prostaglandins, and stanazolol have been tried with varying success.

A diagnosis of Raynaud's phenomenon should always include detailed inquiry into occupational exposure to vibration. The diagnosis of a case of hand–arm vibration syndrome should be viewed as a sentinel event warranting further investigation of the workplace to assess whether improvements in work practices can be implemented to prevent other cases from occurring.

8.5.12 Disasters: earthquakes, volcanic eruptions, hurricanes, and floods

Peter J. Baxter

Deaths from natural disasters present a rising global trend. In the last half of the twentieth century, about 250 great natural disasters hit the planet, killing at least 1.4 million people and disrupting the lives of many millions more. At least 130 million people are affected each year by disasters and this number is rapidly increasing. Between 500 and 700 natural catastrophes are recorded every year and in the late 80s and 90s individual events entailed extremely large economic losses. Most human and economic losses have been from earthquakes, windstorms, and floods (Fig. 1). Global changes responsible for the worsening impact of disasters include the continuing, usually unplanned, expansion of populations into more and more exposed areas and the environmental degradation that is increasing the vulnerability of settlements, especially in heavily urbanized areas. This reckless development is going on throughout the world, even in areas of well-known risk.

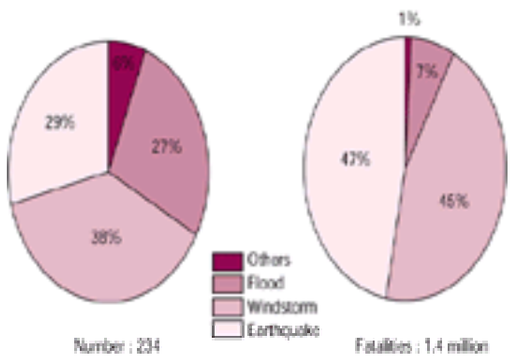

Fig. 1 Great natural catastrophes 1950 to 1999

Climate forecasts of an increase in the world's average temperature of 1.0 to 3.5°C and warming of the oceans could increase the potential for more intense hurricanes over wider areas and, in temperate regions, more severe wind storms and fluctuations in rainfall (floods and drought) and rising sea levels, increasing the frequency of severe coastal floods.

Predisaster measures

Disaster is the result of a vast ecological breakdown in the relation between humans and their environment, a serious and sudden (or slow, as in drought) event on such a scale that the stricken community needs extraordinary efforts to cope with it, often with outside help or international aid. Accurately forecasting the timing and size of natural disasters is rarely possible. This places major constraints on preventing loss of life by timely evacuation of people from the areas at risk. Disasters are quite different from major incidents in that normal lifelines and infrastructure usually break down. But despite their chaotic elements, disasters are amenable to scientific study and communities can develop planning and preparedness measures to reduce their impacts. Health workers have a key role in hazard management in risk assessment, predisaster planning and preparedness, as well as the emergency response.

Earthquakes

Many parts of the world are known to be at risk from devastating earthquakes, but it remains impossible to predict where and when a quake will strike. Most deaths and injuries are caused by collapsing buildings. Secondary causes such as fires can be important. Timber, masonry, reinforced concrete, and other types of buildings inflict injuries in different ways and to different degrees of severity when they collapse. In masonry buildings, an important cause of death is often suffocation from the weight and dust from the wall or roof material which buries the victims. The impacts of falling masonry cause crush injuries to the head and chest, external or internal haemorrhage, and chest compression (traumatic asphyxia). Little is know about the survival time of people trapped in collapsed buildings, but most victims die immediately or within 24 h, depending upon such factors as the severity of aftershocks, fire outbreaks, and rainfall. Rapid extrication of survivors and application of first aid by the uninjured immediately after the event could save up to 25 to 50 per cent of injured victims. The greatest demand for emergency medical services is within the first 24 h and the need for emergency treatment fades after 3 to 5 days. Causes of delayed death include dehydration, hypothermia, crush syndrome, and postoperative sepsis. Most of those requiring medical assistance suffer minor injuries such as lacerations and contusions.

A great earthquake struck Kobe City in Japan on 17 January 1995. It exposed serious flaws in the Japanese emergency services, as well as showing the need for comprehensive planning for medical care and welfare in earthquake-prone countries. The scale of disaster was beyond all expectations. The immediate victims included 5520 dead (10 per cent killed in fires) and 41 527 wounded. Four days later, 342 000 people (10 per cent of the total population of the region) were staying in shelters at a time of subzero temperatures. The plight of the elderly was not appreciated, as many of their carers were either dead or surviving as victims themselves. About 80 per cent of hospitals in the area were damaged, 7 per cent completely destroyed. Undamaged hospitals lacked the structural means to adapt rapidly to deal with overwhelming numbers of casualties requiring emergency care; the breakdown of supplies and water, electricity, and gas and failure of communications badly hampered other hospitals that were still functioning. The transfer of pharmaceuticals and medical equipment took longer than expected. The economic losses exceeded 100 billion US dollars, making it the costliest natural disaster in the world to date.

Volcanic eruptions

About 500 to 600 volcanoes around the world are known to be capable of eruptive activity and several major eruptions occur every year. The vast majority of volcanoes are explosive and unpredictable in behaviour, providing little opportunity for people to escape unless full evacuation measures are taken as soon as premonitory signs develop. This is in contrast to the less common lava flow eruptions, where people can normally escape by the time the lava flow heads towards them. Most deaths and injuries in explosive eruptions (such as engulfed ancient Pompeii) are caused by pyroclastic flows and surges, which are clouds of hot ash and gas that can travel at hurricane speeds. Survival is uncommon but victims will have extensive and severe skin burns, as well as inhalation injuries. The worst volcanic disaster in the twentieth century was at St Pierre, Martinique, in 1902, when 28 000 people were killed in a laterally directed pyroclastic surge. One of the most dangerous volcanoes in the world is Vesuvius, Italy, where uncontrolled building has resulted in over one million people living in an area which could be devastated by pyroclastic flows in a new eruption. Another major cause of death is lahars or wet flows of debris, either ash that has built up on the slopes of the volcano or unstable masses that are mobilized during the eruption or by rain, or rarely by release of water from a crater lake. The eruption of Ruiz del Nevada volcano in Colombia in 1984 triggered a lahar (mud flow) by rapid melting of the glacier at the summit, the melt waters rushing down valleys and mixing with debris as they went. Although adequate warning could have been given to the people below, lack of preparedness meant that the lahar engulfed towns including Armero, killing around 24 000 people. In one of the largest eruptions of the century, at Mount Pinatubo in the Philippines in 1991, 50 000 people were successfully evacuated from the threat of pyroclastic flows, but over 300 people died while sheltering in their homes from the collapse of roofs due to the accumulated weight of rain and ash.

The eruption of the Soufriere Hills volcano on the tiny Caribbean island of Montserrat began in July 1995 and gradually escalated, forcing the evacuation of thousands of people from their homes because of the threat of pyroclastic flows. By 1997, these flows had devastated the southern part of the island, evicting three-quarters of the population of 12 000 people. Air pollution from volcanic gases and ash has been a major consideration because of the close proximity of the

population to the volcano and the frequent eruption of fine, respirable ash containing hazardous amounts of the crystalline silica mineral, cristobalite, which can cause silicosis.

Hurricane and windstorm

Hurricanes are one of a broad class of extreme weather phenomena that include winter storms (snow, sleet, freezing rain, and freezes), thunderstorms (e.g. tornadoes, heavy rains, lightning, wind, and hail), extreme precipitation (e.g. flood and flash floods), and windstorms. Hurricanes (or typhoons as they are called in the Western Pacific) are tropical cyclones that form over warm oceans with ocean surface temperatures over 26°C. Once over land they soon run out of energy and rapidly abate, but can still cause flooding from heavy rain. Very high wind speeds, up to 250 km/h, are restricted to a relatively narrow track, usually no more than 150 km wide, within which localized gusts may even achieve tornado speeds and be extremely destructive. However, most deaths and injuries are not from the effect of wind on people (who normally remain inside for protection) or from building damage (building collapse or being struck by flying debris). Instead, deaths and injuries are very commonly the result of flooding from the sea surge as the hurricane strikes land, concurrent heavy rainfall (typically up to 60 cm, over a larger area and extending further inland than wind speed) and resulting landslides. Hurricanes lift the sea, forming a sea surge that typically rises 3 to 4 m above existing tides, with the wind generating waves on top of these.

Hurricane Andrew, which struck Florida in August 1992, was the most destructive natural disaster in the history of the United States and the third most intense storm to strike the United States in the twentieth century. Andrew developed sustained wind speeds above 250 km/h, even greater in localized tornado-like gusts. Mitigation measures (evacuation of three-quarters of a million people) held the death toll at 43. The most destructive effects of storm surge are on beaches and offshore islands, but in low-lying regions these can extend as far as 40 km inland. A dome of water lifted by the hurricane may be up to 100 km wide on open coasts. Such a surge drowned at least 200 000 people in Bangladesh in 1970. During a 2-week period in October/November 1998, Hurricane Mitch battered Central America. It unexpectedly slowed to a tropical storm and years of rainfall fell on Central America within a few hours. The result was about 13 000 slope failures and landslides, adding to the destruction of extensive flooding. Over 20 000 people were killed and over two million people left homeless.

Over 90 per cent of fatalities in hurricanes are drownings associated with storm surges or floods. Other causes of death include burial beneath houses collapsed by wind, penetrating trauma from broken glass or wood, blunt trauma from floating objects or debris, or entrapment in mudslides. The number of severe trauma patients among survivors is usually small; the greatest need in the postimpact phase is the provision of adequate shelter, water, food, and clothing, and sanitation. Most suffer from lacerations caused by flying glass or other debris, or minor trauma such as closed fractures and puncture wounds. After Hurricane Mitch the incidence of cholera and other water-borne diseases (leptospirosis, dengue, and malaria) increased, particularly in the urban areas.

Floods

In addition to the major losses of life that can be caused by hurricanes and their associated sea surges, floods mostly result from moderate to large events (rainfall, snow melt, high tides) occurring within the expected range of stream flow or tidal conditions. In Britain, as in many countries with low-lying coastal land, the hazard of coastal flooding from sea surges and high tides dominates over river flooding, although the latter is more frequent. Floods have been particularly devastating in China, with such notable historic disasters as the flooding of the Hung Ho in 1887 and 1931 claiming 900 000 and 3.7 million lives respectively. Over 40 million people are estimated to be affected yearly by flood. Flood warning and forecasting, combined with effective land management, community preparedness, and evacuation planning, are as essential as engineered river and coastal defences.

The primary cause of death from floods is drowning, but trauma from impacts with floating debris and hypothermia due to cold exposure is also important. The portion of survivors requiring emergency medical care is small, most injuries being minor, such as lacerations. This absence of victims with severe or multiple trauma is likely to reflect the long delay in reaching survivors, so they die from their injuries or from exposure before search and rescue teams can arrive. Increased morbidity and mortality in survivors who experience flooding was reported in the year after the East Coast Flood in 1953 and a river flood in Bristol in 1968; an increase in suicides and mental health problems were found in the aftermath of severe flooding caused by heavy rains in central Europe in July 1997.

Postdisaster relief

Myths surrounding postdisaster relief include:

- any kind of international assistance is needed;
- the affected population is too shocked and helpless to take responsibility for their own survival;
- natural disasters trigger secondary disasters through outbreaks of communicable diseases;
- life gets back to normal after a few weeks.

Most deaths in sudden-onset disasters happen long before outside aid arrives. However, relief teams have an important role in restoring roads and bridges, bringing in potable water, ensuring solid waste management, food protection, vector control, and sanitation. Attendances at medical facilities may return to normal within a few days of a disaster, and restoration of primary care then becomes a top priority rather than emergency treatment. Epidemiology has an important role in postdisaster assessment and health surveillance, particularly where relocation of large populations has occurred, as well as investigating the causes of mortality and morbidity in disasters, including mental ill health and long-term health sequelae.

9 Principles of clinical pharmacology and drug therapy

*Andrew Herxheimer**

Clinical pharmacology is the application of scientific principles to understanding the ways in which drugs behave and work in humans. Such understanding underlies rational drug therapy. Every decision to prescribe or use a drug comprises a series of separate decisions that are usually taken at great speed and often without enough thought. The main questions that must be decided are:

1. Does this patient's problem require a drug? What is likely to happen if no drug is used?
2. If a drug is needed, what type of drug action would be most appropriate?
3. Which class of drug will best provide the desired action?
4. Which particular drug in that class should be chosen, and in what pharmaceutical form?
5. What dose is to be used, how often, and at what times of the day or in what circumstances?
6. For how long is the drug to be used, initially and in the long term?
7. Will the cost of the drug matter to the patient?
8. How will the drug treatment fit into the overall treatment plan?
9. Will it be necessary to review the treatment? If so, when, how, and by whom?
10. What will the patient need to understand about treatment? Who will communicate this, and how?
11. What other help may the patient need to use the treatment optimally?

In a consultation all these questions cannot be considered from scratch. The physician must therefore answer as many of them beforehand as possible. This can be done with the help of appropriate therapeutic guidelines and a good formulary (which is really a specialized collection of guidelines concerning mainly one aspect of treatment, the choice of drug). Guidelines exist to provide thoroughly prepared decision paths for the common problems. The time and effort saved by using them enables physicians to focus on those aspects of an individual patient and problem that require individual adaptation of or departure from the relevant guideline. A guideline is like the trunk and large branches of an easily climbed tree—a decision tree. Once in the crown one is free to decide which small branch or leaf is the best. Many of the questions listed can only be answered satisfactorily after discussion between patient and doctor. For example, the patient's attitude to and feelings about taking medicines often determines whether or not to use a drug; the formulation chosen is influenced by the patient's needs or preference, for example difficulty in swallowing tablets or aversion to suppositories; the dosage regimen must be practicable for the patient. The best treatment decisions build on the patient's as well as the clinician's knowledge and experience. The clinician therefore has to find out about patients' experience of treatments—this should always be part of taking the history, but it is often forgotten.

The treatment history gives a necessary background for prescribing decisions because it can indicate how effective or ineffective previous treatment has been, and whether previous treatment has caused problems that should be avoided in the future. It can warn of possible interactions. It will show what the patient knows and believes about drugs and other treatments, as well as what he or she does not know about his/her treatment, and would like to know. Areas to ask about include:

- medicines currently being used, including dosage
- previous hospital treatment
- previous treatment from the family doctor
- 'alternative' treatments such as herbal or homeopathic medicines, acupuncture
- self-prescribed medicines
- past bad experiences with medicines, fears or worries about medicines.

Benefit and harm in prescribing

A doctor who prescribes a drug does so expecting that it will help the patient, and believing that any disbenefits, which may range from minor inconvenience or discomfort to a chance of serious harm, are acceptable. Such judgements are often referred to as assessments of the 'benefit/risk ratio', but this is a meaningless and confusing term. Risk means 'probability of harm', whereas benefit usually means 'amount of benefit'. Both benefit and harm have two dimensions, magnitude and probability, which must be clearly separated. Unfortunately we have no word for 'probability of benefit'.

The data that we have on benefits differ greatly from those used to estimate harm. Knowledge of the benefits to be obtained from a drug is almost always greater than knowledge of the harm that it may do. This is because the initial clinical research on a drug is done explicitly to assess the hoped-for benefits, which must occur in a high proportion of patients if the drug is to be useful, whereas harmful effects, especially unexpected ones, cannot be looked for in clinical trials—which are anyway too small to detect uncommon ones. Serious harm tends to affect relatively few patients and often is not suspected or discovered until a drug has been widely used for at least several years. As a result much less is known about the adverse effects of new drugs than about their benefits, and knowledge about harm accrues remarkably slowly in the first few years of a drug's life. If the drug is widely used, more of the iceberg gradually becomes visible. Because of the unknown risks of new drugs, it is better to choose older established drugs unless there is a clear reason for preferring a particular new drug.

Another dimension that must be considered is time: benefits are typically seen quickly, many adverse effects may not occur for years. That makes it even harder to weigh benefits against harm. Often they just cannot be compared. Two examples illustrate the problem.

First, in the case of pneumococcal pneumonia treated with penicillin, a cure is known to be likely and adverse effects are usually few and minor. However, if the patient is known to be allergic to penicillin, the risk of a serious adverse effect becomes too great and the benefit no longer outweighs the risk; in such a case another

antibiotic would be used. In this example the balance of benefit and harm is easily determined.

In contrast, consider the treatment with warfarin of a patient with atrial fibrillation and a history of bleeding peptic ulcer. Which outweighs the other: the potential benefit of preventing an embolic stroke by using the anticoagulant, or the risk of causing serious gastrointestinal bleeding? These two are not readily comparable, but a decision has to be made. It may be decided to use warfarin and hope to prevent serious bleeding with a proton pump inhibitor such as omeprazole, arguing that the degree of morbidity from an embolic stroke is likely to be more serious than that from an acute gastrointestinal bleed, with an approximately equal risk of mortality. But the patient may strongly dislike having to attend for regular monitoring of the anticoagulant effect (international normalized ratio, INR). There is no right answer.

The balance of benefit and harm from a particular treatment depends on four major factors:

1. the seriousness of the illness;
2. the effectiveness of the treatment;
3. the seriousness of possible adverse effects;
4. the risk of possible adverse effects.

If a disease is life threatening, if the drug to be used is highly effective and the only one available, and if the risk of serious adverse effects is negligible, the balance clearly favours the treatment. At the other end of the spectrum, if the disease is trivial, if the treatment is not very effective and more effective and safer alternatives exist, and if the risk of serious adverse effects is high, the likely harm outweighs the benefit. Table 1 illustrates this spectrum. Most cases lie somewhere between these two extremes.

The example of phenylbutazone, a highly effective non-steroidal anti-inflammatory drug, illustrates the principles involved. Use of the drug has a risk of marrow aplasia of between 1 in 30 000 and 1 in 100 000. While no other equally effective drugs existed, the benefit from phenylbutazone was considered great enough to outweigh the relatively high risk of marrow aplasia. However, once other equally effective and safer drugs became available, the risk of its adverse effects was seen to outweigh whatever benefit it gave, and its use was restricted.

Note that in making this decision to restrict the use of phenylbutazone the benefit was considered not in absolute terms but in relation to the severity of the disease and the benefit obtainable from other drugs. While phenylbutazone was more potent therapeutically than other available drugs it was considered highly beneficial, but when equally effective drugs arrived its net benefit was perceived to be less, although the therapeutic effect of the drug itself had not changed during that time. Phenylbutazone is still used today in some cases of severe ankylosing spondylitis that have responded poorly to other anti-inflammatory drugs. In those cases doctors and patients seem to believe that the benefit outweighs the risk of marrow aplasia.

Efficacy, effectiveness, efficiency of drugs

These terms need to be distinguished. Efficacy refers to any arbitrarily chosen effect, which may or may not be clinically relevant. It is best avoided in clinical contexts. Effectiveness means clinical effectiveness, and is defined as the likelihood and extent of the desired effects on the patient.

Efficiency is the ratio of effectiveness to cost: it is clearly more efficient to use the cheaper of two equally effective, equally safe, and equally reliable drugs.

The therapeutic index of a drug

The therapeutic index of a drug is the ratio of the dose at which adverse effects become important to that at which a therapeutic benefit is expected. This index does not have a numerical value, as precise estimates of these doses are not available and vary from person to person. Instead, drugs are divided into two categories, those with high and low therapeutic indices. For example, in the absence of hypersensitivity, penicillins have a high therapeutic index; very large doses can be given without fear of adverse effects. In contrast, digoxin has a low therapeutic index; it takes very little more to cause toxicity than to produce therapeutic benefit. Drugs with a low therapeutic index include the aminoglycoside antibiotics, anticoagulants, anticonvulsants, antihypertensives, some antiparasitic and antiviral drugs, cardiac glycosides, cytotoxic and immunosuppressant drugs, oral contraceptives, sympathomimetics, and drugs that act on the brain.

The benefit for a particular drug is more likely to outweigh the risk of harm if the drug has a high therapeutic index. In choosing between two equally effective drugs, one would choose the one with the higher therapeutic index.

Formularies

Formularies are lists of medicines for prescribers and pharmacists, intended to guide the choice and facilitate the dispensing of medicines. Many give details of the formulation and doses of drugs. Each formulary is produced primarily for a particular group, usually the prescribers in one country or region or institution, or even one practice. Most formularies are restrictive, that is they make a more or less narrow choice of medicines from all those available that could be used. This is typical for the formulary of a hospital, or of a health maintenance organization. A hospital formulary lists only the preparations that are stocked in the hospital pharmacy; a health maintenance organization formulary only those that the organization will pay for. The British National Formulary, probably the best known and most widely used formulary of all, differs in this respect, for it includes all medicines available for prescription in Britain, whether they are good choices and recommended or not. However, in every section concise and critical 'notes to facilitate the selection of suitable treatment' precede the list. These notes help prescribers everywhere (not only in Britain) to think, and add greatly to the value of the book, especially since it is updated twice a year and accessible electronically (http://bnf.org/).

The WHO 'Model list of essential drugs'

In many poor countries large sections of the population have no access to drugs or health care, and governments cannot afford to provide necessary drugs. To help them to use their limited funds in the best ways, the World Health Organization has since 1978 published a regularly updated 'Model list of essential drugs'. Essential drugs are defined as 'those that satisfy the health care needs of the majority of the population; they should therefore be available in adequate amounts and in the appropriate dosage forms'. The WHO list is called a model list because it cannot be used as it stands but must be adapted to the needs and priorities of individual countries. That is not easy, and WHO offers governments help with it and related work. Many developing countries now have an essential drugs programme.

The principles of clinical pharmacology

Drug therapy can be considered under four headings—pharmaceutical, pharmacokinetic, pharmacodynamic, and therapeutic—the four major processes of clinical pharmacology, each of which is associated with a question about drug therapy (Table 2, Fig. 1).

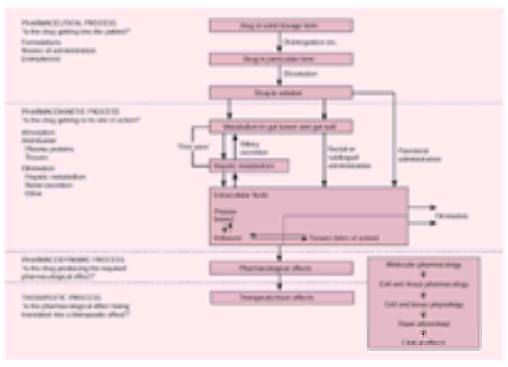

Fig. 1 The four processesses of clinical pharmacology in relation to drug therapy.

The pharmaceutical process

The pharmaceutical process concerns the question 'Is the drug getting into the patient from the appropriate formulation?'

Usually there is no need to worry about the formulation of a drug, beyond deciding whether to use the oral or parenteral route. For example, oral frusemide (furosemide) or bumetanide are prescribed as tablets. But sometimes the decision is harder. For example, in Britain six different oral lithium formulations exist, differing in strength and absorption characteristics. Glyceryl trinitrate is formulated for use orally, sublingually, buccally, transdermally, and as a spray. To understand the differences it is necessary to understand the concept of systemic availability.

Systemic availability

Systemic availability (commonly called bioavailability) is the proportion of administered drug that reaches the systemic circulation and is available for distribution to the site of action. The term usually refers to formulations given orally, but it can also refer to other routes of administration, such as intramuscular or transdermal.

When a drug is given intravenously it all enters the systemic circulation (systemic availability = 100 per cent).

When a drug is given orally in solution all the drug is immediately available for absorption. How much of it enters the systemic circulation will depend on the extent of absorption and the metabolic effect of the liver as it passes through for the first time (the so-called first-pass effect).

When a drug is given orally as a tablet or capsule the amount that enters the systemic circulation also depends on the properties of the formulation, including how fast the tablet disintegrates and how fast the drug particles dissolve in the intestinal fluid—the 'pharmaceutical availability'.

Prescribers rely on the pharmacist and pharmaceutical chemist to provide formulations of high stability and predictable pharmaceutical availability. When different formulations of the same drug are available the doctor may have to decide which to prescribe. This may be particularly important for drugs with a low therapeutic index, for which differences in pharmaceutical availability will matter. For example, if a patient is taking a formulation of low pharmaceutical availability that is producing a good therapeutic effect, switching to one of high availability can cause adverse effects.

Special drug formulations

Most drugs are given orally; oral formulations include elixirs, ordinary (quick-release) tablets and capsules, and modified-release formulations. However, drugs may be given by other routes, including sublingually, buccally, rectally, transdermally, by inhalation, and by injection intravenously, subcutaneously, intramuscularly, or locally.

Modified-release formulations

'Modified-release' formulations are oral formulations with some special release mechanism. Most are intended to prolong the duration of action of a drug and to smooth its effects by gradual release during the dosage interval. Examples include formulations of theophylline, nifedipine, diltiazem, and lithium. Prescriptions of these drugs should specify the exact formulation, as formulations differ in systemic availability.

Sublingual, buccal, rectal formulations

Drugs that are absorbed through the oral or rectal mucosa enter veins and pass into the systemic circulation intact, avoiding first-pass metabolism in the liver. For example, sublingual glyceryl trinitrate is effective in doses about 10 times less than those required by mouth and the effect is rapid. Rectal administration achieves a direct effect on the large bowel (for example corticosteroids in ulcerative colitis).

Transdermal formulations

Some drugs are well absorbed through the skin, and their transdermal administration via 'patches' allows controlled release of small amounts over many hours. Examples are glyceryl trinitrate in the long-term treatment of angina pectoris, transdermal hyoscine for travel sickness, estradiol as hormone replacement therapy, and nicotine for stopping smoking.

Inhalations

Inhaled formulations come in several forms, with different intentions. Sodium cromoglicate is in a powder for inhalation, designed to act locally on the bronchioles in the management of asthma. Salbutamol aerosol, on the other hand, is designed to produce bronchodilatation by a metered dose (100 µg) of droplets, small enough (2–5 µm) to reach the bronchioles. About 10 per cent of any inhaled drug reaches the bronchial tree, the rest being lost in the air, absorbed from the oropharynx, or swallowed. Nebulizers provide continuous administration of aerosolized drugs for short periods.

Subcutaneous, intramuscular, and local injections

The rate of absorption of insulin from the site of subcutaneous injection is controlled by its physical state (for example crystalline or non-crystalline), its zinc or protein content, and the nature and pH of the buffer in which it is suspended. Thus, soluble insulin has a rapid onset and short duration of action (about 6 h), while ultralente insulin, which has large crystals and a high zinc content, begins to act at about 7 h and acts for about 36 h.

Drugs are sometimes absorbed erratically from intramuscular injection sites; for phenytoin and diazepam the intramuscular route should be avoided if possible. Absorption may be retarded by the use of thick oils, which slow down diffusion of the drug from the site of injection and retard intramuscular absorption—for example vasopressin tannate in oil used in diabetes insipidus, and fluphenazine decanoate in oil in schizophrenia.

Some local anaesthetic injections contain adrenaline, which by vasoconstriction prevents rapid removal of the drug from the injection site.

Combination formulations in oral therapy

Combination products are seductive, but should be used only when at least two criteria are met:

- the frequency of administration of the two drugs is the same;
- the fixed doses in the combination product are therapeutically and optimally effective in most cases (i.e. when it is not necessary to alter the dose of one drug independently of the other).

Acceptable combination products include:

- Aspirin plus codeine (cocodaprin) or paracetamol plus dihydrocodeine (codydramol), pairs of drugs that have different analgesic actions (which summate) and different adverse effects (which do not).
- Levodopa plus a peripherally-acting dopa decarboxylase inhibitor (benserazide or carbidopa); the peripheral action of the decarboxylase inhibitor blocks peripheral metabolism of levodopa, which is free to enter the brain, where it is converted to the pharmacologically active product dopamine, producing the therapeutic effect in Parkinson's disease.
- Combined oral contraceptives, which contain an oestrogen and a progestogen.
- Ferrous sulphate plus folic acid, used to prevent anaemia in pregnancy.
- Coamoxiclav (amoxicillin plus clavulanic acid); the b-lactamase inhibitor, clavulanic acid, prevents the breakdown of amoxicillin by bacterial penicillinase, so

broadening its spectrum.

The patient's use of the medicine: compliance and concordance

Compliance is used as a technical term for the extent to which the patient follows a prescribed regimen. However, the word has unwelcome overtones, implying orders that the patient is expected to obey. The word 'concordance' has been introduced to supplant it, to make it clear that therapeutic decisions are best arrived at jointly by prescriber and patient agreeing on what to do. If both understand and accept the reasons for a particular choice, then the patient will be more committed to it than if a choice is imposed without explanation or discussion. This partly accounts for the wide variation in 'non-compliance', which in different studies has been found to be as low as 10 per cent and as high as 90 per cent. Compliance is affected not only by the behaviour of patient and doctor, but also by the nature of the treatment and the type of illness.

The nature of the treatment

Apart from the cost to the patient (which matters greatly in some countries), two main aspects of the treatment itself determine compliance, the complexity of the regimen and adverse effects. The complexity of the prescribed regimen involves two factors: the frequency of administration (the more often during the day patients have to take a drug the less likely they are to take it) and the number of drugs prescribed (the more drugs prescribed the less likely is overall compliance). It is difficult to take several medications at different dosages that involve different numbers of tablets at different times of the day.

If patients experience symptoms that they attribute to adverse drug effects (for example diarrhoea due to antibiotics or sedation due to anticonvulsants), then, unless they can be persuaded that the likely benefits of treatment outweigh the disadvantages, they will stop taking the medicine. Some patients, notably children and the elderly, have problems with certain formulations, for example sickly elixirs or large, dry, bitter tablets.

The type of illness

People who are severely mentally disturbed, for example patients with schizophrenia or manic-depressive psychosis, often take medicines unreliably.

Physical disability may cause difficulty even in patients who want to take their medicine. For example patients with rheumatoid arthritis who cannot reach the tablets or cannot remove the top of a child-proof container, cannot take them without help.

Sometimes a good response to treatment leads patients to stop. For example, patients with tuberculosis need long courses of several drugs to eradicate the infection; motivation may wane once the symptoms have resolved, risking reactivation and the emergence of resistant bacilli.

Some diseases may promote compliance. Patients with insulin-dependent diabetes easily become very ill quite quickly if they forget to take their insulin, and that is likely to make them comply, although they may not use it precisely as advised. Patients in whom a b-blocker or vasodilator has largely prevented anginal attacks will be conditioned to good compliance.

The patient's behaviour

People tend to forget to take medicines, or can't be bothered; they may feel no need for treatment (for example in asymptomatic hypertension); they may be unclear about the prescribing instructions; they may not want to feel dependent or be thought to be dependent on 'drugs'. There may be social or physical reasons why they cannot reach a pharmacist, financial difficulties, or everyday inconveniences in carrying and taking the medication. (See www.dipex.org/hypertension, for interviews in which patients talk about their tablets.)

The doctor's behaviour

The enthusiasm and confidence with which a treatment is prescribed, and the extent to which these attitudes are transmitted to the patient, may influence not only compliance but also the response to therapy. This is partly related to the placebo effect.

Methods of assessing compliance

It is important to assess compliance both in everyday practice and in clinical trials. The most obvious and usually the easiest approach is to ask the patient whether he or she has been taking the drugs, and whether there have been any problems. If the doctor is non-judgmental and indicates that difficulties are common, the patient is encouraged to be open.

Less directly one can ask to see the patient's tablets: this confirms that the prescription has been cashed. Counting the tablets left in the bottle is a guide to how many have been taken, but some may have been thrown away. Recording devices fitted in the caps of medication containers can record the frequency and exact timing of the opening of the container, and are useful in research.

When a patient is vague or untrustworthy, measurement of some compounds in the plasma or urine may give a good indication of compliance, but this does not allow for patients who take their treatment only on the day they visit the doctor. The compound measured may be the drug itself (for example phenytoin or lithium in the plasma, or salicylate in the urine) or a marker (for example riboflavin, which is easily detected in the urine).

Detecting the pharmacological effect of a drug can also give evidence of compliance; for example, the response of the heart rate for b-blockers, the prothrombin time for oral anticoagulants, and the reticulocyte count for haematinics. Failure to detect the pharmacological effect of a drug implies non-compliance or inadequate dosage. During long-term antibiotic therapy for urinary tract infection, antibacterial activity in the urine can be measured.

Obviously, if the desired therapeutic effect occurs the question of compliance is unimportant. However, a good therapeutic outcome may occur irrespective of the treatment used. It would be wrong to attribute a good outcome to the effect of a drug that the patient may not have taken; this is an important principle in clinical trials.

Methods of improving compliance

Compliance can be improved by supervised administration of the drug, by removing barriers to compliance, by simplifying the therapeutic regimen, and by educating the patient on the need to take the medicine, with reminders when possible.

Supervised administration

Administration of a drug by the doctor or nurse ensures compliance. This is possible in hospital or when only occasional administration is required (for example intramuscular injections of vitamin B_{12}, long-acting depot injections of neuroleptics in the treatment of schizophrenia, and supervised twice-weekly antituberculosis therapy). Sometimes a single dose of a drug can be given at the time of consultation, rather than a short course of tablets (for example an intramuscular antibiotic in the treatment of gonorrhoea). In some cases, a relative or other carer can give the drug at home.

Removing barriers to compliance

Compliance may be encouraged by prescribing pleasant-tasting elixirs rather than tablets for children and the elderly, and by using a drug or formulation that minimizes adverse effects.

Simplification of the therapeutic regimen

The therapeutic regimen can be simplified by reducing both the number of drugs a patient has to take and the frequency of administration. This can sometimes be

done with the help of modified-release or combination formulations.

Education and reminders

Educating the patient about why treatment is necessary (for example, treating hypertension or diabetes reduces the risk of serious complications) is time consuming but undoubtedly improves compliance. In the treatment of certain infections (as in patients with AIDS or tuberculosis and in typhoid carriers) the importance to the community should also be explained.

Even when patients are well motivated, reminders to take the treatment may improve compliance as it is easy to forget to take medication. Many medicines for long-term use are dispensed in a 'calendar pack', for example oral contraceptives.

Patients can be helped by a clearly written list of their current drugs, explaining the names, and labelling medicine bottles clearly. Information leaflets may also help to educate and remind them about their treatment.

The pharmacokinetic process

Pharmacokinetics concerns the question 'Is the drug getting to its site of action?' It comprises absorption and systemic availability, distribution, metabolism, and excretion.

Absorption and systemic availability

After an oral dose the amount of drug that reaches the systemic circulation depends on its absorption and how far it escapes metabolism in the gut, the liver, and the lungs. This is called its systemic availability (or bioavailability).

Systemic availability is defined in terms of the amount of administered drug that reaches the systemic circulation intact and the rate at which that happens. The rate of availability depends on pharmaceutical factors (see above) and gastrointestinal absorption, presystemic metabolism being relatively unimportant. But the extent of availability depends on both the extent of absorption and the extent of presystemic metabolism.

Figure 2 illustrates what is meant by the rate and extent of systemic availability. It shows three curves representing the theoretical plasma concentrations resulting over time after the same oral dose of three different formulations of the same drug. Each curve has three important attributes: the peak concentration (C_{max}), the time taken to reach the peak (t_{max}), and the total area under the curve (**AUC**). C_{max} and t_{max} are measures of the rate of availability, and the total AUC is a measure of its extent. In the three hypothetical cases the rates of availability clearly differ. For formulation I the systemic availability is rapid, perhaps too rapid, leading to potentially toxic plasma concentrations. Formulation II is less quickly available and plasma concentrations never reach the potentially toxic range. Formulation III is slowly available and plasma concentrations after a single dose are always subtherapeutic. However, in contrast to the rate of availability, the extent of availability of these three formulations, as assessed by the AUC, is the same in each case.

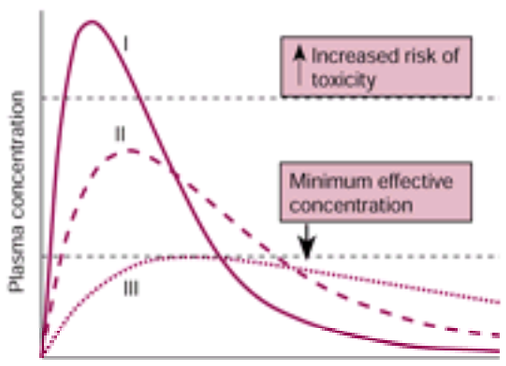

Fig. 2 The theoretical plasma concentrations resulting over time after the oral administration of three different formulations of the same dose of the same drug. The profile in each case depends on both the rate and the extent of systemic availability.

For drugs whose action may depend on the threshold plasma concentration achieved after a single dose (for example analgesics), such differences may be important. Thus, for the rapid relief of pain a soluble aspirin formulation, giving a curve like formulation II, would be preferable to an enteric-coated formulation, giving a curve like that of formulation III.

A curve of type I can be therapeutically useful if a very fast rate of absorption is needed to produce a quick therapeutic effect, for example sublingual glyceryl trinitrate to relieve an acute attack of angina pectoris, although it is also more likely to cause headache by dilating extracranial blood vessels.

For drugs whose action is related to a steady-state concentration during multiple dosing, the differences in rate of availability become less important and the chief consideration is the extent.

The rate of absorption

Gastrointestinal motility

Drugs are absorbed mainly in the upper small intestine, and altered gastric emptying therefore alters the rate. For example, in migraine the rate of absorption of analgesics is reduced because of reduced gastric motility, delaying the response to an oral analgesic. This delay can be reduced by giving metoclopramide, which hastens gastric emptying.

When a drug dissolves more slowly than the stomach empties, increased gastrointestinal motility may reduce both the rate and extent of absorption. Thus, in severe diarrhoea enteric-coated formulations may pass through the gut intact.

Malabsorption

Drug absorption is often impaired in patients with malabsorption, but not always. For example, the absorption of propranolol, cotrimoxazole, and cefalexin is increased in patients with coeliac disease. Digoxin, however, is less well absorbed from tablets in patients with coeliac disease, radiation-induced enteritis, and other gastrointestinal disease, and thyroxine absorption is impaired in coeliac disease.

Food

Food may alter the rate and extent of absorption of drugs. For example, eggs impair iron absorption, and milk (and any calcium, aluminium, magnesium, or ferrous salt) impairs tetracycline absorption by the formation of an insoluble chelate. But such effects are rarely important clinically.

First-pass metabolism

First-pass metabolism is metabolism that occurs before the drug enters the systemic circulation. This may happen in the gut lumen (for example with benzylpenicillin

or insulin), the gut wall (tyramine, chlorpromazine), the liver (the most important), and the lungs (various amines).

Many drugs undergo first-pass metabolism in the liver. For instance, propranolol is metabolized to 4-hydroxypropranolol, which is pharmacologically inactive.

When first-pass metabolism results in the formation of compounds with less pharmacological activity than the parent compound, the drug's efficacy is lower after oral than intravenous administration. In some cases (for example insulin) metabolism is so extensive that oral therapy is impossible. However, such a drug given sublingually, rectally, or transdermally, can bypass the liver (see above).

Distribution

Protein binding

Many drugs are bound to circulating proteins, usually albumin (acidic drugs), but also globulins (hormones), lipoproteins, and acid glycoproteins (basic drugs). Only non-protein-bound drug can bind to cellular receptors, pass across tissue membranes, and reach cellular enzymes, thus being distributed to other body tissues, metabolized, and excreted (for example by the kidney). Thus, changes in protein binding may sometimes cause changes in drug distribution. However, such changes matter only if the drug is more than 90 per cent bound in the plasma and is not widely distributed to body tissues. This is important mainly with phenytoin and warfarin.

The albumin binding of drugs may be changed in renal impairment (the explanation for this is unknown), hypoalbuminaemia (drug binding is reduced when the plasma albumin concentration falls below 25 g/l), the last trimester of pregnancy (during which protein binding is reduced partly because of hypoalbuminaemia), and displacement by other drugs.

The binding of drugs to a_1-acid glycoprotein is increased after trauma and surgery, and in inflammatory diseases and infections. For example, the binding of quinine is increased in malaria.

Tissue distribution

The extent of drug distribution to the tissues of the body varies widely. Some drugs enter only the body fluids, while others are bound extensively in tissues. The distribution of drugs to different tissues is influenced by plasma-protein binding, specific receptor sites in tissues (for example the binding of cardiac glycosides to Na^+,K^+-ATPase in cell membranes throughout the body), regional blood flow (well-perfused organs, such as the heart, kidneys, and liver, accumulate drugs more than poorly perfused organs, such as fat and bone), lipid solubility (non-polar relatively lipid-soluble drugs enter tissues more readily than polar compounds), active transport across cell membranes (for example the adrenergic neurone-blocking drugs), and the effects of other drugs (tricyclic antidepressants inhibit the active transport of the adrenergic neurone blockers, reducing their access to the site of action in the brain, and thus their efficacy).

In some diseases drug distribution is altered for unknown reasons. In renal failure, apart from its effect on protein binding, the distribution of some drugs (for example insulin and digoxin) may also be decreased. In cardiac failure the distribution of some antiarrhythmic drugs, such as disopyramide, is reduced. Obesity and malnutrition influence the distribution of drugs that are highly fat soluble (anaesthetics for example).

Metabolism

Most drugs are metabolized in the liver. Examples of other sites are: suxamethonium in the plasma; insulin and vitamin D in the kidneys; cytosine arabinoside, cyclophosphamide, and other cytotoxic drugs in many cells; and acetylcholine and other neurotransmitters at synapses and within nerves.

Drug metabolism occurs in two phases:

1. Phase I metabolism involves chemical alteration of the basic structure of the drug, for example by oxidation, reduction, or hydrolysis. Oxidation reactions are further subdivided according to whether or not they are effected by the cytochrome-linked mixed function oxidases. Examples of phase I reactions include the *N*-demethylation of diazepam to desmethyldiazepam, an active metabolite with a long duration of action, and the oxidation of ethanol to acetaldehyde.
2. Phase II metabolism involves conjugation, for example by sulphation, glucuronidation, methylation, or acetylation. Some drugs are conjugated without prior phase I transformation, while others undergo phase I metabolism before conjugation can occur. The end products of conjugation are compounds that are more water soluble and therefore more rapidly excreted by the kidneys. They are usually, though not always, pharmacologically inactive. Examples of phase II reactions are the glucuronidation of paracetamol, the *N*-acetylation of hydralazine and procainamide, and the methylation of desipramine to its active metabolite imipramine. A conjugated product may sometimes be further metabolized. For example, oestrogens are excreted via the bile, deconjugated in the gut by bacteria, and then reabsorbed.

The end-result of drug metabolism is inactivation, but during the process compounds with pharmacological activity may be formed. An inactive compound may be metabolized to an active one; inactive drugs administered for the effects of their active metabolites are called 'prodrugs'. Levodopa, for Parkinson's disease, can be regarded as a prodrug because it enters the brain and is there metabolized to dopamine. Usually a pharmacologically active compound is transformed to inactive compounds, but sometimes other active compounds are formed first. Examples of parent drugs with active metabolites include diamorphine (which is rapidly metabolized to morphine) and some benzodiazepines (such as diazepam, metabolized to desmethyldiazepam).

Some active compounds are metabolized to toxic compounds. Examples include pethidine (meperidine), the accumulation of whose toxic metabolite norpethidine limits the duration of therapy, and phenytoin, whose main metabolite may inhibit the further metabolism of phenytoin. The normally minor metabolic pathway by which paracetamol is metabolized to a toxic metabolite is enhanced in overdose because the usual detoxifying pathways are saturated (see Chapter 8.2.1).

The factors that affect hepatic drug metabolism are genetic (see pharmacogenetics below), other drugs (see drug interactions below), hepatic blood flow (for drugs that are rapidly cleared), liver disease (only important in extensive liver disease or when there is arteriovenous shunting), and age. The metabolism of some drugs is impaired in old people and in babies younger than about 6 months, particularly premature babies. In both cases this is due to reduced activity of the hepatic microsomal drug metabolizing enzymes. For example, in neonates uridine 5-diphosphate glucuronyl transferase, which conjugates chloramphenicol, is relatively inactive; neonates eliminate chloramphenicol slowly, and may suffer peripheral circulatory collapse (the 'grey syndrome') when given it in weight-related doses that do not harm adults.

Excretion

The kidney is the main route of drug excretion. Other, usually minor, routes include the lungs (important for paraldehyde), breast milk, sweat, tears, and genital secretions (alarming if the patient is not expecting the orange-red discoloration caused by rifampicin), saliva, and bile. Excretion in bile can lead to the reabsorption of some compounds in the gut, for example chloramphenicol (whose inactive metabolites are reactivated by hydrolysis in the gut), oestrogens (which bacteria in the gut deconjugate), morphine, rifampicin, and tetracyclines.

Renal excretion of drugs involves three main processes (Fig. 3): glomerular filtration, passive tubular reabsorption, and active tubular secretion. Thus:

Total renal clearance = Clearance by filtration + Clearance by secretion – Retention by reabsorption.

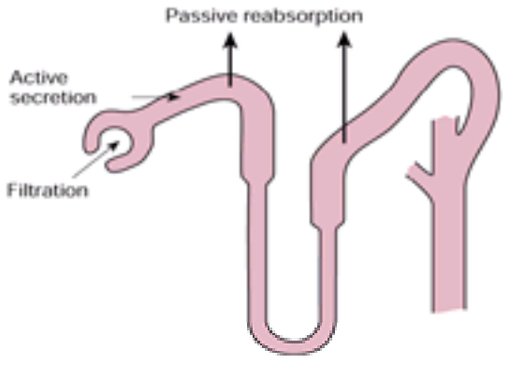

Fig. 3 A diagrammatic representation of a nephron, showing the sites of the three major processes of drug excretion via the kidney.

If a drug is mainly metabolized to inactive compounds, renal function will not greatly affect elimination of the active compound. However, if the drug or an active metabolite is excreted unchanged via the kidneys, changes in renal function will influence its elimination.

Glomerular filtration

All drugs are filtered at the renal glomerulus. The extent of filtration is directly proportional to the glomerular filtration rate (**GFR** = 120 ml/min) and to the fraction of unbound drug in the plasma (*fu*). Thus:

$$\text{Rate of clearance by filtration} = fu \times \text{GFR}.$$

If the total renal clearance of a drug is equal to *fu* × GFR then it is cleared principally by filtration. It may, of course, also be affected by the other two mechanisms, secretion and reabsorption, but in that case those effects must balance each other. Examples of drugs whose clearance is similar to the GFR (after correction for protein binding) are digoxin, gentamicin, procainamide, methotrexate, and ethambutol. As creatinine is cleared mainly by filtration, the creatinine clearance is useful in estimating the clearance rates of these drugs.

Passive tubular reabsorption

Drugs are passively reabsorbed by the renal tubules. The elimination of drugs with very low rates of renal clearance (i.e. approaching urine flow rate, or about 1–2 ml/min) will be significantly affected by changes in urine flow rate (because a doubling of flow rate will increase their rate of clearance by 1–2 ml/min, i.e. twofold). However, for weak acids and weak bases the main factor affecting passive reabsorption is the pH of the renal tubular fluid, because the extent of their ionization (and therefore of their passive reabsorption) depends on the pH when seen in relation to the p K_a of the drug. For example, in an alkaline urine weak acids with a p K_a below 7.5, such as aspirin, are more highly ionized, and therefore less well reabsorbed. The reverse is true for weak bases with a p K_a greater than 7.5, such as amphetamine, whose reabsorption is reduced, and whose clearance is therefore enhanced, by an acid urine. These principles are sometimes put to use in the treatment of overdose (see Section 8). Renal failure alters passive reabsorption indirectly, by changing urine flow rate and pH.

Active tubular secretion

If the renal clearance of a drug is greater than expected by filtration, it is also secreted actively by the proximal tubule. Penicillin is an example. Some drugs inhibit active tubular secretion, and this explains some drug interactions (see below).

Plasma half-life ($t_{1/2}$)

The half-life of a drug is the time it takes for the plasma concentration or amount of drug in the body to halve. In most cases it is constant, no matter what the starting concentration or amount. After one half-life, 50 per cent of the drug will be eliminated, after two half-lives 75 per cent (50 + 25 per cent), and so on. Thus, it takes between four and five half-lives for about 95 per cent of the drug to be eliminated. If the half-life of the drug is prolonged (as for digoxin in renal failure), elimination will take proportionately longer. The rate at which drug accumulates in the body during regular multiple dosing is determined by the half-life. Just as it takes four half-lives for 95 per cent of the drug to be eliminated after withdrawal, it takes four half-lives for about 95 per cent of steady state to be reached during regular administration (Fig. 4(a) and Fig. 5, bottom and middle curves).

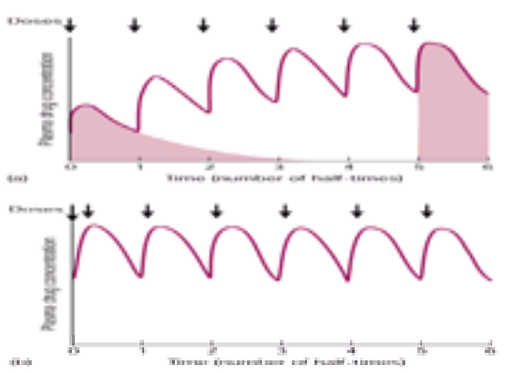

Fig. 4 (a) The theoretical plasma concentrations of a drug over time during its repeated oral administration. With repeated doses the drug accumulates to an eventual steady state. (b) If the correct loading dose is given a steady state can be achieved rapidly and then maintained by giving a smaller maintenance dose. In this example, because the drug is being given once every half-life the maintenance dose is half the loading dose.

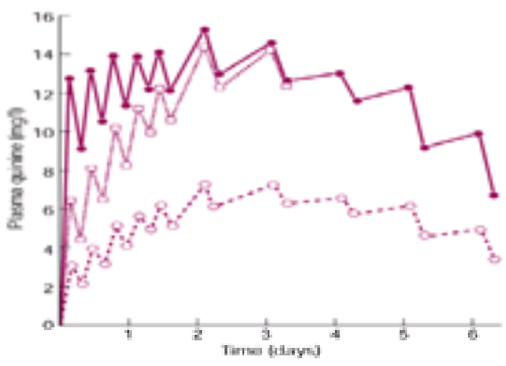

Fig. 5 Plasma quinine concentrations in cerebral malaria during repeated administration of 5 mg/kg every 8 h (bottom curve), repeated administration of 10 mg/kg every 8 h (middle curve), and repeated administration of 10 mg/kg every 8 h after a loading dose of 20 mg/kg (top curve). (From White NJ *et al*. (1983). Quinine loading dose in cerebral malaria. *American Journal of Tropical Medicine and Hygiene* **32**, 1–5, with permission.)

The delay in reaching a steady state can be overcome by giving a loading dose. When a drug has a half-life greater than 24 h (for example digoxin, 40 h; digitoxin 7 days; *S*-warfarin, 32 h), it takes several days or weeks of regular administration of the same daily dose before the steady-state plasma concentration or amount of drug in the body is reached. Such a delay may be unacceptable if the eventual steady-state plasma concentration is needed for a therapeutic effect. In such cases a loading dose can be given in order to boost the amount of drug in the body to the required level. Thereafter the regular maintenance dose is given to maintain the steady state (Fig. 4(b) and Fig. 5, top curve).

Non-linear kinetics

Although the pharmacokinetics of most drugs are linear, some are not. This means that some aspect of their kinetics becomes saturated in the therapeutic dosage range, so that a linear increase in dosage does not produce a proportionate increase in plasma concentration or effect. The prime example is phenytoin, whose enzymatic metabolism in the liver becomes saturated at dosages in the therapeutic range; plasma phenytoin concentrations therefore increase non-linearly with dosage.

The pharmacodynamic process

The pharmacodynamic process describes all those matters concerned with the pharmacological actions of a drug, whether they lead to therapeutic effects or adverse effects. The associated question is 'Is the drug producing the required pharmacological effect?'

Drugs produce their pharmacological effects in many different ways, often by stimulating or blocking a receptor (Table 3).

Actions via direct effects on receptors

Receptors are proteins situated either in cell membranes or within the cellular cytoplasm. For each type a specific group of ligands, drugs or endogenous substances exists that bind to the receptor and produce pharmacological effects. Ligands are of three types: agonists, antagonists, and partial agonists.

Agonists bind to a receptor and produce a response. For example, morphine is an agonist at μ opioid receptors, which mediate its analgesic action.

Antagonists (or blockers) prevent an agonist from binding to a receptor and thus prevent its effects. However, pure antagonists do not themselves have any pharmacological actions mediated by receptors. For example, naloxone is an opioid-receptor antagonist; when it binds to opioid receptors it prevents or reverses the effects of morphine and other opiates.

Unlike a full agonist, which is capable of producing a maximal response when it binds to enough receptors, a partial agonist cannot produce the maximal response of which the tissue is capable, even when it binds to the maximum number of available receptors. Thus, above a certain level of binding a partial agonist may bind to receptors without producing any further increase in effect. However, in so doing it may prevent the action of other agonists, and may thus behave as an antagonist. This mixture of actions is called partial agonism. For example, buprenorphine is a mixed opioid agonist/antagonist at μ receptors. If used in combination with a high dose of a pure agonist it will tend to oppose its action rather than supplement it.

Receptor subtypes

In some cases a receptor may have subtypes, for which certain ligands may have some selectivity. For example, of at least three subtypes of opioid receptors, μ and † are both involved in analgesia, gastrointestinal motility, and respiratory depression, and _ is involved in analgesia, sedation, and miosis. These receptors are variably distributed in the nervous system. Most opiates act at μ receptors, but none is completely selective and they may act at other subtypes.

Long-term effects of drugs at receptors

During long-term therapy the effects of a drug may be altered by adaptive responses, usually accompanied by either increases ('upregulation') or decreases ('downregulation') in receptor numbers. Such changes may explain both beneficial and adverse effects of drugs. Examples include:

- The therapeutic response to antidepressants, perhaps related to changes in receptors in the brain secondary to the actions of these drugs on neurotransmitter uptake. This could explain why the therapeutic response to antidepressants takes a few weeks.
- The way in which the response to levodopa in Parkinson's disease changes during long-term administration (producing, for example, the 'on–off' effect).
- Withdrawal syndromes that may occur because long-term changes become unopposed when the drug is withdrawn, for example after the long-term abuse of opiates, or the use of benzodiazepines in chronic anxiety.

Actions via direct effects on second messengers

When an agonist stimulates a membrane-bound receptor its effect is produced in one of two ways: either through a so-called second messenger (see Fig. 6) or by changing the activity of an ion channel linked to the receptor. Some drugs may act by affecting second messengers directly. For example, lithium may work by inhibiting phosphatidylinositol turnover at different sites. Theophylline and caffeine work by inhibiting the breakdown of cyclic AMP.

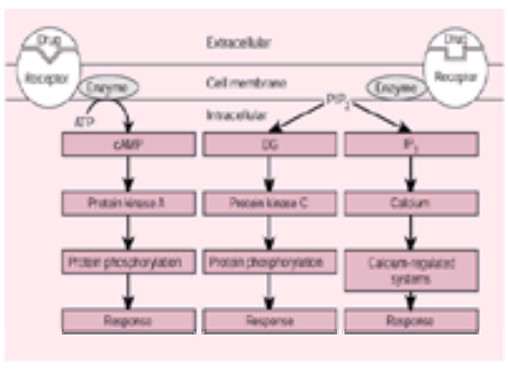

Fig. 6 A schematic representation of the second-messager systems that mediate the effects of drugs acting at receptors. PIP_2, phosphatidylinositol bisphosphate; DG, diacyl glycerol; IP_3, inositol triphosphate.

Actions via indirect alterations of the effects of endogenous agonists

Some drugs indirectly alter the effect of an endogenous agonist rather than acting via a receptor. Some oppose the physiological effects of others. For example, glucagon is a physiological antagonist of the actions of insulin and can be used to treat hypoglycaemia.

Increase in endogenous release

Some drugs enhance the action of endogenous agonists by increasing their release. For example, amphetamines increase the release of dopamine from nerve endings. Because amphetamines can cause a syndrome resembling schizophrenia, this action has led to the idea that schizophrenia may be related to excess

dopamine action in the brain.

Prevention of endogenous release

If a drug prevents the release of an endogenous agonist it will reduce its effects. For example, angiotensin-converting enzyme inhibitors prevent the formation of angiotensin II; this prevents the release of endogenous aldosterone, resulting in potassium retention.

Inhibition of endogenous reuptake

Some drugs inhibit the reuptake of endogenous agonists, enhancing their effects. For example, many antidepressants inhibit the reuptake by neurones of certain neurotransmitters, such as noradrenaline and 5-hydroxytryptamine.

Inhibition of endogenous metabolism

Some drugs potentiate endogenous agonists by inhibiting their metabolism. For example, vigabatrin inhibits the metabolism of g-aminobutyrate in the brain, enhancing its actions and suppressing seizures.

Actions via the inhibition of transport processes

Because cations (such as sodium, potassium, and calcium) and other substances (such as organic acids in the kidneys) have so many important roles in the maintenance of normal cellular function, inhibition of their transport is an important type of mechanism of drug action.

Diuretics

Most diuretics act by inhibiting sodium reabsorption in the renal tubules. The loop diuretics frusemide (furosemide)and bumetanide inhibit Na/K/Cl cotransport in the ascending limb of Henle's loop. The thiazide diuretics inhibit Na/Cl cotransport in the proximal segment of the distal convoluted tubule. The potassium-sparing diuretic amiloride inhibits sodium channels in the distal segment of the distal convoluted tubule.

Calcium antagonists

The calcium antagonists, such as verapamil, diltiazem, and the dihydropyridines (for example nifedipine), inhibit the transport of calcium via potential-operated calcium channels. The different calcium antagonists have different selectivities for calcium channels in different tissues, and have various actions. For example, verapamil has an antiarrhythmic action in the heart, and nifedipine a vasodilator action on peripheral arterioles.

Drugs acting on potassium channels

Potassium channels in cell membranes control the rate of efflux of potassium from the cells. Cellular activity is reduced by drugs that open K^+ channels and increased by drugs that close them.

Drugs that open potassium channels include vascular smooth muscle relaxants, such as minoxidil and hydralazine. Drugs that close them include the sulphonylureas, which increase the release of insulin from pancreatic b cells, and 3,4-diaminopyridine, which increases the release of acetylcholine at the neuromuscular junction.

Actions via enzyme inhibition

Some drugs act by directly inhibiting enzymes.

Neostigmine is a reversible cholinesterase inhibitor. It increases the concentration of acetylcholine at the muscle motor endplate, improving neuromuscular transmission. Xanthine and hypoxanthine are oxidized to uric acid by xanthine oxidase; this is inhibited by allopurinol, which therefore reduces the synthesis of uric acid in gout.

The monoamine oxidase inhibitors inhibit the metabolism of the monoamines 5-hydroxytryptamine, noradrenaline, and dopamine in the brain, and they presumably produce their antidepressant effect by this action. Just as drugs that act via receptors may be selective for a subtype of receptor, so monoamine oxidase inhibitors may be selective for one subtype of monoamine oxidase. For example, selegiline selectively inhibits monoamine oxidase type B: it inhibits the metabolism of dopamine in the brain and enhances the action of levodopa in parkinsonism. However, because gut monoamine oxidase is of type A, selegiline does not produce the 'cheese reaction' (due to tyramine and other amines, see below) that non-selective monoamine oxidase inhibitors do. In contrast, the antidepressant moclobemide selectively inhibits monoamine oxidase A; although it inhibits the metabolism of tyramine in the gut it does not inhibit its metabolism by monoamine oxidase B after absorption.

The cardiac glycosides act by inhibiting the Na/K pump, changing the disposition of sodium, which secondarily changes calcium disposition within cells.

Other drugs that act via enzyme inhibition include warfarin (vitamin K epoxide reductase), aspirin and other non-steroidal anti-inflammatory drugs (the enzymes involved in prostaglandin synthesis), angiotensin-converting enzyme inhibitors, disulfiram (alcohol dehydrogenase), some anticancer drugs such as cytarabine (DNA polymerase), and some anti-infective drugs (bacterial or viral enzymes; for example, trimethoprim inhibits bacterial dihydrofolate reductase, the quinolones inhibit bacterial DNA gyrase, and zidovudine and didanosine inhibit the reverse transcriptase of HIV).

Danazol and stanozolol are examples of drugs that inhibit an enzyme indirectly—they stimulate the production of an inhibitor of C1 esterase and are used to treat hereditary angio-oedema, in which there is reduced plasma activity of the inhibitor.

Actions via enzyme activation or direct enzymatic activity

Some drugs activate enzymes or are themselves enzymes.

The clotting and fibrinolytic factors are enzymes, and certain drugs that act on clotting and fibrinolysis do so by increasing their activity. Heparin acts by activating antithrombin III. The thrombolytic drugs streptokinase, alteplase, and anistreplase activate plasminogen.

Clotting factor deficiencies can be treated by replacing deficient enzymes of the clotting pathway, for example factor VIII in patients with haemophilia, and fresh frozen plasma in warfarin toxicity. Pancreatic enzymes are used in treating malabsorption in patients with chronic pancreatic insufficiency.

L-Asparaginase is an enzyme that hydrolyses asparagine, an essential amino acid in neoplastic cells. Some patients with acute lymphoblastic leukaemia may be helped by depriving their leukaemic cells of asparagine.

Actions via other miscellaneous effects

Chelating agents

Drugs that chelate metals can be used to hasten their removal from the body. Calcium sodium edetate chelates many divalent and trivalent metals and is used to treat poisoning, particularly with lead. Dimercaprol chelates some heavy metals and is used to treat mercury and gold poisoning. Desferrioxamine chelates iron and is used in treating iron poisoning and the iron overload that occurs with repeated blood transfusion (as in thalassaemia). Penicillamine chelates copper and is used in treating

hepatolenticular degeneration (Wilson's disease); it is also used to complex cystine and thus prevent renal damage in cystinuria.

Osmotic diuretics

Mannitol is freely filtered at the glomerulus but the renal tubules reabsorb only a little. It therefore increases the concentration of osmotically active particles in the tubular fluid and takes water with it.

Volatile general anaesthetics

General anaesthetics form a diverse group of agents, such as the halogenated hydrocarbons (halothane, trichloroethylene), and non-halogenated agents (nitrous oxide, ether, cyclopropane), which produce similar effects on the brain. Their main action is probably on the lipid matrix of the biological membrane, changing its biophysical properties, and so altering ion fluxes or other functions that influence neuronal excitability.

Replacement of vitamins and minerals

Some drugs are used simply to replace deficiencies, for example ferrous salts in iron deficiency anaemia and hydroxocobalamin (vitamin B_{12}) in vitamin B_{12} deficiency.

Stereoisomerism and drug action

Stereoisomerism (chirality) of organic compounds is due to asymmetry in one or more of their atoms (usually carbon), resulting in two structures (enantiomers) that cannot be superimposed on each other.

The terminology used to describe chiral compounds is complex, but in summary some are called *R* and *S* (from the Latin *rectus* = right and *sinister* = left), others D and L (from the Latin *dexter* = right and *laevus* = left), and yet others *d* and *l*. Examples of drug enantiomers are *R*-warfarin and *S*-warfarin, D-glucose (dextrose) and L-glucose (laevulose), and *d*-propran-olol and *l*-propranolol.

Of all synthetic drugs used in clinical practice about 40 per cent are chiral and about 90 per cent of those are marketed in the racemic form (i.e. as an equal mixture of the two enantiomers). Examples include *d*,*l*-propranolol and *R*,*S*-warfarin. Naproxen is one of the few examples of a synthetic compound that is marketed as a single enantiomer. In contrast, naturally occurring and semisynthetic compounds are almost all chiral and almost all are marketed as a single isomer. Examples include D-glucose (dextrose) and the naturally occurring amino acids (for example L-dopa).

Enantiomers often have differing actions. For example, *l*-propranolol is a b-blocker, while *d*-propranolol has membrane stabilizing activity like that of local anaesthetics; *l*-sotalol is a b-blocker, while *d*-sotalol has antiarrhythmic effects like those of amiodarone.

Sometimes the difference between enantiomers is a difference between therapeutic and adverse effects, as dramatically demonstrated by the example of thalidomide whose *R* enantiomer is hypnotic but whose adverse effects seem to be due to the *S* enantiomer.

In some cases, differences between enantiomers are limited to differences in potency. For example, *S*-warfarin and *R*-warfarin have the same anticoagulant actions, but the former is about five times more potent.

Sometimes enantiomeric differences tell us something about the mechanism of action of a drug. For example, *S*-timolol is a more potent b-blocker than *R*-timolol, but both are equally effective in reducing intraocular pressure in patients with glaucoma. This suggests that timolol lowers the intraocular pressure by a mechanism unrelated to b-blockade.

One enantiomer may be eliminated differently from the body than the other. For example, the half-lives of *S*-warfarin and *R*-warfarin are 32 h and 54 h, and the routes of metabolism are to 7-hydroxywarfarin for *S*-warfarin and to warfarin alcohols for *R*-warfarin. This is important in some drug interactions with warfarin, because some drugs (such as metronidazole) that inhibit the metabolism of warfarin, primarily affect the more potent enantiomer, *S*-warfarin.

Pure enantiomers of synthetic drugs are expensive to make, but new techniques may reduce the costs and lead to the emergence of more formulations of pure enantiomers for clinical use.

The therapeutic process

The question associated with the therapeutic process is 'Is the pharmacological effect being translated into a therapeutic effect?'

Translation of pharmacological effect into therapeutic effect during short-term therapy

The short-term therapeutic and toxic effects of drugs occur as a result of the pharmacological actions discussed above. However, the translation of molecular and cellular pharmacological effects into the therapeutic or toxic effect is not a simple process, but one that involves several translational stages at different pharmacological and physiological levels.

Take, for example, the action of salbutamol, a b_2-adrenoceptor agonist, in the treatment of asthma. Salbutamol stimulates bronchial b_2-adren-oceptors, and so increases the activity of adenylate cyclase; this is its pharmacological effect at the molecular level. The increase in adenylate cyclase activity leads to an increase in the intracellular concentration of cyclic AMP, a pharmacological effect at the cellular level. The increase in cyclic AMP in some way alters the function of bronchial smooth muscle cells, and results in an inhibition of the release of inflammatory mediators from bronchial mast cells, with effects on cell physiology. All this in turn results in bronchodilatation, an effect on tissue physiology. Bronchodilatation improves lung function, an effect on organ physiology. Finally, the patient can breathe more easily, the desired clinical effect.

This analysis of the short-term effects of drugs teaches us several things about drug action: how drug action may be modified; how therapeutic and adverse effects may be mediated via different pharmacological effects; the relation between the pharmacological effects of a drug and the rate of onset or duration of its action; and drug/disease interactions.

How drug action may be modified

It is often possible to modify the action of a drug beneficially or adversely. For example, one would expect a xanthine derivative, such as theophylline, which increases cellular cyclic AMP concentrations by the inhibition of phosphodiesterase, to potentiate the action of salbutamol at the stage at which it alters adenyl cyclase activity. This turns out to be both a beneficial and an adverse clinical interaction—beneficial because theophylline enhances the therapeutic action of salbutamol, adverse because it also enhances the hypokalaemia that salbutamol may cause by stimulating Na^+/K^+-ATPase.

Different pharmacological actions may mediate therapeutic and adverse or other effects

Some drugs have more than one molecular mechanism of action, and two different therapeutic effects of a drug may result from different actions. For example, tetracycline acts against bacteria by interfering with their protein synthesis, but in acne it helps by interfering with sebum production in sebaceous glands.

Similarly, a therapeutic effect may be brought about by one pharmacological action and an adverse effect by another. For example, the therapeutic effect of salbutamol results from its action on b_2-adrenoceptors, but it causes the unwanted effect of tachycardia by stimulating b_1-adrenoceptors.

Different therapeutic or adverse effects may be produced by the actions of a single drug on the same or a similar molecular mechanism in different tissues. For

example, the inhibition of b_2-adrenoceptors causes bronchoconstriction in the lungs of susceptible people and impairs glycogenolysis in the liver.

Peripheral or non-therapeutic effects of drugs can be clinically important in several ways. For example, aminoglycoside antibiotics can all damage the inner ear, leading to impaired hearing or loss of balance; these effects are quite separate from the antibiotic activity of these drugs but must be considered when choosing dosage regimens and mean that plasma concentration must be monitored.

The relation between the pharmacological actions of a drug and the rate of onset and duration of its effects

The rate of onset of action of a drug depends not only on its pharmacokinetics (i.e. the time it takes for the appropriate amount of drug to build up at the site of action; Fig. 4), but also on how long it takes for the full pharmacodynamic sequence of events to unroll. In the case of salbutamol the time between b_2-adrenoceptor stimulation and bronchodilatation (Fig. 7) is of the order of a few minutes. However, for other drugs the sequence of events takes much longer. For example, corticosteroids react with a receptor protein in cellular cytoplasm to form a steroid–receptor complex. This complex enters the cell nucleus, where it binds to chromatin and directs the genetic apparatus to transcribe RNA. This leads, for instance in liver cells, to the production of enzymes involved in gluconeogenesis and amino acid metabolism. Once the steroid has bound to its intracellular receptor it sets off a sequence of reactions that then has its own timescale, independent of the quantity of steroid, either in the blood or combined with the receptor. The induction of protein synthesis by RNA transcription takes several hours and each new protein has its own biological lifespan. This is why the effect takes hours or days to occur.

Similarly, the duration of action of a drug is related not only to the time it takes for the drug to be cleared from the body, but also to the duration of its pharmacological effects. For example, aspirin inhibits cyclo-oxygenase by acetylating a serine moiety at the active site of the enzyme. In platelets prostaglandin synthesis is thus inhibited for the lifetime of the platelet. So, although aspirin leaves the body within a few hours, its effect on platelets lasts for days.

Drug/disease interactions

Because of the complex links between the pharmacological effects of a drug and its therapeutic or adverse effects, the pathophysiology of the disease being treated, or of other incidental diseases, can variously alter the way in which the pharmacological effect is translated into a therapeutic effect.

The use of digoxin in cardiac failure is an example of the ways in which drug/disease interactions may influence therapy. Digoxin inhibits the activity of the membrane-bound Na/K pump. This is its pharmacological effect at the molecular level, which increases the intracellular concentration of sodium, and thereby alters the intracellular disposition of calcium (a pharmacological effect at the cellular level). This in turn leads to an alteration in the action potential of cardiac muscle (a physiological effect at the cellular level), which then causes an increase in the rate of contractility of the myocardial fibres (a physiological effect at the tissue level). Consequently cardiac output increases (a physiological effect at the level of the whole organ).

If this chain of events occurs without interruption the clinical result will be relief of the signs and symptoms of heart failure. However, drug/disease interactions can alter the therapeutic outcome at various stages in the chain. Thus, potassium depletion enhances the binding of digoxin to the Na/K pump and this increases the extent of inhibition of sodium transport, which can in turn cause digoxin toxicity. In hyperthyroidism the nature of the interaction between digoxin and the Na/K pump is altered, resulting in resistance to the inhibitory effects of digoxin. Increasing the dose may merely cause digoxin toxicity without ever producing a therapeutic effect. In patients with chronic cor pulmonale, digoxin may inhibit the Na/K pump and may even cause cardiac arrhythmias without ever increasing the rate of myocardial contractility. This may be because of tissue hypoxia and acidosis in cor pulmonale, which may also contribute to an increased risk of digoxin-induced cardiac arrhythmias without benefiting patients with acute myocardial infarction. In patients with hypertrophic obstructive cardiomyopathy, although digoxin increases the rate of myocardial contractility, this is not translated into an increase in cardiac output, as left ventricular outflow remains obstructed.

Thus even when it can be shown that a drug is having its expected action at a particular pharmacological or physiological level, it cannot automatically be assumed that it will have a consequent therapeutic effect.

Interactions with circadian phase

Most bodily functions vary in a circadian rhythm - for example sleep and wakefulness, urinary excretion, secretion of hormones—and drug effects are liable to differ at different phases of the rhythm. In some instances the difference is dramatic. For example melatonin taken late in the afternoon evening advances the circadian phase, and sleepiness comes earlier, whereas taken in the morning the same dose retards circadian phase. Bright light switches off the body's own melatonin release, darkness switches it on. So in the morning exogenous melatonin prolongs the effect of darkness, late in the day it switches on the response to darkness early. Another example is related to the secretion of cortisol by the adrenal cortex. A high plasma cortisol concentration inhibits corticotrophin release from the pituitary. Corticotrophin is secreted at night, and plasma cortisol peaks around 8 a.m., and about then the corticotrophin concentration is zero. Exogenous cortisol given at this time cannot inhibit corticotrophin release because none is occurring. But given in the evening it will completely inhibit corticotrophin release during the night. For this reason cortisol given once daily in the morning causes much less pituitary inhibition than the same dose given in the evening, or than doses spread over the 24 hours. Circadian therapeutics are complicated to study, and so far few practical examples are known. An important principle that is likely to find increasing application is that the 'hour of greatest therapeutic effect' will differ from the 'hour of greatest toxicity', since therapeutic and toxic effects are mediated by widely differing mechanisms. This could be exploited to increase the safety margin or tolerability of treatment, for example in cancer chemotherapy.

Translation of pharmacological effect into therapeutic effect during long-term therapy

During prolonged therapy adaptation may develop to the short-term pharmacological effects of the drug (Table 4), with several consequences.

Therapeutic effects through adaptation

In immunization, by adapting to an initial immunological challenge the immune system develops the ability to respond to a subsequent similar challenge, tetanus immunization for example.

Although tricyclic antidepressants rapidly inhibit reuptake of noradrenaline and 5-hydroxytryptamine in the brain, the therapeutic effect of these drugs takes 1 to 2 weeks to become evident. The brain adapts to the increased concentrations of noradrenaline and 5-hydroxytryptamine in the synaptic cleft in certain areas, where the sensitivity of responses to neurotransmitters is decreased by 'downregulation'; part of this adaptive effect could be the pharmacological action through which these drugs produce their therapeutic effects.

Tolerance: increasing ineffectiveness of therapy

Tolerance is a state of decreased responsiveness to a drug, resulting from previous exposure, either to the same drug or to one with similar short-term effects.

For example, it can develop to the vasoconstricting effects of ephedrine nosedrops, used to treat vasomotor rhinitis: as ephedrine acts by releasing noradrenaline from sympathetic nerve endings, when the noradrenaline is depleted the ephedrine can no longer be effective.

Patients who take long-term glyceryl trinitrate, particularly from transdermal patches, become tolerant and may not respond to its acute effects. To avoid this, a patch should be applied for no longer than 18 h. This effect probably reflects depletion of tissue sulphydryl groups by oxidation to disulphide groups.

Physiological tolerance by homoeostatic mechanisms

Secondary hyperaldosteronism is a physiological response to sodium loss produced by loop or thiazide diuretics. The enhanced potassium excretion that it causes may be obviated by using a potassium-sparing diuretic (for example amiloride) or the aldosterone antagonist spironolactone.

Another type of physiological tolerance occurs in patients given the diuretic acetazolamide. This is a powerful kaliuretic and can cause severe potassium depletion when it is first given. However, because it inhibits carbonic anhydrase activity in the kidney it causes bicarbonate depletion, and the resulting acidosis causes

retention of potassium. Thus, potassium depletion due to acetazolamide lasts for only a few days or weeks.

Metabolic tolerance

Metabolic tolerance results from faster metabolism of the drug. The commonest cause is induction of hepatic microsomal drug metabolizing enzymes by drugs such as barbiturates, phenytoin, or carbamazepine. In a particular case, the hepatic inactivation of the carbamazepine is increased after long-term exposure to carbamazepine itself (the phenomenon known as 'autoinduction'), and tolerance occurs spontaneously. Induction of drug metabolism can lead to adverse drug reactions (see below).

Withdrawal syndromes

A common, though not inevitable, outcome of an adaptive response to long-term drug use is the occurrence of a withdrawal response, which occurs either when the drug is withdrawn or when an antagonist is given, and which usually takes the form of some sort of adverse reaction.

A withdrawal syndrome occurs in opiate addicts when the opiate is withdrawn or when an antagonist, such as naloxone, is given. The symptoms consist of yawning, rhinorrhoea, and sweating, followed by shivering and goose flesh ('cold turkey'); later, nausea, vomiting, diarrhoea, and hypertension may occur. The acute syndrome subsides within a week, but the addict may be anxious and sleep badly for several weeks or months after. This syndrome can be avoided by introducing increasing doses of methadone as the opiate is withdrawn, as the later withdrawal of methadone, which has a much longer duration of action than morphine, may not result in this syndrome.

Delirium tremens may occur on withdrawal of alcohol from chronic alcoholics. This syndrome consists of disorientation and visual hallucinations. Withdrawal of benzodiazepines after long-term therapy may result in a disturbance of sleep pattern (rebound insomnia associated with abnormal sleep patterns), agitation, restlessness, and occasionally epileptic convulsions.

The risk of angina pectoris, myocardial infarction, and arrhythmias is increased in patients with ischaemic heart disease when b-adrenoceptor antagonists are withdrawn after long-term use. This may be due to an increase in the numbers of cardiac b-adrenoceptors, with increased sensitivity to the b-adrenergic effects of sympathetic stimulation.

Angina and even myocardial infarction have been reported in munitions workers who have become tolerant of the effects of nitroglycerine (glyceryl trinitrate) and have taken a break from work.

Long-term therapy with corticosteroids suppresses pituitary secretion of adrenocorticotrophic hormone, leading to adrenal cortical atrophy. When treatment is suddenly withdrawn, secretion of adrenocorticotrophic hormone by the pituitary may take several weeks or months to recover. Because the adrenal cortex has to increase in size again in order to become normally responsive to adrenocorticotrophic hormone the patient is at great risk of an addisonian crisis if stressed.

Adverse effects directly due to adaptation

Patients taking a neuroleptic drug (for example chlorpromazine, fluphenazine, or haloperidol) continuously for a long time commonly develop abnormal movements (known collectively as tardive dyskinesia). The face, mouth, and tongue are often affected, with stereotyped sucking and smacking of the lips, lateral jaw movements, and darting movements of the tongue. Occasionally more widespread dyskinesia may resemble choreoathetosis. The long-term blockade of brain dopamine function with neuroleptics is thought to lead to increased sensitivity to the effects of dopamine in certain areas of the brain, perhaps by increasing the number of dopamine receptors. Tardive dyskinesia may result from such increased sensitivity in extrapyramidal areas of the brain.

Adverse drug reactions

Adverse effects are unwanted effects of drugs, and they may be either toxic effects or side-effects. A toxic effect is an adverse effect that arises through an exaggeration of the pharmacological action that is responsible for the therapeutic effect of the drug (for example arrhythmias due to digoxin), and is therefore dose related. A side-effect is an adverse effect that arises through some pharmacological action other than that which produces the therapeutic effect (for example the anticholinergic effects of tricyclic antidepressants); such effects may or may not be dose related. The term 'adverse effects' covers all types of unwanted effects.

Incidence

The risks of adverse drug reactions have been variously estimated as follows:

- 10 to 20 per cent of hospital inpatients suffer an adverse reaction;
- 0.24 to 2.9 per cent of deaths in hospital inpatients are due to adverse reactions;
- 0.3 to 5.0 per cent of hospital admissions are due to adverse reactions.

Classification (see Table 5)

Dose-related adverse reactions

Dose-related adverse drug reactions are usually due to a pharmacokinetic or pharmacodynamic abnormality producing an exaggeration of a known pharmacological effect of the drug. The pharmacological effect that proves adverse may be the same as that which achieves the therapeutic effect (for example hypoglycaemia due to insulin), or due to another effect occurring in parallel (the anticholinergic action of tricyclic antidepressants, producing a dry mouth or urinary retention).

Dose-related adverse reactions may occur because of variations in the pharmaceutical, pharmacokinetic, or pharmacodynamic properties of a drug, often due to some disease or pharmacogenetic characteristic of the patient. These mechanisms are illustrated below.

Pharmaceutical defect

Adverse reactions can be caused by a contaminant, for example pyrogens or even bacteria in intravenous formulations, if quality control breaks down. If a febrile reaction occurs in a patient being given an infusion, the drip should be taken down and all its components sent for bacteriological investigation. The manufacturer should be urgently notified.

Out-of-date formulations may sometimes cause adverse reactions because of degradation products. For example, outdated tetracycline may cause Fanconi's syndrome, because it is degraded to anhydrotetracycline and epiandrotetracycline. The omission of the preservative citric acid from tetracycline formulations has reduced the risk of this effect, but has not removed it completely.

Pharmacokinetic variation

Normal individuals vary greatly in their rate of elimination of drugs. This variation is greatest for drugs cleared by hepatic metabolism and is determined by several factors, which may be genetic, environmental (diet, smoking, alcohol), or hepatic (blood flow and intrinsic drug-metabolizing capacity). On top of this normal variation specific pharmacogenetic or hepatic abnormalities may be associated with adverse reactions. In addition, renal and cardiac disease can change drug pharmacokinetics. Pharmacogenetics is discussed below.

The reserve of the liver parenchyma is large, and adverse reactions due to impaired hepatic metabolism are uncommon. Nevertheless, in patients with severe liver disease care must be taken, particularly with drugs with a low therapeutic index and those subject to extensive first-pass elimination. For example, hepatocellular dysfunction, as in severe hepatitis or advanced cirrhosis, may reduce the clearance of drugs for which the capacity of the liver is limited, phenytoin, theophylline, and warfarin for example. Portosystemic shunting in portal hypertension, associated with cirrhosis, reduces the clearance of drugs normally cleared rapidly by the liver, for

example morphine and other narcotic analgesics, propranolol, labetalol, and chlorpromazine.

Drugs that the kidneys excrete unchanged, or whose active metabolites are excreted, will accumulate in renal failure. Important examples include digoxin, lithium, tetracyclines, aminoglycoside antibiotics, and vancomycin.

Pharmacodynamic variation

People vary greatly in their pharmacodynamic responses, and that variability may be compounded by the effects of disease, as the following examples show.

Liver disease may influence pharmacodynamic responses to certain drugs by several mechanisms. Blood clotting may be impaired in cirrhosis and acute hepatitis because of reduced production of clotting factors; patients with oesophageal and gastric varices caused by portal hypertension in cirrhosis are also at risk of bleeding. Drugs that may impair haemostasis, or that may predispose to bleeding by causing gastric ulceration, should be avoided; these include anticoagulants and non-steroidal anti-inflammatory drugs (for example aspirin, indometacin, ibuprofen).

In patients with hepatic encephalopathy (hepatic coma or precoma), the brain is more sensitive to the effects of sedating drugs. It is therefore wise to avoid opioid and other narcotic analgesics and barbiturates; chlorpromazine dosage should be reduced. Chlormethiazole or a short-acting benzodiazepine may be used cautiously as a tranquillizer.

Diuretics used to treat ascites and peripheral oedema may precipitate hepatic encephalopathy, particularly if diuresis is too rapid.

In hepatic cirrhosis, certain drugs may exacerbate sodium and water retention; they include indometacin, corticosteroids, and carbamazepine.

The pharmacodynamic effects of some drugs may be altered by changes in fluid and electrolyte balance. For example, both hypokalaemia and hypercalcaemia potentiate the toxic effects of digoxin. The class I antiarrhythmic drugs, such as quinidine, procainamide, and disopyramide, may be more arrhythmogenic in hypokalaemic patients, and this combination particularly increases the risk of polymorphous ventricular tachycardia. Hypocalcaemia prolongs the action of muscle relaxants such as tubocurarine. Fluid depletion enhances the hypotensive effects of antihypertensive drugs.

Non-dose-related adverse reactions

Non-dose-related adverse drug reactions are caused by immunological and pharmacogenetic mechanisms. Allergic drug reactions are:

- Unrelated to the usual pharmacological effects of the drug.
- A delay often occurs between the first exposure to the drug and the subsequent adverse reaction.
- Very small doses of the drug may elicit the reaction once allergy is established.
- The reaction disappears on withdrawal; and the illness is often recognizable as a form of immunological reaction, for example rash, serum sickness, anaphylaxis, asthma, urticaria, angio-oedema.

Factors associated with an increased risk of allergic drug reactions include a history of allergic disorders (patients with a history of atopic disease and those with hereditary angio-oedema) and HLA status (the risk of nephrotoxicity from penicillamine is increased in patients with the HLA types B8 and DR3, and reduced in patients with HLA DR7; the risk of skin reactions with penicillamine is associated with HLA DRw6, and that of thrombocytopenia is associated with HLA DR4; patients with HLA DR4 also have a greater risk of the lupus-like syndrome (see below) when it is associated with hydralazine).

Drug allergy and its manifestations are classifiable according to the classification of hypersensitivity reactions, i.e. into four types, I to IV (see Section 5).

Type I reactions (anaphylaxis; immediate hypersensitivity)

In type I reactions the drug or metabolite interacts with IgE molecules fixed to cells, particularly tissue mast cells and basophil leucocytes. This triggers a process that leads to the release of pharmacological mediators (histamine, 5-hydroxytryptamine, kinins, and arachidonic acid derivatives), which cause the allergic response.

Clinically, type I reactions manifest as urticaria, rhinitis, bronchial asthma, angio-oedema, and anaphylactic shock. Drugs likely to cause anaphylactic shock include penicillins, streptomycin, local anaesthetics, and iodide-containing radiographic contrast media.

Type II reactions (cytotoxic reactions)

In type II reactions a circulating antibody of the IgG, IgM, or IgA class interacts with a hapten (drug) combined with a cell membrane constituent (protein), to form a hapten–protein/antigen–antibody complex. Complement is then activated and cell lysis occurs. Most examples are haematological: thrombocytopenia from quinidine or quinine ('gin and tonic purpura'), and occasionally rifampicin; 'immune' neutropenia, which can be difficult to distinguish from neutropenia occurring as a direct toxic effect on the bone marrow—phenylbutazone, carbimazole, tolbutamide, anticonvulsants, chlorpropamide, and metronidazole have all been incriminated; and the haemolytic anaemias that penicillins, cephalosporins, rifampicin, and quinidine can also produce by this mechanism.

Type III reactions (immune complex reactions)

In type III reactions, antibody (IgG) combines with antigen, that is the hapten–protein complex, in the circulation. The complex so formed is deposited in the tissues, complement is activated, and damage to capillary endothelium results.

Serum sickness, with fever, arthritis, enlarged lymph nodes, urticaria, and maculopapular rashes, is the typical drug reaction of this type. Penicillins, streptomycin, sulphonamides, and antithyroid drugs may cause it. Another type III reaction is the acute interstitial nephritis that may be caused by penicillins, some non-steroidal anti-inflammatory drugs, and some diuretics.

Type IV reactions (cell-mediated or delayed hypersensitivity reactions)

In type IV reactions, T lymphocytes are sensitized by a hapten–protein antigenic complex. When the lymphocytes meet the antigen an inflammatory response ensues. Examples are the contact dermatitis caused by local anaesthetic creams, antihistamine creams, and topical antibiotics and antifungal drugs. Rashes in response to sulphonamides and thiacetazone are more common in people infected with HIV.

Pseudoallergic reactions

'Pseudoallergy' (included here for convenience) is a term applied to reactions that resemble allergic reactions clinically but for which no immunological basis can be found. For example, asthma and rashes caused by aspirin are pseudoallergic reactions. In some asthmatics aspirin may trigger an attack of asthma. Aspirin-sensitive asthmatics are often sensitive to other salicylates and to other non-steroidal anti-inflammatory drugs, such as indometacin and ibuprofen. In addition, about half of aspirin-sensitive asthmatics are also sensitive to tartrazine (E102), a yellow dye used to colour some medicines and foodstuffs.

In some patients the administration of ampicillin or amoxicillin causes a maculopapular erythematous rash resembling the toxic erythema which can occur in penicillin hypersensitivity. However, the so-called ampicillin rash seems not to have an immunological origin. It can be distinguished from true penicillin hypersensitivity by its later onset after the first dose (typically 10–14 days compared with 7–10 days in penicillin hypersensitivity, though they overlap) and non-recurrence after re-exposure. Unlike penicillin hypersensitivity it carries no increased risk of a serious allergic response to other penicillins. An ampicillin rash occurs in about 1 per cent of the normal population, but in a much higher proportion of some groups of patients: it occurs almost invariably in patients with some viral infections (for example infectious mononucleosis, cytomegalovirus infection, measles), lymphomas, and leukaemias, and the risk is increased in patients taking allopurinol.

Clinical manifestations of allergic reactions

The immunological mechanistic approach does not always fit the clinical presentation, in which one is generally faced with some allergic syndrome.

Drug fever as an isolated phenomenon can occur with penicillins, phenytoin, hydralazine, and quinidine. Such fevers are usually of low grade and the patient is generally not very ill. The fever subsides within a few days of stopping the drug. With the penicillins it can sometimes be difficult to distinguish drug fever from a fever that persists because of resistant infection. Fever is also a manifestation of the neuroleptic malignant syndrome, a rare serious idiosyncratic adverse reaction of unknown cause, usually manifested by a sudden onset of fever, akinesia, rigidity, reduced consciousness, and autonomic disturbances including tachycardia and hypertension; it can kill, and demands emergency treatment by active cooling and intravenous dantrolene.

Rashes of several types may occur, including toxic erythema (due for example to antibiotics, sulphonamides, thiazide diuretics, frusemide (furosemide), sulphonylureas, phenylbutazone), urticaria (penicillins, codeine, dextrans, radiographic contrast media), erythema multiforme (penicillins, sulphonamides, barbiturates, phenylbutazone), erythema nodosum (sulphonamides, oral contraceptives), cutaneous vasculitis (sulphonamides, thiazide diuretics, allopurinol, indometacin, phenytoin), exfoliative dermatitis and erythroderma (gold salts, phenylbutazone, isoniazid, carbamazepine), photosensitivity (amiodarone, sulphonamides, thiazide diuretics, sulphonylureas, tetracyclines, phenothiazines, nalidixic acid), fixed eruptions (barbiturates, sulphonamides, tetracyclines), and toxic epidermal necrolysis (Lyell's syndrome) (phenytoin, sulphonamides, gold salts, tetracyclines, allopurinol).

Drugs may produce thrombocytopenic purpura (for example quinine, digitoxin, rifampicin) or purpura from capillary damage or fragility without thrombocytopenia (corticosteroids, thiazide diuretics).

A syndrome mimicking systemic lupus erythematosus, often involving joints and generally without renal involvement, may follow treatment with hydralazine, procainamide, phenytoin, or ethosuximide. Although this reaction is conveniently discussed here it is to some extent dose dependent, as the risk is increased at higher drug doses, and with hydralazine and procainamide it is more common among slow acetylators.

Asthma occurring as a pseudoallergic reaction to non-steroidal anti-inflammatory drugs and tartrazine has been noted above. Other adverse reactions in the lung include pneumonitis associated with the lupus-like syndrome (see above), pulmonary eosinophilia, and fibrosing alveolitis.

Jaundice may occur as an allergic response to some drugs through either cholestasis (for example with phenothiazines, erythromycin, and chlorpropamide) or generalized liver damage (for example with halothane, isoniazid and monoamine oxidase inhibitors).

Long-term effects causing adverse reactions

Some adverse effects during long-term therapy are related to both the duration of treatment and the dose.

Adaptive changes

These are the basis of some adverse reactions. Examples include the development of tolerance to and physical dependence on narcotic analgesics, and tardive dyskinesia in some patients receiving long-term neuroleptic therapy for schizophrenia.

Rebound phenomena

When adaptive changes occur during long-term therapy, sudden withdrawal of the drug may result in rebound reactions. Examples include the typical syndromes that occur after the sudden withdrawal of narcotic analgesics or of alcohol (delirium tremens). Sudden withdrawal of barbiturates may result in restlessness, mental confusion, and convulsions, and a similar syndrome in which anxiety features prominently may occur after the sudden withdrawal of benzodiazepines. Sleeplessness may also be a feature of the sudden withdrawal of these and a variety of other hypnotic drugs. Sudden withdrawal of some antihypertensive drugs may result in rebound hypertension; this was common with clonidine. Sudden withdrawal of b-adrenoceptor antagonists may result in rebound tachycardia and arrhythmia, sometimes precipitating myocardial ischaemia.

Sudden withdrawal of corticosteroids can cause acute adrenal insufficiency; after long-term administration withdrawal should be very slow.

Reversal of the effects of heparin with protamine sulphate may be associated with rebound hypercoagulability and an increased risk of thromboembolism. However, this risk may have to be taken when heparin overdosage has caused life-threatening bleeding. But the withdrawal of oral anticoagulants, such as warfarin, does not lead to rebound hypercoagulability.

Other long-term effects

Chloroquine may accumulate in the corneal epithelium (causing a keratopathy) and in the retina (causing a pigmentary retinopathy and blindness). The former occurs in over 90 per cent of patients on long-term therapy; the latter is less common but it is more serious. The risk increases with daily doses of over 4 mg/kg and in patients also taking probenecid.

Some of the long-term adverse effects of amiodarone are caused by the deposition in the tissues of lipofuchsin, including a neuropathy, pulmonary alveolitis, liver damage, microdeposits in the cornea, and skin phototoxicity.

Delayed effects causing adverse reactions

Carcinogenesis

The incidence of vaginal adenocarcinoma is increased in the daughters of women who took diethylstilbestrol during pregnancy (hoping to prevent threatened abortion). The incidence of uterine endometrial carcinoma is probably increased in women taking oestrogen replacement therapy for menopausal symptoms, and oral contraceptives increase the incidence of benign liver tumours. Anabolic steroids carry an increased risk of liver tumours.

Various anticancer drugs increase the risk of tumours. Examples include the increased risk of bladder cancer with long-term cyclophosphamide, and of non-lymphocytic leukaemias with alkylating agents such as melphalan, cyclophosphamide, and chlorambucil. Similarly, patients on immunosuppressive drug regimens, such as azathioprine with corticosteroids, have a greatly increased risk of developing lymphomas. This has mainly been noted after renal transplantation, but also in other patients.

Adverse reactions associated with reproduction

Some drugs impair fertility. For example, cytotoxic drugs can cause ovarian failure with amenorrhoea. Sperm production may be reversibly impaired by sulphasalazine, nitrofurantoin, monoamine oxidase inhibitors, and antimalarials, and irreversibly by cytotoxic drugs.

Teratogenesis

Teratogenesis occurs when a drug taken early in pregnancy causes a developmental abnormality in a fetus. The first trimester of pregnancy, and particularly the period from the second to the eighth weeks of gestation, the period of organogenesis, is the most critical, and during this time drugs may cause structural abnormalities. The brain is vulnerable throughout pregnancy.

For a drug to be teratogenic it must first pass across the placenta. The drugs that do this are those that have a low molecular weight, are poorly ionized at

physiological pH, and are very fat soluble. The few drugs that do not pass across the placenta illustrate these principles. For example, heparin is ionized and of high molecular weight and tubocurarine is ionized and relatively lipid insoluble; neither crosses the placenta. However, most drugs in the maternal circulation do reach the fetus to some extent.

If a drug is a known teratogen in humans or animals then the data sheet will say so. However, if a drug is not known to be teratogenic in humans, lack of evidence of teratogenicity in animals cannot be taken as evidence that the drug is not teratogenic in humans. Many new drugs are introduced with the advice that they should not be taken during pregnancy, simply for lack of evidence. Table 6 gives important examples of drugs to avoid during pregnancy.

Adverse effects on the fetus during the later stages of pregnancy

Some drugs that are not teratogenic may have adverse effects on the fetus if given later in pregnancy. Table 7 lists some important drugs that should be avoided or used with care during later pregnancy (some throughout the whole duration of pregnancy).

What should be done if a woman of childbearing potential is given a drug, and then finds out days or weeks later that she is pregnant? First, it is important to identify the drug and the exact time of exposure to it. If it is a known or a likely teratogen, the relation between the time of exposure and the likely time of conception should be determined. It is sometimes possible to identify the precise date of conception, but if it is not, one should try to estimate the gestational age by carefully documenting the recent menstrual history and, if necessary, date the pregnancy by ultrasound. If exposure to a known teratogen has occurred during the first 8 weeks of pregnancy, further investigation may be necessary to identify precise fetal abnormalities. For example, ultrasound can detect many structural abnormalities, and neural tube defects may be diagnosed by measuring serum and amniotic a-fetoprotein concentrations. In such circumstances any advice on termination of a pregnancy should be based on a consideration of the risk of fetal abnormality from both published information and investigation of the individual case.

Adverse reactions to drugs in breast milk

Some drugs can cause adverse effects in babies after ingestion in breast milk. These include drugs that are so extensively excreted in the milk as to cause dose-related adverse effects in the infant, and drugs that do not necessarily enter the milk in large amounts, but whose adverse effects are not dose related. The latter include drugs that may cause hypersensitivity reactions (for example penicillins and sulphonamides), and drugs that are hazardous to babies with glucose 6-phosphate dehydrogenase deficiency (for example nitrofurantoin and primaquine). Drugs to be avoided are listed, for example, in the British National Formulary and the Physician's Desk Reference. If the safety of a drug is in doubt it is best either to choose another drug or, if the drug must be used, to advise the mother to suspend breast feeding.

Methods used in detecting adverse reactions

During the period of clinical trial that a drug undergoes before its general release only the most frequent of adverse reactions will be detected, because so few patients are studied. We need methods for detecting adverse reactions as quickly as possible after marketing, for confirming that the events detected are truly adverse reactions, and for assessing their overall incidence, so that we can try to judge the balance of benefit and harm. Table 8 summarizes some methods of doing this.

Prevention of adverse effects: the role of consumers†

Ordinary people taking a medicine do not usually expect unwanted effects, even if they have received information about them from their doctor, the pharmacist, or most often in the leaflet with the medicine. Most people are optimists, and believe that a medicine prescribed by a doctor or sold in a pharmacy will not cause them any problem—though others might suffer some unpleasant effects.

The aim of information that patients get about adverse effects is to warn that such effects may occur, so that they can:

1. assess the potential disadvantages of the medicine, before deciding whether to take it ;
2. connect an adverse event with the taking of the medicine and take appropriate action.

What the information rarely, if ever, does is to explain in what specific ways adverse effects may be prevented or at least minimized. There are even many doctors who do not understand this very clearly. The necessary strategy has several components, each related to a particular category of adverse effects.

First come the dose-dependent effects known to occur in everybody if the dose is high enough. They can be prevented or minimized by keeping the dosage as low as possible. If harm is more likely with long continued use of the drug, then the duration of use should be limited, as for example with the neuroleptic antipsychotic drugs.

Second, the effects of drug interactions, which can be prevented by avoiding concurrent use of interacting drugs, or minimized by very careful monitoring if the drugs are essential.

Third are new adverse effects that have not yet been reported, and are a puzzling and unpleasant surprise for everyone concerned. These generally affect such a small proportion of patients that they have remained undetected in premarketing clinical trials. Such surprises are rarer after a drug has been widely used for several years. They can therefore be partially prevented by avoiding the use of new drugs whenever possible, at least during the first few years of their life. If there is a compelling reason for using a new drug, this should be explained to the patient and documented in the records. Furthermore, use of the new drug should be monitored more closely than would be necessary with an older and familiar drug. It is thus important that patients should know whenever the drug prescribed for them is new.

Fourth, adverse effects may result when a prescriber uses a drug with which he or she is insufficiently familiar. So when a doctor is not sure what to prescribe, and at last finds something to try in one of his or her compendia, the patient can reasonably ask how familiar the doctor is with that drug. If it is new to the doctor, then hesitation is appropriate and it may be reasonable to seek a second opinion from someone more experienced.

Fifth, some individuals are especially liable to suffer adverse effects. They may have a genetic abnormality—for example they may be poor metabolizers of a wide range of drugs, or they may lack normal plasma cholinesterase, leading them to suffer suxamethonium apnoea. The development of genetic testing in the coming years will greatly help to identify these people and so enable us to protect them from many kinds of drug-related harm. Meanwhile the best that can be done is always to take a careful medication history, asking about any previous bad experience with medicines, and where a genetic problem is suspected, also a family history. When a genetic abnormality has led to an adverse effect, the patient must be given detailed information about it so that he or she can warn any treating doctor in order to avoid future dangerous exposures.

It can be concluded from all this that all of us, as consumers who are liable to become patients at some time, need to understand a few fundamental principles:

1. All drugs have not only the intended beneficial effects, but can and often do cause harmful or unpleasant effects as well. This knowledge should influence the decision whether or not to accept medication that the doctor or pharmacist or anyone else proposes.
2. Harmful or unpleasant effects are more likely and are often worse with higher than lower doses. It is therefore important to use the lowest dosage that works, and to do so with the doctor's help.
3. Well known and established drugs are safer than new or relatively untried drugs. It is therefore best to avoid new drugs unless there is a convincing reason for using one.
4. If it is necessary to use more than one medicine at the same time, it is important to check that they are safe to use together, and to monitor their use with special care.
5. People can differ greatly in how drugs affect them. We should each learn from our own personal experiences with medicines, and make sure our doctors learn from them too in what they prescribe for us individually.

It will take much effort to educate consumers to the point where they can apply these principles in consultations with health professionals and in their use of

medicines. We as professionals must take the lead and teach them, at least by example.

Finding the lowest effective dose: two examples†

A retired economist's hypertension was well controlled by atenolol 25 mg/day, but she was bothered by her slow pulse rate, often below 60 beats/min, and asked her doctor if she could take a smaller dose. He said yes, why not.

The 25 mg tablets are not scored, but the patient succeeded in cutting them more or less in half, rejecting any fragments that looked too small. The blood pressure remained well controlled on half the previous dose, and the pulse rate rose modestly.

Another patient, a biologist with ischaemic heart disease, had a raised serum cholesterol, which a low-fat diet had reduced only slightly to 6.1 mmol/l. On simvastatin 10 mg/day this fell to 5.3 mmol/l, which was still above the target level of 4.5. Simvastatin is made only in 10, 20 and 40 mg tablets, so the doctor wanted to prescribe 20 mg/day. The patient felt that doubling the dose might be unnecessary, so the doctor suggested taking 15 mg/day or one and a half tablets. (That is easier to remember than taking one tablet (10 mg) and two (20 mg) on alternate days.) Although the tablets are not scored they have an oval shape and are easy to break in two. The dose of approximately 15 mg/day lowered the serum cholesterol to 4.4 mmol/l.

Biological variation is often neglected in clinical trials and in the dosage recommendations that are derived from them. New drugs are commonly marketed at higher doses than some patients need, because the company wants to be sure of achieving a therapeutic effect in the majority.The result is that the most sensitive patients get more than they need or than is good for them. It is worth asking patients about their experience of drugs—whether they have found small doses effective in the past, or whether they have been ineffective. Dose titration with the patient's help can on occasion improve treatment. And to facilitate this, all tablets should be scored—manufacturers please note.

Drug interactions

A drug interaction occurs when the effects of one drug (the object drug) are altered by the effects of another drug (the precipitant drug). Usually this results in an adverse drug reaction, but in a few cases a drug interaction may prove beneficial. Interactions form about 7 per cent of all adverse drug reactions; among the few patients who die from adverse drug reactions (about 4 per cent of all deaths) about a third are due to interactions.

Drugs likely to precipitate interactions include the following: drugs that are highly protein bound (aspirin, phenylbutazone, sulphonamides, and trichloracetic acid, a metabolite of chloral hydrate), as they are likely to displace object drugs from protein-binding sites; those that stimulate the metabolism of other drugs, including various anticonvulsants (phenytoin, carbamazepine, phenobarbital), rifampicin, griseofulvin. Those that inhibit the metabolism of other drugs, including allopurinol, chloramphenicol, cimetidine, metronidazole and other imidazoles (for example ketoconazole), monoamine oxidase inhibitors, azapropazone and related drugs, and quinolone antibiotics (for example ciprofloxacin); those that affect renal function and alter the renal clearance of object drugs (for example diuretics, probenecid).

The most likely object drugs in interactions are those that have a steep dose–response curve (i.e. drugs for which a small change in dose results in a relatively large change in therapeutic effect, important in interactions causing decreased efficacy of the object drug), and those that have a low therapeutic index (i.e. drugs for which the dose at which toxic effects start to occur is little more than the therapeutic dose, important in interactions causing toxic effects of the object drug). Drugs that fulfil these criteria include the aminoglycoside antibiotics, anticoagulants, anticonvulsants, antihypertensive drugs, cardiac glycosides, cytotoxic and immunosuppressant drugs, oral contraceptives, and drugs that act on the central nervous system.

Drug interactions can be classified by mechanism; Table 9 lists some important examples.

Pharmaceutical interactions

Pharmaceutical interactions are physicochemical, either of a drug with an intravenous infusion solution or of two drugs in the same solution. Such interactions result in the loss of activity of the object drug. Pharmaceutical interactions are too numerous to remember in detail, but they can be avoided by adhering to some simple principles. These include giving intravenous drugs by bolus injection if possible or via an infusion burette, by not adding drugs to infusion solutions other than dextrose or saline, and by avoiding mixing drugs in the same infusion solution, unless the mixture is known to be safe (for example potassium chloride with insulin).

Pharmacokinetic interactions

Pharmacokinetic interactions occur when the precipitant drug alters the absorption, distribution, or elimination (metabolism or excretion) of the object drug.

Absorption interactions

One drug can alter the absorption of another, but such effects are rarely important. Exceptions include the interactions of cholestyramine with warfarin and digitoxin, whose initial absorption and reabsorption after biliary excretion are reduced resulting in increased dosage requirements. Oestrogens are metabolized in the liver and some of their metabolites are excreted in the bile, deconjugated by bowel organisms, and reabsorbed. The effect of the combined oral contraceptive can therefore be reduced and pregnancy can result if a poorly absorbed antibiotic such as ampicillin prevents the bacterial deconjugation of the oestrogen.

There are two good examples of beneficial absorption interactions. Metoclopramide hastens gastric emptying and so hastens the absorption of analgesics used to treat an acute attack of migraine (Fig. 7). Charcoal binds certain drugs in the gut and thus prevents their initial absorption or their reabsorption after biliary excretion or intestinal secretion. This is valuable in the treatment of self-poisoning with drugs such as phenobarbital and tricyclic antidepressants.

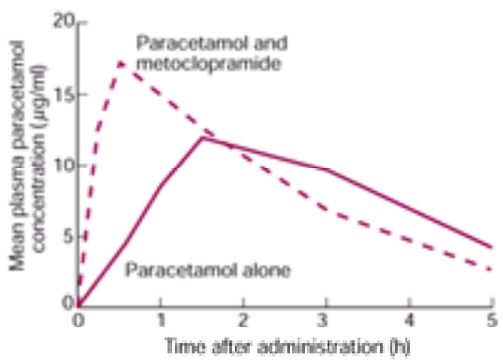

Fig. 7 The effect of metoclopramide on the absorption of paracetamol. When metoclopramide (10 mg intravenously) was given with paracetamol (1.5 g orally) the rate of paracetamol absorption was increased, as evidenced by a higher and earlier peak paracetamol plasma concentration. (Adapted from Nimmo J *et al.* (1973). Pharmacological modification of gastric emptying: effects of propantheline and metoclopramide on paracetamol absorption. *British Medical Journal* **i**, 587–9, with permission.)

Protein-binding displacement interactions

Displacement of one drug by another from its sites of binding to plasma proteins will cause an increase in the circulating concentration of unbound drug, and thus the potential for an increased effect of the displaced drug. Such interactions are important if the object drug is highly protein bound (greater than 90 per cent) and has a low apparent volume of distribution. The important drugs concerned are warfarin, phenytoin, and tolbutamide.

The most common precipitant drugs in protein-binding displacement interactions are sulphonamides, salicylates, and chloral hydrate and some of its congeners (because of their metabolite, trichloracetic acid). In addition, valproate specifically displaces phenytoin.

However, the importance of protein-binding displacement interactions has been exaggerated, and they are often clinically unimportant. The reason is that when drugs such as warfarin, phenytoin, and tolbutamide are displaced their rates of clearance increase in proportion to the degree of displacement. This means that the total concentration of drug in the plasma will fall after displacement, negating the initial effect. Thus, if the patient weathers the initial increase in unbound concentration of the object drug, the interaction will not matter.

Interactions through induction of metabolism

Certain drugs increase ('induce') drug metabolism by increasing the amount of endoplasmic reticulum in hepatocytes and by increasing the content of cytochrome P450 enzymes and cytochrome *c* reductase, which catalyse mainly oxidative reactions. Induction of the metabolism of an object drug in this way causes a reduction in its effects (resulting, for example, in epileptic fits while on phenytoin, or pregnancy while on an oral contraceptive). Drugs that induce drug metabolism include barbiturates, carbamazepine, griseofulvin, phenytoin, and rifampicin.

Interactions through inhibition of metabolism

Certain drugs inhibit drug metabolism. Interactions of this type fall into two categories: those in which the precipitant drug inhibits one or more particular cytochrome P450 enzymes and those involving other specific metabolic pathways.

Important examples of inhibition of drug metabolism by inhibition of oxidative reactions are: inhibition of warfarin metabolism by cimetidine (Fig. 8), metronidazole, and other imidazoles, chloramphenicol, norfloxacin, and other quinolones, phenylbutazone, azapropazone, sulfinpyrazone; inhibition of phenytoin metabolism by isoniazid; inhibition of theophylline metabolism by quinolone and macrolide antibiotics.

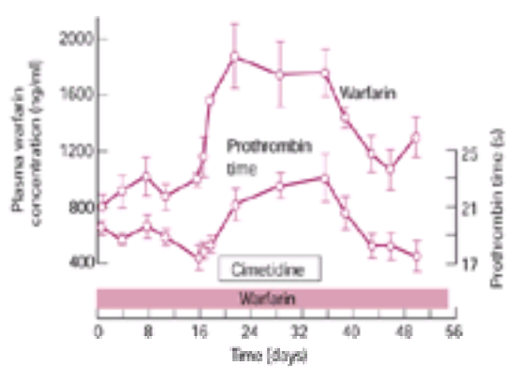

Fig. 8 An example of an interaction involving inhibition of drug oxidation. Plasma warfarin concentrations and the prothrombin time both rose after cimetidine (200 mg three times daily) was introduced in volunteers taking daily maintenance doses of warfarin. (Adapted from Serlin MJ *et al*. (1979). Cimetidine: interaction with oral coagulants in man. *The Lancet* **ii**, 317–19, with permission. ©*The Lancet*.)

The interaction of allopurinol with azathioprine and 6-mercaptopurine results from the effect of inhibition of a specific metabolic pathway. Both 6-mercaptopurine and azathioprine (which is metabolized to 6-mercapto-purine) are metabolized by xanthine oxidase, which allopurinol inhibits.

The interaction of monoamine oxidase inhibitors with dietary tyramine results in severe hypertension, which can kill. Inhibition of monoamine oxidase results in an increase in the noradrenaline content of sympathetic nerve endings. When tyramine is ingested monoamine oxidase normally inactivates it in the gut wall; however, when monoamine oxidase is inhibited tyramine passes through the gut wall and liver and reaches the systemic circulation. Tyramine releases noradrenaline from its increased stores in nerve endings and a hypertensive crisis results.

Excretion interactions

Most interactions involving drug excretion occur in the kidneys.

Inhibition of renal tubular secretion

Probenecid inhibits the tubular secretion of penicillins and cephalosporins, prolonging their therapeutic effects. Quinidine, verapamil, and amiodarone inhibit the tubular secretion of digoxin and salicylates inhibit the active secretion of methotrexate; in both cases toxic effects can occur.

Increased renal tubular reabsorption

Diuretics that inhibit renal tubular sodium reabsorption cause compensatory reabsorption of lithium with consequent toxicity.

Reduced renal tubular reabsorption

Changing the pH of the urine will alter the reabsorption of drugs that are subject to passive reabsorption. This is put to use in the treatment of overdose with salicylates and amphetamines (by alkalinizing or acidifying the urine respectively).

Pharmacodynamic interactions

Pharmacodynamic interactions occur when the precipitant drug alters the effect of the object drug at its site of action.

Interactions at the same site

Direct pharmacodynamic interactions occur when two drugs either act on the same site (antagonism or synergism) or act on two different sites with a similar end result. Many antagonistic interactions are therapeutically beneficial, including the reversal of the effects of opiates with naloxone and the reversal of the actions of warfarin by vitamin K. In contrast, synergistic interactions are often adverse. The effects of warfarin may be increased or decreased by changes in the affinity of warfarin for vitamin K epoxide reductase (clofibrate, D-thyroxine, anabolic steroids), alterations in the synthesis rate of clotting factors (anabolic steroids), changes in the activity of clotting factors (tetracyclines), or decreased availability of vitamin K secondary to decreased plasma lipids (D-thyroxine, anabolic steroids).

The effects of depolarizing skeletal muscle relaxants are potentiated by some antibiotics (for example aminoglycosides, polymixin B, and colistin) and by quinidine and quinine. These interactions are due to the curare-like effects of the precipitant drugs on the motor endplate of skeletal muscle.

Concurrent use of verapamil and a b-adrenoceptor antagonist increases the risks of cardiac arrhythmias and heart failure.

Interactions at different sites

Drugs that depress central nervous function may potentiate each other, whether or not they have effects on the same receptors. The most common example is that of alcohol with any centrally acting drug (Fig. 9).

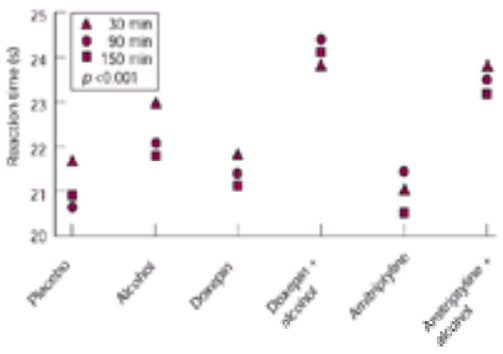

Fig. 9 A pharmacodynamic interaction. Neither doxepin (20 mg three times daily) nor amitriptyline (20 mg three times daily) alone altered the reaction time. Alcohol alone prolonged the reaction time slightly at all times of testing after drug administration (30, 90, and 150 min). However, the combination of alcohol with either doxepin or amitriptyline prolonged the reaction time by much more than one would expect from the separate effects of each component of the combination. (Adapted from Seppala T, *et al.* (1975). Effect of tricyclic antidepressants and alcohol in psychomotor skills related to driving. *Clinical Pharmacology and Therapeutics* **17**, 515–22, with permission.)

Other examples include the many combinations of cytotoxic drugs used to treat lymphomas and leukaemias, and the use of combinations of antibiotics in the treatment of some infections, even when only one organism is implicated (for example in infective endocarditis and tuberculosis). These are beneficial interactions.

Indirect pharmacodynamic interactions

In indirect pharmacodynamic interactions a pharmacological, therapeutic, or toxic effect of the precipitant drug in some way alters the therapeutic or toxic effect of the object drug, but the two effects are not themselves related and do not themselves interact.

Warfarin and other anticoagulants may be involved in indirect interactions if platelet aggregation is reduced (for example by salicylates, dipyridamole, sulfinpyrazone, mefenamic acid, and other non-steroidal anti-inflammatory drugs), when there is drug-induced thrombocytopenia, if a drug causes gastrointestinal ulceration (for example aspirin and other non-steroidal anti-inflammatory drugs), or if a drug causes enhanced fibrinolysis (for example the biguanides).

Alterations in fluid and electrolyte balance may secondarily alter the effects of some drugs. The effects of cardiac glycosides and the arrhythmogenic effects of some antiarrhythmic drugs (such as quinidine, procainamide, and phenytoin) are increased by potassium depletion (due to potassium-wasting diuretics, corticosteroids, and purgatives for example).

Pharmacogenetics

Pharmacogenetics is the study of the influence of heredity on the pharmacokinetics of drugs and pharmacodynamic responses to them.

Pharmacokinetic defects

The extent to which an individual metabolizes a drug is, at least in part, genetically determined. For example, monozygotic twins metabolize drugs similarly, while dizygotic twins often do not. For most drugs the variability in metabolism is unimodally distributed. However, for some the distribution is bimodal or trimodal, indicating that separate populations of people metabolize those drugs at different rates. The important pathways of drug metabolism subject to pharmacokinetic variability are acetylation, hydroxylation, and suxamethonium hydrolysis.

Acetylation

Some drugs are acetylated by the hepatic enzyme *N*-acetyltransferase, which is distributed bimodally. Fast acetylators have more *N*-acetyltransferase in the liver than slow acetylators; this is inherited as an autosomal dominant trait. The ratio of fast:slow acetylators varies among races, being for example 40:60 in Europe, 85:15 in Japan, and 95:5 in the Inuit. Drugs affected are isoniazid, hydralazine, procainamide, phenelzine, dapsone, and some sulphonamides. Slow acetylators require lower doses of isoniazid and hydralazine than fast acetylators in the treatment of tuberculosis and hypertension respectively. They are also more likely to develop the lupus erythematosus-like syndrome caused by isoniazid, hydralazine, and procainamide, and the peripheral neuropathy caused by isoniazid (which can be prevented or treated with pyridoxine). The interaction between isoniazid and phenytoin, in which isoniazid inhibits phenytoin metabolism, resulting in phenytoin toxicity, occurs more frequently among slow acetylators.

The acetylator status of an individual is easily assessed by giving a sulphonamide, such as sulphadimidine or sulphapyridine, orally and measuring the relative proportions of acetylated and total sulphonamide in a sample of urine passed 5 to 6 h later.

Oxidation

Certain varieties of oxidation are bimodally distributed, but in contrast to acetylation this is a heterogeneous group of defects and they are not all uniformly due to decreased amounts of enzyme. Individuals with impaired and normal oxidation are classified as poor and extensive metabolizers respectively. The main type of defect is the debrisoquine type, an autosomal recessive defect of cytochrome P450 of the type CYP2D6. It occurs in about 9 per cent of Caucasians, and has a lower prevalence in other racial types.

Other drugs that are affected include captopril, codeine, flecainide, metoprolol, nortriptyline, propafenone, and timolol. The dose-related adverse effects of these drugs (for example central nervous system toxicity with nortriptyline) are more likely in poor hydroxylators. Quinidine inhibits some oxidative reactions and may turn an extensive metabolizer of the debrisoquine type into a poor metabolizer.

The metabolism of mephenytoin is mediated by cytochrome CYP2C, whose activity is bimodally distributed. Poor metabolizers of proguanil (used to prevent malaria) do not convert it to the active form cycloguanil, and may fail to respond to treatment.

Sulphoxidation of penicillamine is polymorphic. Poor sulphoxidation is associated with a fourfold increase in the risk of adverse effects in rheumatoid arthritis. Adverse reactions to gold salts containing a thiol group may also be linked to poor sulphoxidation.

Disease associations with polymorphic metabolism

As some diseases may be related to the effects of environmental chemicals, it is of interest that polymorphic acetylation, hydroxylation, and sulphoxidation have other clinical associations. For example, the risks of bladder cancer may be increased in slow acetylators, of parkinsonism in poor debrisoquine hydroxylators, of bronchogenic carcinoma in extensive debrisoquine hydroxylators, and of primary biliary cirrhosis in poor sulphoxidizers.

Suxamethonium hydrolysis

Suxamethonium (succinylcholine) is metabolized in the plasma by the non-specific esterase pseudocholinesterase. Normally this happens quickly and neuromuscular blockade lasts only a few minutes. However, in some people the pseudocholinesterase is of abnormal affinity and amount, and metabolizes the suxamethonium only slowly, resulting in prolonged neuromuscular blockade. Three types of abnormalities of pseudocholinesterase occur, each inherited in autosomal recessive fashion, the dibucaine-resistant, fluoride-resistant, and 'silent' gene types.

Some individuals, perhaps 1 in 1000, have a two- or threefold higher concentration of pseudocholinesterase in the plasma and resist the effects of suxamethonium.

Pharmacodynamic defects

Some biochemical abnormalities make individuals peculiarly sensitive or resistant to the effects of certain drugs.

Red cell enzyme defects (see Section 22)

Unusual drug reactions may affect people whose erythrocytes are deficient in any one of three different but functionally related enzymes, glucose-6-phosphate dehydrogenase, glutathione reductase, and methaemoglobin reductase, which help to prevent the oxidation of various cell proteins. If such an erythrocyte is exposed to an oxidizing agent, haemolysis occurs, probably because of unopposed oxidation of sulphydryl groups in the cell membrane.

Porphyria (see Section 11)

The hepatic porphyrias, acute intermittent porphyria and porphyria cutanea tarda, are characterized by abnormalities of haem biosynthesis. Certain drugs may precipitate an attack of porphyria.

Malignant hyperthermia

This is a serious, potentially fatal, complication of general anaesthesia with halothane, methoxyflurane, and suxamethonium. It affects about 1 in 20 000 anaesthetized patients and is inherited in autosomal dominant fashion. The body temperature rises acutely to 40 to 41 °C, with muscle stiffness, tachycardia, sweating, cyanosis, and tachypnoea. Dantrolene, which decreases the amount of calcium released from sarcoplasmic reticulum, is effective.

Corticosteroid glaucoma

Intraocular pressure rises during daily use of corticosteroid eyedrops, and the rise is trimodally distributed, 65 per cent, 30 per cent, and 5 per cent of individuals having small, medium, and large increases in pressure. Those who have a large increase in pressure are at increased risk of glaucoma. Inheritance is autosomal recessive.

Vitamin D-resistant rickets

Three varieties of rickets are resistant to the effects of vitamin D (cholecalciferol): familial hypophosphataemic rickets, vitamin D dependency, and Fanconi's syndrome (see Section 12).

Coumarin resistance

Coumarin resistance is a rare defect in which 20 times the usual dose may be required to produce satisfactory anticoagulation. It has autosomal dominant inheritance; the mechanism may be resistance of the vitamin K epoxide reductase to inhibition by warfarin.

Monitoring drug therapy

Monitoring drug therapy usually involves trying to measure the clinical response directly. If this is difficult, or is not related directly in time to a dose of the drug, another measure of the pharmacological effect may be required. In some cases it may be necessary to resort to measurement of the plasma concentration of the drug.

Monitoring the therapeutic effects of drugs

Some events can be directly monitored in the individual patient, while some are monitored in a population. The latter can be applied to the individual only in terms of a statistical probability derived from the observed population variability. Examples of therapeutic events that can be monitored in the individual include frequency of seizures during anticonvulsant drug therapy, muscle power during treatment of myasthenia gravis, the frequency of attacks of angina pectoris, and body weight during diuretic therapy.

Preventive measures in medicine cannot be monitored in the individual and their effects must be gauged by population studies. Examples include the frequency of infections after immunization, the reduction of the risks of hypertension by diuretics, and the prevention of the complications of myocardial infarction by streptokinase and aspirin.

Monitoring the pharmacodynamic effects of drugs

In some circumstances the pharmacological effect of a drug can be carefully measured, followed sequentially, and used as a guide to drug therapy even though it may not be correlated precisely with the therapeutic effect. Examples include the effect of insulin on the blood glucose concentration in diabetes mellitus, anticoagulants on the prothrombin time, bronchodilators on FEV_1 and peak flow rate in bronchial asthma, and cancer chemotherapy on tumour markers.

Monitoring drug pharmacokinetics (plasma concentration measurement)

This is useful for a few drugs, namely those for which:

- there is difficulty in measuring or interpreting the clinical evidence of therapeutic or toxic effects.
- the relation between dose and plasma concentration is unpredictable.
- there is a good relation between plasma concentration and effect, which have a low therapeutic index, and which are not metabolized to active metabolites.

The drugs for which plasma concentrations are commonly and usefully measured are listed in Table 10.

Measurement may be useful when individualizing therapy (for example at the start of therapy when the relation between dose and plasma concentration in the individual is uncertain, when rapid changes in renal function alter the relation between dose and plasma concentration, or when another drug alters the relation between dose and plasma concentration), in the diagnosis of suspected toxicity, and in assessing compliance (see above).

Phenytoin

Plasma concentrations of phenytoin in the toxic range are quite well related to its acute toxic effects, but not to its long-term adverse effects, such as gingival hyperplasia, hirsutism and acne, and folate and vitamin D deficiencies. At low dosages it takes about 2 weeks of maintenance therapy to reach steady state after a change in dose, and the higher the plasma concentration the longer it takes (up to 3 weeks or longer in some patients). For this reason the dosage should not be changed too frequently. Provided the sample is not taken too soon after a dose (i.e. within 1 to 2 h), the time of sampling hardly matters for phenytoin, as plasma concentrations fluctuate little between doses.

Digoxin

Plasma digoxin concentrations correlate well with toxic effects but not with the therapeutic effect within the therapeutic dosage range. The time of blood sampling should be at least 6 h after the previous dose, and 12 h is the best time in patients taking once daily treatment. During regular maintenance dosage without a loading dose, steady state is reached after about 7 days (normal renal function) to 18 days (functionally anephric). The relation between dose and plasma digoxin concentrations is altered by renal impairment (which reduces the clearance of digoxin), for example in older people, and drug interactions (see above). Factors that alter the link between the concentrations and effects of digoxin, and which make it difficult to interpret the plasma concentration, include potassium depletion (which increases the effect of a given concentration of digitalis on the heart) and thyroid disease (hyperthyroidism decreases responsiveness and hypothyroidism increases it). Children younger than 6 months have lower plasma digoxin concentrations at a given dose than older children and adults, and they are also more resistant to the pharmacodynamic actions of digitalis; in them plasma digoxin concentrations cannot be clearly interpreted.

Lithium

Serum lithium concentrations correlate quite well with the therapeutic effect in the range 0.4 to 0.8 mmol/l. At 1.0 to 1.5 mmol/l the incidence of both acute toxicity and long-term adverse effects is increased. Concentrations above 1.5 mmol/l should be avoided. Blood samples should be taken at exactly 12 h after the previous dose, or as near to that as possible. It takes about 3 days for steady state to be reached during regular maintenance therapy, but patients vary widely, and in some it may take a week.

Monitoring of plasma lithium concentration is necessary for several reasons. Lithium is nephrotoxic and is excreted by the kidneys; toxicity is thus self-perpetuating because it causes renal damage, further retention of lithium, and further toxicity. Systemic availability varies from person to person, is altered by diarrhoea, and varies for different formulations. Changes in sodium balance alter the renal excretion of lithium; for example, renal sodium loss induced by diuretics leads to lithium retention.

Aminoglycoside antibiotics

The same principles apply to all the aminoglycoside antibiotics and we shall take gentamicin as an example. The relation between the plasma concentration of gentamicin and its therapeutic efficacy is complicated by the fact that different organisms have different sensitivities to the antibiotic. The toxic effects of gentamicin on the ears and kidneys are related to the 'peak' concentration (the highest concentration measured after a dose, usually occurring about 1 h after an intramuscular injection or the start of an intravenous infusion) and the 'trough' concentration (the concentration measured just before the next dose is due).

With standard regimens a peak plasma concentration of 5 to 9 mg/l is generally considered necessary, although when gentamicin is used together with benzylpenicillin to treat bacterial endocarditis, lower plasma gentamicin concentrations may be effective. Bacteriological measurement of *in vitro* inhibitory concentrations will help to guide therapy. Expert advice on dosage and target plasma concentrations should be obtained.

Theophylline

Plasma theophylline concentrations correlate well with therapeutic and toxic effects. Measurement is essential in any patient who has been taking oral theophylline and is to be given it intravenously.

Ciclosporin

Ciclosporin is generally measured in whole blood and the result of the assay may depend on whether the measurement technique is by immunoassay or high-performance liquid chromatography. The time to steady state is about 2 days and samples should be taken just before the next dose is due. Factors that alter the whole blood concentration of ciclosporin without a change in dose include reduced absorption (due to diarrhoea or reduced bile-salt production), reduced metabolism (due to liver disease or inhibition by drugs such as ketoconazole and cimetidine or grapefruit juice), and increased metabolism (due to enzyme-inducing drugs).

10.1 Diseases of overnourished societies and the need for dietary change

J. I. Mann and A. S. Truswell

Introduction

Nutrition issues at different stages of technical and economic development

Inappropriate nutrition contributes to illness and premature death in populations throughout the world. The nutritional problems of a country depend more upon the stage of technical and economic development than geographical location (Table 1). Until about 10 000 years ago our ancestors were hunter–gatherers. There are few contemporary hunter–gatherers left, but some of these have been studied, for example !Kung bushmen. Hunter–gatherers collected a wide range of plant foods, but also ate meat and fish. They ate little salt, alcohol, or milk (other than breast milk as infants), little cereal, and no refined sugar apart from honey. Studies of contemporary hunter–gatherers indicate that they do not become obese but may experience seasonal hunger. We infer also that malnutrition was uncommon unless illness or injury supervened. High blood pressure or coronary heart disease would have been rare and plasma cholesterol was probably low. Teeth were worn down by hard food and caries was rare. With prolonged lactation, births were spaced fairly widely. The weaning period of childhood was precarious but general nutritional health was good. *Homo sapiens* evolved as hunter–gatherers and it is unlikely there has been sufficient time to adapt physiologically to many modern foods.

Many contemporary people in the Third World are peasant agriculturists living a way of life similar to that of the rural population of Western Europe and North America until the industrial revolution. They tend to rely on the one crop with the best yield and are vulnerable to crop diseases or crop toxins and droughts. Milling and refining cereals increases the risk of malnutrition. Though some foods are stored, diet is seasonal. Malnutrition can occur from lack of essential nutrients in the staple food, for example vitamin A deficiency, pellagra, kwashiorkor, and iodine deficiency disorders. Hypertension occurs (salt is available) but coronary heart disease is rare.

Urban slum and periurban shanties are homes for an increasing proportion of the growing populations of Third World countries who are pouring into overcrowded, unsanitary accommodation in vast, polluted cities. Conditions are reminiscent of the slums of London, Manchester, and New York in the nineteenth century. These people have lost their contact with the land and food traditions and for them food is expensive. Mothers of young children have to go out to work. Breast feeding is impossible and it is very difficult to keep bottle feeds hygienic. Young children are most susceptible to diarrhoeal and other infectious diseases; these, with the mothers' absence and inadequate food, can lead to marasmus. Among adults, however, some become obese, others may be alcoholics.

In affluent societies, the prosperous people in the First World do not have to worry about the problems of getting food and keeping it uninfected. Food is cheap for them and they can eat their favourite food all year round. There is a multiplicity of nutrition advice and concerns with breakthroughs and scares, science, and pseudoscience about all food. The diet is high in fat and dense in energy. Obesity and its related disorders, coronary heart disease and hypertension (with its complications), are the principal causes of death. While sports are watched on television by millions, many ordinary citizens do not undertake any physical activity that promotes health. Obesity is unfashionable but difficult to avoid and increasing. Malnutrition occurs in the frail elderly and the sick but this malnutrition is usually subclinical and identified mainly by biochemical tests.

As mortality due to infectious disease is reduced by antibiotics and immunization in most Third World countries, and as their people are living longer and increasingly adopting Western foods and labour-saving techniques, non-communicable diseases are the major causes of death. These non-communicable diseases formerly affected only the ruling and merchant elite of developing countries but there is now a growing epidemic of obesity, diabetes, hypertension, and coronary heart disease. Health authorities in all but the least developed countries have the formidable task of providing education and food policies both to prevent malnutrition and at the same time to prevent overnutrition.

Epidemiological methods used to study nutrition-related diseases

The nutritional component of non-communicable diseases is more difficult to study than classical nutrition deficiency diseases because they develop slowly and are multifactorial. The dietary factor may be a 'risk factor' rather than a direct cause. However, there is now convincing evidence that dietary change can appreciably reduce the risk of some important non-communicable diseases. Very often the first clue to the association between a food or nutrient and a disease comes from observing striking differences in disease incidence between countries (or groups within a country) which correlate with differences in nutritional intake. Sometimes, dietary changes over time in a single country have been found to coincide with changes in disease rates. Such observations give rise to hypotheses about possible diet–disease links, rather than proof of causation because many potential causative factors may be confounded by parallel dietary changes.

Retrospective or case–control studies have sometimes been used as a rapid and inexpensive way of testing hypotheses. A series of people who have been diagnosed with, for example, cancer of the large bowel, are asked what they usually eat, or what they ate before they became ill. These 'cases' are compared with at least an equal number of 'controls', people without bowel cancer, matched for age, gender, and, if possible, social condition. Weaknesses of the method include the possibility that the disease may affect food habits, that cases cannot recall their diet accurately before the cancer was diagnosed, that controls may have some condition that affects dietary habits, or that food intakes are recorded from cases and controls in a different way ('bias'). Furthermore, it is conceivable (and for coronary heart disease and cancer, likely) that dietary factors may operate many years before the condition comes to light.

Prospective or cohort studies avoid the biases involved in asking people to recall past eating habits. Information about food intake and other characteristics are collected well before onset of the disease. Large numbers of people must therefore be interviewed and examined; they must be of an age at which bowel cancer (say) starts to be fairly common (i.e. middle aged) and in a population which has a fairly high rate of this disease. The healthy cohort thus examined and recorded is then followed up for five or more years. Eventually, a proportion will be diagnosed with bowel cancer and the original dietary details of those who develop cancer can be compared with the diets of the majority who have not developed the disease. Usually, a number of dietary and other environmental factors are found to be more, or less, frequent in those who develop the disease. These, then, are apparent risk factors, or protective factors. However, they are not necessarily the operative factor. Fruit consumption may appear to be protective but perhaps, in this cohort, smokers eat less fruit and smoking may be more directly related. This confounding has to be quantified by analysing the data to see the relationship of fruit to the disease at different levels of smoking.

Definitive proof that a dietary characteristic is a direct causative or protective factor may come from one or more randomized, controlled, prevention trials. These involve either the addition of a nutrient or other food component as a supplement to those in the experimental group and a placebo taken by the control group, or the prescription of a dietary regime to the experimental group while the controls continue to follow their usual diet. Disease (and death) outcomes in the two groups are compared. Such trials have the advantage of being able to prove causality as well as potential cost/benefit of the dietary change. However, they are costly to carry out because it is usually necessary to study large numbers of people over a prolonged period. Quite often a single trial does not, in itself, produce a definitive answer but by combining the results of all completed trials in a meta-analysis more meaningful answers are obtained.

Much research involving the role of diet in chronic, degenerative disease has centred around the effects of diet on modifying risk factors rather than the disease itself.

For many chronic diseases there are biochemical markers of risk. High plasma cholesterol, for example, is an important risk factor for coronary heart disease. Innumerable studies have examined the role of different nutrients and foods on plasma cholesterol or other risk factors. Such studies are cheaper and easier to undertake than population-based studies since far fewer people are studied over a relatively short period of time. They have helped to find which foods lower cholesterol and so should help protect against coronary heart disease. It is this information that has formed the basis of the public health messages which may have contributed to the decline in the incidence of coronary disease in most affluent societies over the last 20 years.

In this age of evidence-based medicine one would ideally like to see the results of randomized, controlled trials before offering dietary advice. However, this may be impossible to achieve. For example a clinical trial to demonstrate that a particular dietary manipulation will reduce the risk of cancer may require a trial of such magnitude and duration that it is impractical and a decision as to whether or not to recommend dietary change will need to be based on a lesser degree of evidence. Such evidence might include consistent, strong associations in longitudinal studies, biological plausibility, and corroborative experimental evidence. A dose–response relationship between the putative causal factor and the disease provides particularly strong evidence that the association is causal and that modification may reduce risk.

Tools of the trade for nutritionists

The methods for measuring food and drink intake are important tools for those who study diet–chronic disease relationships. Many studies have examined the association between changing patterns of food consumption at a national level and disease rates in various countries. Such studies do no more than provide clues for further research since the dietary data do not accurately reflect the consumption by individuals. Dietary intake of individuals is assessed by means of food frequency questionnaires, diet records, and recalls which all have different strengths and weaknesses. A weakness of most methods of assessing dietary intake is that some people, especially those who are overweight or obese, tend to underestimate their intake. Food composition tables are required to convert information gathered regarding food intake to consumption of energy and essential nutrients. Sometimes it is more reliable to assess the intake of a nutrient by measuring the level in the blood or urine or activity in the body than attempting to calculate intake from a diet record or food frequency questionnaire. Urinary sodium and iodine are examples of such biomarkers. Glutathione peroxidase activity provides a measure of assessing selenium status in those with a relatively low intake.

Coronary heart disease

Experimental, epidemiological, and clinical trial data provide strong evidence for the role of nutritional factors in the aetiology of coronary heart disease and the potential for dietary modification to reduce cardiovascular morbidity and mortality in the population as a whole, in individuals at high risk, and in those who have already experienced a cardiovascular event. Prospective studies suggest a wide range of foods and nutrients which may be involved (Table 2). Foods which increase the risk of coronary heart disease, when consumed in large amounts, probably do so because they are rich in saturated or *trans*-unsaturated fatty acids, and dietary cholesterol. 'Protective' foods contain several different nutrients which may reduce cardiovascular risk. Oily fish is rich in very long chain polyunsaturated fatty acids (eicosapentaenoic and docosahexaenoic acids; C20:5, *n*-3, C22:6,*n*-3). Fruit and vegetables are good sources of antioxidant nutrients, folate, and other biologically active substances. Nuts contain several potentially 'protective' fatty acids (oleic and linoleic acids; C18:1, C18:2) as well as vitamin E. Whole grain cereals are good sources of dietary fibre as well as some unsaturated oils. An example of the findings in one epidemiological study are given in Table 3. Each of the nutrients mentioned has an appropriately favourable or adverse effect on one or more of the cardiovascular risk factors (Table 4). The fact that some prospective studies suggest a protective effect of antioxidants derived from foods, whereas others have found particular benefit from antioxidant nutrient supplements, represents the single inconsistency in a very large body of data.

Clinical trials have shown that when diet is modified to facilitate appropriate changes in the nutrients mentioned above, levels of risk factors are altered in a favourable direction and cardiovascular events are reduced, even when the intervention is started in middle age with cardiovascular disease already present. The various trials have involved different dietary interventions so that formal meta-analysis is inappropriate, nevertheless it is possible to draw certain general conclusions regarding likely benefit from various dietary changes. Most have aimed for a reduction in plasma cholesterol by manipulation of dietary fat intake. For every 1 per cent reduction in plasma cholesterol a 2 to 3 per cent reduction in cardiovascular events occurs. Thus an 8 to 10 per cent reduction in cholesterol, which can be achieved by modifying the nature of dietary fat (replacing saturated fatty acids with mono- and *cis*-polyunsaturated fatty acids and cereals, vegetables, and fruit) will result in appreciable benefit. Trials which have examined potential benefits of dietary manipulations other than those designed to lower plasma cholesterol suggest that further clinical benefit might accrue from favourable changes in other risk factors. Consumption of oily fish two or more times per week, or a small amount of fish oil taken as a supplement, have been shown to reduce cardiovascular death in those with pre-existing coronary artery disease. While increased intakes of vegetables and fruit may confer a cardioprotective effect, there is at present no convincing evidence from clinical trials of benefit associated with the use of antioxidant nutrient supplements. The role of margarines rich in plant sterols and stanols, which may further lower dietary cholesterol by preventing absorption and reabsorption of dietary cholesterol, is yet to be established.

Community programmes, aiming to achieve dietary change along the lines indicated here, have been shown to reduce cardiovascular risk factors and one—the North Karelia Project in Finland—has shown that, in the intervention county, cardiovascular disease mortality decreased to a greater extent than might have been expected on the basis of experience in other Finnish provinces. The availability of appropriate food choices at reasonable cost is an essential component of any programme aimed at reducing cardiovascular risk, since rates are highest in those of the lowest socioeconomic status. While those at the highest personal risk are likely to show the greatest individual benefit from dietary and lifestyle changes, national coronary heart disease rates will only be reduced if changes are made by the population at large. The main purpose of such recommendations is to reduce the risk of morbidity and mortality from coronary heart disease in those who are in the prime of life. Even greater reduction in morbidity and mortality and an improvement in life expectancy may occur in succeeding generations who will have reduced lifetime exposure to risk factors related to lifestyle.

Hypertension

Over 30 years ago, Dahl drew attention to the correlation between salt intake and prevalence of hypertension in populations. This and other similar studies were flawed by methodological difficulties associated with measuring salt intake and blood pressure. The more recent Intersalt Study used standardized blood pressure measurements and 24-h urinary sodium excretion, the best available method of assessing intake. The study, which involved 52 centres in 32 countries, suggested that a difference in sodium intake of around 100 mmol/day over a 30-year period might be expected to result in differences of approximately 10 mmHg in systolic blood pressure and 6 mmHg in diastolic blood pressure. Meta-analyses of observational data and intervention trials show broadly comparable results. In one such meta-analysis, of 68 crossover trials and 10 randomized controlled trials of dietary salt reduction, it appears that a reduction of daily sodium intake of about 50 mmol (about 3 g salt) would, after a few weeks, lower systolic blood pressure by an average of 5 mmHg and by 7 mmHg in those with high blood pressure; diastolic blood pressure would be lowered by half as much. It is estimated that such a reduction in salt intake by a whole Western population would reduce the incidence of stroke by 26 per cent and of coronary heart disease by 15 per cent. Reduction also in the amount of salt added to processed foods would lower blood pressure by twice as much and could prevent as many as 70 000 deaths per year in Britain. The heterogeneity in the response of individuals to sodium restriction suggests the possible existence of a group of hyper-responders but there is as yet no clear indication as to how such individuals might be defined.

Several mechanisms have been suggested to explain the association between salt intake and blood pressure, including reduced urinary sodium excretion and fluid retention by some individuals, increased sympathetic nervous system activity and impaired baroreflex function, and alterations of ion transport in vascular smooth muscle.

Obese people have higher blood pressures than non-obese people and if they lose weight blood pressure falls even if the usual salt intake is maintained on the restricted diet. An Australian trial showed, in a clinical trial setting, that weight reduction (maximum loss of 7.4 kg) compared favourably with metoprolol in the treatment of mild hypertension, and diet was associated with an improved plasma lipid profile not seen on the drug.

In epidemiological studies, blood pressure increases progressively when reported alcohol intake increases above three drinks per day. Several intervention studies have shown that reduction of alcohol intake can produce an appreciable reduction in blood pressure amongst hypertensive heavy drinkers. For example one study showed that replacing standard beer (5 per cent alcohol) with a reduced alcohol beer (0.9 per cent alcohol) produced a reduction in alcohol intake from 450 to 64 ml/week and a significant fall in blood pressure.

High intakes of potassium and calcium and a vegetarian diet have also been shown to be associated with reduced levels of blood pressure. However, it was previously believed that these were relatively unimportant compared with dietary sodium and overweight. The recent DASH (Dietary Approaches to Stop Hypertension) trial has shown a remarkably powerful blood pressure-lowering effect in association with a diet rich in fruit, vegetables, and low-fat dairy products. In hypertensive individuals, systolic and diastolic blood pressures were lowered by 11 and 6 mmHg respectively, compared with the control group. Smaller changes were

seen in the normotensive group, 3 and 9 mmHg for systolic and diastolic pressures respectively. These findings require confirmation.

Diabetes mellitus

Diet undoubtedly plays an important aetiological role in type 2 diabetes mellitus. As early as 1920, Himsworth suggested that excessive intake of energy, deficiency of dietary carbohydrate, and possibly an excessive intake of fat might increase the risk of diabetes. His conclusions were largely based on the improved glucose tolerance observed in non-diabetic individuals eating a high carbohydrate compared with a high fat/low carbohydrate diet. He also noted the association between high carbohydrate intakes and reduced mortality from diabetes and the fact that newly diagnosed diabetic patients were found to have a high intake of total energy (especially energy derived from fatty foods) before the onset of symptoms than non-diabetic controls. Although Himsworth's findings are based on studies which may not fulfil the criteria required of modern nutritional epidemiology, the conclusions have largely been confirmed by subsequent epidemiological and clinical studies.

Epidemiological surveys and longitudinal studies in many countries confirm the striking association between increasing degrees of obesity and the risk of developing type 2 diabetes mellitus. The association is strongest in those with central (android) obesity and those with a family history of the condition, reflecting the importance of genetic determinants (see also Chapter 10.5). While energy intake in excess of requirements is now universally accepted as an important risk determinant, controversy has raged with regard to the extent to which macronutrient distribution and some micronutrients might be involved in the aetiology of type 2 diabetes. Epidemiological evidence suggests that the condition is uncommon in people eating a range of 'traditional diets' high in fresh fruit, vegetables, and cereals, and therefore high in starches and non-starch polysaccharides and low in fat. Diabetes prevalence seems to increase rapidly when traditional lifestyles are exchanged for the Western way of life, particularly when such transitions occur over a short time span. Such changes have been clearly demonstrated in Micronesians, Polynesians, American Indians, and Aboriginal Australians, as well as Chinese and Asian immigrants to Mauritius. A sharp rise in the frequency of type 2 diabetes mellitus also emerges from studies of Asian Indian immigrants to Fiji, South Africa, and Britain, and of Chinese in Singapore, Taiwan, and Hong Kong. The change from traditional to a Western diet is usually accompanied by a reduction in physical activity. As lifestyle change starts to occur in China and India, by far the most populous countries, type 2 diabetes mellitus may create an enormous public health problem. Indeed, it seems reasonable to claim that the disease has already reached epidemic proportions in many indigenous populations amongst whom it is difficult to disentangle the relative importance of genetic and environmental factors. By contrast, North Western Europeans and Anglo-Celts have a relatively low susceptibility to diabetes.

It is not yet clear whether any single attribute of the Western way of life is particularly important in increasing the risk of diabetes. Excess sucrose has been largely exonerated as an important dietary factor in the aetiology of type 2 diabetes, except perhaps when, alongside a high intake of fat, it contributes towards an excessive energy intake. A high intake of saturated fatty acids undoubtedly further decreases insulin sensitivity, an underlying abnormality in type 2 diabetes. One large prospective study of health professionals in the United States has found that a high intake of low glycaemic index foods (i.e. predominantly carbohydrate-containing foods producing a relatively low glycaemic excursion after ingestion when compared with a comparable amount of glucose) tends to protect against type 2 diabetes and that the effect is independent of other individual dietary attributes. A low level of physical activity appears to be an important predisposing factor for obesity and hence type 2 diabetes. Thus, it seems most likely that a combination of factors is responsible.

Australian Aboriginals who have adopted a Western diet have high rates of diabetes. A study in Australia showed that reverting to their traditional lifestyle is associated with a marked improvement in several indices of carbohydrate metabolism. Many studies in affluent societies have shown that weight reduction in overweight people, those with impaired glucose tolerance, and people with diabetes can often result in normal, or near normal, blood glucose levels without the need for oral hypoglycaemic therapy. Furthermore, diets high in soluble forms of non-starch polysaccharides and in which low glycaemic index carbohydrate-containing foods predominate can improve glycaemic control in those with diagnosed diabetes, independent of an effect on body mass. However, in people who are not overweight, sufficient improvement to reduce the need for drug therapy and achieve even near normal blood glucose concentrations is seen only with extreme dietary change (i.e. diets consisting largely of raw and unprocessed foods and exceptionally low in fat). Intervention studies in people with impaired glucose tolerance suggest that risk of progression to diabetes can be reduced and that this results chiefly from weight loss rather than modification of individual nutrients. However, the largest intervention study involving advice to modify diet and increase physical activity carried out so far has been in progress for 6 years, and there is a suggestion that the condition may relapse with time, possibly as a consequence of reverting to previous lifestyle habits. Thus, while it appears that reducing the level of obesity in the population at large is the single measure most likely to reduce overall rates of type 2 diabetes mellitus in high-risk groups, the extent to which risk reduction can be achieved in practice remains to be established.

Although diet is important in the management of type 1 diabetes, nutritional factors do not appear to have contributed to the aetiology of the disease to the same extent as for type 2 diabetes mellitus. Genetic and other environmental factors are believed to be more important. Recent studies have suggested, however, that infants who have been breastfed may have a reduced risk of type 1 diabetes mellitus in later life and this observation could be linked with immune mechanisms known to be associated with this condition.

Cancers

The development of cancer involves several stages and occurs over a long period of time. Nutritional factors may operate at one or more of these stages. During the first stage of initiation, the DNA of the healthy cell is damaged by chance mutation or a carcinogen. During the promotion (second) stage, the 'initiated' cells may be exposed to promoters, environmental factors, which create conditions which favour their growth over that of normal cells. This phase tends to be prolonged and may be delayed or accelerated by environmental factors. Genetic factors also operate. Ultimately, preneoplastic cells are formed which differ in appearance and function from normal cells. During the final stage of progression, additional mutations tend to occur leading to the transformation of preneoplastic to neoplastic cells. Nutritional factors may act as carcinogens or promoters. Given this long natural history of the disease process, it is hardly surprising that few data from intervention trials are available and data relating dietary factors to various cancers are derived from epidemiological associations and animal experiments. Nevertheless Doll and Peto have estimated that about one-third of all cancers in Western countries may be attributed to diet. The dietary and nutritional factors which may play a role in human cancer are listed in Table 5.

Breast cancer is a common cancer amongst women in the Western world. There is a strong, positive correlation between fat intake and breast cancer rates in different countries and a pooled analysis of case–control studies suggest an increase in relative risk of breast cancer associated with a high fat intake in postmenopausal but not premenopausal women. Animals given chemical carcinogens develop fewer tumours if they are given a low fat diet. However, prospective studies have not confirmed higher rates of breast cancer in women with high fat intakes. Thus, it is not absolutely clear whether fat intake is a risk factor *per se* or simply a marker for some other important environmental factor operating in countries with high rates of breast cancer. Furthermore, high fat intakes may be associated with obesity, high circulating endogenous oestrogens, and early menarche, all of which have been clearly established as risk factors. Plant oestrogens (isoflavones from soy products, lignans in wholegrain cereals and vegetables) may also be protective by increasing the length of the menstrual cycle, thus reducing the number of menstrual cycles and reducing exposure to peak hormone levels.

Cigarette smoking is unquestionably the most important cause of lung cancer, one of the most common cancers. However, vegetables and fruit have consistently been shown to have a protective effect in more than 30 case–control and prospective studies. A large clinical trial in which heavy smokers were given supplements of a-tocopherol, b-carotene (presumed to be the protective factors in vegetables and fruit), or placebo, showed no clinical benefit but with hindsight the results were not surprising. It seems most unlikely that the carcinogenic effects of prolonged, heavy cigarette smoking can be reversed by vitamin supplements given over a short period of time.

Colorectal cancer is the second most common cause of cancer amongst males. A low intake of vegetables and non-starch polysaccharide appear to be the most consistent dietary factors associated with increased risk. Non-starch polysaccharide escapes digestion in the small intestine and is fermented in the large bowel by the colonic microbial flora. Short chain fatty acids are produced, one of which, butyrate, is an antiproliferative agent. Non-starch polysaccharide may further reduce the risk of large bowel cancer by stimulating bacterial growth and increasing the biomass as well as the unfermented non-starch polysaccharide binding with water, so leading to an increase in stool weight, dilution of colonic contents, and faster transit time through the large bowel. High fat diets are associated with increased concentration of bile acids in the colon. These are converted to secondary bile acids, of which deoxycholic acid is a known promoter of large bowel cancer. A 4-year intervention trial has shown that a low fat diet (fat providing less than 25 per cent total energy) plus 25 g wheat bran daily can reduce the frequency of large adenomas in the large bowel but this has not been confirmed in two other comparable studies. There is insufficient evidence to reliably incriminate another potentially deleterious factor: high intake of red meat. However, it is possible that the method used for cooking meat may be important. Increased intakes of heterocyclic amines may form on the surface of cooked meat, especially during grilling, frying, or cooking on a barbecue. It has also been suggested that *n*-3 polyunsaturated fatty acids may be protective because they slow down the rate of cell division of mucosal colonic cells.

Cancer of the prostate is the third most common cancer in males, with a seventy-fold variation in incidence, the highest rates (in the United States, Europe, and

Australasia) being associated with the highest intakes of fat. In contrast with most other sites, there appears to be no protective effect of vegetables and fruit.

Cancer at all other sites is less frequent, but nutritional causes appear to be involved for some. Alcohol appears to play an important role in cancers of the mouth, pharynx, oesophagus, and liver. Obesity is an important factor in endometrial cancer and may have some role in postmenopausal breast cancer in women and bowel cancer in men. A high intake of salted foods may be involved in cancer of the stomach and vegetables and fruit appear to be protective against cancers at most sites.

Obesity (see also Chapter 10.5)

Obesity is the most obvious and important nutritional disease in affluent societies, its comorbidities including type 2 diabetes, coronary heart disease, hypertension, stroke, gallstones, osteoarthritis, some cancers, and obstructive sleep apnoea. Obese people may also be disadvantaged in terms of social, economic, and psychological effects. The psychological well being of children may be particularly affected. Most of the adverse consequences of obesity are appreciably reduced by weight loss, though gallstone formation may not be reduced. While the genetic component of obesity is acknowledged, the dramatic increase in prevalence in virtually all westernized countries in recent years provides ample evidence of the overwhelming importance of environmental factors. Inactivity is unquestionably an important cause but increased consumption of readily available 'convenience' and other energy-dense foods contribute to an energy intake in excess of expenditure. It seems unlikely that the epidemic of obesity will be reversed unless the nutritional environment in which we live is altered by creating more opportunities for physical activity and improving availability of food choices, and providing appropriate health education.

Diverticular disease of the colon

The first suggestion that deficiency of non-starch polysaccharides in the diet may be implicated in the aetiology of diverticular disease of the colon came from striking geographical variations in its prevalence and the documented increase in disease rates in several European countries since the 1920s. These variations and trends in rates are certainly compatible with a causative link with low non-starch polysaccharide diets but could also be explained by several alternative dietary and other environmental influences. The best-documented evidence comes from comparisons of asymptomatic groups of vegetarians and meat eaters who volunteered to have a barium meal. Radiological diverticular disease was found more frequently amongst non-vegetarians (33 per cent) than vegetarians (12 per cent) who had appreciably higher intakes of non-starch polysaccharide. Furthermore, when comparing individuals with and without diverticular disease in both the vegetarian and non-vegetarian groups, those with diverticular disease had appreciably lower intakes of non-starch polysaccharide than those with no evidence of diverticulae following barium meals. Animal experiments provide support (for example rats given a diet low in non-starch polysaccharide have been shown to develop diverticulae, as do rabbits fed with white bread, sugar, and vitamins, and given prostigmine). An increase in non-starch polysaccharide intake is widely recommended to patients with symptomatic diverticular disease, a treatment justified by the findings of some (but not all) controlled clinical trials.

Plausible theories concerning pathogenesis have been suggested; small, hard faeces, undoubtedly seen with a diet deficient in non-starch polysaccharide, are associated with narrowing of the colon and the formation of closed segments in which pressure increases. Additional work is needed by colonic muscles to provide the pressure to move the more solid faeces, producing muscular hypertrophy in addition to the diverticula at sites of weakness where blood vessels penetrate the muscular coat.

Dental caries

Dental caries was exceptionally rare among young people in ancient Britain. Surveys over the past 15 years have suggested that as many as 80 per cent of 5-year-olds require treatment for dental caries and about 10 per cent of all children enter school with more than half their teeth seriously decayed. Some 5 per cent of the adult population in England and Wales and 15 per cent of that in Scotland are edentulous by the age of 30 years. Several strands of evidence suggest a nutritional cause. Amongst the indigenous population of many countries where unrefined foods form the bulk of the diet (e.g. China, Uganda) dental caries once had a very low prevalence. Within a few years of the addition of sugar and other refined foods the frequency showed a rapid increase. A similar change has been shown experimentally in monkeys. In a classical experiment carried out in a Swedish mental hospital, volunteers given toffee apples, chocolate, and caramel in addition to their controlled diet had a thirteen-fold greater number of tooth surfaces becoming carious each year, compared with those eating the controlled diet alone. While frequency, timing, and amount of extrinsic sugars may be important in the aetiology there is no doubt that fluoride in the water or in tooth paste can profoundly reduce the risk of dental caries.

Constipation and the irritable bowel syndrome

Nine-nine per cent of a large population sample studied in Britain reported that they defecated at least three times per week but perceived constipation is a frequent complaint. Approximately 3 per cent of all prescriptions written in the National Health Survey (in the United Kingdom) were for purgatives and laxatives, at a cost of around £4 000 000, and many times this amount must have been spent in buying these preparations over the counter. In another survey, 6 per cent of people aged between 18 and 80 years described straining when passing stools. No data are available concerning the frequency of passing small stools. There seems little doubt that constipation is uncommon in populations with a high intake of non-starch polysaccharide. In rural Africa, stool weights are frequently around 500 g daily, and bowel transit times around 40 h. In Britain, stool weights in non-vegetarians are more usually around 100 g (with a very wide range), whereas in vegetarians the average stool weight is over 200 g. Factors other than non-starch polysaccharide might be involved but British vegetarians and non-vegetarians with high average daily intakes of non-starch polysaccharide have transit times of less than 75 h and rarely report constipation, whereas those with lower intakes have transit times ranging from 20 to 124 h and frequently complain of constipation. There is no doubt that increasing the non-starch polysaccharide content of the diet (especially that derived from cereals) relieves the symptoms of constipation, an observation now confirmed by controlled clinical trials. There is no direct evidence of a causal link between a diet low in non-starch polysaccharide and the irritable bowel syndrome, but diets rich in non-starch polysaccharide are widely recommended in its treatment and are believed to be of value, even in the absence of formal clinical trials.

Osteoporosis

Osteoporosis is an important cause of morbidity amongst the elderly, especially in women, and the incidence of osteoporotic fractures is increasing steadily as people are living longer. In 1990, there were an estimated 1.66 million hip fractures world-wide. By the year 2025, it is projected that there will be 1.16 million hip fractures in men and 2.78 million in women due to osteoporosis. The aetiology of osteoporosis is complex; women have a lower peak bone mass than men and then lose bone rapidly after the menopause in association with a decline in oestrogens. Women lose approximately half their trabecular bone and a third of their cortical bone, while men lose a third of their trabecular bone and a fifth of their cortical bone. Genetic factors influence peak bone mass and bone loss and these may operate by some of the well-known risk factors: strong family history of osteoporosis, short stature, early menopause, and white or Asian race. However, there are also clearly established environmental factors, including leanness (genetic factors probably operate in addition), multiparity, cigarette smoking, and excessive alcohol intake. The role of dietary calcium has been uncertain but there is now convincing evidence that the best way of avoiding osteoporotic fractures in later life is to achieve optimal skeletal mass for one's genetic potential and to retain this as long as possible. The best means of doing so is by ensuring lifelong adequate consumption and maximum absorption and retention of calcium. The need for substantial amounts of dietary calcium, taken in conjunction with physiological amounts of vitamin D, is particularly important during the periods of growth, pregnancy, lactation, and in the postmenopausal years.

Other diseases

Gallstones, appendicitis, haemorrhoids, varicose veins, and hiatus hernia all occur frequently in developed countries and rarely in developing countries but the evidence linking these diseases to a nutritional cause in tenuous. Gallstones are undoubtedly associated with obesity. Both gallstones and appendicitis are more common in non-vegetarians than vegetarians and there are some rather indirect data suggesting an association with diets high in sugars and deficient in non-starch polysaccharides. The addition of bran to the diet can make bile less saturated and experimentally induced gallstones in animals tend to be reduced if foods rich in non-starch polysaccharides are given. Data from the United Kingdom and South Africa taken together provide interesting information concerning appendicitis; appendicitis rates were compared in two matched South African Caucasian groups, the privileged group living in university halls of residence and the other living in the establishments for the indigent where the diets contained more fibre. Annual rates were 7.8 and 1.8 per thousand, respectively. Of course, factors other than diets might explain this but the rates were strikingly similar to those found in an almost identical study in Bristol (7.6 per thousand in a public school and 0.8 per thousand in an orphanage).

The case for dietary change

Nutrition research often generates results which may be translated by researchers, self-styled 'experts', or the media into potentially confusing and conflicting messages. It is therefore critically important for governments, who develop food and nutrition policies, for doctors, others involved in health and nutrition education, and for consumers to have authoritative recommendations which represent consensus opinions of nutrition scientists. Terminology regarding such recommendations has been confusing, but the most recent British Government publication suggests a new approach. Dietary reference values are intended for policy makers and health professionals who recommend diets for individuals. These include population averages (sometimes also recommended individual minimum and maximum intakes) for the macronutrients, average requirements for total energy, and reference nutrient intakes (previously referred to as recommended dietary intakes or allowances) for vitamins and minerals. The latter values are defined as levels of intake which will satisfy the requirements of the great majority in any given population. Thus, the reference nutrient intake is set at two (estimated) standard deviations above the average of all individual requirements for each nutrient. While this approach helps to ensure nutritional adequacy, the situation has become more complex with the suggestion that some nutrients might confer protection against certain chronic diseases when intakes exceed the reference nutrient intake. Thus, it is now considered necessary to set an upper safe level beyond which toxic effects may occur. These dietary reference values will be largely meaningless to the population at large. For the general public, dietary guidelines have been developed to translate dietary reference values into practical advice.

The dietary reference values for macronutrients (Table 6) are based to a considerable extent on the evidence-based data which suggest that alteration of dietary fat intake from that typical of most Western countries is likely to reduce population and individual risk of coronary heart disease. The emphasis is on reduction of saturated and *trans* unsaturated fatty acids and the recommendation represents a substantial reduction from present levels of intake. The recommended intake of *cis*-monounsaturated acids is similar to that at present but adherence to the recommendation for saturated fat will inevitably lead to an alteration in source, from animal to vegetable, since at present much of both mono- and saturated fatty acids are derived from the same animal sources. The total intake of *cis*-polyunsaturated fatty acids has been set at a level slightly higher than at present but the proportions of *n*-3 and *n*-6 are not specified. However, a recent European consensus group has suggested that those not eating fish at least once a week should consider obtaining 200 mg of very long chain *n*-3 polyunsaturated fatty acid daily from other sources. In view of the growing evidence that plant *n*-3 polyunsaturated fatty acid might independently reduce coronary heart disease risk, an intake of 2 g/day or 1 per cent total energy from a-linolenic acid is also recommended. The group advised against the use of *n*-3 to *n*-6 ratios but favoured separate recommendations for a-linolenic acid, marine *n*-3 polyunsaturated fatty acid, and linoleic acid.

Only about 50 g of carbohydrate daily is required to avoid ketosis and at the other end of the range of intake many populations maintain an adequate nutritional status when carbohydrate provides up to 80 per cent total energy. However, most Western societies are unaccustomed to a high carbohydrate intake and are reluctant to accept substantial increases. Therefore, a modest increase in total carbohydrate is advised with a limitation on the use of non-milk extrinsic sugars because of their role in dental caries, especially when consumed frequently. Furthermore, foods high in extrinsic sugars are energy-dense and contain relatively few essential nutrients. On the other hand, it is considered appropriate (Table 6) that intrinsic sugars (that is those incorporated into the cellular structure of foods), milk sugars, and starches should provide the balance of dietary energy not provided by protein, fat, and non-milk extrinsic sugars, that is, an average of 37 per cent total dietary energy. Foods containing these macronutrients are usually good sources of essential micronutrients as well as dietary fibre (non-starch polysaccharide), an increase in which is also recommended because of the convincing evidence for benefit in terms of bowel function and possible benefits regarding a range of diseases of the large intestine, diabetes, and cardiovascular disease.

It seems conceivable that these recommendations regarding carbohydrate may be modified in the future. It is becoming increasingly clear that the health benefits associated with carbohydrate-containing foods are principally derived from carbohydrates which are not digested and absorbed in the small intestine but which enter the large bowel where they undergo fermentation or act as stool-bulkers. The process of fermentation leads to the production of fatty acids which are useful not only as fuel sources but by their antiproliferative effect may also reduce the risk of colon cancer. Carbohydrates which undergo fermentation include oligosaccharides, resistant starch, and certain non-starch polysaccharides such as gum, pectins, and mucilages. Those which remain intact and act as stool bulkers include cellulose, hemicellulose, and lignin. The suggestion that complex carbohydrates may confer health benefits is becoming outmoded since many forms of starch are rapidly digested and absorbed as sugars. Thus the extent and speed with which carbohydrates are digested and absorbed in the small intestine provide the best indicator for health-promoting, carbohydrate-rich foods. The most useful, simple indicator of this is the glycaemic index (Fig. 1). A recent World Health Organization Expert Consultation has suggested that this index might guide the choice of carbohydrate-containing foods, the lower glycaemic index foods being the preferred food choices (see Table 7).

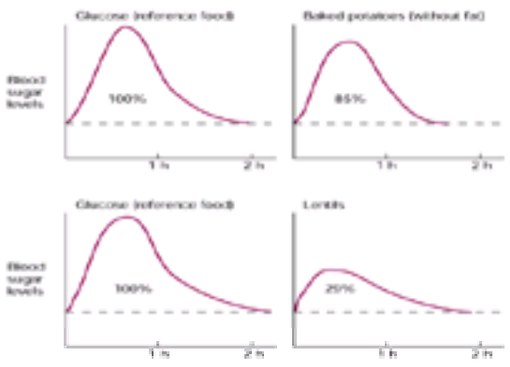

Fig. 1 Calculation of the glycaemic index of a food. The area under the blood glucose curve is calculated geometrically using the fasting level as baseline and expressed as a percentage of that seen after consumption of 50 g pure glucose. In practice, 8 to 12 people are tested and the mean of the group is the glycaemic index of the test food.

The glycaemic index concept does have limitations. It is important to emphasise that it should not be used for carbohydrate-containing foods which are also high in fat. These will usually have a low glycaemic index but are obviously not regarded as the best choices. Sucrose and sucrose-rich foods will also have a relatively low glycaemic index because of their fructose content. While the detrimental effects of sucrose have been overstated in the past, sucrose confers no health benefits other than acting as an energy source. Given the need to reduce energy dense foods in many countries sucrose-rich foods are not generally encouraged.

While appropriate distribution of macronutrients might be expected to reduce cardiovascular risk, improve bowel function, and probably also reduce the risk of certain cancers and other diseases of the large bowel, it is imperative to consider the extent to which diet can influence obesity and its comorbidities, especially type 2 diabetes which accounts for a public health problem of enormous magnitude. Increasing carbohydrate-containing foods rich in non-starch polysaccharide at the expense of saturated fat is likely to enhance satiety and so help to reduce excessive energy intake. However, increasing energy output by increasing physical activity is an equally essential component of public health measures designed to stem the tide of the obesity epidemic occurring in most affluent societies and many developing countries.

Reference nutrient intakes (adequate for most individuals) are provided for vitamins and minerals; selected examples are shown in Table 8. Clinical vitamin deficiencies, discussed in detail in Chapter 10.3 are uncommon in affluent societies except in at-risk subgroups within populations. For example immigrants who have migrated from sunny, tropical to high latitude, cloudy countries may be at risk of vitamin D deficiency; strict vegetarians (who consume no animal or dairy products) may become deficient in vitamin B_{12}, and disadvantaged groups (especially the very young, pregnant and lactating women, and the elderly) may have generally inadequate intakes.

On the other hand, inappropriate intakes of certain minerals are fairly common. Many groups are particularly vulnerable to iron deficiency, due to high physiological requirements (infants and toddlers, adolescents, pregnant women), high losses (menstruating women), or poor absorption (the elderly and people consuming foods high in inhibitors of absorption, such as fibre and tannin in tea). Vegetarians are also at increased risk of iron deficiency even when total intake of iron appears to be adequate since non-haem iron from plant foods is less bioavailable than haem iron from animal sources. Bioavailability is enhanced by the consumption, at the same time, of vitamin C. Iodine and selenium are deficient in soils in various parts of the world. Clinical selenium deficiency has only been reported from China though the consequences of lesser degrees of selenium deficiency have yet to be established with certainty, especially in regions where soils are known to be deficient (e.g. the South Island of New Zealand). Endemic iodine deficiency is widespread, especially in the Himalayas and the Andes, and clinical deficiency states are largely avoided by the use of iodized salt and sanitizers containing iodine used by the dairy industry. Interestingly, in New Zealand where goitre due to iodine deficiency had virtually been eliminated, mild iodine deficiency appears to be reoccurring possibly as a result of reduced use of iodized salt and the introduction by the dairy industry of

alternative sanitizers. Young women often have insufficient calcium to help achieve peak bone mass, and older women may have an inadequate intake to help reduce an age-related bone loss.

Excessive intakes of sodium, to such an extent that it probably contributes to hypertension and its consequences, are common throughout the Western world. Targets for reduction may be more important than reference nutrient intakes for sodium. An intake of 100 mmol/day (2.3 g/day), a level currently exceeded in most countries, might be an appropriate maximum.

Folate is probably the best example of a nutrient for which intakes greater than those recommended have been shown to confer benefit. Intakes of 400 µg or more per day (reference nutrient intake 200 µg/day) can appreciably reduce the risk of neural tube defects. Furthermore, the potential for folate to reduce cardiovascular risk by a reduction in plasma homocysteine concentrations may provide further justification for higher recommended intakes if the trials underway at present demonstrate reduced cardiovascular risk. There is evidence that higher than recommended intakes of several antioxidant nutrients reduces subsequent cardiovascular risk and possibly also the risk of certain cancers. However, there are insufficient data regarding optimum intakes to contemplate firm recommendations at present.

Dietary assessment methods are not sufficiently sensitive to determine accurately intake of several important nutrients so that in order to assess either adequacy or excess in an individual or group of individuals for clinical or research purposes it is necessary to use biomarkers. Intakes of iodine and sodium are assessed by measuring amounts in 24-h urine collections. Measurement of folate concentration in the serum or red blood cells provide a good estimate of intake since the amounts in fruit and vegetables vary enormously and are also dependent upon shelf-life and method of preparation. Fatty acid composition of serum or red cell membrane provides an indication of the nature of dietary fat intake. For some nutrients which are not always readily bioavailable adequacy of intake must be assessed by alternative means. In the case of iron, measurement of ferritin in the blood (indicating iron stores) is a more useful indicator of iron status than dietary intake (see also Chapter 22.4.4).

Substantial changes in what have become traditional eating habits of many affluent societies are required in order to achieve the advised changes in distribution of macronutrients and recommended intake of all essential micronutrients. A multifocal approach is necessary if there is to be a real chance of achieving dietary change. At the policy making and government level, there needs to be a serious commitment to enabling the population as a whole to make appropriate food choices. Fatty cuts of meat, high-fat products (e.g. meat pies), and convenience foods (e.g. fish and chips, burgers) are relatively inexpensive and therefore frequently eaten by those of lower socio-economic status who have the highest rates of coronary heart disease. Policies are required which ensure that more appropriate food choices are available at reasonable cost. This is not easy to achieve in many Western countries where farmers may have considerable political influence and subsidies may be available for some high-fat dairy products such as butter and cheese. Governments and intergovernmental agencies also have the responsibility for ensuring that food labels and health claims are accurate, interpretable, and likely to facilitate health-promoting food choices, a particularly important issue given the increased consumption of packaged food.

Dietary guidelines are necessary to provide clear directions to individuals and families who wish to aim for a healthy diet pattern. These guidelines vary slightly from country to country though some are almost universal (see Box 1). Others are less consistent (see Box 2). The public also need education regarding food groups and the nutrients they contain, the interpretation of food labels, the meaning of health claims, and the methods of food preparation. The increased use of convenience and packaged food has meant that many people no longer possess basic cooking skills. They also need (and want) to know the merits and demerits of obtaining certain essential micronutrients by taking supplements or fortified food products rather than conventional foods.

Box 1 Dietary guidelines for which there is almost complete agreement

1. Eat a nutritionally adequate diet composed of a variety of foods.
2. Eat less fat, particularly saturated fat.
3. Adjust energy balance for body weight control—less energy intake, more exercise.
4. Eat more wholegrain cereals, vegetables and fruits.
5. Reduce salt intake.
6. Drink alcohol in moderation, if you do drink.

Box 2 Additional dietary guidelines in some countries

1. Recommendation regarding sugar and sugary foods may vary from 'no increase' to 'decrease'.
2. Drink plenty of fluids each day.
3. Make sure you get enough calcium or milk.
4. Eat foods containing iron.
5. Do not eat too much protein.
6. Limit caffeine intake.
7. Drink fluoridated water.
8. Preserve the nutritive value of food (by good food preparation).
9. Eat three good meals a day.

Doctors are frequently asked to give nutritional advice but may lack the necessary expertise. Dietitians, nutritionists, and appropriately trained practice nurses, play an invaluable role in providing the public with practical advice to facilitate changes from the typical Western diet as well as providing instruction regarding therapeutic diets for those with diseases requiring specific diet therapy. The enormous potential for dietary change to reduce the effects of a wide range of diseases should encourage physicians to approach the nutritional management of their patients with enthusiasm.

10.2 Nutrition: biochemical background

Keith N. Frayn

Introduction: flux of 'energy substrates'

Food intake is sporadic: for most people it occurs in three major boluses each day. Energy expenditure, however, is continuous, with variations during the day that bear no resemblance to the pattern of energy intake, except that over some reasonable period of time (a week or more) the two will, in most people, match almost exactly. Therefore the body has developed complex systems that direct nutrients into storage pools when they are in excess, and that regulate the 'mobilization' of nutrients from these pools as they are needed. The situation is analogous to the petrol (gas) tank of a motor car and the throttle that regulates fuel oxidation, except that in the motor car there is just one fuel and just one engine: in humans there are three major nutrients and a variety of tissues and organs, each of which may have its own preferences for fuels, that vary with time. The fact that we can carry on our daily lives without thinking about whether to store or mobilize fuels, and which to use, attests to the remarkable efficiency of these control systems.

The body's principal macronutrient stores are listed in Table 1 and are related to daily fluxes in the body.

The regulation of macronutrient flux

The need for the co-ordinated control of nutrient storage and mobilization, to flux between tissues and along the many metabolic pathways, is met by a complex series of control mechanisms. These may be viewed on several levels.

The simplest involves the effects of substrate concentration, and is dependent upon the kinetic properties of enzymes and transport proteins. An illustration is the uptake of glucose by the liver. The facilitated carrier responsible for entry of glucose into the hepatocyte, GLUT2, has a high Michaelis constant, K_m (around 10–20 mmol/l), for glucose and a high capacity. The first enzyme of glucose metabolism in the hepatocyte, hexokinase IV (glucokinase), has similar properties. Therefore, flux of glucose into the hepatocyte is dependent upon the extracellular to intracellular concentration gradient. When glucose is absorbed from the small intestine and transported to the liver in the portal vein the hepatocyte is subject to an external glucose concentration of perhaps 10 mmol/l, and acts as a 'sink' to remove glucose and buffer fluctuations in delivery of glucose to the systemic circulation. In contrast, the glucose transporter in the brain, GLUT3, has a low K_m (around 1–3 mmol/l), and glucose utilization is therefore almost constant while the plasma glucose concentration varies within the normal physiological range. Within tissues the same may be true. The aminotransferases (transaminases) that catalyse the removal of amino groups from amino acids, the first step in their catabolism, have a high K_m and high capacity, and again flux is driven by concentration. Hans Krebs showed that this was one explanation for the old observation that an increase in protein intake is followed by rapid oxidation of the excess amino acids.

The next level involves more specific interaction of nutrients, or pathway intermediates, with enzymes, usually through allosteric effects (binding of the effector alters the conformation of the enzyme and hence its catalytic properties). There are many examples in the metabolism of carbohydrate, fat, and protein. The enzyme 6-phosphofructo-1-kinase (which converts fructose-6-phosphate to fructose-1,6-bisphosphate in the pathway of glycolysis) is a good example, subject to allosteric regulation by many compounds that relate to the 'energy status' of the cell. For instance, it is activated by AMP (indicating energy shortage) and inhibited by ATP. Such mechanisms undoubtedly provide important 'fine tuning' of flux along various pathways entirely in accord with the modern view that regulation of flux does not reside in certain 'rate-limiting steps' but is distributed amongst many steps along a pathway.

These mechanisms operate essentially within one tissue. However, the co-ordination of nutrient metabolism requires considerable interaction between tissues and organs. This co-ordination is largely brought about by the hormonal and nervous systems. Certain hormones play a particularly important role in regulation of macronutrient flux (Table 2). The role of the nervous system in metabolic regulation is often difficult to assess. For instance, whilst the effects of adrenaline are properly regarded as hormonal, liberation of noradrenaline from sympathetic nerve endings in tissues may bring about identical effects and can be difficult to distinguish. The somatic nervous system (motor neurones innervating skeletal muscle) has clear effects, for example stimulation of breakdown of muscle glycogen linked to muscle contraction. The autonomic nervous system probably plays multiple roles, but some are indirect: for example regulation of blood flow and cardiac output, thus affecting delivery of substrate to tissues, and regulation of the secretion of pancreatic hormones.

The effects of hormones are mediated in many ways, but may be divided into acute effects (usually acting within seconds or minutes), often brought about through reversible (de)phosphorylation of enzymes, and longer-term effects (hours or days), brought about by regulation of gene expression. The former are usually exerted through binding to cell surface receptors linked to a variety of second messenger systems, the latter through nuclear receptors (for example for glucocorticoids and thyroid hormones). However, the distinction is not absolute: insulin, for example, brings about both acute and longer-term effects through binding to the same cell surface receptor.

A further level of co-ordination is through the effects of nutrients themselves, or important cellular components such as cholesterol, upon gene expression. This can be seen as a longer-term mechanism to ensure that metabolism is appropriate to the diet being ingested and the lifestyle followed. A variety of nutrient response elements are being discovered in the promoter regions of genes for enzymes concerned with substrate metabolism. Particular examples are the carbohydrate response element (upregulating expression of genes for glucose metabolism such as pyruvate kinase in the glycolysis pathway), the sterol response element (cellular sterols downregulate expression of the low-density lipoprotein receptor and the enzymes of cholesterol biosynthesis) and response elements for fatty acid derivatives. Fatty acids affect gene expression through a family of transcription factors known as the peroxisome proliferator activated receptors which act in turn upon the peroxisome proliferator response elements. These were discovered through the effects of a diverse group of compounds that promote proliferation of peroxisomes in the rodent liver. Now they are recognized as factors that mediate the response to dietary fatty acids. They are summarized in Table 3.

Carbohydrate metabolism in the postabsorptive and postprandial states

The postabsorptive state

In the overnight-fasted (postabsorptive) state, no glucose enters the plasma from the small intestine. Glucose in the plasma turns over at about 2 mg/kg body weight/min (200 g/24 h). About one-half of this will be consumed by the brain. Of the remainder, a considerable proportion will be utilized by blood cells and peripheral tissues by anaerobic glycolysis, thus returning lactate to the liver for reconversion to glucose (Fig. 1). This is the Cori cycle.

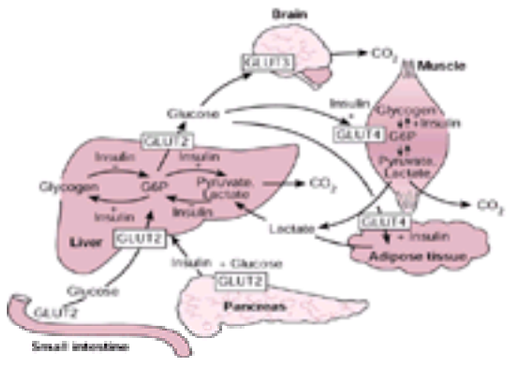

Fig. 1 Overview of carbohydrate metabolism. Pathways in the liver shown as regulated by insulin are probably controlled by the insulin/glucagon ratio (high in the fed state, low in fasting). In muscle, contraction is an important stimulus for glycogen breakdown and glycolysis. Adrenaline also contributes. Not shown is the significant glucose uptake by red blood cells and other glycolytic tissues, returning lactate to the liver. GLUT2 is the high- K_m non-insulin regulated glucose transporter (i.e. the glucose flux is determined by concentration), GLUT3 is the low- K_m brain glucose transporter (the glucose flux is relatively independent of concentration within the normal range), and GLUT4 the insulin-regulated glucose transporter. G6P is glucose 6-phosphate.

Glucose is produced by hepatocytes from glycogen breakdown and from gluconeogenesis. Net glycogen breakdown is stimulated by the relatively low insulin/glucagon ratio after overnight fasting. The major substrates for gluconeogenesis are lactate and pyruvate, released from blood cells and peripheral tissues, together with alanine and glycerol. The pathway of gluconeogenesis predominates over that of glycolysis, again because of the relatively low insulin/glucagon ratio.

Glucose metabolism following a meal

When a meal enters the system, this pattern of metabolism changes rapidly. About 12 g of free glucose are present in the circulation and extravascular space. Typically, a single meal will provide about 100 g of glucose, entering the circulation over perhaps 60 min. In order to minimize variations in plasma glucose concentration, co-ordinated mechanisms come into play to suppress the production of endogenous glucose and to increase the rate of removal of glucose from the circulation.

Much of the incoming glucose may be taken up by hepatocytes as described earlier, but some enters the systemic circulation, from where it can stimulate pancreatic insulin secretion (and somewhat suppress glucagon secretion, although this is not so marked an effect). Insulin is liberated into the portal vein. Thus, the liver is exposed at this time to high concentrations of glucose (from the small intestine) and insulin. The net effect is to reverse net glycogenolysis, so that net glycogen synthesis begins. In addition gluconeogenesis is suppressed and glycolysis favoured (Fig. 1). Hepatocyte glucose output is therefore rapidly suppressed and converted to a net uptake of glucose. At the same time, utilization of glucose by insulin-sensitive peripheral tissues such as skeletal muscle and adipose tissue is increased. The main mechanism of this short-term change is the recruitment of the insulin-regulated glucose transporter GLUT4 to the cell membrane from an intracellular pool. However, the reduction in concentration of plasma non-esterified fatty acids (see below) will also remove inhibition of glucose uptake caused by fatty acid oxidation. Within muscle, glycolysis and glycogen synthesis will be stimulated by insulin. In adipose tissue, increased glucose uptake provides glycerol-3-phosphate (formed from glycolysis) for esterification of fatty acids (see below). Thus, insulin is the key regulator of the rapid changes that occur in glucose metabolism in the postprandial state: it brings about glucose storage as glycogen, and promotes the utilization of glucose at the expense of fatty acids.

Fat metabolism in the postabsorptive and postprandial states

Forms of fat in the circulation (see Chapter 11.6)

Fatty acids circulate in various forms: as non-esterified fatty acids, as triacylglycerol (triglyceride) fatty acids, esterified to glycerol in phospholipids, and esterified to cholesterol as cholesteryl esters. The first two are involved in 'energy metabolism'. The main carriers of triacylglycerol in the circulation are the triacylglycerol-rich lipoproproteins, chylomicrons secreted from the small intestine and transporting dietary fat, and very low-density lipoprotein particles secreted from the liver, transporting endogenous triacylglycerol. In the postabsorptive state, chylomicron triacylglycerol secretion will be virtually zero. Secretion of very low-density lipoprotein is a means of exporting fat from the liver to peripheral tissues. In these tissues it is hydrolysed by the enzyme lipoprotein lipase situated in the capillaries of skeletal muscle, adipose tissue, mammary glands, and other tissues that use fatty acids. Lipoprotein lipase acts on the circulating triacylglycerol-rich particles to liberate fatty acids which may diffuse into the parenchymal cells (muscle fibres, adipocytes, etc.). Lipoprotein lipase in skeletal muscle is downregulated by insulin, whereas that in adipose tissue is upregulated by insulin. In the postabsorptive state muscle lipoprotein lipase is likely to predominate as the site of removal of triacylglycerol from the very low-density lipoprotein particles. The fatty acids can then be used as an oxidative fuel by the muscle. In this process very low-density lipoprotein particles lose their triacylglycerol core and become relatively enriched with cholesterol and phospholipids. After several cycles through such capillary beds, they are reduced to simple particles with a core of cholesteryl ester and an outer phospholipid shell: in fact, low-density lipoprotein particles, the main carrier of cholesterol in the circulation.

Non-esterified fatty acids and 'energy transport'

Fat is mobilized from adipose tissue stores in the form of non-esterified fatty acids (Fig. 2). The adipocyte has a central droplet of triacylglycerol, which is hydrolysed by the intracellular enzyme hormone-sensitive lipase, releasing glycerol and non-esterified fatty acids. These fatty acids are liberated into the plasma bound to albumin for transport to other tissues, including liver and skeletal muscle. Hormone-sensitive lipase is stimulated by catecholamines but powerfully suppressed by insulin, each exerting control over reversible (de)phosphorylation (see Fig. 2) (insulin leads to dephosphorylation and deactivation). Thus, it is active in the postabsorptive state when there is a call upon the body's fat stores. It is also activated during exercise, mainly by catecholamine stimulation. The turnover of non-esterified fatty acids in the plasma is rapid. They are the major oxidative fuel in muscle after overnight fast (glucose only supplies around 5 to 10 per cent of the oxidative fuel for skeletal muscle in this state), and in the liver they are both a fuel for oxidation and a substrate for synthesis of triacylglycerol that will be exported as very low-density lipoprotein. A typical concentration of non-esterified fatty acids in the plasma after overnight fast is 500 µmol/l, one-tenth that of glucose, but because of their rapid turnover and their larger molecular mass fatty acids account for about twice the 'energy turnover' of glucose in the circulation.

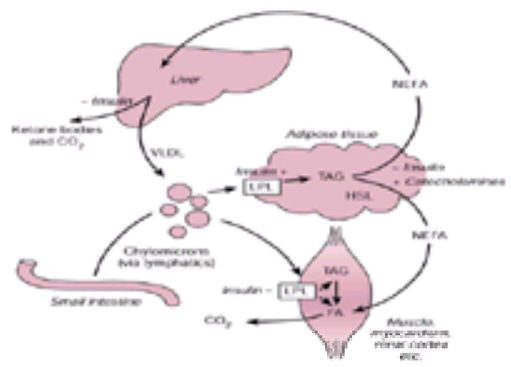

Fig. 2 Overview of fat metabolism. Triacylglycerol (TAG) enters the circulation from the diet in the form of chylomicrons. Fatty acids are taken up by tissues through the action of the enzyme lipoprotein lipase (LPL). Adipose tissue TAG is the major store. It is mobilized in times of energy demand by the enzyme hormone-sensitive lipase (HSL), liberating non-esterified fatty acids (NEFA) into the circulation, from where they may be taken up by a number of tissues and used for synthesis of new TAG and for oxidation. Major points of hormonal regulation are shown (italic).

Disposition of dietary fat

Dietary fat is almost entirely (typically 95 per cent or more) in the form of triacylglycerol. A typical meal might contain 30 to 40 g of fat. The typical plasma triacylglycerol concentration in a healthy subject is 1 mmol/l, confined to the vascular space; this means that about 3 g of triacylglycerol is present in the circulation. Therefore, as in the case of glucose, the amount in a meal could overwhelm the system unless co-ordinated mechanisms come into play to ensure its rapid dispersion.

Dietary triacylglycerol is digested in the stomach and small intestine and packaged by the enterocytes of the duodenum and proximal ileum into chylomicrons, which enter the circulation via the lymphatics (Fig. 2). Therefore, unlike other nutrients absorbed from the small intestine, they bypass the liver on first passage. The chylomicrons also carry other lipid constituents of food, including cholesterol and fat-soluble vitamins. In the circulation their fate is similar to that of very low-density lipoprotein particles, although the tissue-specific regulation of lipoprotein lipase ensures that adipose tissue (where lipoprotein lipase is upregulated by insulin) is a major site of clearance of their triacylglycerol. The pathway of triacylglycerol synthesis in adipocytes, as in the liver, is stimulated by insulin. Therefore, there is a short and energy efficient pathway for storage of dietary fatty acids in adipose tissue (Fig. 2). The half-life of chylomicron triacylglycerol in the circulation is about 5 min. After hydrolysis of most of the triacylglycerol, the remnant particles are removed by receptors in the liver and other tissues. Thus dietary cholesterol which remains in the remnant particles along with most fat-soluble vitamins is transported mainly to the liver.

Provided that a meal contains carbohydrate or protein, stimulation of insulin secretion will rapidly suppress the mobilization of adipose tissue fat stores, and concentrations of non-esterified fatty acids in the plasma will fall after a meal. Therefore utilization of fatty acids by tissues such as skeletal muscle and liver will be reduced simply by lack of availability. As noted above, this reduces competition for oxidation in muscle, further increasing glucose utilization. In liver, the lack of non-esterified fatty acids is likely to decrease the secretion of very low-density lipoprotein triacylglycerol. Insulin appears also to suppress very low-density lipoprotein triacylglycerol secretion directly. This is somewhat controversial, and the effects of insulin may be different in the acute, postprandial situation from the situation of prolonged hyperinsulinaemia (as in insulin resistance). Within the liver, insulin powerfully stimulates esterification of fatty acids (for triacylglycerol synthesis) at the expense of oxidation of fatty acids (see below), so the suppressive effect of insulin on very low-density lipoprotein triacylglycerol secretion can only be short-term. Nevertheless, it seems an exact parallel with the suppression of hepatic glucose output by insulin.

Inter-relationships between carbohydrate and fat metabolism

Links between carbohydrate and fat

In mammals, fat cannot be converted to glucose in a net sense (for each molecule of acetyl CoA entering the tricarboxylic acid cycle, two molecules of CO_2 are produced). Glucose can, however, be converted to fat: acetyl CoA produced by pyruvate dehydrogenase leaves the mitochondrion (being transported across the mitochondrial membrane as citrate, then 'liberated' by the cytosolic enzyme ATP-citrate lyase), and is then a substrate for the pathway of *de novo* lipogenesis, which begins with the enzyme acetyl CoA carboxylase (forming malonyl CoA). At one time it was believed that *de novo* lipogenesis was a major route for laying down storage fat. Although this may be true in small rodents under some conditions, many measurements made in recent years have confirmed that this pathway makes a quantitatively small contribution to triacylglycerol synthesis in humans. Instead, it seems that almost all the triacylglycerol that we deposit in adipose tissue arises from dietary fatty acids, taken up from circulating triacylglycerol-rich lipoproteins by the lipoprotein lipase pathway (see Chapter 4.3).

The lack of quantitatively significant interconversion of carbohydrate and fat has led to the suggestion that we may view carbohydrate and fat balance as independent. This view is entirely erroneous. Despite the lack of interconversion, carbohydrate balance strongly influences fat balance, and vice versa. These influences occur at a number of levels.

At a chronic level, ingestion of a high-carbohydrate diet will induce enzymes of fat synthesis and downregulate enzymes of fatty acid oxidation, through insulin- and carbohydrate-response elements in the promoter regions of the genes in question. On a whole-body but more acute level there are clear hormonal effects. Principal amongst these is carbohydrate-induced insulin secretion. Insulin, as outlined above (see Chapter 4.3), powerfully suppresses the release of non-esterified fatty acids from adipose tissue. Therefore, when carbohydrate is readily available, fat stores are conserved.

The glucose–fatty acid cycle

Beyond this, there are specific cellular mechanisms that regulate the relative oxidation of carbohydrate and fat. These probably operate in a number of tissues although they have been most studied in skeletal and heart muscle and in liver. In 1963 Philip Randle and colleagues described the glucose–fatty acid cycle, which encompasses one aspect of this mutual relationship between carbohydrate and fat oxidation. It is summarized in Fig. 3. The concept was based upon observations that availability of fatty acids reduced the oxidation of glucose in skeletal and cardiac muscle. The mechanism involves generation of acetyl CoA from b-oxidation of fatty acids. A high ratio of acetyl CoA to free CoA within the mitochondrion inhibits pyruvate dehydrogenase. In addition, export of citrate to the cytoplasm would inhibit phosphofructokinase, and consequent accumulation of glucose-6-phosphate would inhibit uptake of hexokinase and glucose. The precise mechanism has since been disputed, but the basic observation has been confirmed many times. The glucose–fatty acid cycle describes the normal interplay between fat and carbohydrate oxidation, but has also been invoked (following a suggestion made in the original paper in 1963) to explain pathological situations involving excess availability of fat and insulin resistance of glucose uptake (for example type 2 diabetes and obesity).

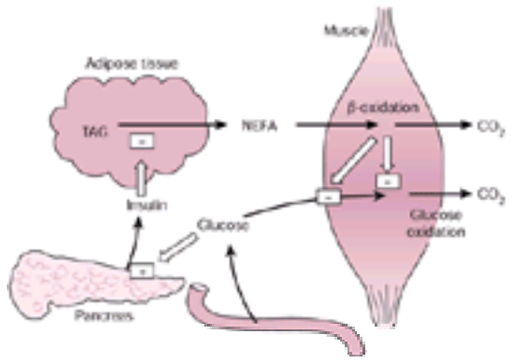

Fig. 3 The glucose–fatty acid cycle. When glucose and insulin concentrations are high, release of non-esterified fatty acid (NEFA) from adipose tissue is suppressed, and glucose utlization predominates in insulin-sensitive tissues such as skeletal muscle. In the fasting state (glucose and insulin concentrations are low) NEFA utilization predominates, reinforced by inhibitory effects of the products of b-oxidation of fatty acids on glucose uptake and oxidation. This may have pathological significance in that states in which NEFA concentrations tend to be high (e.g. type 2 diabetes) will be associated with resistance of glucose utilization to insulin.

Glucose and the regulation of fatty acid oxidation

An additional mechanism was first described in 1977 by Denis McGarry and Daniel Foster. They were following up a longstanding observation that the generation of ketone bodies by the liver (a reflection of b-oxidation of fatty acids) was suppressed by insulin or in livers from carbohydrate-replete animals. They showed that malonyl CoA, the first committed intermediate in the pathway of *de novo* lipogenesis (produced by acetyl CoA carboxylase; see above), strongly inhibited fatty acid oxidation. This inhibition is mediated via the enzyme carnitine palmitoyltransferase-1 (also called carnitine acyltransferase-1) in the mitochondrial membrane. Carnitine palmitoyltransferase-1 is responsible for the transport of fatty acids from the cytoplasm to the mitochondrion for b-oxidation. Acetyl CoA carboxylase is activated by insulin (both by increased gene transcription and by reversible dephosphorylation). Hence in a carbohydrate-replete state malonyl CoA will be formed and fatty acid oxidation inhibited (Fig. 4).

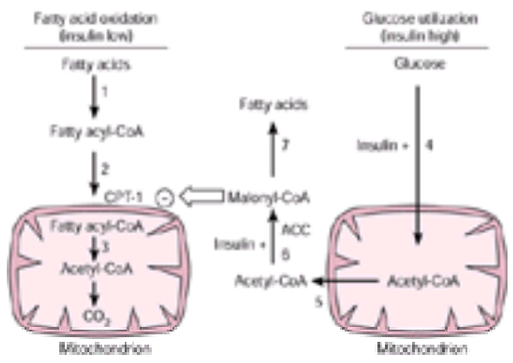

Fig. 4 The inhibition of fatty acid oxidation when glucose and insulin concentrations are high. Pathways are: 1, fatty acid 'activation' (fatty acyl CoA synthase); 2, transfer of acyl CoA into the mitochondrion via carnitine palmitoyltransferase-1 (CPT-1); 3, b-oxidation; 4, glycolysis (cytosolic) followed by pyruvate dehydrogenase (mitochondrial); 5, transfer of acetyl CoA to the cytosol via the citrate shuttle (details not shown); 6, acetyl CoA carboxylase (ACC) to form malonyl CoA, which is a powerful inhibitor of CPT-1; 7, fatty acid synthesis (not present in all tissues in which this mechanism operates, for example skeletal muscle).

This is now recognized as a widespread regulatory mechanism. There are two isoforms of acetyl CoA carboxylase. Acetyl CoA carboxylase 1, expressed in lipogenic tissues such as liver and adipose tissue, appears to be involved in *de novo* fatty acid synthesis. Acetyl CoA carboxylase 2 is expressed more in tissues oxidizing fatty acids such as heart and skeletal muscle and is thought to produce malonyl CoA for regulatory rather than synthetic purposes. In fact, in muscle the pathway of fatty acid synthesis does not occur (fatty acid synthase is not expressed). Muscle carnitine palmitoyltransferase-1 is more sensitive to inhibition by malonyl CoA than is the liver enzyme. The ability of glucose to inhibit the oxidation of fatty acids in muscle has recently been clearly demonstrated *in vivo*, and has been termed the 'reverse glucose–fatty acid cycle'.

Protein and amino acid metabolism and their regulation

Since there are 20 different amino acids incorporated into protein, and a variety of other amino acids that have important biological rules, it is essential for this purpose to generalize somewhat about amino acid and protein metabolism.

The body pools of protein and amino acids, and their turnover, are summarized in Fig. 5. Insulin exerts a net anabolic role on body protein, mainly in skeletal muscle, whereas thyroid hormones and cortisol are generally 'catabolic'. Anabolism is also stimulated by anabolic steroids, by physical training, and during growth by the insulin-like growth factors.

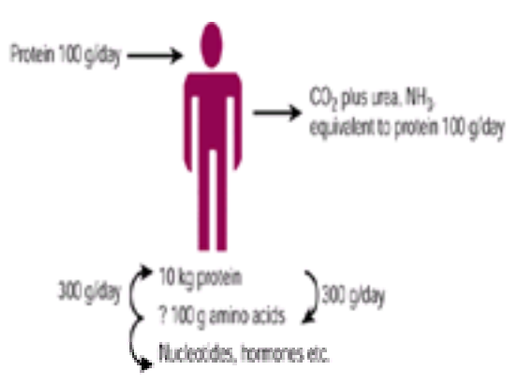

Fig. 5 The body pools of protein and amino acids, and their turnover. Figures are approximate.

Dietary protein, digested in the small intestine and absorbed as free amino acids and short peptides, enters the portal vein. In the enterocytes of the small intestine some amino acids, especially glutamine, are removed for use as an oxidative fuel. The remaining products of digestion next meet the liver where further preferential extraction takes place. Amino acid oxidation is, under most circumstances, the major oxidative pathway in the liver. About 60 per cent of incoming amino acids may be directed into immediate oxidation. The rate of hepatic protein synthesis is also high, and since much of the protein is secreted (for example albumin), this represents a net loss of amino acids from the liver (perhaps a further 20 per cent of the incoming amino acids). The remaining mixture of amino acids, around 20 per cent of those absorbed, enters the systemic circulation. This mixture is enriched in the branched chain amino acids leucine, isoleucine, and valine, which have a special role in muscle.

Urea synthesis takes place only in the liver. (The pathway is present in the brain but this is not a significant site of blood urea production.) Therefore, amino acids released from proteolysis in peripheral tissues must be transported, or must transfer their amino nitrogen, to the liver. This results in considerable interaction between the pathways of amino acid, carbohydrate, and fat metabolism. Measurements of arteriovenous differences across muscle and adipose tissue show that the release of the two amino acids alanine and glutamine predominates. Since glutamine carries two nitrogens it is, under most circumstances, the predominant carrier of nitrogen. Arteriovenous difference measurements across the splanchnic bed (by catheterization of the hepatic vein) show an almost identical pattern for uptake: removal of alanine and glutamine far exceeds that of other amino acids. Therefore amino acids in tissues including muscle and adipose tissue must transfer their amino nitrogen to alanine (by transamination with pyruvate) and glutamine (formed from glutamate, itself arising by transamination with 2-oxoglutarate). The aminotransferases (transaminases) bring about this transfer. It is important that the 2-oxoacid acceptors, pyruvate and 2-oxoglutarate, are common metabolic intermediates and thus readily available.

Much of the alanine released from skeletal muscle comes from transamination of pyruvate formed in glycolysis. Within the liver the amino group can be transferred further, for example to oxaloacetate, forming aspartate which is one of the immediate donors of nitrogen to the urea cycle. The pyruvate thus formed may be a substrate for gluconeogenesis, producing glucose that can be recycled to peripheral tissues. This metabolic cycle has been called the glucose–alanine cycle. It closely parallels the Cori cycle (see above).

The other route of entry of nitrogen into the urea cycle is ammonia. In peripheral tissues ammonia may be formed by the oxidative deamination of glutamate, catalysed by glutamate dehydrogenase. This reaction, in combination with the aminotransferases, can be seen to capture amino nitrogen from a number of amino acids. However, blood ammonia concentrations are very low (it is highly toxic) and instead it seems to be 'fixed' in the amido group of glutamine by the enzyme glutamine synthetase. In the liver the ammonia required for the urea cycle may be formed from the amido nitrogen of glutamine, removed by the enzyme glutaminase, or by the oxidative deamination of glutamate. There is also a supply of ammonia from the small intestine.

An important aspect of the large store of muscle protein is that it represents a potential source of synthesis of new glucose during fasting. In that situation, while the brain continues to require glucose for oxidation, and as glycogen reserves are depleted, new glucose can only be formed from glycerol, released in adipose tissue lipolysis, and from amino acids. The pathways described above are for the transfer of nitrogen, but not necessarily of carbon, to the liver. To explain the latter, we have to invoke pathways whereby amino acid carbon can also be exported. Amino acids whose 2-oxoacid can enter the tricarboxylic acid cycle may generate pyruvate (which can also accept amino nitrogen to become alanine). Pairs of amino acids can provide all the carbons necessary for glutamine synthesis.

10.3 Vitamins and trace elements

M. Eastwood

Vitamins are diverse organic compounds that the body cannot synthesize; they are required in small amounts to contribute to health.

Historical background

Our understanding of the role of vitamins comes from clinical observations, nutritional experiments in animals, and studies using purified preparations of the active principle used to treat deficiency states. Early pioneers differentiated dietary deficiency from infection and other causes of disease. Scurvy was once the scourge of mariners and explorers, but the clinical trials of Lind (1753), confirmed by Captain Cook on his voyages, showed the benefits of citrus fruits. Many years later, Holst and Froelich (1907) produced scurvy in guinea-pigs by dietary deprivation.

Rickets arose in sun-starved urban slums, and Trousseau noted the beneficial effects of cod liver oil (1860). Ejikmann and Grijns fed chickens the same diet as their patients who had beriberi (1897); neuropathy in the chickens resolved when the diet contained whole-grain, rather than polished, rice. In the 1900s Gowland Hopkins, the discoverer of vitamins, described a fat-soluble, essential growth accessory food factor A in milk. This was differentiated from water-soluble accessory food factor B by McCollum and Davis. Mellanby treated rickets in puppies with a fat-soluble food factor D. Lucy Wills described the megaloblastic anaemia of pregnancy in 1931, which is now known to be caused by a deficiency of folic acid.

In 1894 Atwater published a table of food composition and dietary standards for the United States. The first *USA Recommended Daily Allowances* was published in 1941. Food rationing in Britain during the Second World War was a triumph for the science of applied nutrition. The natural development of this work was the emergence of recommended daily intakes that recognized the differing requirements of the young and growing, pregnant and lactating, middle-aged and old, and ill; with this, developed the concept of the optimal intake for optimal nutritional status. The isolation and chemical synthesis of the vitamins and their active principles provided formidable challenges to scientists, rewarded by eight Nobel prizes in Medicine and Physiology and four in Chemistry. In 1976, Linus Pauling advocated gram intakes of ascorbic acid as a prevention against the common cold. Pauling thus founded 'orthomolecular medicine'.

The traditional classification of vitamins into water and lipid soluble and by their associated deficiency conditions becomes less useful as their biochemical roles are better understood. An inadequate dietary vitamin intake will result in specific cellular failure and even death. There is a dose–response relationship with vitamin intake from the physiological through the pharmacological to the toxic. Recommendations for vitamin intake for different ages, needs, and communities are based on dietary intake, bioavailability, steady-state concentrations in plasma and tissue at defined intakes, urine excretion, adverse effects, biochemical and molecular function, and freedom from deficiency. With increasing intake, either orally or as an infusion, a vitamin is distributed through the body fluids and tissues until the saturation point is exceeded. The prescription of vitamins parenterally, bypassing the absorptive processes, also has dosage implications.

The carotenoids illustrate the complexity of vitamins in physiology, pharmacology, and as toxins. Carotenoids are used by archaebacteria to reinforce cell membranes, their long, rigid carbon backbone acting as a rivet across the membrane. The polyene chain of between 9 and 11 double bonds serves to harvest light energy in plants, and, as the pigment retinal, is a visual pigment in animals. The linear system of conjugated C=C bonds make for a high reducing and antioxidant potential. Carotenoids act as the coloration in plants and to protect egg proteins against the enzymatic activity of proteases. Retinoic acid in animals and abscisic acid in plants act as hormones. When retinoids and carotenoids were used in lung cancer chemoprevention trials, the incidence of cancer increased, ascribed possibly to the increase in the oxidized products of b-carotene. A mix of vitamins and antioxidants might prevent such oxidation. Such a mix can be found in fruit and vegetables, which emphasizes the benefit of a good diet containing five portions (60 to 150 g) of fruit and vegetables a day.

Vitamin C (ascorbic acid)

Ascorbic acid is a simple sugar that reversibly oxidizes to dehydroascorbate. Dietary sources are fresh fruit and fruit juices, especially blackcurrants, guavas, green leafy vegetables, and fresh milk. Ascorbic acid is readily oxidized during cooking—a process accelerated by traces of copper in alkaline solution. Since humans, guinea-pigs, the Indian fruit-eating bat, the red vented bulbul, and some birds are unable to synthesize ascorbic acid, it thus represents a vitamin in these species. Ascorbic acid

- is a water-soluble, non-specific radical-trapping antioxidant and reducing agent which is present in all tissues;
- acts synergistically with vitamin E;
- is involved in copper-containing hydroxylase enzymes (e.g. proline and lysine hydroxylase), and is important in collagen metabolism and 2-oxoglutarate-linked iron hydroxylases;
- is involved in carnitine biosynthesis, which is necessary for fatty acid transport from the cytosol into mitochondria; and
- is involved in the synthesis of hormones (e.g. epinephrine (adrenaline)).

Ascorbic acid is rapidly absorbed from the small intestine. The plasma concentration (5 per cent as dehydroascorbate) and dietary intake are in a sigmoidal relationship (80 µmol/l on 100 mg/day) which plateaus at 1000 mg/day intake. The body pool size is 900 mg (5 mmole in the normal adult): approximately 3 per cent, irrespective of pool size, is degraded each day and excreted in the urine as free ascorbic acid, dehydroascorbate, or diketogulonate. High tissue concentrations at birth steadily decline with increasing age.

A shortfall in vitamin C intake without clinical scurvy may be associated with a reduction in the body's water-soluble antioxidant capacity, the consequences of which are still being debated. The young and elderly are particularly at risk of scurvy, which results from an inadequate intake of ascorbic acid. Clinical scurvy appears after

4 weeks on an ascorbic acid-deficient diet when the body pool is less than 300 mg (1.7 mmole). There is a failure of connective tissue collagen synthesis, and cartilage, bone, and dentine growth are all compromised. Tissues bleed readily, and heal poorly due to defective intracellular linkages between the endothelial cells and capillary basement tissue. Individuals are initially lethargic and irritable. Characteristic livid-coloured, spongy, bleeding gingivitis of the gums develops, and scurvy buds appear in the papillae between the teeth. Large or microscopic haemorrhages occur in the gums, as well as in the eyes (especially bulbar conjunctiva), subcutaneous tissues, synovia of joints, and beneath the periosteum of bones. Perifollicular bleeding occurs in the dependent parts of the body, later becoming more generalized. Fatal haemorrhages may also occur in the brain or heart muscle. Keratin-like material heaps on the surface of hair follicles, through which a deformed corkscrew hair projects. Other signs include dependent oedema, oliguria, depression, megaloblastic or normoblastic anaemia, and superinfection. Infants present with irritability, tender legs, and pseudoparalysis. Scurvy buds, but not gingivitis, occur in edentulous infants. Large subperiosteal haemorrhages develop over the long bones, especially the femur.

Diagnosis requires an awareness of the condition, a careful dietary history, and a clinical examination. The patient can improve on hospital diet alone. Ascorbic acid is measured in plasma or whole blood. While leucocyte or buffy-coat vitamin C concentrations reflect tissue concentrations, this is complicated in disease by different leucocytes types which vary in number and ascorbic acid content.

Requirements

The optimum dietary intake of ascorbic acid has yet to be defined. The body can be saturated with 1 g/day for 5 days. Recommendations for dietary intake range from 40 to 200 mg per day. An upper limit of intake is recommended at 1 to 2 g/day, based upon body saturation figures rather than toxicity. During pregnancy and lactation, intake should be between 100 and 200 mg daily. The ascorbic acid content of breast milk varies between 30 and 80 mg/l which provides 25 mg per day, clinical scurvy has not been observed in fully breast-fed infants. The ascorbic acid intake of the elderly is generally adequate but should be monitored. The pharmacological use of ascorbic acid is extensive and imaginative.

Biotin

Biotin contains a ureido group in a five-membered ring fused with a tetrahydrothiophene ring with a five-carbon side chain terminating in a carboxyl group. Dietary biotin is found in yeast, bacteria, liver, kidney, egg yolks, cooked cereals, pulses, nuts, chocolates, and some vegetables. Biotin is a cofactor for the acetyl-coenzyme A (**CoA**), propionyl CoA, and pyruvate carboxylase systems involved in the incorporation of bicarbonate as a carboxyl group into substrates in fatty acid synthesis and gluconeogenesis. Biotin is absorbed from the upper gastrointestinal tract. Raw egg white contains the glycoprotein avidin (molecular weight, 68 000) which binds biotin with a high affinity and prevents biotin absorption. Biotin is transported in plasma to the liver for storage. It is metabolized before excretion in the urine as biotin, bisnorbiotin, and biotin sulphoxide.

Biotin deficiency results in fatigue, depression, sleepiness, nausea, loss of appetite, muscle pain, hyperaesthesia and paraesthesia, alopecia, dermatitis, conjunctivitis, smooth tongue, and dry skin. Individuals receiving treatment for epilepsy are at risk of biotin deficiency. There are no indications that excess biotin is toxic. Body stores are measured by plasma biotin concentrations, and lymphocyte propionyl CoA carboxylase and its activation index (ratio of enzyme activity incubated with and without biotin) or urinary 3-hydroxy isovalerate.

Requirements

The dietary requirement of biotin is not known with certainty. The average intake of a British adult ranges from 10 to 70 µg/day, which is seen to be adequate. In infants, preterm to 5 years, an intake between 5 and 25 µg/day is suggested.

Niacin: nicotinic acid and nicotinamide

Niacin is a B vitamin. It occurs in food as nicotinic acid, as a pyridine nucleotide coenzyme derivative (NAD and NADP), as an amide, nicotinamide (niacinamide), or as a nicotinoyl ester, niacytin in maize. Nicotinic acid is found in meat, poultry, fish, wholemeal cereals, pulses, and coffee. Nicotinic acid is synthesized from tryptophan, catalysed by kynureninase and kynurenine hydroxylase which are vitamin B_6 and riboflavin dependent. A deficiency of either vitamin B_6 or riboflavin may aggravate niacin deficiency. Some 60 mg of dietary tryptophan generates 1 mg of nicotinic acid. The nicotinic acid equivalent is the dietary nicotinic acid content plus 1/60th of the dietary tryptophan.

Nicotinamide is a component of the coenzymes nicotinamide adenine dinucleotide (**NAD+**) and nicotinamide adenine dinucleotide phosphate (**NADP+**, also known as triphosphopyridine nucleotide (**TPN+**)). NAD coenzymes are biological carriers of reducing equivalents, that is to say electrons, during metabolic oxidation to NADH+. $NADH^+$ acts as a true coenzyme in enzymes involved in epimerization, aldolization, and elimination.

The various conjugated forms of niacin are hydrolysed and absorbed in the upper gastrointestinal mucosa as the free acid. Niacytin from maize is neither hydrolysed nor absorbed. In Central America, maize is eaten as tortillas, in which lime water hydrolyses the nicotinoyl ester component. Niacin and tryptophan deficiencies occur in poor populations dependent upon maize for their protein intake. Zein, the principal maize protein, is deficient in tryptophan. Protein energy malnutrition, dietary amino acid imbalances (for example, an excess leucine intake), anaemia, and other vitamin deficiencies worsen the problem. Dietary fortification with other proteins is necessary.

An inadequate dietary intake of 1- to 2-months' duration leads to significant tissue depletion and pellagra, which if untreated progresses to death. There is no apparent tissue storage of this vitamin. The vitamin is excreted in the urine as nicotinuric acid, nicotinamide- *N*-oxide and 5'-methylnicotinamide. Pellagra is characterized by dermatitis, diarrhoea, and dementia; the disease is chronic with a seasonal periodicity. Individuals suffer weight and stamina loss, which is worsened by secondary bacterial and parasitic infections. Erythematous dermatitis is symmetrically distributed on skin exposed to sunlight and mechanical irritation. In chronic pellagra the skin looks sunburnt. In severe cases, gastrointestinal disturbances occur with diarrhoea. There can be glossitis, angular stomatitis, cheilosis, and an inflamed tongue, and secondary infection of the mouth. Mild mental changes include anxiety and irritability progressing to manic depressive illness. There may be paraesthesia in the lower limbs, with loss of vibration sense and proprioception leading to ataxia and spasticity.

Pellagra can occur in alcoholism, malabsorption syndromes, and Hartnup disease. Mild cases rapidly improve on treatment with niacin or a suitable dietary protein supplementation. Oral nicotinamide (100 mg every 4 h) results in symptom resolution within 24 h, although mental symptoms, especially dementia, may be unresponsive to treatment. Nicotinic acid may cause unpleasant flushing and burning sensations. A supplementary diet containing good-quality protein and all of the vitamins is important. Nicotinic acid, but not nicotinamide, is used therapeutically for hyperlipidaemias at a dose of 2 to 6 g/day, but it can be hepatotoxic.

Microbiological methods provide the most sensitive means of measuring niacin and nicotinamide in serum, urine, and food. Alternatively, urinary nicotinamide, *n*-methyl nicotinamide (**NMN**), is measured over a defined time or as a ratio of creatine in urine. Urinary *N*-methyl-2-piridone-5-carboxamide (2-pyridone) excretion is a more sensitive measurement in borderline cases of nicotinamide deficiency, and is expressed in relation to urinary creatinine excretion.

Requirements

These are related to dietary tryptophan intake. A protein intake of between 60 and 85 g/day contains approximately 13 mg tryptophan/g, equivalent to between 13 and 17 mg/day of niacin. The recommended intake as niacin equivalents is 6.6 mg (54 µmole)/4185 J (4.185 J = 1 kCal). Hormonal changes during pregnancy affect tryptophan metabolism, so that 30 mg of tryptophan is equivalent to 1 mg of dietary niacin. Breast milk should provide not less than 3.5 mg preformed niacin/4185 J. Mature human milk provides preformed niacin (2.7 mg/l), therefore an increment of 2 mg/day niacin for the nursing mother is suggested.

Pantothenic acid

Pantothenic acid is the dimethyl derivative of butyric acid joined by a peptide linkage to a-alanine. The active form, 4'-phosphopantetheine, is present in all tissues. Pantothenic acid is thermo- and acid-labile. It is widely available in animal-based foods, especially liver, although cereals and legumes are also sources. 4'-Phosphopantetheine is a constituent of CoA and acyl carrier protein. CoA plays a central role in intermediary metabolism, fatty-acid b-oxidation, sterol synthesis, and other acetylation processes. Acyl carrier protein is an acyl carrier in the synthesis of lipids. Pantothenic acid is found in food as the coenzyme CoA or acyl carrier

protein form and is hydrolysed by a pancreatic enzyme before absorption. Urinary excretion is in the free acid form.

Pantothenic acid is not stored in the body. Although no specific deficiency syndrome has been recorded, pantothenic acid deficiency may occur as part of the overall problem in people who are severely malnourished. No toxic intakes have been recorded. There is no biochemical method for measuring pantothenic acid status in humans.

Requirements

Most human diets provide 3 to 10 mg of pantothenic acid per day. A safe and adequate intake is between 3 and 7 mg per day, including during pregnancy and lactation. Infants require 1.7 mg/day; human milk provides 2.6 mg/day. Infant formula milk should contain at least 2 mg/litre.

Riboflavin

Riboflavin is a substituted alloxazine ring linked to ribotol, an alcohol derived from the pentose sugar ribose. It is light sensitive. Dietary sources are liver, milk, cheese, eggs, some green vegetables, and beer. Other sources are yeast extracts (for example, Marmite) and meat extracts (for example, Bovril). Riboflavin in the diet exists in either the free form or the phosphorylated coenzyme form.

Riboflavin links with phosphoric acid as flavin mononucleotide (or riboflavin–5'-phosphate) (**FMN**), which with adenosine monophosphate (**AMP**) forms flavin adenine dinucleotide (**FAD**): the prosthetic groups of the flavoprotein enzymes. Flavoproteins are involved in redox processes involving the hydrogen-transfer chain in the mitochondria and the production of ATP. FAD/FMN acts as a coenzyme in oxidation/reduction reactions, electron transport, oxidative phosphorylation (for example, succinic dehydrogenases), and fatty-acid b-oxidation.

Riboflavin is absorbed from the upper gastrointestinal tract, there is no specific storage tissue, and it is excreted in the urine either free or in small amounts of hydroxylated products. Chronic infection can affect urinary riboflavin excretion. A deficiency of riboflavin causes cheilosis, angular stomatitis, superficial interstitial keratosis of the cornea, and nasolabial seborrhoea. Riboflavin deficiency may impair iron absorption. No toxic effects have been shown for riboflavin.

Riboflavin status can be estimated from the urinary riboflavin:creatinine ratio, which is insensitive at low intakes. The erythrocyte glutathione reductase activation coefficient (**EGRAC**) measures tissue saturation and long-term riboflavin status.

Requirements

Adults, including the elderly, need between 1 and 1.5 mg of riboflavin per day. The average riboflavin content of breast milk in Britain is approximately 0.3 mg/l, which is dependent upon maternal intake. Intakes should increase by 0.3 mg/day during pregnancy, and 0.5 mg/day during lactation. Recommended intakes for children range from 0.4 mg/day for infants up to 3 months of age and 1.0 mg/day thereafter.

Thiamin

Thiamin hydrochloride consists of a substituted pyrimidine ring linked by a methylene group to a sulphur-containing thiazole ring. All animal and plant tissues contain thiamin, usually in the phosphorylated form. The important sources are plant seeds and cereal germ, nuts, peas, beans, pulses, and yeast. Losses occur with cooking and alkaline pH. Thiamin diphosphate is the coenzyme in a-ketoacids and decarboxylation reactions involved in the oxidative decarboxylation of pyruvic acid to acetyl-CoA, and the transketolase reaction in the hexose monophosphate shunt. Thiamin may also play a role in neural excitation mechanisms.

Absorption is from the upper gastrointestinal tract, followed by phosphorylation to the active diphosphate form. There is no body store and the only reserve is the vitamin functionally bound to enzymes. Multiple endproducts are excreted in the urine. Beriberi is caused by dietary thiamin deficiency, a disease that was endemic in the East as a result of the ingestion of polished rice which is deficient in the vitamin. Carbohydrate metabolism is impaired by a deficiency of thiamin pyrophosphate, a coenzyme necessary for the decarboxylation of pyruvate to acetyl-CoA. Pyruvic and lactic acid accumulate in the body. The clinical presentations of thiamin deficiency are:

- wet beriberi (high-output cardiac failure);
- dry beriberi (polyneuropathy);
- infantile beriberi;
- neuropathy and cardiomyopathy in chronic alcoholism; and the
- Wernicke–Korsakoff syndrome.

Initially the symptoms are of non-specific malaise and evidence of early cardiac failure and neuropathy. Wet beriberi is characterized by left- and right-sided high-output cardiac failure, cardiomegaly, hypotension, rapid deterioration, and death. Dry beriberi is a polyneuropathy affecting motor and sensory nerves. Initially there is paraesthesia progressing to painful muscle wasting and polyneuritis. Total sensory loss occurs and patients become immobile and emaciated; they are at a high risk for the development of Wernicke–Korsakoff's encephalopathy. Infantile beriberi occurs in breast-fed infants of thiamin-deficient mothers, usually when they are between 2- and 5-months old. In the acute form, the child is restless, distressed with evidence of high output cardiac failure; convulsions may develop and the child becomes comatose. In the chronic form, the child is fretful, sleeps poorly, and the muscles may be flaccid. Cardiac failure, gastrointestinal symptoms, and sudden death are common. Alcoholic neuropathy presents with a sensory and motor neuropathy sometimes complicated by cardiomyopathy. Sensory nerve dysfunction includes paraesthesia and severe nerve pain. Motor nerve lesions are of both upper and lower motor neurone type. A patient with Wernicke–Korsakoff syndrome is disorientated and apathetic. Nystagmus, ataxia, and confabulation are not infrequent consequences of lesions in the brainstem, diencephalon, and cerebellum.

Treatment is with intramuscular thiamin 25 mg twice daily for 3 days, and thereafter 10 mg two or three times daily. The reversal of the wet type of beriberi is rapid. Improvement is slow for dry beriberi, especially for the neurological abnormalities. In infantile beriberi, both mother (10 mg thiamin twice daily) and the infant (thiamin intramuscularly 10 to 20 mg/day for 3 days, and thereafter 5 to 10 mg twice daily) are treated. Beriberi can be prevented by eating thiamin-containing foods, unmilled or thiamin-fortified rice, or thiamin supplements.

Long-term intakes in excess of 50 mg per kg body weight/day are toxic, leading to headaches, irritability, insomnia, rapid pulse, weakness, contact dermatitis, pruritus, and even death. Thiamin status can be measured by urinary thiamin and the thiamin:creatinine ratio with or without a loading dose, or by the reactivation of the cofactor-depleted red-cell enzyme transketolase *in vitro*.

Requirements

Thiamin requirements are related to energy and carbohydrate metabolism. The average requirement for adults, normal pregnancy or lactation, and children is 0.4 mg/4185 J and not less than 0.8 mg/day for adults with a supplement of 0.6 mg/4185 J during pregnancy and lactation. Human breast milk contains the equivalent of 0.3 mg/4185 J. The elderly may require 1 mg/day.

Vitamin B_6 (pyridoxine)

Pyridoxine is to be found in several forms: pyridoxal, pyridoxamine, and pyridoxine. This family of vitamin B_6 compounds is found in many foods: cereals, meat (particularly liver), fruits, and leafy and other vegetables. The free form is common in plants, the phosphorylated form, pyridoxamine phosphate, in animal tissues. Pyridoxal-5'-phosphate is a coenzyme and plays a major role in the intermediary metabolism of amino acids, in a-decarboxylation, aldolization, and transamination reactions. Pyridoxal-5'-phosphate acts as a coenzyme with glycogen phosphorylase in muscle, and has a role in the actions on hormones which modulate gene expression. Vitamin B_6 is absorbed in the free form and phosphorylated for use in enzymes. There is no specific storage in tissues and it is excreted in urine largely as 4-pyridoxic acid.

Primary dietary deficiency has not been reported in adults, largely because of the wide availability of the vitamin. A biochemical deficiency occurs in alcoholics. Patients taking isoniazid may develop a pyridoxine deficiency and neuropathy. Women taking massive supplements of between 2 and 7 g/day, a dose which has been recommended for alleviating premenstrual symptoms, may develop a sensory neuropathy.

There is no single marker sensitive at all levels of dietary intake. Biochemical markers include plasma pyridoxal phosphate concentrations, red-cell transaminase activation, and the urinary excretion of vitamin B_6 degradation products. Metabolic loading tests also measure vitamin B_6 status, including the tryptophan- and methionine-load tests.

Requirements

The total body pool of vitamin B_6 is 15 µmole (4 mg)/kg, 80 per cent of which is in muscle, with a half-life of 33 days. Adults, pregnant and lactating women, and the elderly require a daily intake of 13 µg/g of protein (approximately 4 mg/day). The vitamin B_6 content of human breast milk is low at between 40 and 100 µg/l (or 3–8 µg vitamin B_6/g protein). Infants under 3 months of age require 6 µg/g protein, increasing to up to 13 µg/g protein at 7 to 10 years.

Folate (folic acid, folacin)

Sources of folate include liver, yeast extract, and green leafy vegetables. Folates are derivatives of folic acid (pteroylglutamic acid) including the folylpolyglutamate found in foods. Folic acid is a pterin ring (2-amino, 4-hydroxypteridine) attached to *p*-aminobenzoic acid conjugated to L-glutamic acid (**PteGlu**). Variants include:

- di-(7,8-tetrahydrofolic acid) (**DHF**) and tetra-(5,6,7,8-tetrahydrofolic acid) (**THF**) reduced forms of the pteridine ring;
- one-carbon substitution (methyl, formyl, methenyl, methylene, or formimino) at positions N5 or 10: 5-formyl-THF, 10-formyl-THF, 5-formimino-THF, 5,10-methenyl-THF, 5,10-methylene-THF, and 5-methyl-THF;
- a chain of 4–6 glutamates attached to the L-glutamate.

Folic acid gives and receives 1-carbon groups on the N5 or N10 position in nucleic acid and amino acid biosynthetic reactions. Most dietary folate is in the polyglutamyl form, which is hydrolysed to monoglutamate before being absorbed from the duodenum. A brush-border glutamyl carboxypeptidase is inhibited by alcohol, which is of relevance in alcoholic folic deficiencies. Folate bound to a milk protein is absorbed from the ileum. Folic acid is stored in the liver. Plasma folates are mainly 5-methyl-THF monoglutamate. Within cells, 5-methyl–THF is converted to THF polyglutamates, the main cellular forms of folic acid.

Folate polyglutamates do not readily cross cell membranes. The polyglutamate form has two functions: storage; and as a coenzyme for normal 1-carbon metabolism (for which it is the most efficient coenzyme). The 5-methyl group is transferred to homocysteine (creating methionine and THF); the enzyme is the vitamin B_{12}-dependent methionine synthase, wherein methionine, folic acid, and vitamin B_{12} interlink.

Reactions in which folate is involved include:

- methylation of amino acids;
- serine reversibly interconverting with glycine;
- methionine interconverting with homocysteine (methionine is the precursor of *S*-adenosyl-L-methionine (**SAM**), a methyl donor in the methylation of lipids, hormones, DNA, cell division, and proteins); and
- thymidine and purine synthesis.

Folic acid deficiency may arise:

- as a dietary deficiency;
- in malabsorption syndromes;
- where there are excessive demands, as with increased cell proliferation (for example, in leukaemias and haemolytic anaemias);
- where drugs interfere with folic acid metabolism; and
- in the rare inborn errors of folic metabolism.

Folic acid deficiency is an important cause of megaloblastic anaemia, never to be confused with vitamin B_{12} deficiency.

Neural tube defects (**NTDs**) are congenital deformities of the spinal cord and brain: spina bifida, anencephaly, encephalocele, and iniencephaly. Folic acid is involved in the aetiology of NTDs. The precise mechanism is unclear, but there may be an underlying genetic predisposition involving a variant of 5,10-methyl-THF reductase. Closure of the neural tube occurs early in pregnancy thereby making aetiological studies difficult. The results of recommendations to take folic acid supplements prophylactically are encouraging.

Epidemiological studies suggest an increased risk of vascular disease associated with hyperhomocysteinaemia. Homocysteine is reversibly methylated to methionine, a step which involves folate, vitamin B_{12}, and vitamin B6. Supplementation of these vitamins has been proposed to reduce the putative dangers of hyperhomocysteinaemia.

Folate status is measured by the folate concentration in serum and red cells. Red-cell folate levels reflect body stores. A coincidental measurement of serum vitamin B_{12} is important.

Requirements

Children and adults, including the elderly, need a folate intake of 200 µg/day. Women planning a pregnancy should increase their intake of folic acid to 0.4 mg/day by capsule supplement. If there has been a previous NTD-affected pregnancy then 5 mg of folic acid/day preconception is suggested. A problem is that some pregnancies are unplanned. Dietary supplementation is impractical. Total folic acid excretion in breast milk averages 40 µg/day, and an additional maternal intake of 60 µg per day is required.

Vitamin B_{12}

Vitamin B_{12} is a cobalt-containing corrinoid, four linked pyrrole rings (corrin) co-ordinating with a central cobalt atom. The cobinamides necessary for human well being are methylcobalamin, adenosylcobalamin, hydroxycobalamin, and cyanocobalamin. Micro-organisms, including colonic flora, synthesize cobalamin. Yeast is a source of cobalamin, primarily as adenosyl- and hydroxocobalamin. Methyl cobalamin is found in egg yolk, cheese, and cow's milk. A vegan diet carries a risk of vitamin B_{12} deficiency.

The reactions requiring vitamin B_{12} include:

- isomerization of methylmalonyl-CoA to succinyl-CoA (methyl malonic acid concentrations increase in cases of vitamin B_{12} deficiency);
- methyltransferase reactions: for example, homocysteine to methionine, i.e. the transfer of a methyl group from 5-methyl-TFH to homocysteine which converts homocysteine to methionine.

Vitamin B_{12} has an important role in the maintenance of myelin. Deoxyadenosyl B_{12} is essential for propionyl-CoA reactions by transmutation of methylmalonyl-CoA to succinyl-CoA.

Vitamin B_{12} binds to food proteins and is released by saliva, acid pH, and pepsin, depending upon the mode of cooking and type of food protein. Vitamin B_{12} at stomach pH forms complexes with glycoproteins, transcobalamin, haptocorrin, and intrinsic factor. In the duodenum, cobalamin is released by pancreatic enzymes and alkaline pH and binds solely to intrinsic factor. The vitamin B_{12}/intrinsic factor complex is absorbed from the ileum through a specific receptor. Cobalamin is released from intrinsic factor, converted (80 per cent to methyl and also adenosyl and hydroxy forms) and carried in the blood by transcobalamins I, II, and III. Of these, transcobalamin II releases vitamin B_{12} to the tissues to be stored in the adenosyl form. The total body cobalamin content in adults is between 2 and 5 mg, most of which is stored in the liver. Turnover is 0.1 per cent of the body pool each day. There is efficient conservation by the kidneys and the enterohepatic circulation. Most vitamin B_{12} is excreted in urine and small amounts in faeces, including unabsorbed bacterially synthesized vitamin B_{12}. The relationship between dietary intake and serum concentrations is not linear because the body stores of vitamin B_{12} are largely in the liver.

Vitamin B_{12} deficiency results in megaloblastic anaemia and neurological disorders, especially in the posterolateral columns of the spinal cord. Causes of deficiency are dietary (vegans), lack of intrinsic factor (Addison's pernicious anaemia, gastric resection), intestinal colonization by bacteria and parasites (for example, tapeworms), and ileal resection. The megaloblastic anaemia is due to a lack of vitamin B_{12} for methionine synthase, insufficient methionine regeneration, and 5,10-methylene-THF and deficient thymidylate synthesis. In vitamin B_{12} deficiency, odd number 15- and 17-carbon fatty acids and branch-chain fatty acids are synthesized and incorporated into an unstable myelin nerve sheath. An inability to regenerate methionine from homocysteine, for the *S*-adenosylmethionine generation necessary for myelin proteins, leads to demyelination.

The efficiency of vitamin B_{12} absorption is measured by the Schilling test or by a whole-body scanner.

Requirements

A dietary intake of between 1 and 2 µg/day for adults of all ages is protective. In pregnancy there is a compensatory increased absorption so that 1.5 µg/day is sufficient. During lactation an increment of 0.5 µg/day should ensure an adequate supply in breast milk (0.2 to 1.0 µg/l). The requirement for infants is of the order of 0.1 µg/day and for children aged 3 to 10 years, 0.5 to 1.0 µg/day. Vitamin B_{12} has extremely low toxicity and as much as 3 mg/day may be taken.

Vitamin A

The vitamin A family (retinoids) are related to the plant pigment carotene. Dietary vitamin A comes in two forms: from animal sources, preformed, vitamin A fatty-acid esters; or from plant, provitamin A carotenoids. b-Carotene, a provitamin A carotenoid, consists of two retinol molecules. Retinol is vitamin A alcohol, a hydrocarbon chain with a betaionone ring at one end and an alcohol group at the other, usually esterified with a fatty acid (retinyl esters) as the *all-trans* stereoisomer. The *cis* configuration isomer (11 or 13 position) is less potent. Retinol can be oxidized to an aldehyde (retinal) or acid (retinoic acid). Retinol and carotene are readily oxidized and are protected by vitamin E.

Retinol is present in dairy products, liver, and fatty fish liver oils. Carotenes are found predominantly in green vegetables as well as in yellow and red fruits and vegetables. Vitamin A is essential for the maintenance of epithelial tissue, visual function, and the immune system. Most actions of vitamin A in development, differentiation, and metabolism are mediated through retinoid receptors of the nuclear steroid receptor family of proteins that bind retinoic acid and regulate gene expression.

The photopigment rhodopsin is formed by the protein opsin and 11-*cis* retinal. A photon of light converts the *cis* retinal to the *trans* form, which reversibly dissociates from the opsin and is seen as light. Retinyl esters are hydrolysed by pancreatic hydrolases and the enteric mucosa. b-Carotene is cleaved to two retinols by b-carotene 15,15'-deoxygenase, and carotenoids oxidatively cleave to retinal and apocarotenoids. Retinal is reduced to retinol, esterified with long-chain fatty acids, and transported to the liver as retinyl long-chain fatty esters in chylomicrons through the lymph. Retinol is a major liver storage form and circulates to tissues, bound to retinol binding protein. There is an enterohepatic circulation of retinoids.

Vitamin A deficiency is a major worldwide cause of blindness, due to a poor dietary intake of green vegetables, fruit, and dairy produce. Malabsorption is a less common cause. Vitamin A deficiency results in reduced rhodopsin in the retinal rods resulting in loss of vision. Xerophthalmia causes blindness in 500 000 young children each year, especially amongst bottle-fed infants and breast-fed infants with vitamin A-deficient mothers. Protein calorie malnutrition compounds the problem during weaning. Vitamin A deficiency aggravates damage from other causes of keratoconjunctivitis, for example measles. Epithelial surfaces undergo squamous metaplasia, followed by corneal ulceration and irreversible visual damage. Clinical forms are:

- conjunctival xerosis (Bitots's spots are white plaques of thickened conjunctival epithelium indicative of vitamin deficiency in the young);
- corneal xerosis;
- keratomalacia, leading to blindness;
- night blindness, an early symptom with or without xerophthalmia;
- xerophthalmia fundi; and
- corneal scars.

Vitamin A is important in epithelial metabolism. Deficiency leads to epithelial metaplasia and inappropriately keratinized epithelium in the mucous membranes of the respiratory, gastrointestinal, and genitourinary tract. Sebaceous glands become blocked thereby causing follicular keratosis.

Prophylaxis demands education in the eating of dark-green vegetables. Where xerophthalmia is endemic, vitamin A is given prophylactically in capsule form or by food fortification. Frank deficiency is treated by high-potency Vitamin A: 200 000 IU for 2 days, and a third dosage at least 2 weeks later. Thereafter, improved diet and supplementation is obligatory. Corneal ulceration is treated by antibiotics, and the response is rapid. Vitamin A deficiency is a putative risk factor for childhood morbidity and death, especially for the underweight and premature infant.

b-Carotene is not toxic, but high intakes lead to a yellow appearance sparing the eyes (hypercarotenaemia). Polar bear's liver, rich in retinol, is toxic and ingestion can cause drowsiness, headache, vomiting, and excess peeling of the skin. Large intakes of retinol are teratogenic. Pregnant women should be careful not to exceed the recommended intake of vitamin A in the first trimester.

Plasma retinol is an insensitive indicator of vitamin A status. The relative-dose-response (**RDR** test), which measures retinol transport by the retinol binding protein, is used as a functional test for calculating retinol stores. The concentration of plasma carotenoids reflects short- to medium-term intakes. The following are equipotent to 1 µg of *all-trans*-retinol equivalents/day: 3.33 IU vitamin A, 3.5 nmol retinol or retinyl ester, or 6 µg *all-trans*-b-carotene.

Requirements

Adults require 500 µg retinol equivalents/day; infants, 250 to 350 µg retinol equivalents/day; children, 350 µg retinol equivalents/day; pregnancy, an increment of 100 µg retinol equivalents/day, particularly during the third trimester. Lactation requires an increment of 300 µg retinol equivalents/day. Breast milk vitamin A concentration should exceed 1.5 mmol/l.

Vitamin D

The vitamin D family of sterols includes vitamin D_3 (cholecalciferol) and vitamin D_2 (ergocalciferol). Cholecalciferol is to be regarded as a hormone rather than a vitamin, and is produced by the ultraviolet irradiation of dietary 7-dehydrocholesterol (provitamin D_3) in the skin. The extent of exposure to sunlight determines production. Cholecalciferol is also available in fatty fish (for example, cod), eggs, and chicken liver. Ergocalciferol is also the result of the exposure of ergosterol (provitamin D_2) to ultraviolet light. Ergocalciferol differs from cholecalciferol in having an extra methyl group at C-24 and a double bond at C-22,23.
1,25-dihydroxycholecalciferol vitamin D (**1,25(OH)2D**) regulates calcium and phosphate absorption, metabolism, and export into the bloodstream. Such regulation is through steroid:thyroid hormone nuclear receptors. $1,25(OH)_2D$ is also a developmental hormone inhibiting proliferation and promoting differentiated function in cells.

Dietary vitamin D is absorbed in the small intestine, as a lipid, transported to the liver bound to a-globulin (*trans*-calciferol) in chylomicrons. Both vitamin D_2 and vitamin D_3 are inactive. They are converted in the liver by a P-450 inducable microsomal enzyme into 25-hydroxy vitamin D (**25(OH)D**), which has modest biological activity, before plasma transport on a specific globulin. The active form of vitamin D is 1,25(OH)2D formed in the kidney by a mitochondrial hydroxylase acting on 25(OH)D. The half-life of $1,25(OH)_2D$ is less than 24 h. All forms of vitamin D are stored in fat. Vitamin D is 24-hydroxylated and, as the glucuronide, is excreted in bile into an enterohepatic circulation.

The prime consequence of vitamin D deficiency is rickets, caused by a failure to mineralize the bony skeleton. The epiphyseal cartilage replacement is defective, leading to an overgrowth of subperiosteal osteoid tissue and poor mineralization of the bone matrix resulting in soft bones. The type of bony abnormalities depends on the age of onset and the weight-bearing bones involved. The appearance of the rachitic child is deceptive, the child may appear quite well or be restless with hypotonic muscles and twisted limbs' postures. The abdomen is swollen and the child suffers from diarrhoea, respiratory infection, and delayed tooth development. In the infant, the commonest abnormality is enlargement of the end of the radius and the costochondrial junction—termed the ricketic rosary. Later there is bossing of the frontal and parietal bones and delayed closure of the anterior fontanel; so-called 'pigeon chest' can result, which is an undue prominence of the sternum and a transverse depression from the costal margins towards the axillae. All are due to pressure on the soft bones when the child is supine. In the walking child, the weight-bearing bones bend, kyphosis of the spine and bowing of the lower ends of the femur, tibia, and fibula result. Pelvic deformity can make delivery difficult in subsequent pregnancies. Tetanic spasm can occur, whereby spasm of the hands, feet, and vocal chord result in high-pitched cries and breathing problems.

Diagnosis is based on the clinical appearance and measurements of plasma alkaline phosphatase (although interpretation of the results is difficult in the growing child) and plasma 25(OH)D levels. There are several risk factors:

- inadequate exposure to sunlight (dependent on latitude, in the United Kingdom 30- to 90-min exposure of the face and legs per day will restore 25(OH)D concentrations;
- strict vegetarianism;
- a vitamin D-deficient mother breast feeding her baby;
- high melanin content in the skin, which screens the metabolically active skin sites; and
- malabsorption.

Prevention of vitamin D deficiency requires a supplement of 10 µg of vitamin D daily or regular exposure to sunlight in well-nourished individuals.

Osteomalacia, may present with muscular weakness and a waddling gait. Bone pain, tetany, and spontaneous fractures may develop. Radiographic features include bone rarification, pseudofractures, and Looser's zones at points of compression stress. Renal disease, from many causes, may be associated with impaired renal synthesis of $1,25(OH)_2D$. A failure of 25-hydroxylation of vitamin D can occur in hepatic disease. Dietary vitamin D intake may be important in immunity to tuberculosis, and 25-OH vitamin D deficiency may contribute to the occurrence of tuberculosis. Hypervitaminosis occurs during infant supplementation and replacement therapy. Plasma calcium concentrations increase with tetany, ECG changes with resultant convulsions, and occasionally death. Vitamin D in milligram amounts is poisonous, and is used as a rodenticide.

The best measure of the vitamin status in humans is the plasma 25(OH)D concentration.

Requirements

No minimum dietary intake has been identified for adults exposed to ample sunlight. However, 10 µg/day vitamin D is recommended for those with poor sun exposure. Breast-milk vitamin D concentrations are low (0.25–1.25 µg/litre) and are reduced in the winter. Vitamin D intakes are a problem for the 6- to 12-month-old baby dependent upon modestly fortified weaning foods. The diet thereafter expands and the plasma 25(OH)D concentrations are usually satisfactory. Pregnant and lactating women should receive supplementary vitamin D at 10 µg/day. Where the elderly are insufficiently exposed to the summer sun, their stores may be reduced and a supplement of 10 µg/day vitamin D is recommended.

Vitamin K

Vitamin K, a naphthoquinone, occurs in two forms in human nutrition: vitamins K_1 and K_2. Vitamin K_1 of plant origin is a phytylmenaquinone (also known as phylloquinone or phytylmenadione) and consists of 2-methyl-1,4-naphthoquinone (menadione or menaquinone) attached to a 20-carbon phytyl side chain. Vitamin K_2 is one of several homologues produced by bacteria with 4 to 13 isoprenyl units in the side chain (menaquinone-4 to -13). Vitamin K_1 is present in fresh green vegetables (for example, broccoli, lettuce, cabbage, and spinach) and beef. Vitamin K is involved in the synthesis of proteins central to blood coagulation, namely prothrombin and factors VII, IX, and X. Vitamin K is necessary for the post-translational carboxylation of glutamic acid in the coagulation proteins. g-Carboxyglutamate allows the binding of calcium and phospholipids in the formation of thrombin.

Vitamin K is absorbed as a lipid, and is transported from the intestine in the blood in chylomicrons as b-lipoproteins. Vitamin K_2 of bacterial origin is absorbed from the colon. When there is vitamin K deficiency, the blood clotting time is prolonged and factor VII, IX, and X activities are reduced. Deficiency is uncommon in adults. However, in infants deficiency results from a sterile intestinal tract and the inadequate vitamin K content of human and cow's milk. The problem is compounded by the immature liver of the infant being slow to synthesize prothrombin. Acquired deficiencies occur as a result of any cause of lipid malabsorption and after bowel sterilization with broad-spectrum antimicrobial agents. Vitamin K deficiency may also result from the regular ingestion of liquid paraffin, since the vitamin partitions preferentially into this non-absorbed, non-polar hydrocarbon oil and is excreted rather than absorbed. Liquid paraffin is still used in many parts of the world as a regular aperient, principally by the elderly.

Natural vitamin K preparations are free from toxic effects. There are naturally occurring vitamin K antagonists—for instance, spoilt sweet clover produces a dicoumarol that prolongs the prothrombin time of the cow, thereby causing a bleeding condition. Drugs designed to prolong prothrombin time were developed as a result of this observation. Vitamin K deficiency can be detected by the 'prothrombin time' test which measures prolongation of clotting time.

Requirements

The children and adult dietary requirements of phylloquinone are between 0.5 and 1.0 µg/kg body weight per day. Vitamin K in human breast milk is as the phylloquinone and the concentration varies between 1 and 10 µg/l. An adequate intake for breast-fed infants is 8.5 µg phylloquinone/day. Vitamin K is given as supplements in malabsorption syndromes and prophylactically for haemorrhagic disease of the newborn.

Vitamin E

The vitamin E family consists of fat-soluble biologically active tocopherols and tocotrienols. The tocopherols are the most potent, their activity depending upon the position and number of methyl substitutions. a-Tocopherol, is the most potent; g-tocopherol and g-tocotrienol have activity of 48 and 20 per cent, respectively, when compared to a-toco-pherol.

Vegetable oils—wheat germ, sunflower seed, cottonseed, safflower, palm, rape seed, and other oils are abundant sources of vitamin E. The free-radical scavenging properties of vitamin E are a function of the fused chroman ring system, the phytyl side chain facilitates entry into the hydrophobic environment of the membrane. Ascorbic acid may reduce tocopheroxyl radicals formed by the scavenging of free radicals during metabolism. This enables a molecule of tocopherol to scavenge many radicals. The absorption of the vitamin is incomplete and varies between 20 per cent and 80 per cent. Vitamin E enters the systemic circulation in chylomicrons and very low-density lipoproteins (**VLDL**) and coincidentally protect the polyunsaturated fatty acids (**PUFA**) which are also transported. Lipoprotein lipase controls uptake by the liver or transfer to other lipoproteins. The normal lipoprotein concentrations of vitamin E as a-tocopherol range from 11 to 37 µmol/l. a-Tocopherol forms 90 per cent of the vitamin E found in tissues, including all cell membranes where it inhibits the non-enzymatic oxidation of PUFA by molecular oxygen. Biochemical deficiency may occur as a result of gastrointestinal malabsorption and in premature infants. Vitamin E deficiency has been implicated in peripheral neuropathy associated with malabsorption syndromes and often accounts for the acanthocytosis, retinitis pigmentosa, and neurological features in Bassen-Kornzweig disease (abetalipoproteinaemia). Patients with fat malabsorption due to cystic fibrosis, coeliac disease, prolonged cholestasis, and after massive small intestinal resections

are particularly at risk from vitamin E deficiency; supplements prevent and may slowly ameliorate the neurological deficit. Homozygosity for inactivating mutations in the a-tocopherol transfer protein is a cause of isolated vitamin E deficiency and ataxia which closely resembles the spinocerebellar ataxia of Friedreich's disease. Patients with Friedreich's ataxia in the absence of frataxin mutations should be investigated for vitamin E deficiency and defects in the tocopherol transfer protein; vitamin E supplements may slowly improve this condition. Longstanding profound deficiency of vitamin E is associated with progressive spinocerebellar ataxia, visual loss due to retinitis pigmentosa, haemolysis (with red cell acanthocytosis), upward visual gaze palsies, dementia, and muscle weakness. If detected, vigorous long-term vitamin E supplementation is indicated as well as attention to the primary cause of the deficiency. There appears to be no adverse effects from large doses of vitamin E up to 3200 mg/day.

Vitamin E status can be measured from the plasma tocopherol concentration, or expressed as a ratio of total blood lipids or vitamin E:cholesterol. A functional test of vitamin E status is the hydrogen peroxide haemolysis test (erythrocyte stress test).

Requirements

The average intake in Britain is 6 mg/day, most of which is derived from fats, oils, and cereals. The dietary requirement is determined by the PUFA content of membranes and tissues and the PUFA content of the diet. The relationship between PUFA intake and vitamin E requirements is not a simple linear relationship. Intakes of 4 mg and 3 mg of a-tocopherol equivalents per day, respectively, for men and women have been regarded as adequate, but may be too low. Alternatively, and better, would be 0.4 mg a-tocopherol equivalents per gram of dietary PUFA/day, thereby increasing the recommendation to 7 mg. This formula might also be used for infants. Human breast milk contains 10 mg of a-tocopherol equivalents/l in colostrum, reducing to 3.2 mg/l at 12 days and thereafter.

Trace elements

Trace elements are important, since they:

- act as cofactors in enzyme oxidation–reduction reactions;
- maintain the specific configuration of proteins;
- are incorporated into the structure of hormones; and
- play a structural and catalytic role in gene expression and transcriptional regulation of genes.

Trace elements are required in small amounts. The trace elements contained in soil and drinking water vary from area to area, which determines the variation in intake seen in different communities. The amount and chemistry of dietary constituents eaten with the trace elements affects the absorption efficiency of the essential elements. The absorption of calcium and trace metals (for example, zinc) can be inhibited by dietary phytate. Copper absorption is reduced by competitive interactions affecting its solubility. A mild degree of iron depletion increases not only iron absorption but also lead, zinc, cadmium, cobalt, and manganese.

Individual trace elements

[The following abbreviations are used below: At wt, atomic weight; val, valency; iso, natural isotope; Abund, natural abundance in earth's crust as a per cent of the total.]

Cobalt

At wt: 59; val: 2, 3; iso: 59; abund: 0.0018 per cent

Sources are wholemeal flour and seafoods. Cobalt's role is as a component of vitamin B12. Uncomplexed cobalt can be absorbed and subsequently excreted in urine. Intakes of cobalt are approximately 5 µmole/day and the total body content is 1.5 mg (7.5 µmole). In Quebec, a cobalt-containing beer improver (15 µmol of cobalt/l) proved to be toxic; its best customers developed severe cardiomyopathy.

Chromium

At wt: 52; val: 2, 3; iso: 50, 52, 53, 54; abund 0.033 per cent.

Chromium is present in most foods especially wheat germ, molasses, green beans, and broccoli. Dietary intakes vary between 5 and 100 µg/day, but absorption is meagre at 1 per cent. The plasma concentration of chromium is 0.3 µg/ml bound to transferrin, and it is excreted in urine. Deficiency increases the risk of type II diabetes mellitus and cardiovascular disease. The recommended adult intake is 0.5 µmole/day and between 2 and 19 nmole/kg per day for children and adolescents. The adult body contains 100 to 200 µmole. The chromium content of human milk is 0.06 to 1.56 ng/ml. Chromium in high dosage is well tolerated.

Copper

At wt: 64; val: 1, 2; iso: 63, 65; abund: 0.010 per cent.

Good sources of copper include green vegetables, fish, oysters, and liver. Copper is required by the immune, nervous, and cardiovascular systems for skeletal development, iron metabolism, red-cell formation, and enzymes including cytochrome oxidase and superoxide dismutase. Between 35 and 70 per cent of ingested copper is actively absorbed, but this is affected by age and the chemistry of accompanying food. Copper is concentrated in the liver, excreted in bile, and lost in faeces. In plasma, copper is bound to caeruloplasmin and albumin. The total amount of copper in an adult is approximately 2 mmole (50 to 120 mg). Copper accumulates in the fetal liver for early extrauterine life, premature birth results in depleted copper stores. Copper deficiency in adults has not been reported, but patients taking large doses of the chelator penicillamine for cystinuria and as a second-line agent in rheumatoid arthritis, are at risk. Poisoning with copper presents with haemolysis and brain and hepatocellular damage. The requirement for adults (including during pregnancy) is 1.5 to 3 mg/day, children range 0.6 to 1.5 mg/day. An infant requires 0.4 to 0.6 mg/day.

Iodine

At wt: 127; val: 1; iso: 127; abund: 6×10^{-6} per cent.

Iodine is present in modest amounts in most food and drinking water. Seafood, milk, and meat are good sources. Iodine is required for thyroxine 3,5,3',5'-tetraiodothyronine (T4) and 3,5,3'-tri-iodothyronine (T3). Selenium and zinc are important in the conversion of T4 to the active T3, catalysed by selenium-dependent iodothyronine deiodinase. Dietary iodine from food and water is absorbed as inorganic iodide and transported to the thyroid gland. The body content of iodine is between 20 and 50 mg (160 to 400 µmole).

Goitre results from iodine deficiency and is endemic in mountainous areas. Some 800 million people are at risk of iodine deficiency, of whom 190 million may develop goitres and more than 3 million are cretinous. These populations have an iodine intake less than 25 µg/day—the required intake being 80 to 150 µg/day. Iodine replacement is essential for these populations and may be added to food, salt, or water or by the direct administration of iodine. Goitre may also arise through eating plants containing goitrogens (for example, thiocyanate in cassava, maize, bamboo shoots, etc.) Maternal iodine deficiency is associated with perinatal death, stillbirths, spontaneous abortions, endemic cretinism, and congenital abnormalities. Thyroxine is essential for brain development during the first 2 years of life. A modest increase in the incidence of hyperthyroidism occurs following the ingestion of iodized salt preparations in individuals over 40 years of age.

Thyroid hormone and urinary iodine measurements reflect iodine status. Adults require 140 µg/day, babies 40 µg/day, infants 50 µg/day, and children 50 to 140 µg/day. Intake should increase to 175 µg/day during pregnancy and 200 µg/day with lactation. Breast milk contains 44 to 93 µg/litre, an adequate iodine intake.

Magnesium

At wt: 24; val: 2; iso: 24, 25, 26; abund: 1.94 per cent

Magnesium is present in most foods, particularly chlorophyll-containing vegetables. Magnesium is absorbed from the distal intestine and excretion is through the kidneys. Magnesium homeostasis includes reabsorption of endogenous magnesium from enteric secretions. The plasma concentration varies between 0.6 and 1.0 mmol/l, and adult whole-body magnesium is 1 mole or 25 g—two-thirds in bone with phosphate and bicarbonate, the remainder being complexed with ATP. Magnesium is a cofactor for cocarboxylase and is involved in the replication and transcription of DNA and translation of RNA. Magnesium deficiency is manifested by progressive muscle weakness, failure to thrive, neuromuscular dysfunction, arrhythmias, hallucinations, positive Trousseau's sign, coma, and death. Malabsorption, alcohol abuse, and diuretics are causes of a low serum magnesium levels.

Urinary magnesium is an approximate measure of dietary intake. Typically, a diet in the United Kingdom contains between 8 and 17 mmole of magnesium/day (200 to 400 mg). Adults (including during pregnancy), require between 8 and 10.3 mmole/day (200 to 250 mg). Human breast milk contains 0.12 mmole (2.8 mg)/litre. The lactating mother should increase her magnesium intake by 2.0 mmole/day (50 mg). Babies require 30 mg/day, infants 75 mg/day, and children 80 to 200 mg/day

Manganese

At wt: 55; val: 2, 4; iso: 55; abund: 0.085 per cent.

Tea, cereals, legumes, and leafy vegetables are good sources of manganese. Manganese is a cofactor and enzyme activator. Manganese absorption is only 3 to 4 per cent efficient. Calcium, phosphorous, fibre, and phytate interact with and reduce manganese absorption. The plasma concentration is between 1 and 2 µg/g bound to transferrin, the body pool contains 0.3 mmole, and excretion is in bile. Manganese deficiency in man has not been reported. The average intake in Britain is 2 to 5 mg/day, half from tea. Safe intakes for adults are more than 1.5 mg (25 µmole)/day and for children and infants more than 16 µg (0.3 µmole)/kg per day. Breast milk contains 15 µg/litre.

Molybdenum

At wt: 96; val: 2, 3, 4; iso: 92, 94, 95, 96, 97, 98, 100; abund: 7×10^{-4} per cent

Important dietary sources are wheat flour and its germ, legumes, and meat. Molybdenum is a cofactor for oxidases important in the metabolism of DNA and sulphites. Intestinal absorption efficiency is high at 40 to 100 per cent. Plasma concentration is 1 µg/100 ml, and molybdenum is bound to protein. Storage is in the liver and excretion in urine. There are no reports of molybdenum deficiency in man. Gout has been attributed to high molybdenum intakes of 10 to 15 mg/day. Adults require between 75 and 200 µg of molybdenum/day (0.75 to 4 µmole/day). Breast-fed infants require 1.0 µg/kg per day. Babies require 15 to 30 µg/day, infants 20 to 40 µg/day, and children 40 to 100 µg/day.

Nickel

At wt: 59; val: 2, 3; iso: 58, 60, 61, 62, 64; abund: 0.018 per cent

It has not been established whether nickel is essential in humans. Absorption is 3 to 6 per cent of the dietary intake. Plasma concentrations are between 2 and 4 µg/100 ml, some of which is bound to albumin. Nickel is excreted in urine. Nickel deficiency might result in depressed growth and haemopoesis.Requirements are unknown, but intakes in the United Kingdom are about 140 µg/day (2.4 µmole/day).

Phosphorus

At wt: 31; val: 3, 5; iso: 31; abund: 0.12 per cent.

Phosphorus is present in all natural foods, the usual diet in Britain providing 1.5 g of phosphorus daily. Phosphorus is an important physiological component: with calcium, of the bony skeleton; of adenosine triphosphate (ATP) in oxidative phosphorylation; in nucleic acids through phosphorylation of nucleotides; and in enzyme control through phosphorylation by protein kinases. Phosphorus is absorbed as free inorganic phosphorus from the diet (controlled by 1,25(OH)$_2$ vitamin D) at both the brush-border and basolateral membranes. The plasma concentration of phosphorus is between 0.8 and 1.4 mmol/l and it is excreted in both urine and faeces. The bony skeleton contains 80 per cent of the body content of phosphorus as the calcium salt, 19 to 29 mmole (600 to 900 g). Recommended phosphorus requirements are equimolar to calcium.

Selenium

At wt: 79; val: 2, 4; iso: 74, 76, 77, 78, 80, 82; abund: 8×10^{-5} per cent

Selenium is found in food as selenoamino acids, selenoproteins, and as selenide, selenite, or selenate. The main sources of selenium are cereals, meat, and fish. Selenium is a cofactor of certain enzymes (for example, iodothyronine deiodinase and glutathione peroxidases). Both selenium and vitamin E are important in stabilizing lipid membranes by inhibiting oxidative damage. Absorption is efficient at 35 to 85 per cent. The plasma concentration of selenium is between 7 and 30 µg/100 ml protein bound. Excretion is in urine and possibly bile. In New Zealand, Venezuela, and China both the soil and population can be deficient in selenium. In China, selenium deficiency is associated with the childhood cardiomyopathy, Keshan's disease.

In certain areas of Tibet and Nepal, Kashin-Beck disease, a degenerative arthropathy associated with selenium deficiency, is endemic. Iodine deficiency, resulting in hypothyroidism and goitre, is an associated risk factor for Kashin-Beck disease even in individuals with normal serum selenium concentrations. The precise relationship between iodine deficiency and selenium status in areas where selenium deficiency is endemic remains to be established—especially in patients with Kashin-Beck disease.

Urinary selenium output, red-cell selenium levels, or glutathione peroxidase activity are markers of recent and medium-term dietary intake. Adults require 75 µg/day (0.9 µmole/day). Fertility requires an adequate selenium intake, but the pregnant woman has no additional dietary selenium requirements. Lactation requires an increase in dietary intake of 15 µg/day (0.2 µmole/day). Breast-fed infants should receive approximately 10 µg/day (0.1 µmole/day) and children 15 to 30 µg/day (0.2 to 0.4 µmole/day). Breast milk contains 20 to 60 µg/litre of selenium.

Silicon

At wt: 28; val: 4; iso: 28, 29, 30; abund: 25.8 per cent

Cereal grains and other sources of dietary fibre are important sources of silicon. The role of silicon in human nutrition may be important in cartilage and connective tissue as the human aorta, trachea, lungs, and tendons are rich in silicon. Silicic acid is readily absorbed. The body storage pool is approximately 3 g (1 mole) in a 60-kg man; the plasma monosilicic acid concentration is 500 µg/100 ml. The dietary requirements of silicon are unknown.

Sulphur

At wt: 32; val: 2, 4; iso: 32, 33, 34, 36; abund: 0.048 per cent

Sulphur occurs in: proteoglycans; dermatan, chondroitin and keratin sulphate; glutathione; and coenzymes including coenzyme A. Cysteine, methionine, and disulphide crosslinkage are important in proteins, and sulphate is involved in detoxification processes. Sulphur is absorbed as amino acids, which are subsequently desulphated, and excreted in urine as sulphates. Dietary intake is of the order of 0.7 mg (22 µmole)/day. The dietary requirements of sulphur are unknown.

Zinc

At wt: 65; val: 2; iso: 64, 66, 67, 68, 70; abund: 0.02 per cent

Dietary sources are meats, whole grains, legumes, and oysters. Zinc is required as a cofactor in DNA synthesis, cell division, and protein synthesis. Zinc-finger 'proteins' are important as gene transcriptional regulators. It has long been believed that zinc is important for wound healing. Approximately 20 per cent of dietary zinc is absorbed complexed with amino acids, phosphates, and organic acids. Phytates and oxalates form insoluble complexes which inhibit absorption. The normal plasma concentration of zinc is between 80 and 110 µg/100 ml, complexed with albumin. The adult body content of zinc is over 2 g (30 mmole). Bone, the prostate, semen, and the choroid of the eye all contain high concentrations of zinc. Loss of zinc from the body is in faeces.

Zinc is widely available in foods so dietary deficiency is rare, and only reported in malabsorption and in male dwarfs in Iran. The clinical signs are growth retardation, hypogonadism, bullous-pustular dermatitis, paronychia, lethargy, hepatosplenomegaly, and iron deficiency anaemia which responds to zinc supplements (15 mg three times/day). Zinc deficiency has been reported as a feature in a number of diseases, including the florid deficiency state and skin condition acrodermatitis enteropathica, an autosomal recessive trait leading to selective impairment of zinc uptake by the upper small intestinal mucosa. Similar signs may be observed in patients with severe malabsorption due to Crohn's disease and other intestinal disorders, especially those associated with a loss of inflammatory cells in the gut lumen. Excessive zinc can lead to nausea, vomiting, and fever.

The plasma concentration of unhaemolysed zinc is a measure of a person's current zinc status. Zinc in the red-blood cells and hair gives a long-term assessment of zinc status. Adults of all ages (and during pregnancy and lactation) require between 12 and 15 mg of zinc (110 to 145 µmole)/day. Infants need between 4 and 5 mg/day; however, human milk is not a rich source of zinc (2–3 mg/litre) and the infant depends very much on the stores obtained during its last 3 months of interuterine life. Children require 10 to 15 mg/day

10.4 Severe malnutrition

Alan A. Jackson

Introduction

Severe malnutrition reflects a society which is not able to meet its basic needs for health care and survival. It is the consequence of a range of factors which together characterize underdevelopment, poverty and deprivation, an insanitary environment, frequent infections, and food which is poor in quality or limited in availability. A series of vicious cycles operate within individuals and across generations, limiting the ability of vulnerable groups, families, and individuals to cope with the harsh realities of a hostile environment, either through the exigencies of nature or a human unwillingness to share the available resources with greater equity. Across the globe, severe malnutrition is a common condition during childhood and is most prevalent amongst the poorest in developing countries, but it is also found with uncomfortable frequency amongst the most deprived of every society, including those in Europe and North America. It is a frequent aspect of clinical medicine in patients who, for any reason, have a loss of appetite or a reduction in food intake. The same principles of management and care apply wherever the problem is found.

Malnutrition at any age impairs the ability to perform and function. Children with severe malnutrition are at risk of serious, life-threatening problems which require urgent attention. More insidiously, malnutrition during childhood stunts development and leaves a scar which remains for the rest of that person's life. This lost potential can express itself as an increased risk of ill health, as impaired intellectual development leading to poor school performance, or in limited physical development leading to poorer work performance. Once part of an individual's potential for development has been lost, the clinical and social implications tend to be cumulative. On a global scale, the sum total of the loss of individual capability represents a fundamental brake on aspirations for social and economic development. Throughout the world, 54 per cent of childhood deaths can be attributed directly or indirectly to malnutrition, amounting to 11.6 million 1995. This burden is not spread evenly between different parts of the world. For the worst affected countries, as many as 50 per cent of children under 5 have malnutrition which is severe enough to threaten life, most frequently in sub-Saharan Africa and Southeast Asia. This is representative of the day-to-day situation, and is not a peculiarity of special emergencies.

Notwithstanding the large number of children with severe malnutrition, over the past 20 years there has been a shift to the right of the curve for the distribution of the height and weight of children, indicating a general improvement and marked success for specific interventions. Thus, change is possible and when suitable measures are put in place sustained improvement can be achieved. However, there is absolutely no basis for complacency, as recent figures suggest a slowing down, or even a reversal, of this improvement. This may relate to an inability to control infections effectively, with tuberculosis, malaria, and diarrhoea continuing to play a major role and the HIV epidemic making a significant contribution. The world's population continues to increase, so an improvement in percentage terms does not necessarily mean a decrease in the absolute numbers of malnourished people across the globe.

Severe malnutrition is a late stage in a process where an individual has had inadequate access to sufficient energy and nutrients for a period of time. During this time the function of the body changes and there are important ways in which severely malnourished children are different from normal children. They do not respond to medical treatment in the way that would be expected, and if they are treated in the same way as normal children they will very likely die. Based upon best practice mortality would be expected to be around 5 per cent, but in many centres case mortality has remained unchanged for 50 years, around 50 per cent, with four major errors in care occurring in about 80 per cent of centres (Table 1).

The World Health Organization (**WHO**) has produced guidelines on effective treatment in 10 steps (Fig. 1). During the early period of care the order in which different aspects of treatment are carried out is critical for a successful outcome. A central feature is that as a first step the body's cellular machinery has to be repaired if function is to be restored. Silent infections are common. There have been unusual losses of nutrients from the body which cannot be corrected adequately on a standard diet. The damaged systems of the body are not able to cope with excess energy or further stress. Effective treatment requires the ordered correction of the underlying problems before any attempts are made to correct the tissue deficits.

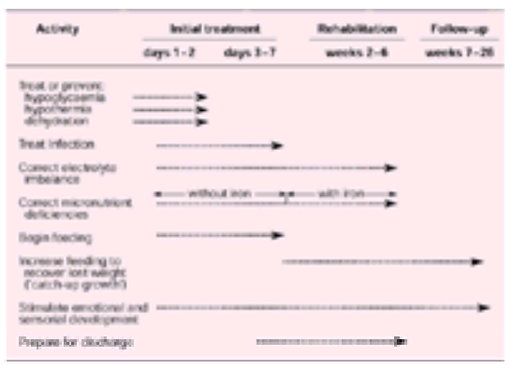

Fig. 1 WHO recommendations for the 10-step approach to the management of severe malnutrition.

Clinical syndromes

Severe malnutrition can present with an array of clinical symptoms and signs, which depend upon the duration of the illness, the extent of coinfection, the particular pattern of nutrient deficiencies and metabolic disturbances, and other associated complications such as diarrhoea and vomiting with attendant disturbances in fluid and electrolytes (Table 2). All descriptions of the condition emphasize one or other feature of the presentation. The archetypal descriptive terms for childhood malnutrition, kwashiorkor, marasmus, or marasmic kwashiorkor, were originally used to characterize clinical syndromes.

The first description of the kwashiorkor syndrome emphasized the development, location, and timing of the skin lesion, with progression from friable hyperpigmented skin, which stripped to reveal hypopigmented skin which ulcerated easily to provide a ready portal for infection—lesions distinct from pellagra. Other features such as abnormal affect and hepatomegaly were noted, but were less remarkable. Placing emphasis upon variability in clinical presentation has made comparison difficult and encouraged the idea that the underlying pathophysiology, and hence its treatment, differs in important ways between locations. This has diverted attention from

similarities in the fundamental changes which take place across the range of clinical presentations. Identifying differences in clinical presentation for this complex disorder are less important than thought previously for successful management.

The function of the body is controlled through the integration of many systems. A fault in any one has implications for the function of all the others. Thus, there is the need for adequate amounts of energy, energy-generating nutrients (carbohydrate, lipid, and protein), minerals, and a range of micronutrients for the body to function effectively in a harmonized way. Lack of any component, or an imbalance, leads to deranged handling of others. By adopting an agreed classification relevant comparisons have been drawn and it is clear that the range of clinical features represent varying manifestations of a clinical disorder with the interaction of qualitative and quantitative factors. The quantitative change results from an inadequate intake of food and leads to a wasting syndrome, classically marasmus, with the progressive loss of tissue, especially marked for subcutaneous fat and muscle. The result is a thin appearance, with pinched features, thin arms and legs, and a scaphoid abdomen. Qualitative changes are usually associated with unusual losses of nutrients from the body, for example through diarrhoea or infection, reordered metabolism to deal with metabolic stress, or the toxic effects of a range of noxious exposures. The end result of this process is likely to be the loss of cellular integrity and control, leading to oedema.

Classification

Severe malnutrition is defined as severe wasting (less than 70 per cent, or a score of less than –3 standard deviations, weight for height, compared with the National Centre for Health Statistics/World Health Organization (NCHS/WHO) reference), or the presence of oedema of both feet, or clinical signs of severe malnutrition, reflecting that there are quantitative and qualitative changes taking place (Table 3). The more severely malnourished an individual, the greater the risk of complications and the risk of an adverse outcome is related to the severity of the weight deficit or the extent to which normal function is deranged. An effective classification differentiates those at greatest risk, guides suitable interventions, and helps determine the extent to which interventions have successfully corrected the problem. These changes can all be marked either quantitatively or qualitatively.

Quantitative measures indicate the extent to which the expected pattern of growth in height and weight has not been achieved: low height for age, low weight for height, and low weight for age. Low height for age (shortness or stunting) is indicative of longer-term malnutrition or poor health. Low weight for height (thinness or wasting) implies recent or continuing current severe weight loss. Low weight for age (insufficient weight relative to age) implies stunting and/or wasting. Weight is more easily measured than height and assessing weight for age is the simplest way of excluding severe malnutrition in the absence of oedema. This has been the basis of a widely used system of classification—the Gomez classification. Weight for age is influenced by both height for age and weight for height. Where deprivation is common there is a high prevalence of low height for age, and weight for age is more strongly influenced by stunting than by wasting, and requires broader public health approaches for its alleviation being unlikely to respond in the short term to aggressive clinical intervention. The prevalence of stunting starts to increase at around 3 months of age, and the process of stunting slows down at around 3 years of age, after which mean heights run parallel to the reference. Weight for height has the advantage that it can be used when age is not known reliably and suggests recent severe weight loss, indicating those children who are most likely to benefit from immediate aggressive nutritional intervention and support. The rate at which weight improves is used to assess progress during recovery, and success of care is indicated by the achievement of a weight which is appropriate for the individual's height. The Waterlow classification usefully identified the relationship between height and weight and suitable cut-off points for intervention.

Qualitative criteria are more difficult, because of their variability and uncertainty about whether they mark any particular pathophysiological process. It has been agreed that the presence of pitting oedema is the archetype of qualitative change, identified as kwashiorkor in the Wellcome classification and now called oedematous malnutrition. In milder forms oedema might be restricted to the limbs, but embraces the entire body in more severe forms. Obtaining a reliable measure of body weight is difficult in the presence of oedema, because of the uncertain contribution of oedematous fluid. The overall appearance might be of a child who superficially appears full, but has evident wasting below the oedema when examined carefully with the clothes removed. Poor appetite or anorexia might be very common, but is not used as a diagnostic criterion. Multiple infection is common and often silent, so that specific sites of infection may be difficult to identify or localize. A high index of suspicion is required for the presence of silent infections, which should be presumed to be present. Infection is not part of the diagnostic criteria.

Natural history and clinical presentation

Inadequate nutrition slows the pace of growth and development and the greater the severity of the limitation or insult, or the longer its duration, the greater the difference between the achieved development and that expected. The stress of an insult of greater severity evokes a metabolic response which is associated with a loss of body weight and a reordering of function, so that resources and effort devoted to growth and development are diverted to maintain the integrity of the individual. The nutritional health of the infant is critically determined by how well prepared the mother was to carry the pregnancy, and the effectiveness with which breast feeding is established and maintained. During pregnancy and for the first months of life the infant is totally dependent upon the mother for its nutrient supply. During early pregnancy there is the elaboration and maturation of function in the fetus. The last trimester is of critical importance as it is when the fetus accumulates effective reserves of nutrients, helping survival and facilitating development during the first year of life. The fetus accumulates reserves of energy, as subcutaneous lipid, and of minerals and vitamins, such as iron, zinc, copper, vitamin A, riboflavin, or pyridoxine, in liver and muscle. At birth the relative protection of the intrauterine environment is replaced by the many hazards of the external world. Gastrointestinal and respiratory infection are amongst the serious dangers to survival and breast feeding provides effective protection from both. Even in affluent societies breast feeding provides the infant with a level of protection against ill health that identifies effective breast feeding as a singularly important feature in any rational policy in public health nutrition. There is a massive increase in the risk of ill health for infants who are not breast fed during the early months of life. This risk is magnified enormously for infants exposed to unsanitary environments with limited access to health care. Anything which limits the growth of the fetus, impairs its development, or causes it to be delivered early will limit its ability to cope with extrauterine life, and increase the risk of problems, infections, and malnutrition. There is enhanced mother–infant bonding and emotional development with breast feeding, and other special benefits include the remarkable bioavailability of energy and nutrients, the presence of non-nutritional factors, protective factors, and growth factors.

Screening: identification and prevention

Malnutrition is a preventable condition and the early identification of those at risk and the implementation of interventions which correct underlying problems and prevent further deterioration is central to strategies for effective care. Early growth failure can be detected by regular weighing, as an integral part of immunization and other health programmes. A series of plotted weights is most valuable and intervention is required for those whose weight crosses two growth centiles on successive measurements. If measurements are only available for a single time point, then height for age and weight for height provide an indication of any past or ongoing growth failure. Advice and demonstration of best practice in child care and feeding may be sufficient to correct a mild degree of growth failure, but persistent or more severe growth failure require closer investigation to exclude underlying problems. Poor anthropometry, with a history of poor appetite and weight loss, should always be taken very seriously and pursued until a cause has been identified and corrected. Severe malnutrition is a medical emergency.

Childhood malnutrition is a clinical problem for the individual, but is also a symptom of ineffective public health policy. Targeted interventions should address the immediate needs of the child, but should also embrace broader considerations. For the child, there is the need to effectively immunize against infection, recognize and treat infection in a timely way, and ensure an effective period of nutritional support following infection. For the family, there is the need to enhance the child rearing skills of the parents, create a stimulating environment, acquire and practice simple skills in hygiene and food preparation, and strengthen family dynamics and coping strategies. For the community, there is the need to improve the economic base of households, increase food purchasing power, increase food security or household food availability, and to treat specific nutrient deficiencies. Sound hygienic practices have to be strengthened at the group or household level, and where necessary the amount and quality of water and the safe and effective removal of solid waste improved. Each activity can exert a beneficial effect on growth and development. Any one might be relatively easy to introduce, but the real difficulty is to ensure that all are sustained. The need is for a fundamental change in the health culture and the creation of a framework of behaviour in which development activities become rooted and take place as a matter of course. A failure to establish and maintain an effective system of health care leads to a progressive deterioration in the clinical state of the most vulnerable infants leading eventually to severe malnutrition.

Aetiology and pathophysiology

Children may become malnourished simply because there is not enough food available, but sick malnourished individuals have no appetite for food. It seems paradoxical that a child who has obviously lost weight and needs to eat may refuse food even when it is readily available. If food is forced there is the possibility that the child will become worse, or even die. In managing severe malnutrition appetite is one of the most important symptoms. A loss of appetite is an important protective mechanism against consuming food which is likely to stress the systems of the body. In experimental studies there are two major biological reasons why appetite is lost: a deficiency of a specific nutrient and infection. Severe malnutrition is a disorder which results from the interaction of three distinct but related processes, each of

which appears to be related directly to the food consumed, but none of which can be easily understood simply by a consideration of food:

- reductive adaptation
- inflammatory and immune responses
- specific nutrient deficiencies.

Food helps meet the many needs for normal function, growth, and development in childhood, but also the ability to cope with environmental challenge. A diet which is adequate but marginal under normal circumstances is inadequate for the increased demands during recovery from frequent intercurrent illness with the double burden of the need for catch-up growth and to make good the unusual losses of nutrients during the infective episode itself. The time available for successful convalescence, before the next bout of infection, is too short to adequately make up the deficit.

Reductive adaptation: failure to meet the usual demands of the body for macronutrients

Reductive adaptation takes place when the demands of the body for energy and nutrients are not adequately met by the dietary intake. The general features are similar regardless of the basis for the inadequate intake. It is a general response to preserve essential function, but carries a cost. Normal metabolism takes place within a highly regulated environment, through the control and integration of exchange and turnover amongst cells and tissues. For the cellular machinery of the body to remain functionally intact and operationally effective requires a constant supply of energy and other nutrients. An estimated one-third of resting energy expenditure may be consumed through the synthesis and degradation of macromolecules such as protein, and a further third is associated with the movement of material across membranes, for example through the pumping activity of the sodium/potassium pump, Na^+/K^+-ATPase. These processes represent the internal work of the body at cellular level and underlie the functioning of all the organs and tissues. They take place continuously and the total activity can be measured as energy expenditure. As food consumption is intermittent the processes are independent of the immediate food intake. However, a sustained lack of food leads to progressive impairment of the cellular machinery as damage due to the wear and tear of normal use can no longer be replaced effectively.

Structure

When food consumption is significantly reduced, metabolic processes continue to enable the body to function, and the energy to support these processes is derived from reserves within the body. The body is in negative energy balance, and tissue mass cannot be maintained, leading to loss in weight. The losses are uneven between tissues, with major losses in subcutaneous fat and muscle and relative preservation of the metabolically more active visceral tissues. One important consequence is that heat generated by muscle is reduced and at the same time insulation in the skin is impaired leading to greater heat loss. The altered body composition underlies all anthropometric methods which are used to assess nutritional status. In addition to the changes in mass, efficiencies in the utilization of energy have to be found.

Function

Efficiencies are achieved by reducing the amount of work carried out by the body. External work is reduced by decreasing physical activity. Internal work is reduced by decreasing cellular metabolic activity, with subsequent effects upon tissue function. Significant efficiencies might be achieved for the major energy-consuming processes such as membrane pumping, protein turnover, and cellular replication. Fundamental to maintaining the chemical environment of cells is the relative distribution of potassium in the intracellular space and sodium in the extracellular space. As potassium tends to leak out of the cell and sodium tends to leak into the cell, for the cell membrane to maintain the effective partitioning of electrolytes requires that sodium is pumped out of the cell in exchange for potassium, consuming ATP. The cell membrane tends to become more 'leaky' in malnutrition as its lipid composition changes, and the Na^+/K^+-ATPase is downregulated as one way in which to reduce energy expenditure. Therefore compared with normal, all people with malnutrition have reduced intracellular potassium and increased intracellular sodium, hence decreased total body potassium and increased total body sodium, which is not identified necessarily on standard biochemical tests. The ability to maintain protein synthesis is fundamental but energetically expensive; energetic efficiency requires a reduction in protein synthesis, which is not divided equally amongst tissues. Liver normally accounts for about 25 per cent of protein synthesis, with the synthesis of nutrient transport proteins playing a critical role in the delivery of lipid, minerals, and vitamins to the other tissues. Reduced synthesis of nutrient transport proteins may save energy, but at the cost of reduced delivery to peripheral tissues; thus for example limited synthesis of apolipoproteins limits the delivery of lipid to peripheral tissues and enhances the accumulation of lipid in liver. Cellular replication is energetically demanding, requiring the ready availability of all nutrients. A reduction in cellular replication provides efficiencies in energy and nutrient use but impairs the function of systems critically dependent upon cellular replication: the skin, gastrointestinal tract, respiratory tract, and the immune system.

Functional and metabolic cost of reductive adaptation

The function of the cells in all tissues is affected by reductive adaptation. With relative protection of more vital functions, the cost is a reduction in those functions which are not immediately vital but which provide the functional reserve capability which enables the metabolic flexibility to respond to a changed internal environment or a challenge from the external environment. As a consequence, changes which would be readily managed in the normal state present a metabolic stress in the reductively adapted state. What would normally be a modest challenge can induce a major metabolic perturbation. Reductive adaptation represents the loss of reserve capacity, which leads to increased metabolic brittleness and vulnerability. The cellular machinery is no longer capable of responding effectively to the usual challenges. There is a change in the function of all systems.

Gastrointestinal tract

There is loss of mucosa and submucosal tissues, loss of gastric acidity, and a reduced capacity for digestion and absorption. This leads to impaired bioavailability of nutrients from food, decreased transit time, and predisposition to small bacterial overgrowth. An impaired ability to repair and maintain the integrity of the endothelium predisposes to bacterial translocation and overexposure to endotoxins.

Skin

The skin wastes, loses its ability to maintain heat, and readily becomes breached and infected.

Immune system

There is increased exposure to pathogens and a decreased capacity to respond (inflammation and immune response see below).

Liver

There is downregulation of synthetic and excretory processes. The reduced functional reserve makes it more difficult to maintain glucose homeostasis in the face of increased bacterial exposure. Intermediary metabolism is impaired and transport proteins for the delivery of lipid, vitamins, and minerals to other parts of the body are reduced. The formation of clotting factors is impaired. Reduced bile and bile salt formation affect digestion. Metabolism and clearance of drugs, toxins, and xenobiotics is also reduced.

Cardiovascular system

A reduction in the functional reserve of the heart, slower pulse, and increased circulation time make heart failure more likely if excess fluid is given intravenously. There is poor circulatory control with a tendency to reduced intravascular volume with an expanded interstitial fluid space.

Iron is an integral part of haemoglobin in red cells, involved in the transport of oxygen from the lungs to the tissues. The mass of red cells is related to the amount of oxygen which has to be transported, which in turn relates to the mass of active lean tissue. As part of reductive adaptation there is a decrease in the lean tissue of the body with an associated decrease in the red cell mass. The iron which is released from haemoglobin is not required immediately for the formation of more red cells. The level of iron in the body is controlled by the rate at which it is absorbed from the gastrointestinal tract, as once in the body there are no recognized mechanisms through which iron can be lost. Therefore, the iron released from red cells cannot be excreted and is placed into storage. Free iron is highly reactive and acts as a focus for uncontrolled excess generation of free radicals, thereby damaging other cellular components. Excess iron is stored in the liver, bound to ferritin. A demand

for ferritin synthesis is energetically expensive and diverts amino acids from the formation of other proteins. As part of reductive adaptation, the ability to effectively sequester iron in a chemically quiescent state is impaired.

Renal

There is decreased functional capacity of the kidney, with an impaired ability to concentrate, dilute, or acidify urine.

Muscle

Muscle mass is reduced and muscle function impaired by reduced potassium, which together lead to reduced generation of heat.

Brain

Brain function is relatively well preserved. Nevertheless there is blunting of higher functions with decreased mentation, apathy and depression, and impaired control of hormonal and integrative responses. There is a decrease in activity, poor work performance, and a decrease in discretionary activities, which together contribute to a slowing of learning.

Infection: the inflammatory and immune responses

Survival in a potentially hostile world requires effective non-specific and specific defence mechanisms. Non-specific physical barriers (skin and mucous membranes) and chemical protection (gastric acidity, secretions such as tears, mucins, etc.) depend upon cellular replication, which is less well maintained during reductive adaptation and even minor damage leads to a breach which is not repaired. Local damage with bacterial invasion usually elicits local inflammation, a systemic or acute phase response, and a specific immune response. The mounting, co-ordination and regulation of an effective response requires energy, increased cellular replication, and protein synthesis. The changes in hormones and cytokines associated with reductive adaptation impair the establishment and control of normal inflammatory and immune responses. The localized signs of tissue damage or infection—enlarged lymph nodes, enlargement of the spleen or liver, and the normal features of the acute phase response (fever, rapid pulse, and respiration)—are blunted or lost in malnutrition, making diagnosis more difficult.

Loss of appetite is a central feature of a more severe acute phase response, as the body raids its own tissues for the nutrients it requires to satisfy this unusual demand. There is a shift from the usual pattern of protein synthesis with less emphasis on growth. As muscle wastes the amino acids are made available for the synthesis of proteins for the immune system and the liver shifts from synthesizing large amounts of nutrient transport proteins to the formation of acute phase response proteins which limit cell damage and help repair. Albumin synthesis is inhibited, and it is redistributed to the third space leading to a reduced plasma albumin concentration. The low albumin which is frequently seen in malnourished people reflects the presence of an ongoing infection rather a dietary deficiency of protein. Correcting the problem requires that the underlying infection be effectively treated, not that dietary protein be increased. The cells of the inflammatory and immune systems increase their utilization of glucose, with increased gluconeogenesis from amino acids. A feature of the acute phase response is a profound change in the handling of micronutrients. There is a block in the absorption of iron. Net tissue breakdown releases components for which there is no immediate use. The circulating concentrations may be reduced (iron and zinc which are sequestered in the liver), or increased (copper), and there may be increased losses from the body in urine or stools (zinc and vitamin A). In childhood, diarrhoea is a frequent accompaniment of infection, which adds an excessive loss of nutrients from the body, especially potassium, magnesium, zinc, and vitamin A.

Specific nutrient deficiencies

Deficiency of specific nutrients is the most difficult aspect of severe malnutrition to manage effectively. Whereas in classical deficiency states, inadequate dietary intake is usually the major underlying cause, in severe malnutrition it is the failure to correct excessive losses of nutrients which leads to major imbalances. Major losses of intracellular nutrients can be difficult to identify with reliability for three reasons:

1. Losses of intracellular content may not be readily identified using standard biochemical tests on blood, for example potassium.
2. Bone acts as a very effective buffer for many nutrients and therefore severe total body depletion can develop without obvious biochemical change or loss of function, for example magnesium.
3. During an inflammatory response, redistribution of nutrients within the body makes standard tests for nutrient deficiency very difficult to interpret, for example vitamin A, zinc, or iron.

Infection causes an unbalanced loss of nutrients, which may be obvious in association with diarrhoea and vomiting, but may be more subtle as in the increased urinary losses of vitamin A and zinc which are an integral feature of the acute phase response. For an individual consuming a diet which is marginal in one or other nutrient, increased losses may make the critical difference to achieving balance, which cannot be restored unless additional nutrients are provided during the convalescent period. All cellular functions are likely to be affected to a greater or lesser degree by specific deficiencies, but one process which is of special importance is the ability to cope with 'free radicals' or oxidative induced cell damage.

Antioxidant protection

In severe malnutrition there is a major imbalance between the potential for damage induced by free radicals and protective antioxidant systems. Infection, oxidative burst, and free iron all contribute to an increased potential for damage. Mortality is greatest in those with an obvious impairment of the antioxidant defences. Children with oedematous malnutrition have severely reduced concentrations of glutathione in blood and mortality is highest in those with impaired activity of glutathione peroxidase. Although the pattern varies with location, deficiencies of micronutrients are common and result in impaired cell function and membrane damage. The many layers of antioxidant protection which are specific for each compartment of the cell provide a measure of safety. However, the system is potentially vulnerable to deficiencies or limitations in multiple micornutrients, for example niacin, folate, thiamine, riboflavin, cobalamin, ascorbic acid, carotenoids, tocopherol, selenium, zinc, copper, magnesium. A deficiency might not be readily identifiable, either clinically or biochemically, and a high index of suspicion is required.

Oedema

Oedema reflects an inability to maintain the correct distribution of fluid in the intracellular space, the vascular space, and the interstitial space, and is a final common pathway representing a loss of metabolic control. Incorrect approaches to the management of oedema—the use of diuretics or the use of high protein diets—are amongst the commonest reasons for increased mortality. The rationale behind the incorrect approach to management presumes that oedema is simply the consequence of hypoalbuminaemia, itself the result of inadequate dietary protein. There are profound perturbations of protein metabolism in kwashiorkor, but these are due to concurrent infection, loss of appetite, and increased losses of nitrogen in stools rather than a diet deficient in protein. A low plasma albumin usually indicates an acute phase response to an unrecognized infection. Treatment with a high-protein diet or infusions of albumin does not correct the oedema, but does increase mortality. A low plasma concentration of albumin might contribute to formation of oedema, but is seldom the sole or primary cause. Although diuretics exert a direct effect on cell membranes, giving a diuretic is less likely to be effective if the intravascular space is reduced. Diuretics which lead to increased urinary losses of potassium make the underlying problem of a deficiency of body potassium even worse.

The normal distribution of water between the different body compartments is tightly controlled through a number of interlinked factors. Disruption of one or more of these factors may lead to the development of oedema, and will need to be corrected for the oedema to be effectively cleared (Table 4).

Potassium deficiency leads to retention of sodium. Altered membrane structure and reduced activity of Na^{+}/K^{+}-ATPase allows intracellular potassium to fall and intracellular sodium to rise. All malnourished individuals should be presumed to be deficient in potassium and to have excess intracellular sodium, regardless of the composition of the plasma measured on routine biochemistry. Indeed plasma sodium concentrations might be low and it is tempting to give extra sodium, which is absolutely the wrong thing to do. There is more than enough sodium in the body, but it is in the wrong place. A direct approach which seeks to correct the disordered biochemistry is less likely to succeed than an approach which recognizes that the fundamental problem is that of disordered cellular function. Similar factors lead to cellular damage in any severely undernourished person, and by treating the malnutrition and repairing the metabolic machinery of the cells of the body, oedema will be effectively treated. What is required is generous supplements of potassium and correction of the underlying membrane dysfunction, which enables fluid and electrolyte balance to be restored. There is a close metabolic interdependence of potassium and magnesium, both of which are readily lost from the body in diarrhoea. It is extremely difficult to correct potassium deficiency in the presence of an associated magnesium deficiency, or to correct a magnesium deficiency in the

face of a potassium deficiency. They have to be corrected together.

Principles of care

Phases of treatment: the 10 steps (Fig. 1, Table 5)

One of the important reasons why mortality from malnutrition has not been reduced in many centres is because the primary objective of treatment has been to try and correct the obvious weight deficit. In attempting to replace the lost tissue as soon as possible, generous intakes of food have been provided, encouraged and even forced. If appetite is poor, or anorexia is a feature, then generous forcefeeding by nasogastric tube has been used. This can be very dangerous. The 10-step approach to treating malnutrition clearly identifies that treatment must be divided into different phases: the cellular machinery has to be repaired before it can be used to enable tissue growth.

Two clinical features which are directly related to specific nutrient deficiencies and are particularly difficult to manage are oedema and persistent diarrhoea. Any specific nutrient deficiency impairs cellular function and increases the risk of infection. Infection increases nutrient losses through tissue wasting as an intrinsic feature of the acute phase reaction and as vomitus or diarrhoea. Increased generation of free radicals is part of the body's attempts to deal with infecting organisms, and deficiencies of specific micronutrients directly impair the ability to cope with free radical generation. Even if an individual recovers from an infection, nutrients which have been depleted from the body are not easily replaced. This has two important effects. Firstly, the individual is deficient in a specific nutrient and carries the specific and general features of the deficiency, importantly loss of appetite. Secondly, if the deficiency is severe it may be very difficult for it to be corrected by consuming a normal diet without the addition of specific nutrient supplements. Under this circumstance, poor appetite, persistent reductive adaptation, and continued risk of further infection is maintained.

If energy is provided in excess of the requirements for maintenance, there are few ways in which it can be excreted or handled metabolically. Any significant excess is deposited as new tissue, either as cells or as cells filled with fat. There is a considerable underlying drive to form new cells, but in addition to energy this requires the availability of all the nutrients contained within the cell structure. When specific deficiencies have not been corrected individual nutrients are limiting for cell formation and it is not possible to handle the excess energy through the formation of new tissue. The excess energy creates a very serious metabolic upset (see recovery syndrome below). Therefore, during the period when nutrient deficiencies are being corrected and infections treated it is important to give sufficient energy to cover the needs of the body, but not so much that the body is forced to make new tissue. This is the basis for identifying the different phases of treatment: first to repair the machinery and gain control of metabolism by providing only enough energy to satisfy the needs for maintenance, but not enough to drive growth. Managing reductive adaptation, specific nutrient deficiencies, infection, and free radical-induced membrane and cellular damage lie at the heart of the problems associated with immediate care during the resuscitation period.

A loss of appetite is an important protective mechanism limiting food consumption which is likely to stress the systems of the body. In experimental studies there are two major biological reasons why appetite is lost: a deficiency of a specific nutrient and infection. Hence, the loss of appetite is a cardinal sign of an underlying metabolic problem which is ongoing. If the problem is identified and corrected, then appetite is restored very quickly. Most malnourished children have a profound loss of appetite due to a combination of infection and deficiencies of specific nutrients which interact to make the problem worse. Correcting the loss of appetite is central to effective care. The restoration of appetite marks the restoration of metabolic control and is a key component of therapy and a marker of progress. Once the emergency treatment required to resuscitate the child has been completed, the emphasis of care is to treat the underlying problems which are associated with a loss of appetite.

Resuscitation

Severely malnourished children present a medical emergency because of two sets of problems: the deadly triad of infection, hypothermia, and hypoglycaemia, and marked fluid and electrolyte disturbances (Table 5).

The deadly triad: hypoglycaemia, hypothermia, and infection

Brain cells are absolutely dependent upon a regular supply of glucose and oxygen to maintain the availability of ATP. Death occurs within 5 min if the supply of either is impaired, through poor circulation, reduced respiration, or a low blood glucose. The glucose required is either made in the liver or taken in the diet. Reductive adaptation limits the capacity for glucose formation and delivery and a regular dietary supply is required if blood concentrations are to be maintained. The availability of glucose for the brain can be impaired if there is competition from other tissues or functions, for example in order to maintain body temperature or to deal with infection. Malnourished individuals generate less heat and have reduced thermal insulation and therefore cool rapidly when exposed. Any attempt to generate more heat consumes glucose and other energy-providing fuels. A normal effective response to infection is a burst of activity in white blood cells which place heavy demands on available glucose, competing with the brain and leading to hypoglycaemia, and increasing the rate of heat loss leading to hypothermia. Therefore, the triad of hypoglycaemia, hypothermia, and infection indicate a very serious situation in which the body is no longer able to adequately maintain the supply of glucose to support essential functions. The treatment is to increase the supply by giving oral or intravenous glucose, reducing competing demands through decreasing the amount of heat lost, and by effectively treating infections. To deliver glucose and oxygen to the brain effectively requires an adequate circulation, which is compromised with intravascular dehydration. The correction of dehydration is closely associated with the correction of electrolyte imbalances, with energy homeostasis, and with normal cellular function. Care has to be taken to ensure that each is corrected in concert with the other to ensure that imbalances do not arise. All malnourished individuals are deficient in potassium and carry excess sodium.

Specific micronutrients: vitamin A, zinc, and iron

Iron is highly reactive chemically, and fulfils many important functions related to the generation of energy for normal cellular function. High reactivity, if not adequately controlled, carries the potential for cell damage. Red cell mass reduces in malnutrition as the lean body mass decreases. The iron is not used for further haemoglobin formation and cannot be excreted so has to be stored innocuously, as any which is unbound is liable to increase oxidative cell damage. In severe malnutrition there is increased stored iron and free iron. The available iron is not used for haemoglobin formation and giving iron supplements to treat anaemia simply adds to the load, stresses the system further, and increases mortality, especially in the presence of infection such as malaria. Initially, it is more important to repair and restore the capacity to cope with free radicals by improving vitamin and trace element status. Later, when the acute problems have been resolved, the iron will be removed from storage and used to form new tissue. As stored iron is used up, supplemental iron will have to be provided to keep pace with the rate of tissue demand.

Blindness and other eye signs of overt vitamin A deficiency are common in many parts of the world. Less obvious changes lead to impaired integrity of mucosal surfaces in the gastrointestinal and respiratory tract, lowering resistance to gastroenteritis and respiratory infections. During infection vitamin A is lost from the body, severe deficiency may develop rapidly, and the eye signs often deteriorate during early treatment. In areas where vitamin A deficiency is common, a large dose of vitamin A given very early in the treatment is an urgent necessity.

Zinc is required for the function of a wide range of enzymes, and a deficiency has widespread effects. A shortage of zinc impairs the replication of cells such as the gut mucosa, leading to further mucosal damage and increased diarrhoea. Zinc deficiency leads to diarrhoea and diarrhoea leads to zinc deficiency. Similar changes take place in damaged skin leading to ulcerated skin which is readily damaged with mild trauma.

Persistent diarrhoea

Many malnourished children have diarrhoea which can take time to settle. The diarrhoea may be infective in origin or have an infective component, due to viruses, bacteria, fungi, or helminths. However, diarrhoea which has persisted for any time will also have an element due to specific nutrient deficiencies (zinc and vitamin A) or chemical injury (bile salt deconjugation). With continued diarrhoea there are ongoing losses of nutrients. Few bacteria exist in the healthy small intestine, but small bowel overgrowth develops readily in malnutrition, due to a combination of gastric achlorhydria, reduced motility (potassium and magnesium deficiency), leading to bile salt deconjugation, damaged mucosa, and bacterial translocation. For the bowel to repair and re-establish its resistance requires adequate nutrients, most especially zinc, vitamin A, and folates. Thus the effective treatment of chronic diarrhoea requires a three-pronged approach: correction of potassium deficiency, treatment of bacterial overgrowth (with metronidazole), and effective repletion of specific nutrient deficiencies (such as zinc, vitamin A, and folate).

Management

The objectives of the resuscitation phase are to stabilize vital functions, by giving oxygen, supporting respiratory and cardiac function, and correcting fluid imbalance, to ensure that adequate amounts of glucose are delivered to the brain. Body temperature must be maintained by maintaining glucose supply to the system, limiting heat loss through the skin, and starting to control infection. As the capacity for the body to carry out metabolic functions is impaired, external support has to be supplied regularly on a 24-h cycle. The regular intake of small amounts over 24 h (especially at night) is a very effective way of achieving this (Table 5). All infections must be treated. Specific nutrient deficiencies must be corrected, but no iron or extra sodium should be provided. The metabolic state must be controlled by limiting the intake of energy and protein to that required to maintain body weight, and ensuring that there is no excess (see below). These steps will enable the repair of the metabolic machinery and allow cellular function to move towards normal. The response to a successful intervention will be a return of appetite; the patient will feel better and smile.

Recovery syndrome

Limited availability of one or more nutrients leads to competition between all cells for the little available. Some nutrients become relatively more deficient, upsetting the balanced function between tissues and the clinical signs of a deficiency become more obvious. There is a similar explanation for why the clinical signs of a deficiency are not always apparent, even though the body might be particularly deficient. During reductive adaptation, the demand for nutrients is decreased, and the signs of a deficiency are masked. Signs of deficiency become exposed in rapidly dividing tissues, when the demand for nutrients is greatest. Vitamin A and zinc are examples, but the same principles apply to many other nutrients, especially the B vitamins. The recovery or refeeding syndrome develops when individuals who have undergone reductive adaptation are suddenly provided with a relative excess of food. Excess energy drives metabolism while specific nutrient deficiencies are inadequately corrected and the metabolic machinery is still compromised. The syndrome may vary in its details, but consists of left- and right-sided heart failure associated with an overloaded circulation. This may progress to vascular collapse with abdominal distension as the circulating vascular volume is poured into the bowel as a profound secretory diarrhoea. The first sign of the onset of the recovery syndrome is an increase in pulse and respiratory rate. If food continues to be consumed at the same rate the load on the heart will progress to heart failure. This is a medical emergency, and it is vitally important that the food intake is reduced or stopped. If the changes are identified early and are relatively mild, then food intake should be reduced. If the condition has advanced and is severe then it may be necessary to stop all food for 12 to 24 h. The problem will then resolve.

Replacing lost weight

The ultimate objective of treatment is to replace the lost tissue. Cellular hypertrophy and hyperplasia are critically dependent upon and limited by the available energy and nutrients. For tissue of average composition the formation of 1 g tissue requires 20 kJ of energy. A normal 1-year-old infant gains 1 g/kg body weight/day, but for catch-up weight gain during recovery from malnutrition weight it is possible to form tissue at up to 20 g/kg/day, by consuming an additional 400 kJ/kg/day. Achieving this requires an energy-dense diet which is consumed throughout the 24 h of the day. Energy is necessary but not sufficient for new tissue formation. The nutrients needed for the formation of cell membranes and protoplasm are required in adequate amounts and suitable proportions. As the lean body mass grows it has an increased need for oxygen, and the red blood cell mass increases. Iron is taken out of storage to form new red cells, and eventually these stores are depleted with the need to add supplemental iron to the diet. There is an increased demand for amino acids to meet the needs of new tissue formation. It is safe to allow quite large intakes of protein. As the amino acids are deposited in tissue and do not accumulate in the free form there is no risk of toxicity. However, to meet the pattern of amino acids required by the body will require the endogenous biosynthesis of relatively large amounts of the 'non-essential' amino acids in the body, which in itself will require the generous availability of minerals and vitamins.

Important general aspects of care

The physical care which is provided to correct the biochemical, metabolic, and infective problems is critical for success. However, there is also the need to address the broader needs of the child for healthy development. In part this is provided by creating a warm, caring environment, in part by suitably structured activities which provide an appropriate level of stimulation to encourage brain function to recover and develop.

All aspects of care need skill and sympathy. The severely malnourished child is desperately sick and must be nursed as a critically ill child with minimum physical disturbance. With correct treatment, progress can be very rapid, and it is desirable to involve the parents and siblings, to encourage and demonstrate preferred childcare practices. This will facilitate the transfer between hospital and home, and make it more likely that the practices become embedded. Less seriously ill children can be effectively managed as outpatients, using the same principles and approach to the management decisions.

10.5 Obesity

Peter G. Kopelman and Stephen O'Rahilly

Historical introduction

Obesity is now so common that it may replace undernutrition and infectious disease as one of the most significant contributors to global ill health. Modern research shows that obesity represents an important and defined medical disorder. Investigations into the genetic contribution to weight gain and the intra-abdominal distribution of fat (central obesity) have identified certain ethnic groups and susceptible families who are specifically at risk. There is, moreover, increasing awareness that overweight and obesity are key factors in the development of other chronic diseases, in particular type 2 diabetes and coronary heart disease, to which they contribute to the high mortality. Obesity can no longer be dismissed as a cosmetic problem affecting certain individuals: it is, in effect, an epidemic that requires effective measures for its prevention and management.

Definition of overweight and obesity

In clinical practice body fat is most commonly and simply estimated by using a formula that combines weight and height. The underlying assumption is that most variation in weight for persons of the same height is due to fat mass. The formula most frequently used in epidemiological studies is the body mass index (**BMI**), which is the weight in kilograms divided by the square of the height in metres. BMI is strongly correlated with densitometric measurements of fat mass adjusted for height in middle-aged adults. The main limitation of the BMI is that it does not distinguish fat mass from lean mass.

Measurements of body circumference are important because excess visceral (intra-abdominal) fat is itself a potential risk factor for chronic diseases, independent of total adiposity. Waist circumference and the ratio of waist circumference to hip circumference are practical measures for assessing upper body fat distribution, although neither provides a precise estimate of visceral fat. Measurement of skinfold thickness with callipers provides a more precise assessment of body fat, especially if taken at multiple sites. Skinfolds are useful in the estimation of fatness in children, for whom standards have been published. However, these measurements are more difficult to make in adults (particularly in the very obese), are subject to considerable variation between observers, require accurate callipers, and do not provide any information on abdominal and intramuscular fat. In general they are not superior to simpler measures of height and weight.

Measurement of bioimpedance is based on the principle that lean mass conducts current better than fat mass because it is primarily an electrolyte solution. A measurement of the resistance to a weak current (impedance) applied across the extremities provides an estimate of body fat when combined with height and weight and an empirically derived equation. Although impedance devices are simple and practical to use, they neither measure fat nor predict biological outcomes more accurately than the simpler anthropometric measurements. Table 1 lists the methods used to characterize obesity.

Defining a 'healthy weight' for a particular society is not straightforward. There are methodological difficulties that derive from a definition based on total mortality rates. People frequently lose weight as a consequence of illness, unrecognized at the time of survey, that is ultimately fatal. This gives an appearance of a higher mortality among those with lower weights (reverse causation). The effect can be minimized by either excluding persons with diagnoses that might affect weight and/or those who report recent weight loss, or excluding those who die during the first years of follow-up. A second concern is the confounding factors that may distort the association between body weight and mortality: cigarette smoking is of particular importance. The Nurses Health Study, which prospectively studied 116 000 women in the United States during a 17-year period, shows a U-shaped relationship between mortality and BMI in an overall age-adjusted analysis. However, the relationship becomes a simple positive association when reverse causation is accounted for and the analysis is limited to those who have never smoked.

There is a close relationship between BMI and the incidence of several chronic conditions caused by excess fat (Fig. 1)—type 2 diabetes, hypertension, coronary heart disease, and cholelithiasis. This relationship is approximately linear for a range of BMIs less than 30: American women with a BMI of 26 have a twofold increased risk of coronary heart disease compared with women with a BMI of less than 21, and an eightfold increased risk of developing type 2 diabetes. The equivalent figures for American men are a 1.5-fold increase and a fourfold increase. The risk of hypertension is doubled in both men and women with a BMI of 26. All risks are greatly increased for those subjects with a BMI greater than 29, independent of gender.

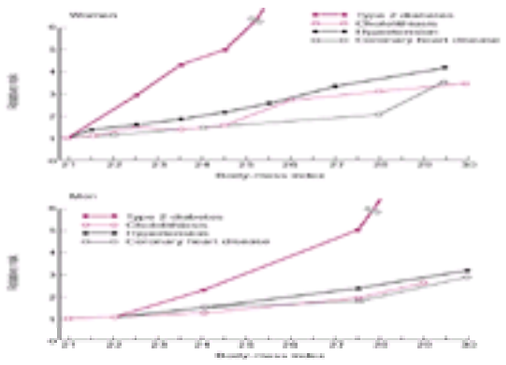

Fig. 1 Relation between body mass index (BMI) up to 30 and the relative risk of type 2 diabetes, hypertension, coronary heart disease, and cholelithiasis. Panel A shows these relations for women, initially 30 to 55 years of age, who were followed up for 18 years. Panel B shows the same relations for men, initially 40 to 65 years of age, who were followed up for 10 years. (From Willett WC, Dietz WH, Colditz GA (1999) *New England Journal of Medicine* **341**, 427–33, with permission of the authors and the Editor.)

Body mass index can be used to estimate the prevalence of obesity within a population and the associated risks. It does not, however, account for the wide variation in the nature of obesity between different individuals and populations. A World Health Organization Expert Committee has proposed a classification of overweight and obesity that applies to both men and women and to all adult age groups (Table 2).

Waist circumference correlates with measures of risk for coronary heart disease such as hypertension or blood lipid concentrations. The choice of cut-off points on the waist circumference continuum involves a reciprocity between sensitivity and specificity similar to that for BMI. An expert panel has suggested increased risks if the waist circumference is more than 102 cm for men and more than 89 cm in women. However, lower cut-off points are associated with a two- to threefold increase in the relative risk of type 2 diabetes. Gender-specific cut-off points for waist circumference may guide the interpretation of values for adults: proposed cut-off levels are shown in Table 3. Level 1 is designed to alert clinicians to potential risk while level 2 should initiate therapeutic action. It must be emphasized that these figures reflect knowledge acquired largely from epidemiological studies in developed countries. Preliminary information from developing nations indicates that lower cut-off levels for both BMI and waist circumference are appropriate for certain populations, who are at particular risk from comparatively modest degrees of overweight.

Epidemiology of overweight and obesity

The value of estimating prevalence and secular trends in overweight and obesity for identifying those at risk cannot be overemphasized. Conservative estimates of the economic costs of obesity in developed countries are between 2 and 7 per cent of the total health costs: this confirms that obesity represents a significant portion of expenditure in national health care budgets.

The range of BMI varies significantly according to the stage of economic transition and associated industrialization of a country: the shift from dietary deficit to one of dietary excess. As the proportion of the population with a low BMI decreases, there is an almost reciprocal increase in the proportion of the population with a BMI above 25. This indicates the tendency for a population-wide shift as socio-economic conditions improve so that overweight replaces thinness. Importantly, changes in adult prevalence of overweight and obesity are reflected by an even more striking changes in childhood and adolescence in both industrialized and developing countries. The early onset of obesity leads to an increased likelihood of obesity in later life, as well as an increased prevalence of obesity-related disorders.

Obesity, defined as a BMI of more than 30, is a common condition in Europe and the United States. The most comprehensive information in Europe comes from the data collected between 1983 and 1986 for the MONICA study. On average 15 per cent of men and 22 per cent of women were found to be obese, with overweight being much more common among women than men. More than half the adult population between 35 and 65 years of age in Europe were either overweight or obese. In England and Wales the most recent health survey has confirmed an increase in the prevalence of obesity in adults from 6 per cent of men and 8 per cent of women in 1980 to 17 per cent of men and 21 per cent of women in 1998. National surveys in the United States have shown a marked increase in the prevalence of obesity over time. The striking increase in prevalence between 1980 and 1994 confirms that population-wide increases in overweight and obesity may occur over short periods. The most recent data from the United States, derived from the third NHANES (1988 to 1994), shows about 20 per cent of American men and about 25 per cent of American women to be obese. Subanalysis shows African-American women and other minority populations to have particularly high rates of obesity. Obesity is likewise prevalent in Latin America and is a particular problem in the Caribbean.

The increasing prevalence of obesity is not confined to Europe and the Americas. In Southeast Asia a dramatic rise is being seen in all populations. Obesity is now more prevalent in Malaysia than undernutrition in both urban and rural communities, but the most striking figures come from the Pacific region. In urban Samoa the prevalence of obesity is estimated as greater than 75 per cent of adult women and 60 per cent of adult men. High prevalence rates are also observed in the Middle East.

Aetiology of human obesity

At its simplest level the 'cause' of obesity is already known. By definition it results from an imbalance between energy intake and energy expenditure. In any individual, excessive caloric intake or low energy expenditure, or both, may explain the development of obesity. A third factor, so-called 'nutrient partitioning', a term reflecting an individual's propensity to store excess energy as fat rather than lean tissue, may contribute but will not be discussed further here. Multiple studies over several decades have attempted to clarify the relative roles of energy intake, energy expenditure, and nutrient partitioning in human obesity. The lack of consensus, despite intensive efforts, reflects a number of problems inherent in the study of the obese state. These include the heterogeneity of human obesity and errors in measurements of energy intake and expenditure, combined with the minor degrees of energy imbalance required to accumulate fat tissue over time, and the confounding effect of obesity *per se* on the measurement of physiological parameters.

Role of altered energy intake in the pathogenesis of obesity

It is surprising that no direct correlation has been reported between increasing prevalence of obesity and increased energy intake in developed nations given the ready availability of highly palatable foods. Underreporting of food intake confounds the understanding of the role of energy intake in the aetiology of obesity. Underreporting is an almost invariant feature of obesity, with comparisons of energy intake and expenditure in obese subject showing a consistent shortfall in self-reported food intake of approximately 30 per cent of the energy requirements. It is thus extremely difficult to obtain reliable data on the energy intake of free-living obese subjects.

Role of altered energy expenditure in the development and maintenance of obesity

The principal components of energy expenditure are resting metabolic rate, which represents the energy cost of maintaining physiological homeostasis, and physical activity, being the most variable component and representing 20 to 50 per cent of total energy expenditure. Resting energy expenditure is readily measured by indirect calorimetry, and the use of water labelled with two stable isotopes allows accurate measurements of total energy expenditure over a 10- to 20-day period. Studies of age- and sex-matched pairs of lean and obese women following an imposed activity schedule clearly demonstrate consistently higher energy expenditure in obese subjects compared with their lean pairs. The measurement of energy expenditure within the home, using doubly labelled water, shows comparable values between obese and lean subjects when corrected for different body sizes. Thus, a defect in metabolic mechanisms controlling energy expenditure has not been identified in human obesity. However, studying subjects when they are already obese is always confounded by the energy cost of the increased fat and associated lean mass, and corrections made for these may be insufficiently precise.

Prospective studies of energy expenditure in groups of individuals are more informative. Longitudinal studies of Pima Indians in Arizona suggest that the risk of a weight gain of 10 kg during a 4-year follow up is sevenfold higher in those in the lowest tertile of relative resting metabolic rate compared with those in the highest tertile. Nevertheless, even in a population which is predisposed to obesity, resting metabolic rate only predicts 40 per cent of the weight gain. No association has been observed between resting metabolic rate and 10-year weight gain in a Dutch population, and results from other studies have also questioned the validity of such

an association.

In developed countries there is a relationship between low levels of physical activity and obesity. A longitudinal Finnish study found that those reporting physical exercise three or more times each week had on average lost weight since a preceding survey. By contrast, those who undertook little physical activity gained weight and had twice the risk of gaining 5 kg or more. Among children in the United States, the relative risk of obesity is 5.3 times greater for children who watch television for five hours or more each day compared with those children who watch for less than two hours, even after correcting for a wide range of socio-economic variables.

In the United Kingdom, a study combining data on energy intake and physical activity in relation to the secular increase in adult obesity showed no relationship between total energy intake or fat consumption and the prevalence of obesity, but a close relationship between proxy measures of physical activity (television viewing and car ownership).

Environmental and cultural factors in obesity

The evidence for the critical role of environmental factors in the development of obesity comes from migrant studies and the 'Westernization' of diet and lifestyles in developing countries. The dramatic increase in age-standardized prevalence of obesity (> 60 per cent in men and women) in the Naurians in Micronesia and Polynesians in Western Samoa is closely paralleled by alterations in diet and lifestyle. A marked change in BMI is frequently witnessed in migrant studies, where populations with a common genetic heritage live under new and different environmental circumstances. Pima Indians living in the United States are on average 25 kg heavier than Pima Indians living in Mexico.

In men and women the prevalence of overweight and obesity increases with age until 50 to 60 years; it is particularly apparent between the ages of 20 and 40 years. There are large, usually unexplained, variations between ethnic groups—this is particularly apparent in women in the United States with the rapidity of change occurring with increasing affluence of particular groups (22 per cent of Cauasian women are obese, 30 per cent of African-American women, and 34 per cent of Mexican-American women). In industrialized countries, a higher prevalence of overweight and obesity is observed in those with lower educational attainments and low income, although the reverse may be seen in developing countries. There is a tendency for overweight to increase after marriage and with increasing parity. Dietary intake and physical activity are crucially important factors in increasingly affluent societies.

The analysis of the prevalence of obesity by socio-economic status in England and Wales demonstrates a strong social class gradient, especially in women, ranging from 10.7 per cent in social class 1 (high) to 25 per cent in social class V (low). Interestingly, this is accompanied by marked differences in measures of physical activity, with social classes IV and V spending significantly more time watching television and being more likely to define themselves as inactive than those in social class 1.

Genetic factors in obesity

Evidence from twin, adoption, and family studies shows unequivocally that inherited factors contribute importantly to interindividual differences in fat mass. Studies of identical twins raised separately are particularly striking; they demonstrate a much closer correlation of BMI with biological rather than adoptive family members. The identification of genetic variants influencing human fat mass is a cherished goal of obesity research; it is only recently that the first mutations causing human obesity have been found. In general, mutations have been found in those rare children with extreme obesity and clear evidence for monogenic inheritance. The discovery of these defects has been dependent on rapid advances in mouse genetics. The seminal murine discovery is that of the novel adipocyte hormone leptin, which is deficient in the obese ob/ob mouse. Administration of recombinant leptin by injection restores ob/ob mice to normal body weight and corrects the associated metabolic and reproductive malfunction.

The discovery of leptin and the identification of its receptor, which is highly expressed in the hypothalamus, has advanced the understanding of molecular mechanisms within the hypothalamus that regulate appetite and energy expenditure. A particularly important element of this system is the group of neurones in the arcuate nucleus expressing pro-opiomelanocortin and the melanocortin 4 receptor, to which peptides derived from pro-opiomelanocortin bind. Thus far, five different genetic defects causing monogenic human obesity have been identified. These include mutations in leptin and the leptin receptor and two defects involving the pro-opiomelanocortin system, mutant pro-opiomelanocortin and mutant melanocortin 4 receptor. A single obese subject with mutations in a prohormone convertase enzyme shows major defects in pro-opiomelanocortin processing that may account for the obese phenotype (Table 4). These discoveries have shown for the first time that rare forms of severe human obesity may occur as a result of unitary molecular lesions within the appetite control pathway making such cases largely resistant to voluntary or imposed dietary restrictions.

Genetic studies in the more common forms of obesity have yet to have the same tangible success that has been seen with monogenic subtypes. Nevertheless, rapid progress has been made in the identification of chromosomal loci containing genes conferring susceptibilty to obesity. In particular, a region of chromosome 2 has been reported in independent studies of different racial groups to influence obesity-related phenotypes. It is of note that this region contains the pro-opiomelanocortin gene. Given the speed of progress of the Human Genome Project, it may not be long before this locus and other variants responsible for obesity syndromes are identified.

Gene/environment interaction

Obesity represents a heterogeneous group of conditions with multiple causes. Body weight is determined by an interaction between genetic, environmental, and psychosocial factors acting through the physiological mediators of energy intake and expenditure. Fatness runs in families, but the influence of the genotype on the aetiology of obesity may be attenuated or exacerbated by non-genetic factors. The genetic influences appear to operate through susceptibility genes. Such genes increase the risk of developing a characteristic but are not essential for its expression or, by themselves, sufficient to explain the development of a disease The susceptible gene hypothesis is supported by findings from twin studies in which pairs of twins were exposed to periods of positive and negative energy balance. The differences in the rate of weight gain, the proportion of weight gained, and the site of fat deposition showed greater similarity within pairs than between pairs. This suggests that differences in genetic susceptibility within a population determine those who are most likely to become obese in any given set of environmental circumstances. Implicit to the susceptible gene hypothesis is the role of environmental factors that unmask latent tendencies to develop obesity.

Pathophysiology of obesity

Obesity causes or exacerbates many disorders, both independently and in association with other diseases. In particular, it is associated with the development of diabetes mellitus, coronary heart disease, an increased incidence of certain forms of cancer, obstructive sleep apnoea, and osteoarthritis of large and small joints. The Build and Blood Pressure Study has shown that the adverse effects of excess weight tend to be delayed, sometimes for 10 years or longer. Life insurance data and epidemiological studies confirm that increasing degrees of overweight and obesity are important predictors of decreased longevity. In the Framingham Heart Study, the risk of death within 26 years increased by 1 per cent for each extra pound (0.45 kg) increase in weight between the ages of 30 and 42 years, and by 2 per cent between the ages of 50 and 62 years. Despite this evidence many clinicians consider obesity to be a self-inflicted condition of little medical significance.

Obesity and type 2 diabetes mellitus

Obesity is accompanied by an elevated fasting level of plasma insulin and an exaggerated insulin response to an oral glucose load. Overall fatness and the distribution of body fat influence the metabolism of glucose through independent but additive mechanisms. Increasing upper body obesity is accompanied by a progressive increase in the response of glucose and insulin to an oral glucose challenge, and there is a positive correlation between increasing upper body obesity and resistance to the effects of insulin. Posthepatic insulin delivery is increased in upper body obesity, leading to more marked peripheral insulin concentrations which, in turn, lead to peripheral resistance to insulin.

Differences in the ability of insulin to suppress lipolysis, and of catecholamines to stimulate lipolysis, also vary according to fat distribution. These factors contribute to an exaggerated release of free fatty acids from abdominal adipocytes into the portal system. Free fatty acids have a deleterious effect on uptake of insulin by the liver and contribute to the increased hepatic gluconeogenesis and hepatic glucose release observed in upper body obesity. Insensitivity to insulin is not confined to adipocytes, and is accentuated by the resistance of skeletal muscle to insulin.

The elevation in plasma free fatty acids, particularly postprandially when their concentration is usually suppressed by insulin, leads to an inappropriate maintenance of glucose production and an impairment in the use of glucose by the liver (impaired glucose tolerance). Reduced hepatic clearance of insulin leads to increased

peripheral (systemic) insulin concentrations and to a further downregulation of insulin receptors.

In the initial phases of this process, the pancreas can respond by maintaining a state of compensatory hyperinsulinaemia. With ever increasing plasma concentrations of free fatty acids, the insulin-resistant individual cannot maintain this state of compensatory hyperinsulinaemia, and hyperglycaemia prevails. Hyperinsulinaemia and insulin resistance contribute to the characteristic alterations in the profile of plasma lipids which are associated with obesity: elevated fasting concentration of triglycerides in the plasma, reduced high-density lipoprotein (**HDL**) cholesterol, marginal elevations in the concentration of cholesterol and low-density lipoprotein (**LDL**) cholesterol, and an increase in the number of ApoB-carrying lipoproteins.

Prospective population studies confirm a close association between increasing body fatness and type 2 diabetes. In the Nurses Cohort Study, BMI was the dominant predictor of the risk of diabetes after adjustment for age. In this study the risk of diabetes was increased fivefold for those with a BMI of 25, 28-fold for those with a BMI of 30 and 93-fold for those with a BMI of 35 or greater. Women who gained 8 to 10.9 kg in weight during the period of study had a 2.7-fold increased risk of diabetes compared with women of stable weight. Similarly, the risk of diabetes in men increases for all BMI levels of 24 or above. The distribution of fat tissue is also independently associated with diabetes: a waist circumference of more than 102 cm (40 in) increases the risk of diabetes 3.5-fold even after controlling for the BMI.

Fetal nutrition

Recent evidence suggests that undernutrition of the fetus during intrauterine development determines the later onset of obesity, hypertension, and type 2 diabetes, independent of genetic factors. Such a phenomenon suggests the possibility of long-term programming of genetic expression as a consequence of altered intrauterine growth: Barker has proposed that an adverse nutritional environment *in utero* causes defects in the development of body organs, leading to a 'programmed' susceptibility that interacts with later diet and environmental stresses to cause overt disease many decades later. In support of this hypothesis is the finding of an inverse relationship between birthweight and systolic blood pressure and type 2 diabetes in both men and women in later life, with the highest mean systolic blood pressures and blood glucose concentrations being observed in those with the lowest birthweight and highest current weight.

Cardiovascular function in obesity

The effects of increased body fatness on cardiovascular function are predictable. Total body oxygen consumption is increased due to an increase in lean tissue mass as well as the oxidative demands of metabolically active adipose tissue, and this is accompanied by an absolute increase in cardiac output. However, the values are within the normal range when they are normalized to body surface area. The total blood volume in obesity is increased in proportion to body weight, such that obesity can be regarded as a state of expanded volume. This increase in blood volume contributes to an increase in the left ventricular preload and an increase in resting cardiac output. The increased demand for cardiac output is achieved by an increase in stroke volume while the heart rate remains comparatively unchanged. The obesity-related increase in stroke volume results from an increase in diastolic filling of the left ventricle. The volume expansion and increase in cardiac output lead to structural changes in the heart. The increase in left ventricular filling results in an increase in the size of the left ventricular cavity and an increase in wall stress. As left ventricular dilatation is accompanied by myocardial hypertrophy, the ratio between the radius of the ventricular cavity and wall thickness is preserved. This thickening of the wall with dilatation results in eccentric hypertrophy. The mass of the left ventricle increases directly in proportion to BMI or the degree of overweight. The blood pressure is a function of cardiac output and the vascular resistance against which the blood is pumped—systemic vascular resistance. An elevated cardiac output is common with moderate obesity, but not all obese patients are hypertensive. However, in those subjects where systemic resistance is increased, the combination of hypertension and obesity results in an increase in the dimensions of the ventricular wall disproportionate to the chamber radius, which eventually leads to concentric hypertrophy.

The cardiovascular adaptation to the increased intravascular volume of obesity may not completely restore normal haemodynamic function. Marked systolic dysfunction occurs when the ventricle can no longer adapt to volume overload. Dilatation of the left ventricular cavity radius reduces ventricular contractility. Despite an elevation in cardiac output, obese individuals have been shown to have depressed myocardial contractility proportional to excess weight. With left ventricular hypertrophy, reduced ventricular compliance alters the ability of the chamber to accommodate an increased volume during diastole and this results in diastolic dysfunction. A combination of systolic and diastolic dysfunction progresses to clinically significant heart failure. Body weight, independent of several traditional risk factors, was directly related to the development of congestive cardiac failure in the Framingham Heart Study.

In addition to congestive cardiac failure, the presence of hypertrophy of the left ventricle has been associated with a greater risk of morbidity and mortality from coronary heart disease and sudden death as well as arrhythmia. In the Framingham Heart Study, the 26-year incidence of coronary heart disease in women and men was related proportionately to excess weight. The incidence of coronary heart disease increased by a factor of 2.4 in obese women and a factor of two in obese men under the age of 50 years. The independent risk of coronary heart disease attributed to obesity in multivariate analysis may reflect other important mediators such as upper body fat, altered blood flow and haemostasis, hyperinsulinaemia, or sleep apnoea.

Sleep-breathing abnormalities in obesity

An increased amount of fat in the chest wall and abdomen has a predictable effect on the mechanical properties of the chest and the diaphragm and leads to an alteration in respiratory excursions during inspiration and expiration, reduced lung volume, and mismatched regional ventilation. The increased mass of fat additionally decreases compliance of the respiratory system as a whole. All of these changes are significantly exaggerated when an obese person lies flat. The mass loading effect of fat requires the respiratory muscles to exert increased force to overcome the excessive elastic recoil and there is an associated increase in the elastic work of breathing. The changes in respiratory function related to obesity are most important during sleep.

During rapid eye movement sleep, there are decreases in voluntary muscle tone with reduced arterial oxygen saturation and a rise in carbon dioxide in all individuals, but these changes are especially marked in obese subjects. Irregular respiration and occasional apnoeic episodes often occur in lean people during rapid eye movement sleep but obesity, with its influence on respiratory mechanics, increases their frequency and may result in severe hypoxia and cardiac arrhythmias. Studies of obese men and women have demonstrated that the obstruction occurs in the larynx and is associated with loss of tone of the pharyngeal and glossal muscles, in particular the genioglossus muscle. Relaxation of the genioglossus allows the base of the tongue to fall back against the posterior pharyngeal wall, occluding the pharynx. This results in a temporary cessation of breathing (apnoea) and transient hypoxia. It is not uncommon to observe saturation values as low as 6.5 kPa during rapid eye movement sleep in some obese subjects while their awake arterial blood gases are normal.

A few obese patients suffer a marked depression in both hypercapnic and hypoxic respiratory drives accompanied by abnormal and irregular patterns of breathing during sleep and (eventually) in the waking state. Characteristically, such individuals show frequent and prolonged episodes of sleep apnoea—sleep is disturbed with frequent awakening related to the resumption of breathing following an apnoeic episode. Daytime somnolence soon intervenes accompanied by persistent hypoxia/hypercapnia, pulmonary hypertension (superimposed upon an increased circulatory volume), and right-sided cardiac failure. Such changes constitute the clinical manifestation of the obesity-hypoventilation syndrome (formerly known as the Pickwickian syndrome).

In the Swedish Obese Subjects study (SOS), which examined 3034 subjects with a BMI over 35, over half of men and one-third of women reported snoring and apnoea. In contrast, 15.5 per cent of Swedish men of comparable age were self-reported habitual snorers.

An increased risk of myocardial infarction and stroke has been reported in sleep apnoea. Snoring is a strong risk factor for sleep-related strokes, while symptoms of sleep apnoea increase the risk for cerebral infarction.

Other complications associated with obesity

Gallbladder disease is the most common digestive disease in obese individuals; it has a progressive and linear risk from a BMI of 20 upwards. Liver abnormalities are described in obesity mainly due to fatty infiltration but, on occasions, associated with fibrosis and/or cirrhosis. Certain forms of cancer are more common in obese subjects: colorectal and prostate in obese men, carcinoma of the gallbladder, breast, and endometrium in obese women. Osteoarthritis frequently accompanies obesity, while bone density tends to be increased in obese subjects. Obesity in women is also associated with menstrual irregularity and infertility; obesity may be, but is not always, associated with the polycystic ovary syndrome. Table 5 lists the morbidity associated with increasing body weight.

Clinical assessment

Clinical setting

The usual principles for a medical consultation are applicable to the assessment of an overweight patient. The consultation room should preferably be properly equipped with larger than average chairs, access for wheelchairs for patients with mobility problems and medical equipment of appropriate size (examination couch, blood pressure cuff, weighing scales, stadiometer, and tape measure).

Historical background

Table 6 outlines the areas of medical history that should be investigated. The history of weight gain should be described in detail to identify possible causes and to assess the patient's insight and understanding of the factors causing weight gain. It is also useful to distinguish obesity which began in childhood from that occurring later in life either in relation to specific physiological 'critical periods' or illness. A number of syndromes are associated with the onset of obesity in childhood, but the longevity of the history and the associated clinical features generally make such cases obvious (Table 4). Disease involving the hypothalamus can often be distinguished from 'spontaneous' or 'simple' obesity by a shorter duration of weight gain and specific symptoms related to associated endocrine disturbances. The identification of the single gene disorders involving leptin and its signalling pathways are somewhat more difficult to distinguish from simple obesity, but extreme weight gain from early childhood, a positive family history, and the associated clinical features described in Table 4 are all characteristic. The most common single gene disorder causing obesity, melanocortin 4 receptor deficiency, is problematic as there are no pathognomonic features, but the diagnosis should be considered in cases of early onset familial obesity, usually with a clear dominant inheritance.

The measurement of serum leptin is not recommended as a routine examination, but in cases of severe early onset obesity this should be undertaken, since, although it is rare, congenital leptin deficiency is a potentially treatable disorder.

Clinical examination

An outline of a scheme for clinical examination is given in Table 7. Height should be measured accurately using a stadiometer and weight measured by accurate scales calibrated against known weights. Fat distribution is assessed by measurement of the waist circumference and is used to refine an assessment of risk for patients with a BMI of 25 to 34.9. Waist circumference is taken as the midpoint between the lower rib margin and the iliac crest. An examination of the skin is important: thin, atrophic skin is a feature of excess corticosteroids; acanthosis nigricans (pigmented 'velvety' skin creases, especially in the axillae) suggests insulin resistance; severe hirsutism in women may indicate polycystic ovary syndrome. A neck circumference of more than 43 cm (17 in) indicates a likelihood of obstructive sleep apnoea, while abnormal external gonadal status accompanied by intellectual impairment may suggest a rare genetic syndrome.

Assessment of risk

An assessment of an obese patient's absolute risk status requires an assessment of associated disease conditions (established coronary heart disease, other atherosclerotic diseases, type 2 diabetes, and sleep apnoea), other obesity-associated diseases such as gynaecological abnormalities, osteoarthritis, gallstones, and stress incontinence, and cardiovascular risk factors. These will include cigarette smoking, hypertension, high-risk LDL cholesterol (> 4 mmol/litre), low HDL cholesterol (< 1 mmol/litre), impaired fasting blood glucose levels, and a family history of premature coronary heart disease. Patients can be classified as being of high absolute risk if they have three of these risk factors and will usually require therapeutic intervention.

In the obese patient who smokes, cessation of smoking is a major goal of risk management. An obstacle to cessation of smoking is the attendant weight gain. The weight gained on stopping smoking is less likely to impair health than is continued smoking. For this reason, cessation of smoking should be advocated at the same time as measures to prevent weight gain.

Assessment of motivation to lose weight

Not all patients are prepared for weight reduction despite a referral to a medical practitioner. It is often useful to confirm that a patient understands the need for weight loss and is prepared to follow medical advice to achieve and maintain an agreed weight goal.

Treatment

The recommendation to treat overweight and obesity is based on evidence that relates obesity to increased mortality and the results from randomized controlled trials which demonstrate that weight loss reduces the risk of disease. Professional, governmental, and other bodies have drawn up guidelines for obesity management. These strategies for providing care to the obese patient provide useful and evidence-based guidance for clinical management.

Aims for a weight loss programme

Any treatment programme for overweight and obese patients should place equal importance on the problem of weight reduction and the maintenance of the lowered weight. Obesity may not respond to conventional methods of treatment such as a low-calorie diet: its management frequently requires an individually tailored approach.

Goals of weight loss

The success or failure of a treatment programme may be judged by an arbitrarily chosen target weight or percentage weight loss. After an initial period of relatively rapid reduction of weight, an average continuing loss of anything up to 1 kg per week should be considered acceptable. Assessment of success must take account of the age of the patient, the initial degree of obesity, the presence of indicators of associated risk or complications, and previous attempts at weight control. Weight loss goals for overweight and obese patients should be tailored to the individual. A weight loss of 5 per cent of the initial body weight will result in some improvement, while a loss of 10 per cent is of major benefit with clinically useful changes such as a lowered blood pressure, reduction in levels of plasma total cholesterol and triglycerides, an increase in HDL cholesterol, and a significant improvement in diabetic control (Table 8). The primary goal of treatment is a 10 per cent reduction from the initial weight; successful weight loss should be regarded as a loss of more than 5 per cent of the initial weight with the consequent amelioration of risk factors; very successful weight loss would be a loss of more than 20 per cent in obese patients. Weight loss should be approached incrementally with new goals for weight loss negotiated with the patient once the original target has been achieved. Goals for older patients (more than 65 years) will be different from those for younger patients—data suggest that a population becomes heavier with age whereas the risk from obesity does not increase proportionately. In some patients, particularly older patients, prevention of further weight gain may be more appropriate than actual weight loss.

Dietary treatment of obesity

Control of diet is the focus of management of overweight and obese patients, and its primary importance must be emphasized. Long-term changes in food choices, eating behaviour, and lifestyle are needed, rather than a temporary restriction of specific foods. The treatment should be nutritionally sound and aim to promote a healthier diet while moderating energy intake and increasing physical activity. Such a treatment may require a period of supervision for at least 6 months. A review of 48 randomized control trials shows that an average weight loss of 8 per cent of the initial body weight can be obtained over 3 to 12 months with a low-calorie diet, and that this weight loss effects a decrease in abdominal fat.

The weight-reducing dietary regimen tailored to an individual's need should initially provide a 600 kcal/day (2.5 MJ/day) energy deficit, based on estimated initial maintenance energy. The diet may best be achieved by a reduction in overall fat intake and will mean, for example, an energy prescription of approximately 1500 kcal/day (6.27 MJ/day) for a moderately active woman of average height aged between 31 and 60 years, and approximately 1800 to 2000 kcal/day (7.52 to 8.36 MJ) for a man of similar age and activity. For overweight patients with a BMI in the range of 27 to 35, a decrease of 300 to 500 kcal/day (1.25 to 2.1 MJ/day) will result in weight loss of about 0.25 to 0.5 kg/week. For more severely obese patients, with a BMI greater than 35, deficits of 500 to 1000 kcal/day (2.1 to 4.2 MJ/day) will lead to weight loss of 0.5 to 1 kg/week. After 6 months, the rate of weight loss usually declines and the weight remains constant because of less expenditure of energy at the lower weight. A further adjustment of calorie intake will be indicated at this stage.

Very low calorie diets

The use of very low calorie diets should only be considered after the failure of determined attempts to lose weight with conventional restriction of normal diets. Their use should follow all of the recommendations from the Committee on Medical Aspects of Food Policy, in particular that such preparations must provide a minimum of 400 kcal (1.7 MJ) per day for women and 500 kcal (2.1 MJ) per day for men. It must be recognized that these diets do not alter eating habits or weight loss beneficially in the longer term. Very low calorie diets may occasionally be useful in the hospital setting for rapid weight loss before surgery. Evidence from randomized trials confirms that over the longer term (more than a year) weight loss following very low calorie diets is no different from that obtained with a low-calorie diet.

Behaviour management

Behavioural interventions seek to alter an individual's lifestyle. Behavioural weight control programmes encourage patients to become more aware of their eating and physical activity and focus on changing the lifestyle and environmental factors that influence their behaviour. All dietary regimens should ideally be linked to behavioural therapy: such therapy may be used by self-help groups. The key difference between behavioural methods and other forms of treatment for obesity is that they lay particular emphasis on personal responsibility for initiating and maintaining treatment rather than the imposition of external authority.

In most trials, behavioural intervention has produced consistent short-term weight loss. Recent studies suggest that a focus on calorie restriction and reduced fat intake, as part of the behavioural approach, is more successful than calorie restriction alone. Studies of methods that seek to avoid circumstances that induce excessive eating are inconclusive, whereas behavioural programmes which provide appropriate foods may be of value. Evidence from randomized controlled trials confirms that behavioural strategies reinforce changes in diet and physical activity in obese adults to produce weight loss in the range of 10 per cent over 4 months to 1 year. Longer-term follow-up shows a return to baseline weight in the absence of continuing behavioural intervention. Trial evidence suggests that behavioural therapy, when used in combination with other weight loss methods, induces further short-term (up to a year) weight loss and that extended treatment programmes improve long-term maintenance of weight.

Exercise and physical activity

When physical activity or exercise alone is used in the treatment of obesity, weight losses are modest and average 2 to 3 kg. This weight loss, although small, exceeds that predicted if direct energy expenditure calculations are performed. For any given weight loss, the loss of fat-free mass is less in exercising versus non-exercising subjects: this is important because fat-free mass is the best predictor of resting metabolic rate which is the largest contributor to total daily energy expenditure. A review of randomized controlled trials provides strong evidence that physical activity alone in obese adults results in modest weight loss and increased cardiovascular fitness.

Regular exercise results in reduction in blood pressure, both in association with or independently of weight loss, and an improvement in atherogenic lipid profiles. A reduction in plasma triglycerides and low-density lipoprotein cholesterol and elevation of high-density lipoprotein cholesterol has been reported with exercise and physical training in obese patients. Exercise also has beneficial effects on glucose metabolism and the sensitivity of skeletal muscle to insulin. However, persuading an obese person to participate in long-term exercise programmes, and to maintain exercise as part of daily routine, is not easy. It is not necessary for the obese patient to increase maximal oxygen uptake by strenuous exercise to derive benefit from exercise: metabolic evidence of improvement in fitness is achieved with less vigorous exercise such as walking increased distances and swimming. The risks from exercise are small, provided it is introduced gradually and pre-existing conditions such as osteoarthritis and ischaemic heart disease are taken into account. The results from randomized controlled trials suggest that a combination of diet and exercise generally produces more weight loss than diet alone, including decreased abdominal fat. More importantly, subjects who exercise adhere to the prescribed diet better than those who do not exercise. One of the most consistent findings in randomized controlled trials of the effect of exercise is the maintenance of weight loss for 2 years.

Drug treatment

The criteria applied to the use of an antiobesity drug should be similar to those applied to the treatment of other relapsing disorders. Many drugs have been advocated over the years as treatment for obesity. Some of these compounds are effective, but many are ineffective.The use of drugs in the management of obesity is bedevilled by the limitations of the available published scientific evidence. It is therefore important that doctors who use these drugs make themselves fully familiar with either the primary literature for any drug, or an authoritative summary document.

Indications for antiobesity drug treatment

It may be appropriate to consider drug treatment if after at least 3 months of supervised diet, exercise, and behavioural management, or at a subsequent review, a patient's BMI is equal to or greater than 30 and weight loss is less than 10 per cent of the presenting weight. In certain clinical circumstances it may also be appropriate to consider antiobesity drug treatment for those patients with established comorbidities whose BMI is 27 or greater, if this is permitted by the drug's licence.

The initiation of drug treatment will depend on the clinician's judgement about the risks to an individual from continuing obesity: drug treatment may be particularly appropriate for patients with comorbid risk factors or complications from their obesity. A drug should not be considered ineffective because weight loss has stopped, provided that the lowered weight is maintained. However, continuation of the drug should depend on the balance between the health benefits of maintained weight and the potential adverse effects of the drug.

Types of drug treatment for obesity

There are currently two categories of antiobesity drugs—those which act on the gastrointestinal system (pancreatic lipase inhibitors) and those which act on the central nervous system to suppress appetite.

Drugs acting on the gastrointestinal system (pancreatic lipase inhibitors)

Orlistat inhibits pancreatic and gastric lipases thereby decreasing the hydrolyisis of ingested triglycerides. It produces a dose-dependent reduction in absorption of dietary fat that is near maximum at a dose of 120 mg three times daily. These actions lead to weight loss in obese subjects. Adverse effects of Orlistat are predominantly related to malabsorption of fat. These include loose or liquid stools, faecal urgency, and oily discharge; they can be associated with malabsorption of fat-soluble vitamins. As the consumption of a high-fat meal will inevitably lead to severe gastrointestinal symptoms, it is possible that some of the weight loss with Orlistat treatment results from an 'antabuse effect', enforcing behavioural change; Orlistat is not itself systemically absorbed.

Centrally acting antiobesity drugs

Drugs which act on the central nervous system can be divided into three groups: those acting via serotoninergic (5-hydroxytryptamine) pathways, for example fenfluramines, those acting via noradrenergic pathways, for example phentermine, and those acting via serotoninergic and noradrenergic pathways, for example sibutramine.

- Drugs acting on serotoninergic pathways: The two drugs from this category, fenfluramine and dexfenfluramine, principally act by releasing serotonin from synapses in the central nervous system; they have only a modest action on inhibiting the reuptake of serotonin into nerve terminals. Because the fenfluramines have been withdrawn they will not be considered further.
- Drugs acting on catecholamine pathways: Phentermine is a phenylethylamine derivative with minor sympathomimetic and stimulant properties whose antiobesity action is due to suppression of appetite. Phentermine has also been withdrawn and will not be considered.
- Drugs acting on noradrenergic and serotoninergic pathways: Sibutramine promotes a sense of satiety through its central action as an inhibitor of serotonin and noradrenaline reuptake. It may also have an enhancing effect on thermogenesis through stimulation of peripheral noradrenergic receptors. Sibutramine is well absorbed following oral ingestion and undergoes first-pass metabolism in the liver to produce two active metabolites that have long elimination half-lives. This enables sibutramine to be given on a single daily basis at a starting dose of 10 mg. Adverse effects include nausea, dry mouth, rhinitis, and constipation. The noradrenergic actions of the drug may cause an increase in blood pressure and heart rate in some patients, or prevent the expected fall in these parameters

with weight loss. The drug should be used with caution in hypertensive patients.

Drugs not appropriate for the treatment of obesity

There is no published evidence to suggest that bulk forming agents (e.g. methyl cellulose) have any beneficial long-term action for weight reduction. Diuretics, human chorionic gonadotrophin, amphetamines, dexamphetamines, and thyroxine are not treatments for obesity and should never be used to achieve weight loss. Under no circumstance should thyroxine be prescribed for obesity in the absence of biochemically proven hypothyroidism. Metformin and acarbose may be useful in the management of the obese non-insulin-dependent diabetic patient: they have no proven efficacy for obesity alone and are not licensed for such use.

Prescribing antiobesity drug treatment

A review of randomized controlled trials provides good evidence that pharmacological therapy combined with diet, lifestyle modification, and physical activity results in weight loss in obese adults that is significantly greater than placebo when the drugs are used for 6 months to 2 years. Experience of the use of antiobesity drugs gained during 12- to 24-month randomized controlled trials indicates that approximately 30 to 40 per cent of the actively treated patients respond as judged by a 5 to 10 per cent reduction in body weight maintained over 12 months. The weight loss occurs in the 'responder' group within 12 weeks. This indicates a suitable time period when 'responders' to drug treatment can be identified and a decision taken to continue the medication. Continual assessment of drug therapy for efficacy and safety is essential. If the drug is effective in helping a patient to lose and/or maintain weight loss, and there are no serious side-effects, it may be continued. If not, it should be discontinued. Once a weight loss target has been achieved, there should be an opportunity for renegotiation of a new target, if indicated, and/or long-term monitoring with reinforcement. Combination therapy of two drugs is contraindicated because of lack of evidence of safety.

Figure 2 summarizes recommendations for the appropriate use of an antiobesity drug.

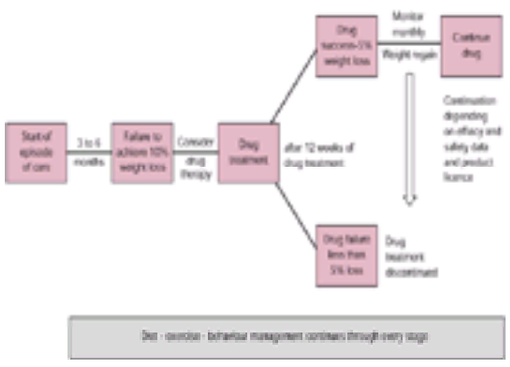

Fig. 2 Suggestions for the practical management of antiobesity drug treatment.

A system of regular medical audits should be a prerequisite of a weight management programme with a record of results and audit action.

Surgical treatment of obesity

There are two operative procedures currently used for the surgical treatment of obesity: gastric restriction and gastric bypass operations.

Gastric restriction involves the creation of a small capacity compartment (less than 20 ml) by either a combination of vertical stapling and a constrictive band opening or a circumgastric band pinching off a small proximal pouch. A modification of the latter procedure is an inflatable circumgastric band attached to a subcutaneous reservoir which allows access by a hypodermic syringe to inject or withdraw fluid thereby tightening or enlarging the band width.

Gastric bypass is performed by stapling shut a vertically oriented pouch of less than 20 ml and connecting this pouch to the jejunum transected 50 cm from the ligament of Treitz (Roux-en-Y gastric bypass). Published evidence confirms that this procedure produces greater weight loss but is accompanied by more frequent adverse effects including 'dumping'.

Most surgical procedures used in the treatment of obesity have been performed laparoscopically which reduces the requirement for sedating pain medication and facilitates prompt postoperative mobilization.

The initial findings from the Swedish Obese Subjects study of severely obese subjects (those with a BMI of more than 40) indicate that weight loss of approximately 30 kg over 2 years is associated with a 60 per cent reduction in plasma insulin, a 25 per cent decrease in plasma glucose and triglycerides, and a 10 per cent reduction in blood pressure. Furthermore, this degree of weight loss resulted in a 14-fold reduction in the risk of developing diabetes and a three- to fourfold risk reduction for the development of hypertension, hypertriglyceridaemia, and low HDL cholesterol levels. Poor health-related quality of life was dramatically improved after gastric restriction surgery, while only minor fluctuations in health-related quality of life were observed in subjects treated by conventional dietary methods. The positive changes in health-related quality of life at 2 years were related to the magnitude of weight loss: the greater the weight loss, the greater the improvement in health-related quality of life.

Randomized controlled trials confirm that surgery for obesity is an option for carefully selected patients with clinically severe obesity (BMI ³ 40 or BMI ³ 35 with comorbid conditions) when less invasive methods of weight loss have failed, and the patient is at high risk for obesity-associated morbidity and mortality. The nature of the surgical procedures necessitates long-term hospital follow-up for such patients.

Weight maintenance

In most patients obesity results not from an inability to lose weight but a profound difficulty in maintaining a lowered weight. A programme to enable the individual to maintain their lowered weight must follow any successful weight loss. A combination of appropriate eating, physical activity, and reinforcement of behavioural methods is the most successful in the long term. Physicians and others can reinforce the importance of this approach but the ultimate responsibility for following such advice must lie with the patient.

Management of obesity during pregnancy

In pregnancy, a weight gain of 12 kg in women of normal weight is associated with the best outcome. By contrast, in women who start pregnancy with a BMI of more than 28, the lowest perinatal mortality is seen with a weight gain of only 4 kg. In pregnancy the aim is thus to limit total weight gain in obese women to 4 kg: the mother-to-be can achieve this by following a nutritionally balanced eating programme prescribed by a registered dietitian, throughout pregnancy.

Management of obesity in childhood

The management of overweight and obesity in children follows the same principles as for adults except that the use of medication is not recommended. Dietary intervention to reduce calorie intake needs to be tempered by a necessity to provide adequate micronutrients such as iron and calcium. Early treatment of childhood obesity has the advantage that it provides the opportunity for the child to 'grow' into their weight. In other words, height may continue to increase for many years and the child maintaining his/her weight will achieve a more favourable body habitus. Any form of dietary restriction must be combined with a regular exercise programme—the design of the activity programme needs to be tailored to the skills of the child and may include walking, swimming, and jogging.

Prevention

The two priority areas for public health strategies aimed at preventing obesity are increasing physical activity and improving the quality of the available diet within a community. However, such strategies must address the need to improve the population's understanding of the nature of obesity and its management and reduce exposure to an environment which promotes obesity. Achievement of these aims requires the involvement of individuals, their families, health professionals, health services, and a commitment from all sectors of the community.

10.6 Special nutritional problems and the use of enteral and parenteral nutrition

M. Elia

Anorexia is a common consequence of disease. Undernutrition may increase morbidity after elective surgery and accidental injury, produce non-specific symptoms such as lethargy, depression, and fatigue, reduce tolerance to cytotoxic drugs or radiotherapy, and prolong the hospital stay.

It is possible to administer sufficient nutrients to individuals at risk of malnutrition, including those with gastrointestinal failure and severe burns, and those who are unconscious. Artificial nutritional support may be given in nursing homes and even at home so that it has become an important aspect of treatment.

The benefits of nutritional support depend on the severity of the disease and on nutritional status; this assessment of clinical and nutritional status is the first important step in rationalizing its use.

Nutritional screening and assessment

A well-structured history may provide useful information about possible undernutrition and the likelihood of specific nutrient deficiencies. Detecting malnutrition in routine clinical practice should be simple, reliable, and reproducible. Criteria for detecting malnutrition include the following: a body mass index of less than 18.5 kg/m ^{2} (chronic protein–energy undernutrition) or less than 20 kg/m ^{2} with a history of weight loss; unintentional weight loss of more than 10 per cent of body weight during the preceeding 6 months; and associated reduction in food intake/reduced appetite. The history may also reveal underlying psychosocial problems (loneliness, bereavement, isolation, alcoholism) and physical disabilities (active disease; for example painful mouth conditions, difficulties with eating and swallowing, inability to self-care) that are likely to have contributed to the weight loss. It is obvious that these underlying problems will also have to be addressed as part of the management.

The clinical history may indicate specific nutrient deficiencies: blood loss leads to iron deficiency; previous gastric surgery to vitamin B_{12} or iron deficiency; coeliac disease may lead to folic acid and iron deficiency; and intestinal resections or fistulae associated with large amounts of intestinal effluents lead to deficiency of many nutrients including sodium, magnesium, and zinc. However, it is often difficult to establish the diagnosis of specific nutrient deficiencies from the history alone.

A dietary history may alert the clinician to major reductions in dietary intake and may indicate the likelihood of specific nutrient deficiencies. For example: anaemia in a vegan may be due to an inadequate intake of vitamin B_{12}; a diet poor in fruit and vegetables may predispose to vitamin C deficiency; a diet poor in fish and margarine (which is normally supplemented with vitamin D) may predispose to rickets or osteomalacia, especially in housebound individuals not exposed to sunlight.

Clinical examination

The relationship of height to weight provides a useful indication of nutritional status. In children an inadequate intake frequently results in growth retardation. Centile charts are useful for this assessment, particularly if sequential measurements are made. In adults an inadequate intake leads to wasting. The body mass index (weight (in kg)/height^2 (in m^2)) can give some indication of the extent of depletion (Fig. 1), as can skinfold thickness (measured with a caliper), arm circumference, and arm muscle area (calculated from the arm circumference and skinfold thickness at the level at which the circumference was measured) (Fig. 2). However, the range of normality is large, and it is possible for subjects to lose a substantial amount of body weight, adipose tissue, or muscle mass and still exhibit normal indices (Fig. 1 and Fig. 2), or even above the normal range (for example obese individuals). It is therefore more useful to undertake sequential rather than single measurements.

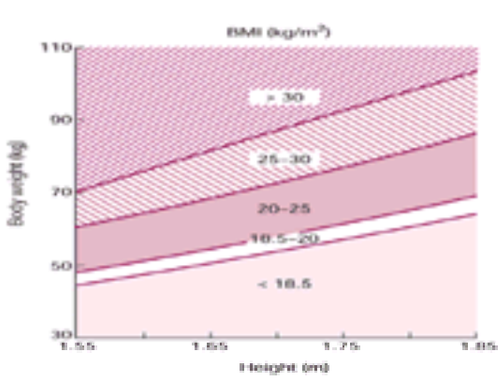

Fig. 1 Ranges of body mass index (weight (in kg)/height^2(in m^2)): less than 17, moderate to severe chronic protein–energy malnutrition (severe if less than 15); 17 to 20, chronic protein–energy malnutrition but some normal subjects; 20 to 25, desirable (some authorities 19 to 25); 25 to 30, mildly overweight (grade 1 obesity); 30 to 40, grade II obesity; over 40, grade III obesity.

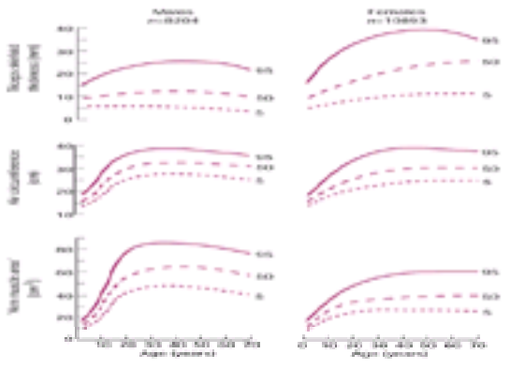

Fig. 2 Percentile curves of triceps skinfold thickness and the estimated mid-upper arm cross-sectional muscle are of American citizens. Based on the United States Health and Nutrition Survey (Frisancho 1981, 1984).

An overall impression of nutritional status (subjective global assessment) may emerge from a combination of history and clinical examination. The examination should assess muscle wasting, the amount of subcutaneous fat, and the presence of oedema. Many other signs may be useful, especially on examining the limbs and integument (Table 1): chelosis or stomatitis may be the result of deficiency of vitamin B complex (but angular stomatitis is common in elderly subjects and may also result from badly fitting dentures); atrophic glossitis may result from folate or vitamin B_{12} deficiency (this may also result from antibiotic therapy); koilonychia may result from severe iron deficiency; tetany may occur in patients with vitamin D deficiency, or hypomagnesaemia; and a rash (acrodermatitis enteropathica) may occur in zinc deficiency. In alcoholics the presence of Wernicke's encephalopathy, Korsakoff's psychosis, and peripheral neuropathy point to the likelihood of thiamin deficiency. Easy bruising may be a sign of scurvy or vitamin K deficiency.

Since the signs and symptoms of many nutrient deficiencies are non-specific, they are often present in a severe form before they can be detected clinically. Deficiencies are usually present in combinations rather than in isolation. The key is to remember to include nutritional causes in the differential diagnosis.

Preventing and treating malnutrition and the indications for artificial nutritional support

Malnutrition in a variety of clinical conditions has been linked to poor outcome. This, together with the high prevalence of malnutrition reported in hospitals, has contributed to enthusiasm for artificial nutritional support. However, there are many simple things that the clinician can do to improve nutritional state. Nausea may be helped by an antiemetic. A person with dysphagia due to an oesophageal stricture may be helped by the provision of sloppy or liquid meals rather than solid foods. In contrast, patients with neurological disorders of swallowing may benefit from more viscous liquids. Pain causes anorexia, and its relief may improve appetite. Dedicating time to feeding weak and elderly patients may do much to improve their nutrition or at least prevent malnutrition. This task may be undertaken by nurses, health care assistants, or relatives.

When intake is inadequate, oral supplements may be tried. If these fail, enteral or parenteral nutrition may have to be used (see below for indications). In some patients it is immediately obvious that artificial nutritional support is necessary. This applies to patients who are unconscious (and likely to remain unconscious for a long period), and those who are unable to swallow or have intestinal failure. It also may apply to patients subjected to major surgery, for example oesophagogastrectomy, who are routinely prevented from eating for a week or more until the anastomosis has adequately healed, and patients receiving aggressive chemotherapy for haematological malignancies (bone marrow transplantation). These latter patients typically develop severe inflammation of the mouth and other parts of the gastrointestinal tract, so that artificial nutritional support (enteral or parenteral nutrition) may be required.

Oral or enteral nutrition should be used where possible because it is simpler, cheaper, and more physiologically acceptable than parenteral nutrition. In addition, enteral nutrition appears to be better than parenteral nutrition in maintaining the integrity of the 'gut barrier', which prevents bacteria and associated endotoxins from entering the systemic circulation. General and specific recommendations about the use of enteral tube feeding are given in Table 2. Some of these guidelines also apply to parenteral nutrition but only when the gut is not available for feeding. Well-recognized indications are prolonged gastrointestinal failure in the form of ileus, peritonitis, severe and recurrent pancreatitis, high intestinal fistulae, short bowel syndrome, or severe inflammatory disease of the intestine, for example severe mucositis following cytotoxic therapy, or Crohn's disease complicated by fistulae. The use of parenteral nutrition in the postoperative period is discussed separately.

Infusion of nutrients into peripheral veins has often been associated with rapid development of phlebitis and venous occlusion. These complications may be reduced by infusing solutions of lower osmolarity (a larger volume, less glucose, and more fat—since fat emulsions have an osmolarity close to that of blood), through suitable fine-bore cannulae. Small doses of heparin and/or corticosteroids and vasodilatory glycerin trinitrate skin patches may prevent venous occlusion. However, peripheral parenteral venous feeding has obvious limitations for patients with poor peripheral venous access and for those requiring prolonged infusions of hypertonic solutions.

Nutritional requirements

Protein and energy

Recommendations about nutrient intake depend on disease activity and nutritional state. Figure 3 shows the effects of increasing nitrogen intake on the nitrogen balance in subjects who are close to energy equilibrium. Normal individuals in energy balance achieve nitrogen balance at a mean intake of 0.1 g N/kg. The World Health Organization recommends a minimum of 0.12 g N/kg, to take into account the variability between individuals (+2 standard deviations). A greater intake produces little improvement in nitrogen balance in normal subjects. In contrast, depleted individuals, particularly those without associated inflammatory or infective disease, achieve a progressively greater positive balance as more nitrogen is taken in (Fig. 3).

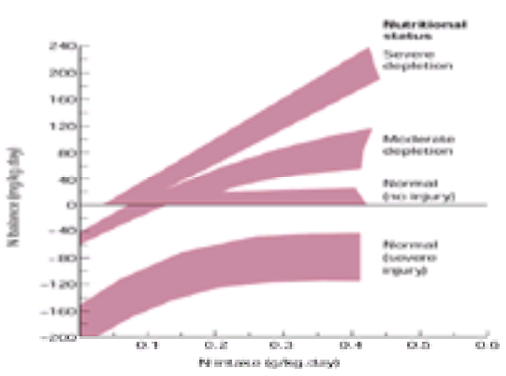

Fig. 3 Relationship between nitrogen intake (1 g N = 6.25 g protein) and nitrogen balance in subjects who are receiving sufficient energy to be close to energy balance (see text).

Negative nitrogen balance in catabolic states is due to a combination of the disease itself, which enhances both net muscle proteolysis and liver gluconeogenesis, immobility, and the effect of drugs such as steroids. The catabolism is usually greatest within the first few days of injury but in patients suffering from burns it may continue for weeks. In well-nourished patients (such as those with sepsis, trauma, or burns) who are close to energy balance, an increase in nutritional intake results in improved nutritional balance. However, as Fig. 3 indicates, the relationship between intake and nitrogen balance is disturbed so that the more severe the injury, the greater the catabolism. In practice, many patients become malnourished following a severe catabolic injury, so that the response to nutrient intake is intermediate

between malnutrition uncomplicated by disease and severe injury uncomplicated by malnutrition.

From these different responses (Fig. 3) some general recommendations emerge for nitrogen intake. (Fig. 4). The recommended energy intake also varies with the clinical state. In well-nourished individuals who are likely to receive nutritional support for long periods, it is wise to aim for energy balance. In the depleted patient, it is desirable to achieve a positive energy balance (as well as a positive nitrogen balance), whereas in obese individuals, loss of adiposity (while limiting the loss of lean tissue) is desirable.

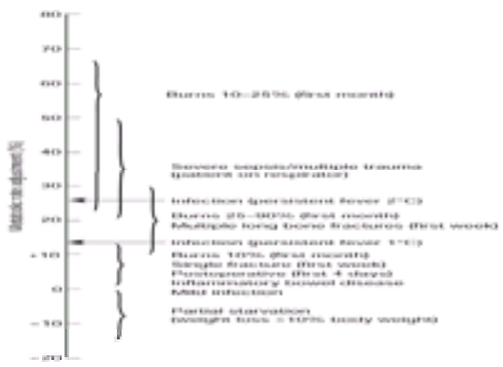

Fig. 4 Guidelines for estimating the approximate energy and nitrogen (N) requirements (1 g N = 6.25 g protein) for an adult patient receiving artificial nutritional support (based on Elia 1994). Energy: 1, Estimate the approximate basal metabolic rate of a normal adult with the same weight as the patient from standard reference tables. 2, Adjust the basal metabolic rate for disease according to the accompanying nomogram. 3, Add a combined factor for activity and thermogenesis (mainly diet induced)—bed-bound plus10 per cent; bed-bound, mobile/sitting, plus 15 to 20 per cent; mobile on ward, plus 25 per cent. 4, If an increase in energy stores is required add 400 to 800 kcal/day (1680 to 3360 kJ/day). If a decrease in energy stores is required energy intake can be reduced. Protein: 1, Consult the nonogram to determine the degree of hypermetabolism—0 per cent, 0.17 g N/kg/day ('normal' protein requirement); 5 to 25 per cent, 0.2 g N/kg/day; more than 25 per cent, 0.20 to 0.25 g N/kg/day. 2, If patient is depleted can increase to 0.25 (0.2 to 0.3) g N/kg/day For obese individuals with a body mass index of 30 to 40 kg/m ^{2} use about 75 per cent of the value estimated from body weight and for those with a body mass index over 40 kg/m^2 use about 60 to 65 per cent of the value estimated from body weight

In calculating energy requirements it is also important to remember that reduced physical activity often offsets any increase in basal metabolic rate due to disease. Even in ambulatory patients receiving parenteral nutrition in hospital and at home, total 24-h energy expenditure has often been found to be 1700 to 2300 kcal/day (7140 to 9660 kJ/day).

Energy requirement varies substantially with body size, nutritional status, and disease activity. Approximate estimates for requirements are given in Fig. 4. Most hospitalized adult patients generally require 1500 to 2500 kcal (6300 to 10 500 kJ)and between 10 and 15 g N/day. In prescribing artificial feeding it is often possible to approximate the requirements to the contents of three or four standard regimens, to monitor the patient's progress, and to adjust accordingly. The intake of energy can sometimes be reduced in the acute phase of disease, when there is metabolic instability and substantial intolerance to nutrients such as glucose, or in obese individuals. The intake of protein may be reduced in hepatic encephalopathy, and in renal failure if the aim is to reduce the uraemia and either to avoid dialysis or to increase the interval between dialyses. However, protein requirements are frequently administered and the patient is dialysed according to needs. Fluid restriction may limit the administration of nutrients and a compromise between the general clinical and nutrient needs may be necessary.

Fluid

Usually 1.5 to 3.0 litres of fluid are given to adults receiving enteral (around 1.5–2.0 litres) or parenteral nutrition (around 1.5–3.0 litres), but different intakes may be required. Particularly high fluid and electrocyte requirements are necessary in patients with large-output intestinal fistulae. Usually the fluid allocated to nutritional support is restricted, partly because the patient may already be receiving fluid for other purposes (for example infusions of drugs and blood), and partly because the clinical conditions demand it. Low fluid intake may be necessary in oedematous patients, those with renal hepatic or cardiac failure, and patients who have suffered a recent head injury. After head injury fluid restriction is frequently recommended to limit brain oedema, which can adversely affect clinical outcome; however, some head-injured subjects may develop diabetes insipidus, when extra fluid is required. Patients with burns also have high fluid requirements. On the other hand, many acute diseases (such as various forms of trauma or injury) are associated with impaired renal excretion of water and salt loads, and therefore fluid balance has to be monitored carefully. In the intensive care unit, fluid intake is often modified according to measurements of central venous pressure. Major changes in body weight from one day to the next can also help in the assessment of fluid requirement since these predominantly reflect changes in fluid balance.

Minerals and trace elements

For many adult patients receiving artificial nutritional support, the recommended intake of sodium and potassium is 50 to 100 mmol/day. Chloride intake is usually similar to that of sodium, and phosphate is usually prescribed at a dose of 20 to 40 mmol/day. However, since artificial nutrition is used in a wide range of patients with different disorders it is not surprising that mineral requirements vary considerably. For example, sodium restriction may be necessary in patients with renal, hepatic, and cardiac failure who are prone to fluid retention. Additional sodium is required in patients with increased gastrointestinal effluents. The additional requirements of sodium and potassium can be predicted from effluent composition as indicated in Table 3. Note that the loss of 1 litre of gastrointestinal fluid may more than double the sodium requirements while affecting potassium requirements to a much smaller extent. However, more potassium may be required in patients with excessive renal losses. Potassium requirements may double in patients receiving amphotericin B, which is often given to recipients of a bone marrow transplant. Adequate amounts of potassium and phosphate, which are predominantly intracellular ions, are also necessary during repletion of lean tissue. Indeed, deficiencies of these substances can exacerbate negative nitrogen balance.

The recommended intakes of calcium, magnesium, and many trace elements are quite different for oral/enteral nutrition compared with intravenous nutrition (Table 4). This is because the gut only absorbs a proportion of these nutrients, sometimes less than 10 per cent (for example in the case of chromium). Prolonged intravenous administration of trace elements at the dose recommended orally may prove to be toxic. One of the functions of the gut is to limit the uptake of potentially toxic substances that may be present in excess in the diet or in the gut. The gut is the most important organ regulating the availability to the body of some trace elements, as in the case of iron and manganese for which there is little capacity for disposal by other organs such as the kidney or liver. However, the gut does not appear to be so important in the regulation of fluorine, iodine, or selenium status.

The requirements of trace elements in various diseases are not clearly established, although patients with intestinal fluid losses may have substantially greater requirements for zinc (see footnote to Table 4).

Vitamins

In contrast to the intravenous recommendations for trace elements, which are generally lower (sometimes by severalfold) than those given orally, the reverse is true for vitamins (Table 5). This is partly because the vitamins are generally absorbed to a much greater extent than most trace elements, and partly because their requirement probably increases in many diseases. Although the vitamin requirements in particular diseases, especially infective and active inflammatory ones, are not well established, the requirements for some vitamins may be considerably greater than in health. In addition, some vitamins may degrade during the preparation and storage of parenteral nutrition solutions. For example vitamin A, riboflavin, and vitamin K are photosensitive, and vitamin C may degrade in the presence of trace elements and oxygen. Thiamin can degrade in the presence of sulphite, which is used as a preservative, and vitamin A palminate may be adsorbed on some plastic storage bags or administration sets. It should be also be remembered that some patients are depleted of vitamins prior to the initiation of therapy, and therefore extra intake is necessary to replete the stores.

Manufactured enteral feeds have a long shelf-life and contain trace elements and vitamins. Parenteral feeds have a shorter shelf-life and vitamins and trace elements are often added shortly before use because of the concern about stability (see above). Vitamin K need not be added routinely in parenteral feeds and particular care must be taken in patients who are on anticoagulants. Sufficient quantities of this vitamin are normally synthesized in the gut but a weekly intramuscular dose is often

recommended, especially in those receiving antibiotics that affect the metabolism of intestinal bacteria. More frequent doses may be given to patients with liver disease who have a coagulation problem and are at risk of gastrointestinal bleeding.

Although deficiencies are not likely to develop for months or possibly years (vitamin A, vitamin D, vitamin B_{12}), it is usual practice to administer a mixture of trace elements and vitamins from the outset even if nutritional support is only likely to be required for a few weeks. This is because the stores of some (mainly water-soluble vitamins such as thiamin and riboflavin) are very small. Furthermore, some patients are malnourished at presentation so that the stores of other trace elements or vitamins may already be depleted.

Complications of artificial nutritional support: prevention, treatment, and monitoring

A summary of the complications that may be encountered during parenteral and enteral nutrition is given in Table 6.

Parenteral nutrition

Mechanical

Complications related to the insertion of a central venous catheter, usually into the subclavian vein, are not common, although pneumothorax may occur in 2 to 3 per cent of cases (the frequency depends on the expertise of the person involved in the procedure). The insertion of the catheter is carried out under aseptic conditions and the position of the catheter tip is confirmed radiologically after insertion. Radiography also helps exclude other complications such as pneumothorax.

Many of the risks associated with parenteral nutrition can be reduced by following appropriate protocols. For example, laying the patient head down while changing feeds and checking the position of locks prevents air embolism. The use of strict aseptic techniques is essential to prevent catheter-related sepsis (see below).

Occlusion of the catheter may result from reflux of blood into the catheter, but it may also result from coagulation of the feed, especially when all-in-one solutions which include lipid are infused. The incidence of catheter blockage depends on how long the catheter is used for, the diameter of the catheter, the type of catheter (soft polyurethane and Teflon catheters are said to have a lower risk of thrombosis than rigid polyethylene catheters), and the type of feed administered (all-in-one mixtures tend to cause line blockage more readily). In patients receiving cyclic nocturnal feeding, flushing the catheter with heparin (50 IU/ml) at the end of feeding reduces the risk of thrombosis. Some recommend routine inclusion of heparin (2–3 IU/ml) in the parenteral nutrition solution to prevent both catheter blockage and local venous thrombosis. Several methods may be tried to unblock an occluded catheter. Gentle suction may remove the clot. The clot may be lysed by inserting a solution of urokinase (5000 U/ml) for about 1 h. Alcohol (50 per cent) may be used in a similar way to dissolve lipid-associated occlusions. Insertion of hydrochloric acid (1 M) into the catheter is another potentially effective method.

Infections

Catheter-related infection is an important complication. The infecting organisms are typically derived from the skin (for example *Staphylococcus aureus*, *Staphylococcus epidermidis*), although a variety of other organisms from the systemic circulation including Gram-negative organisms and fungi may seed on to the catheter tip, especially when it is associated with a fibrin clot. Catheter-related sepsis can largely be avoided by the use of aseptic techniques during insertion of the catheter and during the change of feeds, and by avoiding the use of the central venous catheter for purposes other than feeding, such as blood sampling or the administration of drugs and blood.

When catheter-related sepsis is strongly suspected and the patient is unwell and deteriorating, the catheter should be removed. However, it should be remembered that most episodes of pyrexia are not due to catheter-related sepsis, and the skill of the physician/surgeon in diagnosing alternative causes (such as wound infection, pyrexia of trauma, urinary tract infection in patients with urinary catheters, pulmonary embolism) can prevent unnecessary removal of central venous catheters and the hazards that accompany recannulation. Blood cultures taken both from the central venous line and a peripheral vein and a swab from the catheter enteral site may help to identify the type of organism causing sepsis, and the likelihood that it is related to the catheter.

The procedure of tunnelling the line under the skin from its site of insertion (typically the subclavian vein) to the anterior chest wall makes dressing and care of the catheter easier, and the location is often more comfortable for the patient. However, there is little evidence that the use of a tunnelling procedure reduces the incidence of catheter-related sepsis.

Multilumen catheters are sometimes required for multiple uses (sampling and administration of blood, and use for infusion of parenteral solutions including drug therapy). They have the advantage of convenience, especially in patients with limited peripheral venous access. Reports suggest that such catheters become infected more frequently than single-lumen catheters used solely for parenteral nutrition but this is not surprising because multilumen catheters are used in patients who have more severe disease.

Metabolic complications

Fluid and electrolyte abnormalities are common during parenteral nutrition. This is largely because the underlying condition may result in excess fluid and electrolyte losses (postoperative nasogastric losses, intestinal fistula, etc.) or retention (renal, cardiac, and hepatic failure). Drug therapy may also affect acid–base fluid and electrolyte status. Clinicians involved with the nutritional support of the patient must liaise closely with those involved with other aspects of management. The nutrition team has an important role, partly because it can make the necessary daily adjustments of fluid and electrolytes in the parenteral nutrition solution and partly because it can make adjustments to other minerals or micronutrients that are not administered routinely to ill patients, for example additions of zinc and magnesium in patients with persistent loss of intestinal effluent. Magnesium deficiency may lead to neuromuscular excitability and tetany. It may also produce hypocalcaemia which is not corrected by calcium administration. Zinc deficiency may impair wound healing and produce severe dermatitis.

Hyperglycaemia is common in patients receiving parenteral nutrition in hospital. This is largely because glucose intolerance is frequently associated with severe disease. It can be managed by reducing the intake of glucose (with or without an increase in lipid intake) or by administering insulin, either as a constant infusion or by intermittent subcutaneous or intramuscular injections, at a dose determined by blood glucose concentrations. Particularly high glucose concentrations may occur if the rate of infusion of nutrients is not adequately regulated. Without the use of an infusion pump the rate of infusion may increase severalfold to cause severe hyperglycaemia, hyperosmolarity, headaches, vomiting, and an impaired level of consciousness.

Abnormal liver-related tests are frequently observed in patients receiving parenteral nutrition in hospital, for example increased activities of glutamate oxaloacetate transaminase, serum glutamic pyruvic transaminase, and alkaline phosphatase. These frequently reflect the underlying disease (such as sepsis, malignancy, inflammatory bowel disease, pre-existing liver disease) but other factors may be involved: infusion of lipid or excess glucose (leading to hepatic steatosis); bacterial overgrowth in the intestine; and biliary sludge and even gallstones. The prolonged absence of oral intake during parenteral nutrition fails to stimulate normal gallbladder contraction and this is probably responsible for the development of biliary sludge. Detailed investigation of abnormal liver function (biochemical tests, ultrasound scans, and sometimes liver biopsy) may, on occasion, be necessary to discover the underlying pathology.

Deficiencies of phosphate and essential fatty acids have both been reported during parenteral nutrition, arising from their lack of inclusion in parenteral nutrition solutions. Phosphate deficiency can cause muscle weakness and impair the utilization of protein. It also causes hypercalcaemia and, in the long term, bone disease. Deficiency of essential fatty acids produces alopecia, thrombocytopenia, anaemia, and a skin rash as early as 6 weeks after starting intravenous nutritional support without fat. Biochemically, it is diagnosed by an increase in the triene to tetraene ratio (> 0.4) since, in the absence of linoleic acid, oleic acid is metabolized to eicosatrienoic acid. The condition is more likely to develop in patients receiving continuous rather than intermittent parenteral nutrition, because essential fatty acids from the endogenous lipid stores are continually prevented from being released by hyperinsulinaemia. The deficiency syndrome is rapidly reversed by administering an intravenous lipid. Regular application to the skin of oils containing essential fatty acids allows sufficient absorption of fatty acids to treat or prevent this syndrome.

In patients intolerant of lipid (for example patients with hyperlipidaemia and some patients with renal or hepatic disease or diabetes) hypertriglyceridaemia results. This may affect the assays of a number of standard biochemical tests and dilute other plasma constituents (thereby causing pseudohyponatraemia). Visual inspection of plasma for lipid several hours after cessation of the lipid infusion can alert the clinician to this problem. Measurement of plasma triglycerides provides a more

accurate assessment.

Lipid infusion has been implicated in affecting the function of some organs. For example, hepatic steatosis may cause abnormal liver function tests, and lung deposition in patients with respiratory distress can impair pulmonary function by reducing the permeability of the lung to gases.

Excessive administration of glucose may also have adverse respiratory effects. This is because glucose produces 30 per cent more CO_2 per MJ than fat, and an even greater amount of CO_2 per MJ when there is net lipogenesis from carbohydrate. Furthermore, excessive administration of glucose increases energy expenditure (dietary-induced thermogenesis) to a greater extent than fat. In patients with impaired pulmonary function this may precipitate respiratory failure, or impair weaning of a patient with respiratory failure from a respirator. However, with the typical amount of glucose infused in most patients this is a theoretical rather than a practical occurrence and the use of high-fat regimens is generally not indicated.

Metabolic bone disease (mainly osteoporosis) is associated with long-term parenteral nutrition (usually home parenteral nutrition). Several factors may contribute, including corticosteroid therapy, the underlying disease, and immobility. Excess amino acid intake and heparin have also been implicated. Aluminium toxicity has been implicated as a cause of a painful metabolic bone disorder.

Trace element and vitamin deficiencies may occur in patients on long-term parenteral nutrition. Usually this is due to the prescription of insufficient amounts, but excessive losses of intestinal effluents may also be responsible. Deficiencies of several trace elements have been described, for example copper, zinc, iron, selenium, as well as case reports of chromium and molybdenum deficiencies. Several vitamin deficiencies have also been described, including biotin deficiency (eczematous dermatitis, hair loss, depression, anorexia) which is rare under normal circumstances, and night blindness due to vitamin A deficiency. These should be uncommon if appropriate protocols are followed.

Enteral nutrition

The complications most associated with enteral feeding in hospitalized patients include nausea or vomiting (10–20 per cent), abnormal bloating and cramps, diarrhoea (5–30 per cent), and constipation (but mainly in long-term feeders at home). Delayed gastric emptying is a feature of many conditions including postoperative abdominal surgery, head injury, and severe sepsis. Gastric stasis may lead to accumulation of feed in the stomach, so that eventually the patient develops nausea and vomiting.

In unconscious patients and those with an impaired swallowing reflex, vomiting may lead to aspiration pneumonia, which is one of the most serious complications of enteral nutrition. Gastro-oesophageal regurgitation may also predispose to aspiration pneumonia. Some of the effects of poor gastric emptying can be prevented by administering the feed directly into the small intestine. A nasogastric tube may be placed in the small intestine under radiographic control, endoscopically, or during surgery. In those at risk of gastric stasis/regurgitation, gastric pooling can be checked by intermittent aspiration through tubes with a sufficiently wide bore. Continuous infusion of feed into the stomach can prevent the sudden gastric disturbance associated with bolus feeding. The use of an infusion pump to control delivery of feed into the stomach can prevent gastric flooding associated with inadequate manual flow control systems. The use of metoclopramide or erythromycin, which stimulate gastric emptying, may be beneficial. Erythromycin acts as a motilin receptor agonist.

Despite the frequency of diarrhoea in patients receiving enteral tube feeding in hospital, the mechanism is not entirely understood. However, it is often associated with antibiotic therapy. Lactose intolerance has also been implicated but most enteral feeds are free of lactose. Rapid delivery of nutrients into the gastrointestinal tract may lead to diarrhoea, especially if the delivery is postpyloric. Here the protective effect of the pylorus in regulating delivery of nutrients into the small intestine is bypassed. Other factors have been implicated, including bacterial contamination of enteral diets, an underlying gastrointestinal disease, the use of laxatives, lack of dietary fibre, and neuroendocrine reflexes whereby the administration of feed in the stomach or upper small intestine cause secretion of fluid in the small and large bowel. Diarrhoea may be prevented by taking care not to contaminate the feed with bacteria, controlling the rate of feed infusion, and/or treating the underlying condition. Drugs such as codeine phosphate or loperamide may help to control the symptoms.

Constipation may also complicate long-term enteral nutrition, particularly in elderly, inactive subjects. Lack of fibre has been implicated, but the constipation remains despite fibre supplements.

Another potential problem is regurgitation of feed in patients with impaired gastro-oesophageal function, such as elderly people with a hiatus hernia who have an impaired swallowing reflex. This may lead to aspiration pneumonia which can be avoided by administering the feed with the upper part of the body elevated to an angle of about 30°; in those with a high risk of aspiration, it is best to administer the feed directly into the small intestine (jejunostomy feeding).

Several metabolic disturbances have been described during enteral feeding: hyperglycaemia in glucose-intolerant subjects; rebound hypoglycaemia after sudden withdrawal of feed; disturbances in plasma potassium, depending on the patient's renal and gastrointestinal function and the potassium content of the feed; hypophosphataemia during refeeding. Refeeding malnourished subjects may produce hypophosphataemia and hypokalaemia as lean tissues containing these eletrolytes are accreted. New legislative regulations implemented in the European Community in 1999, which demand that the micronutrient to energy ratio is within a specific range, should reduce the incidence of trace element, mineral and vitamin deficiencies.

The complications of enteral nutrition at home are similar to those in hospital. However, lack of enteral access (due to tube blockage or dislodgement) can be an important problem, because it may lead to dehydration, especially in those with swallowing-related problems who are prevented from drinking. Flushing of the tubes with water at the end of each feeding period can prevent tube blockage. A blocked tube may be unblocked by flushing it with water in the first instance, followed by a warm solution of sodium bicarbonate or by digesting the coagulated feed with pancreatic enzymes. Fizzy cola drinks may also be effective in unblocking tubes. If a gastrostomy or enterostomy tube has been dislodged, it is important to replace it quickly because the stoma may rapidly close up and make further access difficult.

General monitoring of patients on artificial nutritional support

Careful observations should be made of the patient shortly after the start of enteral or parenteral nutrition to assess feed tolerance. In patients receiving parenteral nutrition, urine should be analysed every 4 h to check for glycosuria, and blood glucose should be measured in these patients and others with suspected glucose intolerance. The development of glycosuria in previously stable patients without glycosuria may indicate the development of a complication such as infection before it has been diagnosed clinically in hospital. Routine measurements of temperature, pulse, blood pressure, and fluid balance are also essential. Changes in daily weight are the best indices of day-to-day changes in fluid balance. In the longer term, changes in weight usually indicate changes in lean and adipose tissue in response to the support provided.

The frequency with which other investigations are carried out depends on the patient and the underlying condition (see also above). In patients with large losses of gastrointestinal fluids or those on long-term parenteral nutrition (especially when there is little or no enteral or oral intake) an assessment of trace element and/or vitamin status is often necessary. The catheter site should be inspected regularly as a possible source of infection, and fresh dressings applied according to standard protocols.

In patients receiving enteral tube feeding, it is important to assess feed tolerance by ensuring that gastric pooling does not occur, especially in those at risk of gastric stasis and those with an impaired swallowing reflex. The development of diarrhoea should be investigated promptly so that appropriate action (such as adjustment of infusion rate or eradication of specific gastrointestinal pathogens) can be taken.

Nutritional aspects of specific conditions

The reader is referred to other sections for information on nutritional and fluid and electrolyte aspects of various clinical conditions, for example acute and chronic renal failure, malabsorption syndrome, hyperlipidaemia, diabetes mellitus, cystic fibrosis, short bowel syndrome, and enterocutaneous fistulae. Nutritional aspects of other conditions that have recently gained prominence are discussed here.

Acquired immune deficiency syndrome (AIDS)

AIDS has important nutritional consequences. Early studies suggested that weight loss at death was commonly over 20 per cent of body weight, and sometimes more

than 40 per cent of body weight. Severe weight loss occurs in low-income countries but in more developed countries where protease inhibitors have been extensively used, survival has been prolonged and the frequency of severe undernutrition has been reduced. These changes have been associated with the development of a syndrome that includes abnormal central fat distribution, hyperlipidaemia, and a tendency to lactic acidosis. In the long term, the risks of malnutrition may be replaced by an increased risk of cardiovascular disease. Important clinical problems evident in the era before antiprotease therapy remain relevant to patients in high-income countries, especially at presentation, as well as those in countries where protease inhibitors are not widely used.

Acute weight loss is usually a consequence of acute infections, whereas more chronic loss is usually associated with an enteropathy. There are many direct causes of weight loss. Food intake is usually decreased during acute infections, but during recovery it may be normal or even greater than normal. In advanced AIDS decreased food intake is often associated with opportunistic infections in the mouth, pharynx, and oesophagus, which may cause pain and dysphagia. Associated malignancy (Kaposi's sarcoma and non-Hodgkin's lymphoma) may also lead to anorexia. Furthermore, antifungal and antiviral drugs can cause nausea, vomiting, and anorexia, and the use of chemotherapeutic agents for malignancy can produce stomatitis, pharyngitis, and oesophagitis, which can make swallowing painful and distressing. The enteropathy can be caused by many pathogens and can lead to steatorrhoea, fluid and electrolyte disturbances, and trace element and vitamin deficiencies. Neurological disease is also often associated with malnutrition. Dysphagia and coma obviously lead to reduced nutrient intake and malnutrition, and 'dementia', which may affect half the patients with advanced AIDS, may make dietary assessment and management particularly difficult.

Treatment of the underlying condition, such as mouth, throat, and other systemic infections which cause dysphagia, or systemic infections which cause anorexia, can do much to improve nutritional status. There is substantial anabolic potential between acute infective episodes, and the rapid diagnosis and treatment of such infections produce better nutritional results than delayed treatment.

Nutritional assessment should begin at the outset and changes in body weight in relation to the disease process should be closely monitored. Psychological evaluation and social counselling should not be neglected. Anxiety, apathy, and depression are common and may lead to self-neglect, irregular food intake, and deterioration of nutritional status. Support should begin with general nutritional advice about diet, but it may need to progress to the use of supplements and, occasionally, enteral tube feeding or parenteral nutrition.

Surveys have shown that many patients with AIDS take supplements of vitamins and trace elements. In some cases, ingestion of a large excess of micronutrients leads to toxicity.

Burns

Severe burns provide one of the most powerful catabolic stimuli. The injury response may persist for weeks or months during the period of wound healing. It is not surprising that the nutritional requirements of such patients are greater than for most other catabolic states (see Fig. 4). Inappropriate nutritional support to metabolically unstable patients (burned or non-burned subjects) may cause severe metabolic disturbances: thus before aggressive nutritional support is started, shock and acid–base disturbances should be at least stabilized.

With minor burns a normal oral intake, with or without supplements, is all that is required. However, with severe burns, anorexia is frequently severe and prolonged, and artificial nutritional support is usually required.

Feeding through a nasogastric tube is often well tolerated. However, the use of enteral tube feeding may be restricted early after burns because of gastric stasis or ileus. In most patients gastrointestinal motility improves within 2 to 4 days, so that more nutrients can be administered. Nevertheless, it is important to aspirate the gastric contents intermittently, especially in the early phase after burns, to ensure that there is no gastric pooling. The fluid and electrolyte requirements are often considered in association with nutritional needs, and frequently extra fluid is drunk or given through the enteral feeding tube or an intravenous line, to match the increased fluid losses from the skin surface. Some units routinely provide extra micronutrients, but the extent to which vitamin and trace element requirements are increased after burns is poorly defined.

In patients with severe burns, and those with other associated problems such as intra-abdominal injuries and sepsis, smoke inhalation, and multiorgan failure resulting in artificial ventilation, ileus often persists. In others, the gastrointestinal tract may not tolerate sufficient enteral nutrition to meet the increased requirements of the patient. Some patients, particularly those with severe burns, may thus need both enteral and parenteral nutrition. The enteral feeding is to be encouraged because it may maintain gut integrity, prevent bacterial translocation from the gut into the systemic circulation, and speed up the transition from parenteral nutrition to normal oral intake.

Head injury

Head injury provides another important indication for artificial nutritional support, especially since many patients have an impaired level of consciousness for prolonged periods.

Head injury frequently coexists with other major injuries, with the result that there is a severe hypermetabolic and catabolic response (for example, the negative nitrogen balance may be greater than 20 g N/day in the first week after injury even when a limited intake of nutrients is provided).

Immobility contributes to the loss of muscle bulk and weight loss can occur very rapidly. One of the main constraints to the use of enteral tube feeding is delayed gastric emptying, which frequently lasts for more than 10 days after severe head injury. This may be due to the injury alone but it may also be due to associated abdominal trauma. The use of traditional nasogastric feeding techniques in such patients often makes it difficult to provide the full nutritional requirements within 1 to 2 weeks. The impaired level of consciousness and poor or absent swallowing reflex also means that gastric pooling and aspiration are not uncommon. Parenteral nutrition has been used routinely in some centres but more recently increasing emphasis has been placed on enteral feeding, partly because it may prevent mucosal atrophy and bacterial translocation from the gut, and partly because parenteral nutrition is associated with a number of potentially serious complications, such as catheter-related sepsis (see above). Therefore, attempts have been made to improve methods of delivering nutrients enterally. This includes the use of pump-assisted delivery and the use of metoclopramide and erythromycin to stimulate gastric emptying. Attempts have also been made to introduce feeds directly into the small intestine, either endoscopically or under radiological control. Bypassing the stomach can allow sufficient delivery of feed to be achieved, but displacement of the tube back into the stomach may occur. Another way of dealing with the problem of gastric stasis is to place jejunostomy tubes, using a laparoscopic percutaneous procedure. Preliminary results of feed tolerance in non-randomized studies of injury are encouraging but further work is needed, particularly since the tubes may be regurgitated back into the stomach.

In patients in whom enteral feeding is not successful, for example when there is poor gastric emptying, difficulties in placing a nasojejunal tube, or severe feed-induced diarrhoea, parenteral nutrition is indicated.

Acute pancreatitis

In patients with acute pancreatitis, malnutrition may arise because of anorexia, prolonged ileus, and catabolic complications such as necrotizing pancreatitis (in around 15 per cent of patients) and pancreatitic infection (in around 4 per cent of patients). There is also concern that enteral feeding will stimulate pancreatic exocrine function and precipitate further attacks of pancreatitis or delay recovery from the initial attack. Therefore, parenteral nutrition was routinely advocated for severe and complicated cases of acute pancreatitis. Parenteral nutrition continues to have an important role in the management of acute pancreatitis, especially when it is complicated by enteric fistulae or when enteral nutrition cannot be used to administer sufficient nutrients to meet needs. However, the recent trend is to use less parenteral nutrition and more delivery of nutrients directly into the jejunum. This trend has come about because there is no evidence that parenteral nutrition improves clinical outcome compared with no nutritional support in patients with mild to moderate pancreatitis. There is also no evidence that jejunal feeding adversely affects outcome by stimulating exocrine pancreatic secretions. Indeed, three recent randomized controlled trials suggest that early nasojejunal feeding (2 days after the onset of pancreatitis) has advantages over parenteral nutrition with respect to the severity of subsequent disease (Ranson criteria, in a study of predominantly mild acute pancreatitis, and other indices of the inflammatory response in a study of more severe pancreatitis), and septic complications (in studies of severe pancreatitis). Enteral tube feeding is more physiological and cheaper. Although clinical attitudes are changing, it is necessary to confirm by large randomized controlled studies that jejunal feeding attenuates the inflammatory response and improves clinical outcome to a greater extent than parenteral nutrition. In practice it is also necessary to ensure that there are adequate facilities for placing nasogastric tubes (for example radiologically or endoscopically), and for dealing with tubes that coil back into the stomach.

Transplantation

Artificial nutritional support is variably required for patients requiring a transplanted organ. With renal transplantation, where the gastrointestinal tract is not affected unless surgical complications occur, it is usual to eat normally shortly after the surgery.

Patients with liver or heart plus lung transplants are usually artificially ventilated in the intensive care unit after transplantation. Artificial nutritional support is often given during this period, especially in those with pre-existing malnutrition or postoperative complications. In those with substantial malnutrition, attempts should be made to improve nutritional status before the procedure.

Artificial nutritional support may also be required following treatment with cytotoxic drugs or radiotherapy. In bone marrow transplantation the use of aggressive cytotoxic therapy or radiotherapy may result in inflammation of the mucous membranes of the gastrointestinal tract from mouth to rectum beginning a few days after cytotoxic therapy. Swallowing then becomes painful and diarrhoea a problem. The severity of this mucositis may limit the dose of cytotoxic drugs used. A nasogastric tube is often uncomfortable to such patients, and bleeding may occur from friction with the inflamed mucosa, especially in those with thrombocytopenia, and parenteral nutrition is often required.

There is much research interest in the use of specific nutrients or bioactive substances to protect the mucosa of the gut from damage by cytotoxic drugs or radiotherapy but these have not found their place in routine clinical practice. Graft-versus-host reactions may also be accompanied by gastrointestinal symptoms. Severe, prolonged, watery diarrhoea, amounting to several litres a day, presents a serious problem. Parenteral nutrition is usually necessary after intestinal transplantation, partly because the pre-existing bowel disease produces malnutrition (many patients receiving bowel transplants are on long-term parenteral nutrition prior to the transplant), and partly because it is necessary to ensure that sufficient time has been allowed after transplant surgery to ensure that anastomoses have adequately healed and that mucosal integrity has recovered. Fluid electrolyte and trace elements may need to be given in increased amounts to balance the increased loss associated with gastrointestinal effluents. The protein and energy requirements of patients receiving transplants can be calculated according to the scheme indicated in Fig. 4.

Perioperative nutrition

Although malnutrition may be present before to elective surgery, it is more likely to occur postoperatively, especially in those with complications. Many studies have been undertaken to assess whether perioperative artificial nutritional support reduces the complication rate after surgery. They have produced conflicting results, with some suggesting improvements, others no significant effect, and in yet others an increase in infective complications (such as catheter-related sepsis) when parenteral nutrition is used. These conflicting results have occurred at least partly because of the multiple other factors that affect the outcome of surgery (age, sex, severity of disease, skill of the surgeon, nursing care, presence or absence of a nutrition team, and preoperative nutritional status). The results are also affected by the type of nutritional support provided. Preoperative enteral tube feeding has been reported to improve clinical outcome, but few studies of this exist. Postoperative oral supplements and supplementary enteral tube feeding have been have been reported to improve clinical outcome in malnourished patients with a fractured hip or femur. Postoperative supplements and enteral tube feeding in more well-nourished individuals has produced clinical benefit in only some studies. Perioperative parenteral nutrition has been more controversial.

The largest multicentre trial of perioperative parenteral nutrition (The Veteran Affairs Total Parenteral Nutrition Co-operative Study Group) involved several hundred patients undergoing elective abdominal and thoracic surgery. The routine administration of parenteral nutrition (from up to 2 weeks before surgery and at least 3 days after surgery) provided no overall benefit. However, in the subgroup of patients who were severely malnourished, perioperative nutritional support decreased the non-infective complications from 42 per cent to between 5 and 23 per cent (depending on the method used to define malnutrition). This and other studies emphasize the importance of patient selection for nutritional support. It is obvious, for instance, that other patient groups, such as those with prolonged ileus, massive bowel resection, fistulae, or recurrent severe pancreatitis, are likely to benefit from parenteral nutrition. Meticulous fluid and electrolyte balance is of major importance (see Table 3) in those with fistulae, nasogastric aspirates, or multiorgan failure.

Patients with prolonged anorexia and intra-abdominal sepsis are also likely to benefit from nutritional support. Parenteral nutrition may be required for long periods, for instance in the patient in whom the fluid output from a fistula gradually decreases in the absence of oral food intake, or after massive intestinal resection (short bowel syndrome) when intestinal adaptation may take weeks or months. In some patients with the short bowel syndrome (less than 25 cm of the small intestine remaining) such support will be required indefinitely.

Home nutritional support

One of the most important recent developments in clinical nutrition is the use of artificial nutrition in the community. In many developed countries there is now more tube feeding taking place in the community than in hospital. Furthermore, the increasing emphasis on home enteral tube feeding is likely to continue. Home parenteral nutrition is also increasing, but it is used there much less than in hospitals. In low-income countries the trend towards home care has been limited by the lack of an adequate infrastructure and organization, which are necessary to train, discharge, and monitor patients, and to ensure that the feeds and accessories are delivered to the home regularly and reliably.

Artificial nutritional support at home has a number of advantages over treatment in hospital. Patients frequently feel more comfortable in the familiar home environment, where many of them not only care for themselves but also for other family members. Affected adults may frequently go to work and children attend school. The treatment of patients at home is cheaper and frees beds for the use of other patients. Treatment at home does involve a major commitment on the part of the patient or carer and serious complications may arise.

Indications

Since most malnutrition occurs in the community, it is necessary to identify patients who are likely to benefit from simple dietary measures, the use of mixed macronutrient supplements, and home parenteral nutrition or home enteral tube feeding. The type of treatment depends on whether the gastrointestinal tract is available for the digestion and absorption of nutrients. In the case of artificial nutritional support, it is necessary to ensure that the patients or carers are able to perform the necessary tasks to a sufficiently high standard.

Food and oral supplements

When malnourished patients do not respond adequately to simple dietary advice (for example frequent ingestion of appetizing high energy density meals or snacks), mixed solid or liquid macronutrients can be given. A systematic review of 84 trials of oral nutritional supplements in the community concluded that the supplements were much more likely to produce benefit in patients with a body mass index of less than 20.0 kg/m^2 than in those with a body mass index of more than 20 kg/m^2. Furthermore, in patients with a body mass index of less than 20 kg/m^2 the supplements largely added to oral intake, whereas in those with a body mass index of more than 20 kg/m^2 they largely replaced oral food intake. The benefits varied according to the disease. In patients with chronic obstructive airways disease the supplements increased muscle strength, walking distance, and well being. In children with cystic fibrosis they improved growth, and in elderly subjects they reduced the number of falls and increased activities of daily living. In patients with HIV infection they improved immune function tests. In general improvements were not noted unless body weight increased by more than 5 per cent. Supplements were found to be of little or no value in patients who had a body mass index of more than 20 kg/m^2.

Home parenteral nutrition

Intestinal failure due to Crohn's disease (with or without fistulae) is the most common indication in the United Kingdom. The short bowel syndrome, motility disorders (such as scleroderma, and pseudo-obstruction), congenital bowel disease, and radiation enteritis are also important indications. Home parenteral nutrition has also been used in patients with malignancy (usually those with intestinal obstruction) and in patients with AIDS who are unable to tolerate enteral nutrition.

Home enteral tube feeding

The principal indications are those associated with swallowing difficulties. These may be obstructive (such as malignancy of the upper gastrointestinal tract) or non-obstructive and due to neurological disorders (for example strokes, Parkinson's disease, motor neurone disease, multiple sclerosis, and primary muscle diseases that affect swallowing). In children, although a neurological disorder of swallowing is an important indication, chronic anorexia leading to failure to thrive is perhaps more common (due to, for example, congenital malformations, severe cystic fibrosis, inborn errors of metabolism, and some gastrointestinal disorders such as Crohn's disease).

Age distribution

Many patients receiving enteral nutrition at home are elderly: this is not surprising since conditions such as stroke, motor neurone disease, and oesophageal malignancy typically occur in the elderly. Home tube feeding is also relatively common in children, mainly in those aged less than 10 years. This age distribution has particular implications for home care. Many elderly people are unable to care for themselves because of weakness, immobility, arthritis, poor eyesight or hearing, etc., and therefore a carer, usually a family member, has to be identified. Similarly, carers are frequently required for children on home enteral nutrition.

The age distribution of patients on home parenteral nutrition is different, partly because the indication is often Crohn's disease, which occurs predominantly in subjects aged 20 to 50 years.

Management

The principles of artificial nutritional support at home are similar to those in hospital. Management begins with nutritional screening, so that patients with malnutrition or at high risk of malnutrition are identified, as well as the underlying risk factors (see section on nutritional screening and assessment). Nutritional goals are set, the underlying psychosocial and physical problems (active disease) are addressed, and nutritional counselling and support are provided. Normal food is encouraged whenever possible, but when this is inadequate supplements may be used. This type of nutritional support is normally initiated in the community, whereas home enteral and parenteral nutrition is usually initiated in specialist centres. Special considerations apply to patients receiving home enteral and parenteral nutrition.

Psychological evaluation

The thought that artificial nutritional support may have to be given at home for months or years may surprise some patients and they may find it difficult to accept the concept. Nevertheless, given appropriate support, as the patient or carer gains confidence their fears and anxieties frequently subside. It is always essential to involve family members (or the carer) as well as the patient. Contact with patients who are already on home treatment may do much to reassure. School-age children may also have particular difficulties in coming to terms with this form of therapy, but careful counselling and the use of nocturnal feeding alone frequently allows them to adjust, attend school, and lead a reasonably normal life.

Training

The training should be supervised only by those experienced in the field. Despite pressure for hospital beds, discharge should not take place until it is clear that the patient is adequately skilled and appropriate arrangements have been made at home.

Patients (or carers of the patients) requiring artificial nutrition at home should learn the basic principles of nutritional support and of asepsis. They should know how to program the infusion pump that delivers the nutrients, how to add solutions to the feed (if required), how to connect and disconnect the feeds to the catheter/tube, how to change dressings, how to recognize problems associated with feeding, such as a blocked catheter and infection, and how to recognize hyper/hypoglycaemia, measure blood glucose, and screen for glycosuria. Training is often helped by audiovisual aids and written instruction, and reinforced by repeated practice. A trial of home nutritional support over a weekend may be a useful way of assessing the patient's ability to adjust and cope.

Evaluation of the home environment

An assessment of the home environment is essential before discharge. There must be space available for the storage of feeds and accessories. A refrigerator is usually necessary for storage of parenteral nutrition solutions and drugs. Modifications to the home can be made to allow routine activities to be carried out more efficiently. A wheelchair or other extra equipment may be very useful for some patients, such as a bed harness for very disabled patients and adjustable V-shaped boards for children with cystic fibrosis who require physiotherapy and postural drainage of lung secretions.

Financial arrangements

Financial arrangements for home artificial nutrition clearly vary from country to country and in different parts of the same country. A clear statement about finances should be made prior to discharge. In many countries patients and/or carers are entitled to some sort of financial or other support. These should be made known to those entitled to receive them.

Written instructions and follow-up arrangements

Prior to discharge all patients should have written instructions for the routine procedures for home nutritional support and how to recognize and act when complications arise. Patients/carers should also have the telephone number of the appropriate health professional to contact in an emergency, on a 24-h basis.

Outcome

The outcome of home nutritional support varies considerably, depending on the underlying condition and the initial selection criteria.

Home parenteral nutrition

The most extensive analysis of outcome of patients on home parenteral nutrition has come from North America (Fig. 5). For a variety of conditions (congenital bowel disease, Crohn's disease, motility disorders of the gut, and radiation enteritis), there is a substantial mortality in the first 2 years (10–30 per cent), but few deaths occur after this period. The mortality is usually due to the underlying condition, although a few deaths arise from complications of parenteral nutrition. Mortality in patients receiving home parenteral nutrition for AIDS and malignancy has been reported to be high (Fig. 5). For example, in one survey the mortality of AIDS patients receiving parenteral nutrition in the pre-antiprotease era was as high as 93 per cent in a year. This mortality in AIDS and malignancy clearly depends on when nutritional support is started in relation to the stage and severity of the disease. Such a high mortality dictates that such treatment should only be offered to those in whom there is good reason to expect a substantial consequent improvement in the quality of life.

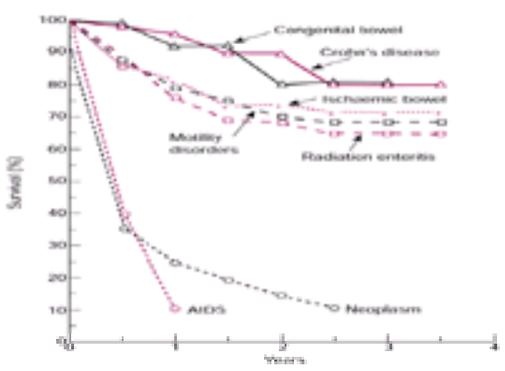

Fig. 5 Survival of different groups of patients receiving home parenteral nutrition (from Howard *et al.* 1991).

In that context in general, the British Artificial Nutrition Survey has revealed that 71 per cent of patients on home parenteral nutrition undertook full normal activity, 13 per cent limited activity, and the remaining 16 per cent were housebound. Seventy-one per cent were independent, 19 per cent required some help or total help, and only 10 per cent of patients were severely disabled and heavily dependent on others.

Home enteral tube feeding

The British Artificial Nutrition Survey has provided outcome data on patients receiving home enteral and parenteral nutrition (Table 7). Only 62 per cent of patients on home enteral tube feeding were continuing at 1 year. Twenty-two per cent died whilst receiving tube feeding, but the total mortality is likely to have been greater because some patients almost certainly died after stopping tube feeding. However, there was great variability in the outcome, which was related to age, and both type and stage of disease.

Despite the high mortality, many family members feel that the quality of life of affected individuals frequently improves, or does not deteriorate. They appreciate and enjoy being with the affected family member, even in the face of a poor prognosis. In a survey of children receiving home tube feeding, predominantly for failure to thrive, parents reported greater freedom because they did not have to spend so much time trying to feed their children as previously. They also reported that their children were happier and more active than before tube feeding.

Monitoring

Patients on home nutritional support should be seen at regular intervals, at a frequency determined by the needs of the patient or carer and the stability of the clinical condition. It is necessary to assess whether the initial goals have been met, and if not a decision has to be made whether new goals should be set or the management changed in an attempt to meet the initial goals. Functional outcome measures, such as walking distance in patients with respiratory or motor disabilities, or eating capabilities, are particularly important. For example, patients with swallowing problems may improve and return to normal oral feeding. If swallowing function is not assessed intermittently in certain patient groups (for example those with strokes) home enteral tube feeding may continue unnecessarily. Nutritional assessment is often based on changes in growth or body weight (taking into consideration the presence or absence of oedema), but changes in skinfold thicknesses and arm muscle circumference and a variety of biochemical parameters may also be used (for example urinary creatinine in accurately collected 24-h urine specimens is a reasonable index of muscle mass).

The need for blood counts, urea and electrolytes, and liver function tests varies, depending on the clinical situation. They are more often required for those taking parenteral nutrition. Measurements of trace elements and vitamins are sensible for patients receiving long-term artificial nutrition, particularly those receiving parenteral nutrition.

Ethical considerations

Legal and ethical considerations about indications and when to start and terminate home nutritional support vary from country to country. Furthermore, the law prohibits discontinuation of nutritional support in some states in America but not in others. Particularly difficult ethical issues concern patients with dementia who stop eating for unknown reasons, and those who are unconscious or have very severe disabilities that are likely to deteriorate.

The role of nutrition teams in the management of patients in hospital and at home

Nutritional support is required for a wide range of patients distributed in different wards. A nutrition team, consisting of a clinician, a specialist nurse, dietitian, pharmacist, and possibly others such as a chemical pathologist and bacteriologist, can advise, supervise, and co-ordinate the management of patients, and maintain high standards of care. It has been shown repeatedly that such teams minimize the incidence of complications associated with nutritional support, avoid unnecessary nutritional support, and reduce wastage of feeds. The reduction in the incidence of catheter-related sepsis alone, from a rate of 25 per cent to 3 per cent has substantial economic implications, since one episode of catheter-related sepsis in a British hospital is currently estimated to cost between £1500 and £5000. Nutrition teams also have an important role to play in training patients for home support, providing advice, co-ordinating the supply of feeds and other equipment to the home, and supervising follow-up.

11.1 The inborn errors of metabolism: general aspects

Richard W. E. Watts

There are around three to four thousand known unifactorially inherited diseases, that is familial diseases, the inheritance of which can be described as being autosomal recessive, autosomal dominant, sex-linked recessive, or sex-linked dominant (Mendelian inheritance). The inborn errors of metabolism are those inherited diseases in which the phenotype includes a characteristic constellation of chemical abnormalities that can be ascribed to an alteration in the catalytic activity of a single specific enzyme. There are unifactorially inherited diseases in which the current techniques are too insensitive for a chemical abnormality to be identified, so that the syndrome has to be defined in clinical, gross structural, and/or pathological terms; further study may bring these into the category of inborn errors of metabolism.

Almost all the unifactorially inherited diseases arise from mutations in the nuclear genome which spans about three billion base pairs of deoxyribonucleic acid (**DNA**). A few mitochondrial proteins have their structures encoded in the mitochondrial DNA (**mtDNA**). This genetic information is transmitted only through the female line and the category of inborn errors of metabolism includes this group. Both the nuclear and the mitochondrially inherited diseases stem from single mutations within a cistron (the functional unit of DNA) which directs the synthesis of a single specific polypeptide chain. The molecular changes in the enzyme protein may affect the primary, secondary, tertiary, or quaternary structure, decreasing, increasing, or abolishing its catalytic activity. Some mutations affect the function of an activator protein, others reduce the binding of hormones and paracrine factors to cell surfaces and/or subcellular structures, and some derange the migration of proteins within cells; another group impairs the transport of metabolites across cellular and subcellular membranes (Table 1). Most intracellular enzymes are located in the cytosol where they are correctly orientated in relation to one another, sometimes as macromolecular complexes, and to their substrates. Some are bound to cellular and subcellular membranes and a minority are located in anatomically defined subcellular structures or organelles: the mitochondria, lysosomes, and peroxisomes.

Mitochondrial diseases

The mitochondrial genome is a circular double strand containing 16.5 kilobases of DNA. It encodes 13 of the respiratory chain enzymes the remainder of which, about 60, are encoded in the nuclear DNA. Abnormal mitochondrial function impairs the supply of energy for biochemical work in all tissues and therefore has wide-ranging effects. Each mitochondrion also contains 24 RNA genes that participate in intramitochondrial protein synthesis. Transcription and translation of mtDNA are regulated by the nucleus through the non-coding D-loop region of the mitochondrial genome. Human cells contain about a thousand copies of mtDNA, but the individual mitochondria in a cell may not all carry a given specific mutation and different cells carry different proportions of mutated mitochondria (heteroplasmy). The proportion of mutant mtDNA must exceed a critical level before the mitochondrial respiratory chain disease declares itself. This variability, as well as tissue-specific differences in dependence on oxidative metabolism, explains, at least partially, why some tissues are preferentially affected in patients with mtDNA diseases. Postmitotic tissues (e.g. neurones, muscle, endocrine tissues) have high levels of mutated mtDNA and are often clinically affected, whereas rapidly dividing tissues (e.g. bone marrow) are less often clinically affected. Differences in the proportions of mutated and non-mutated mtDNA between and within family members also contribute to the wide phenotypic range encountered in the mitochondrial diseases. The spermatozoal cytoplasm, including its mitochondria, is entirely lost at fertilization and, for this reason, mitochondrial diseases are only transmitted through the female line. Clinically affected women rarely transmit a mtDNA deletion to their children. However, a woman with a heteroplasmic mtDNA point mutation or duplication may transmit a variable amount of mutated mtDNA to her progeny. The number of mtDNA molecules in each oocyte is reduced and then amplified to a total of about 10^5 during early development of the oocyte; this, presumably random, process contributes to the different amounts of mutated mtDNA in different children in the same family. Women whose gametes contain high concentrations of mtDNA are more likely to have clinically affected children than mothers with lower levels of mtDNA. The general clinical manifestations of the mitochondrial diseases are shown in Table 2 and specific examples of mitochondrial diseases are given in Table 3.

Peroxisomal diseases

Some enzymes that are encoded in the nuclear DNA are specifically expressed in peroxisomes, to which they are imported soon after translation. Mutations in the relevant genes result in the diseases listed in Table 4.

Lysosomal storage diseases

Lysosomes are subcellular organelles containing hydrolases with low optimum pH values ('acid hydrolases') which catalyse the degradation of macromolecules. The macromolecules are either derived from the metabolic turnover of structural cellular components or have entered the cell by endocytosis. The products of this macromolecular degradation process leave the lysosomes by specific efflux processes.

In most of the lysosomal storage diseases an inborn error of metabolism affects a specific lysosomal enzyme so that either undegraded or partially degraded macromolecules accumulate in the lysosomes. The engorged lysosomes distort the internal architecture of the cell, disturb its function, and inhibit the activities of other lysosomal enzymes so that macromolecules other than those related to the primary enzyme deficiency also accumulate.

Cystinosis (cystine storage disease) and Salla disease (*N*-acetylneuraminic (sialic) acid storage disease) are due to metabolic lesions involving the specific efflux processes whereby these two low molecular weight products of macromolecule metabolism (cystine and sialic acid respectively) leave the lysosome (Table 1).

Lysosomal enzymes are glycoproteins which are subject to exocytosis and re-uptake by endocytosis. Their protein moieties are synthesized on the rough endoplasmic reticulum and the oligosaccharide side chains are added in the Golgi apparatus. The addition of a terminal mannose-6-phosphate residue recognition marker is necessary if the enzyme molecule is to be correctly routed into the lysosomes, and if it is to be available for receptor mediated re-uptake from the interstitial fluids. The types of lysosomal storage diseases and the nature of their metabolic defects together with examples of each group are presented in Table 5.

Heterogeneity in the inborn errors of metabolism

The individual inborn errors of metabolism are defined on the basis of the phenotype, including the specific enzyme lesion, and by their pattern of inheritance. Close study of any particular inborn error of metabolism reveals unexpected heterogeneity. This is due to:

- Multiple allelism.
- Mutations at different gene loci affecting the structure of different polypeptide chains in a single enzyme protein.
- Mutations at different gene loci affecting different proteins with similar catalytic functions.
- Differences in the overall genetic background against which the single mutation acts.
- Environmental factors.

Clinical pointers towards a diagnosis of an inborn error of metabolism

Although the symptoms of metabolic disease may appear vague and protean, and an inherited disease cannot be diagnosed in the absence of an appropriate family history, some clinical settings suggest the presence of an inborn error of metabolism (Table 6). In taking the family history special inquiries should be made about affected siblings, possible parental consanguinity, paternity, miscarriages, perinatal deaths, abortions, about the sexes of possibly affected relatives and their placement on the maternal or paternal side of the family, the ages at death of relatives, as well as the ethnic and geographical origins of the parents.

General approaches to the treatment of inborn errors of metabolism

The treatments available for the individual inborn errors of metabolism cover a wide range and may need to be specially developed for individual patients. However, the principles involved can be broadly classified as in Table 7. Palliative surgical and other measures may be needed to deal with specific complications (for example corneal grafting to restore vision in patients with corneal clouding due to one of the mucopolysacchridoses). Consideration should also be given to meeting the educational and social needs of these patients as well as to optimizing their overall clinical state and correcting the biochemical parameters. The successful management of patients with inborn errors of metabolism requires a multidisciplinary approach which utilizes the special skills of dieticians, social workers, educationalists, and occupational therapists as well as those of physicians, surgeons, biochemists, and geneticists. It is particularly important to plan for the handover of specialist care from the paediatrician to the most appropriate adult physician when follow-up in a paediatric department becomes inappropriate. The perfect outcome is to achieve a physically and mentally normal adult who is capable of begetting normal children. Unfortunately the nature of many of the inborn errors of metabolism mitigates against the attainment of this ideal so that treatment has to aim at optimizing the child's potential in all its physical, mental, and social aspects. Treatment and support also have to be extended to the parents and siblings who, if not overtly affected themselves, may be carriers of the abnormal gene concerned and require appropriate advice about the genetic and other aspects of the disease.

The ability to clone human genes into bacteria and yeasts which can then produce large amounts of the human gene product is widening the horizons for future treatment by enzyme administration. The development of macrophage-targeted b-glucocerebosidase enzyme replacement therapy for Gaucher disease (glucosylceramidase deficiency) type I is a notable recent development in this field and is now regarded as the definitive line of treatment. Attempts to utilize transplanted fibroblasts and amniotic cells as a source for enzyme replacement therapy have not been successful. Bone marrow transplantation has been used for the treatment of two groups of inherited metabolic disorders: those in which it is desired to replace a particular type of non-functioning bone marrow cell by its normally functioning counterpart and those in which an attempt has been made to utilize the fact that the bone marrow produces 50 to 100 g of polymorphonuclear leucocytes per day and that these cells exocytose (release) their lysosomal enzymes for endocytic uptake by enzyme-deficient cells in the body tissues generally. This strategy has been more successful with the first group of diseases, which includes disorders of neutrophil function (e.g. cyclic neutropenia), functional abnormalities of lymphocytes, and osteopetrosis. The beneficial effect on the last disease is due to the introduction of normal osteoclast precursors. The results in the second group of diseases, namely those in which the white cell lineage derived from the transplanted bone marrow is used to supply normal enzyme to enzyme-deficient tissues, for example Hurler disease (mucopolysaccharidosis IH) and metachromatic leucodystrophy, have been less successful particularly in terms of neurological function. Haemopoietic stem cells have been implanted into the fetus *in utero* to correct severe congenital immunodeficiency but this has not, so far, been applied to diseases without immunodeficiency. This procedure takes advantage of the immunological tolerance of the fetus. The possibility of using liposomes and resealed erythrocyte envelopes as carriers of therapeutic enzymes is also being explored.

Liver transplantation is used as a sophisticated form of enzyme replacement therapy in some inborn errors of metabolism where this organ is the specific site of the metabolic lesion. Liver transplantation has the advantage that the enzyme is introduced in the correct organ, the correct cell with its correct subcellular location, and correctly orientated with respect to its substrate and other enzymes with which it must act in concert. Liver transplantation can also be regarded as a form of gene replacement therapy in that the donor liver contains the normal gene which will direct the synthesis of a normal enzyme protein. Prenatal transplantation of fetal liver stem cells has potential in the treatment of some inborn errors of metabolism. Successful engraftment at the 12th to 24th week postfertilization with partial correction of the metabolic defect has been demonstrated in b-thalassemia. Treatment by gene replacement, using retroviral vectors and gene constructs to introduce the desired DNA sequence into the patient's explanted haemopoietic stem cell genome, these genetically corrected cells being cultured and then returned to the patient's circulation, may have some potential in diseases where expression of the metabolic lesion in the haemopoietic system determines the phenotype, or in those situations where genetically corrected migratory cells of haemopoietic origin can deliver normal enzyme to the enzyme-deficient tissues. Although somatic cell gene therapy possibly using viral vectors and/or gene constructs to introduce the desired DNA sequences into other cell types is currently being investigated extensively in *in vitro* model systems and in animal models of some human inborn errors of metabolism using, for example, hepatocytes, none of these have reached application in clinical practice. For example, the possibility of using herpes simplex virus type 1 as a means of introducing corrected genes into the nervous system is being explored. Another approach is to use either resealed erythrocyte cell membranes or liposomes as carriers of therapeutic enzymes. Thus, although there are some prospects of correcting some enzyme defects in the somatic cell genome, the correction of defects in the germline seems remote although the development of advanced *in vitro* fertilization techniques, preimplantation DNA analysis, gene transfer, insertion or conversion, and embryo implantation procedures may render this judgement premature. Ethical objections to human germline modifications are also being raised, and could lead to this work being discontinued.

Screening for inborn errors of metabolism

The realization that very early diagnosis is essential in order to achieve good results in the treatment of some inborn errors of metabolism, such as phenylketonuria and galactosaemia, has stimulated interest in the possibility of examining either whole populations or selected groups of predisposed individuals for the biochemical differences which characterize particular inherited metabolic diseases. Diagnosis is needed at a stage which is not only presymptomatic but which precedes the onset of self-perpetuating secondary pathological changes.

Screening for inborn errors of metabolism may be either non-selective (whole population) or selective. The latter, which includes carrier detection studies, aims to cover a part of the population. This may be defined on clinical, genetic, ethnic, or geographical grounds. Phenylketonuria and congenital hypothyroidism are the only members of this group of disorders for which neonatal whole-population screening is generally practised, although the inclusion of galactosaemia, cystic fibrosis, and congenital adrenal hyperplasia (21-hydroxylase deficiency) has been proposed. Whole-population screening should only be established for treatable or preventable diseases, and the consistency of the association of the proposed biochemical or other marker and the serious clinical phenotype must have been proved beyond any doubt. There must be a reliable and robust analytical method suitable for use with a sample of blood or urine which can be obtained without distressing either the parents or the baby. The possibility that metabolic screening will bring to light previously unrecognized variants, which are either mild and do not require treatment, or which by virtue of a fundamentally different biochemical lesion will resist the currently established therapies, has to be borne in mind. Phenylketonuria illustrates these problems. Here, beside classical phenylketonuria, whole-population screening has identified both the clinically unimportant essential (mild) hyperphenylalaninaemia, and the devastatingly serious, but treatable, inborn errors of tetrahydrobiopterin synthesis which produce the 'malignant' hyperphenylalaninaemia syndrome. It is also possible that in some cases immediate postnatal screening and treatment may be too late to prevent minor manifestations of the disease, (e.g. in congenital hypothyroidism).

The incidence of disease which merits whole-population screening should be at least similar to that of phenylketonuria in Caucasians (between 1 in 6000 and 1 in 12 000). Cystic fibrosis has an incidence of 1 in 2500 (gene frequency l in 25) in Caucasians and would merit neonatal whole-population screening on this basis. Molecular genetic approaches are potentially useful. If the disease is not too genetically heterogeneous and when the full range of possible causative mutations is known the specific mutation could be sought directly. Otherwise, after DNA amplification the mutational change in the DNA structure could be detected either by the presence of a restriction endonuclease site or by probing with another primer that hybridizes with only one of the alleles. An appreciable proportion of individuals classified as being homozygotes on the basis of classical genetic analysis prove to be double heterozygotes, that is they carry two different mutations in the same gene. The number of inborn metabolic errors in which the affected individuals and the heterozygous carriers can be identified by molecular genetic analysis is increasing rapidly. It includes such numerically important diseases as sickle cell anaemia, b-thalassaemia, haemophilia, Duchenne muscular dystrophy, cystic fibrosis, and phenylketonuria, as well as rarer but devastating conditions such as the Lesch–Nyhan syndrome.

Prenatal diagnosis

The procedures used in prenatal diagnosis are:

- Direct examination of the fetus by ultrasonography and fetoscopy.
- Chemical analysis of amniotic fluid.
- Biochemical and cytological analysis of cultured amniotic cells (amniocytes) obtained by amniocentesis at the fifteenth to sixteenth week of pregnancy.
- DNA analysis on uncultured amniocytes.
- Karyotypic enzymological and DNA analysis of chorionic villi obtained by biopsy at the eighth to tenth week of pregnancy.

- Biochemical studies on tissue obtained by biopsying the fetus *in utero*.

Carrier state diagnosis

Carriers are either individuals carrying the gene for a recessive disorder, which does not express itself in the heterozygous state (e.g. phenylketonuria), or those who carry the gene for a dominant disorder, that is one which does express itself in the heterozygous state, but in which symptoms occur in later life (e.g. Huntington's chorea (Huntington's disease)).

The general approaches to carrier state diagnosis are:

- The detection of minor clinical, radiological, and clinicopathological abnormalities.
- The demonstration of levels of enzyme activity in tissue (e.g. leucocytes or cultured fibroblasts) which are intermediate between those observed in individuals homozygous for the abnormal and the normal forms of the enzyme respectively (the observed level of activity may not be exactly 50 per cent of the normal value).
- The demonstration of intermediate levels of a characteristic metabolite in an accessible body fluid.
- The demonstration of mosaicism with respect to the product of the mutant gene on the X chromosome in the case of sex-linked recessive disorders.
- Direct gene analysis using either a specific gene probe or a linked restriction fragment length polymorphism.

The ability to recognize asymptomatic carriers of serious recessive diseases and presymptomatic individuals in the case of dominant disorders raises major ethical and social issues with respect to the psychological impact that this information will have on the affected individuals and their families. This is especially so with the clinically normal carriers of a crippling, lethal, and untreatable disease such as Huntington's chorea.

In vitro fertilization and the inborn errors of metabolism

The human embryo produced by *in vitro* fertilization can be biopsied at a very early stage of development (i.e. at the eight-cell stage). A single cell is removed and examined for the DNA mutation responsible for the disease which the parents are known to be carrying. This enables only fertilized ova which do not carry the mutant gene to be implanted.

Animal genetic models of inborn errors of metabolism in man

Animal genetic models of the inborn errors of metabolism can be useful in the early stages of investigating new approaches to treatment before attempting to transfer these to man. It is also possible to investigate the pathophysiology of the diseases at different stages of their evolution more easily, rapidly, and predictably than if one has to rely entirely on the *ad hoc* availability of clinical and pathological material. However, there are obvious limitations when cognitive and behavioural abnormalities are part of the clinical phenotype.

11.2 Inborn errors of amino acid and organic acid metabolism

P. J. Lee and D. P. Brenton

History

Following the early insights of Garrod and pioneers such as FØlling, it was the use of paper chromatography by Dent and the automated column chromatography of Moore and Stein which led to modern developments in the field of inborn errors of metabolism. The laboratory contributed more discoveries with the advent of gas–liquid chromatography and later mass spectroscopy. More recently the rise of genetics and molecular biology have revolutionized the field and now tandem mass spectroscopy is proving a powerful tool in screening and diagnosis. The inborn errors of metabolism has been a spectacularly developing field for several decades and provides vivid examples of the successful application of molecular cell biology to the diagnosis and treatment of human disease.

Introduction

An overview of amino acid metabolism and genetic defects

Humans depend upon dietary protein as a source of amino acids; some amino acids cannot be synthesized in the human body, and all are used very economically. Stool nitrogen losses are only about 1 g/day and bacterial protein accounts for much of this. Renal conservation of amino acids is extremely effective, with low clearance values (Table 1). Amino acids taken in excess of requirement are not stored but are used for energy. After the removal of the amino group for conversion to ammonia and urea (Fig. 1), the carbon skeletons degrade to major metabolic intermediates such as acetyl coenzyme A, acetoacetyl coenzyme A, pyruvate, or to citric acid cycle intermediates (Fig. 2) via individual amino acid pathways. Amino acids are referred to as glucogenic when their carbon skeletons degrade to intermediates used in gluconeogenesis and ketogenic when their degradation products can form ketone bodies. Degradative enzymes frequently have important coenzymes and inherited defects of catabolism may be due to defects of the apoenzymes or their vitamin coenzymes. Table 2 shows one biochemical classification of the genetic defects of amino acid metabolism. A clinical classification would be more practical but is difficult because of the non-specific nature of many clinical features, for example mental retardation.

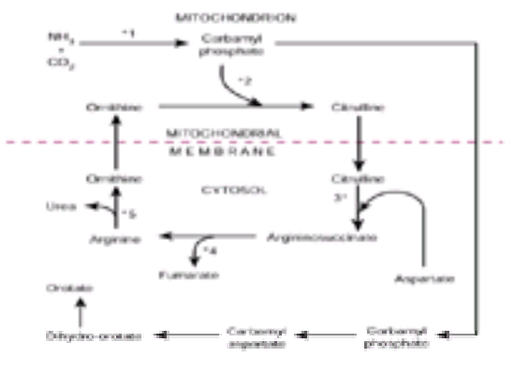

Fig. 1 The urea cycle functions partly in the mitochondrion and partly in the cytosol. Carbamyl phosphate, if it accumulates, may be diverted to orotic acid synthesis.

Asterisked enzymes are: 1, carbamyl phosphate synthetase; 2, ornithine transcarbamylase; 3, argininosuccinate synthetase; 4, argininosuccinate lyase; and 5, arginase.

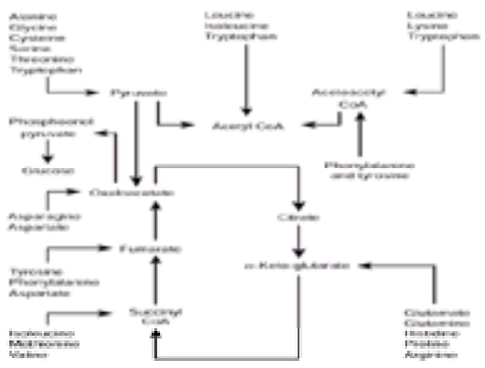

Fig. 2 Amino acids as a source of energy. The multiple entry points to the citric acid cycle for the metabolites of carbon chain catabolism.

Nitrogen balance and dietary treatment

Some biochemical defects such as homocystinuria respond well to vitamin (coenzyme) supplementation and others are treated by diet. Generalized moderate protein restriction is a usual approach to urea cycle defects and one or two other diseases, but very specific restriction of one or two amino acids applies crucially to a small number of essential amino acid disorders. Thirty years ago Rose and colleagues defined the eight essential amino acids in adults (Table 3) and the minimum daily requirements for sustaining nitrogen balance. This also requires an additional intake of 'non-essential' amino acid nitrogen and an adequate calorie intake. Histidine and taurine may be essential in the neonate. Dietary restriction can be used to treat specific metabolic defects of essential amino acids but is unlikely to be successful for disorders of non-essential amino acid metabolism.

Almost all ingested protein in the infant (recommended intake about 2 g/kg/day) is utilized in the synthesis of new protein for growth. This persistent anabolic state, however, is easily upset by intercurrent infection, starvation, trauma, or surgery, with a rapid swing to a catabolic state and negative nitrogen balance. The amino acids released from protein hydrolysis increase the load on urea formation and their normal pathways of intermediary metabolism. This renders infants and young children prone to frequent clinical illness with some amino acid disorders. In adults an intake of natural protein of 60 to 80 g/day is probably about twice that needed to maintain nitrogen balance and health. Adults are less prone to become catabolic than infants but the same circumstances may nevertheless precipitate it. In addition periods of particular risk include late adolescence when the growth spurt ceases and the postpartum period. Insulin and glucose can be used to reverse a catabolic state and produce positive nitrogen balance in some inborn errors.

Amino acid transport defects

General pathophysiology

Historically, the renal tubular aspects of amino acid transport have been of major importance following Dent's (1948) successful introduction into clinical practice of paper chromatography for the analysis of urinary amino acids. Table 4 sets out a classification of amino aciduria. Normal renal clearance values for the amino acids are given in Table 1. A general account of amino acid transport would need to cover not only the renal tubule but the intestinal mucosa, the placenta, the blood–brain barrier, cell membranes in a host of tissues, and intracellular membranes. No attempt is made here to address the generality of transport issues.

The generalized amino acidurias

The Fanconi syndrome

General aspects

There are four components to the Fanconi syndrome:

1. characteristic low-molecular-weight proteinuria, e.g. a $_1$-microglobulin, b$_2$-microglobulin, b$_1$-glycoprotein, and retinol binding protein;
2. tubular transport defects;
3. metabolic bone disease, rickets, or osteomalacia;
4. slow loss of glomerular function.

Glycosuria, generalized amino aciduria, and phosphaturia are a classic triad. The conservation of sodium, potassium, bicarbonate, and urate is impaired and the plasma concentrations of the last three decreased. Many examples of the Fanconi syndrome are not primarily disorders of amino acid metabolism (cystinosis is an exception) but the effects of exogenous or endogenous toxins (e.g. galactose-1-phosphate) which accumulate in other genetic defects (Table 5). The Fanconi–Bickel syndrome is a distinct genetic entity.

Maleic acid (maleate) has been used to produce experimental models of the Fanconi syndrome, as have 4-pentenoate and succinyl acetone (see below). Experimentally, maleate lowers intracellular concentrations of amino acids and sugars predominantly by increasing efflux. Maleate affects mitochondrial oxidation processes, impairs 1a-hydroxylation of 25-hydroxycholecalciferol and may directly affect cell membranes. It has still not proved possible to be sure whether the Fanconi syndrome should be regarded as a disorder of proximal or distal tubules, or both, whether efflux from cell to lumen is more important than reabsorption defects, and whether all causes of the syndrome act through a final undefined common mechanism. A central role for impaired energy production is suggested by new reports of tubular defects in mitochondrial disorders, for example cytochrome c oxidase deficiency and the Kearns–Sayre syndrome.

The Fanconi–Bickel syndrome

This is a rare autosomal recessive disorder caused by mutations in a glucose transporter gene expressed in kidney, liver, intestine, and pancreas. It is associated with hepatomegaly, glycogen storage, fasting hypoglycaemia, short stature, and proximal tubular nephropathy.

The dominantly inherited Fanconi syndrome

This disorder, of unknown cause, characteristically presents in the second to fourth decade and slowly evolves into late adult life when renal failure may be advanced (Fig. 3). The clinical presentation is commonly with rickets or osteomalacia, which require treatment with calcitriol. Potassium, sodium bicarbonate, and phosphate supplements may also be needed.

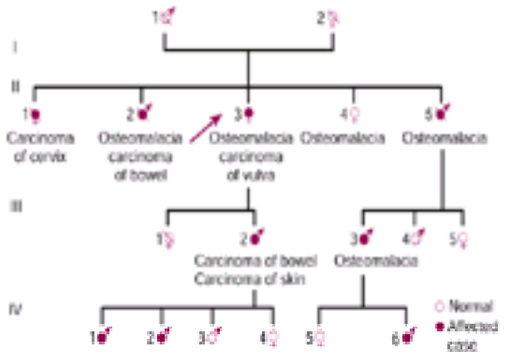

Fig. 3 Pedigree of dominantly inherited Fanconi syndrome. (From Brenton *et al*. (1981) with permission.)

The oculocerebrorenal syndrome of Lowe

This is an X-linked disease characterized by dwarfism, severe mental retardation, and blindness secondary to cataracts, microphthalmos, and glaucoma. The tubular defect includes proteinuria, rickets but not usually glycosuria, and an amino aciduria with relative sparing of the branched chain amino acids. The *OCRC1* gene is on the long arm of the X chromosome and codes for inositol polyphosphate-5-phosphatase.

Cystinosis

Clinical

Cystinosis results from defective carrier-mediated transport of cystine through the lysosomal membrane, which may rupture due to cystine crystallization in hexagonal or rectangular forms causing cell damage. In the proximal renal tubule this leads to the Fanconi syndrome. In the severe infantile form clinical presentation occurs after a few months of life with polyuria, thirst, salt and water depletion, hypokalaemia, and proximal renal tubular acidosis. Poor feeding and failure to thrive are characteristic. Hypophosphataemia and impaired 1-hydroxylation of 25-hydroxycholecalciferol contribute to florid rickets.

Photophobia develops with the accumulation of cystine crystals in the cornea and retinopathy. Hypothyroidism is common and renal failure develops leading to death by 10 years of age. Growth is invariably impaired even before kidney transplantation and the concomitant steroid immunosuppression. Sexual development is late. Intelligence is normal in early life. In transplanted patients retinopathy and visual loss may progress and central nervous system changes may occur. Cystine crystals are not seen here, but tissue cystine concentrations are very elevated. Cortical atrophy and memory defects occur in some older patients. frank neurological features are now more commonly described in survivors after renal transplantation, and may respond to treatment. The spectrum of organ defects is likely to widen in long-term postrenal transplant survivors.

Variant forms

A benign adult form presents with photophobia due to corneal crystals. There may also be crystals in the bone marrow and leucocytes but the kidney is spared and life expectancy is normal. An intermediate form is like the classic infantile form but presents in late childhood or early adult life. Renal involvement and renal failure occur.

Biochemistry

It is probable that all tissues accumulate cystine, but not equally, and some (e.g. muscle and brain) never seem to develop crystals. Crystals occur in the tissues with the highest cystine concentrations, increasing with age to values several hundred times normal. Cultured fibroblasts and leucocytes have values of 50 to 100 times normal, but cultured lymphoid cells are only four to five times normal. Leucocyte cystine content is higher in the intermediate than the benign form, and highest in the severe classic infantile form. The intralysosomal cystine originates from proteins catabolized within the lysosome and extracellular cystine transported into the cell. Cystine egress from the lysosome is defective. The carrier is not shared by other amino acids, which have other lysosomal transport systems. Cystine loaded renal tubules have severely compromised ATP production due to a deficient intracellular phosphate concentration.

Diagnosis

This is based on the clinical features, features of the Fanconi syndrome, and the presence of cystine crystals. In the cornea these can be seen with a hand lens or a slit lamp in an older child but in infancy they are best seen in bone marrow aspirates (Fig. 4) fixed in alcohol and examined under polarized light. Analysis of peripheral leucocytes for their cystine content is possible in only a few laboratories.

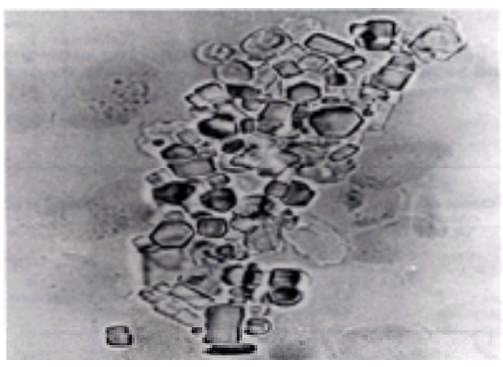

Fig. 4 Cystine crystals in the marrow of a child with cystinosis (× 2200, partially polarized light). (By courtesy of Dr B. Lake, The Hospital for Sick Children, Great Ormond Street, London and with the permission of Heinemann Medical Books.)

Genetics

The disease is autosomal recessive. The incidence is about 1 in 200 000 live births. A higher incidence has been reported from parts of France. Heterozygotes are clinically normal but have raised leucocyte cystine concentrations. Patients have mutations in a gene (*CTNS*) on the short arm of chromosome 17 encoding a lysosomal membrane protein cystinosin. Over 30 mutations in the *CTNS* gene have been recognized in nephropathic cystinosis and others in variant forms.

Prenatal diagnosis

This has been successfully achieved using cultured amniocytes and measuring ^{35}S cystine uptake, or by direct analysis of chorionic villus samples for cystine content. Mutation analysis is now possible.

Treatment

Renal losses of salt, bicarbonate, and potassium may require initial intravenous replacement, but oral supplements including phosphate suffice later although the need for them may be substantial. Phosphate alone may not heal the rickets without the addition of calcitriol. Oral cysteamine, or phosphocysteamine, given in divided doses, depletes leucocyte cystine and gives improved growth and preservation of renal function. Cysteamine eye drops have been used in very young children to clear corneal crystals. The role of cysteamine in preventing the consequences of cystine accumulation in non-renal tissues after transplantation is under study. Dialysis and/or renal transplantation are required for renal failure. Transplanted kidneys do not accumulate cystine. Thyroxine is needed for hypothyroidism. Growth hormone treatment increases height but has been reported to hasten the need for renal replacement. others have not found this, and cysteamine treatment in early childhood improves growth anyway. Plasma carnitine concentrations are often low and can be increased to normal by the use of supplements but this may not help any muscular weakness.

Specific amino acidurias

The recognition of genetic disorders characterized by the excretion of a specific group of amino acids has stimulated research into amino acid transport. Major clinical problems are found in cystinuria and lysinuric protein intolerance.

Cystinuria

Clinical

Cystine stone formation in the kidneys and its attendant complications of pain, haematuria, renal obstruction, and infection is the classic clinical presentation. Only 1 to 2 per cent of all renal stones in adult life are cystine stones but the proportion is higher in childhood. The stones may have grown to large staghorn calculi before diagnosis. They are radio-opaque.

Biochemistry

Cystine has a solubility of 400 mg/litre at neutral pH and excretion varies from 400 to 1200 mg/day in affected individuals, with increased excretion of lysine (up to 2 g/day), ornithine, and arginine, and impaired intestinal absorption of the free amino acids. All are absorbed as dipeptides in combination with another amino acid outside the group. There is no deficiency of any amino acid and no urea cycle defect. The faecal and urinary excretion of diamines such as putrescine and cadaverine result from the action of intestinal bacteria on unabsorbed lysine and arginine. Experimental work indicates that one renal transport defect in cystinuria affects a low-K_m system in the brush border shared by the four amino acids. Other transport systems for cystine and the dibasic amino acids exist. Cystine excretion can exceed the glomerular filtration rate, implying the possibility of tubular secretion.

Diagnosis

Diagnosis requires an amino acid chromatogram and quantitation of cystine excretion. Calcium-containing stones have been observed in cystinuria—possibly because infection predisposes to deposition of calcium salts on small cystine deposits. Confusion is most likely when stone analysis is used for diagnosis without a chromatogram.

Genetics

Three subtypes of cystinuria were identified 30 years ago from studies of amino acid excretion and intestinal absorption. A gene on chromosome 2p with over 20 described mutations probably provides the basis for type I cystinuria with high cystine excretion and a high risk of stone formation. A second cystinuria locus on chromosome 19q may be responsible for types II and III cystinuria. Combinations of alleles at these loci probably explain the different subtypes of cystinuria and the confusing family histories. For example type I cystinuria heterozygotes have normal cystine excretion and the disease is always clearly recessive. However, type II heterozygotes excrete substantial amounts of cystine and the pedigrees can appear dominant.

Prenatal diagnosis

This has not been described.

Treatment

As the relationships between genotype, cystine excretion, and risk of stone formation especially in childhood become clearer so will the recommendations become clearer. The daily fluid intake must not be less than 3 litre/day in adults and this must include 500 ml before retiring to bed with a nocturnal rise to pass urine and drink a further 500 ml. Keeping the urine dilute over the 24-h period is the difficult part, but may be sufficient treatment for those without stones.

Reduced protein intake diminishes cystine excretion but this is not much used in treatment. Cystine is much more soluble at alkaline pH (> 7.5). Use of sodium bicarbonate is limited by the large doses (6 g/day or more) needed to raise urine pH significantly. High sodium intakes are contraindicated in hypertension or renal failure. In addition, alkaline urine may dispose to the precipitation of calcium salts. However, high fluid intake with potassium citrate supplements is recommended by some in childhood if cystine excretion is high.

Penicillamine treatment produces the much more soluble disulphide—half cystine and half penicillamine and an overall reduction of cystine excretion greater than can be accounted for by disulphide formation. The effective dose (1 to 3 g/day) should reduce the free cystine excretion to around 200 mg/day if stones are to dissolve. It is usual to start at a dose of 125 mg/day and increase over several weeks to full dose. The unwanted side-effects include blood dyscrasias, rash with arthralgia, fever, and lymphadenopathy. A syndrome with skin lesions resembling pseudoxanthoma elasticum, elastosis perforans serpinginosa, may complicate long-term penicillamine use, as may pyridoxine deficiency. This latter effect is prevented by coadministration of 25 to 50 mg pyridoxine daily. Patients on penicillamine need blood counts every 2 weeks initially and then monthly. Regular urinalysis is needed. Proteinuria is common and above 2 g/day may necessitate stopping penicillamine, as do blood dyscrasias or other severe reactions. Penicillamine is a helpful preventive treatment in patients with recurrent stone formation at lower doses. Large doses are reserved for trying to dissolve large calculi, which may take 1 to 2 years. It is usually well tolerated in cystinuria.

a-mercaptopropionylglycine is an alternative to penicillamine to which it has structural similiarities. It has been used less than penicillamine but should be considered in patients showing the serious toxic effects of penicillamine. Captopril is a sulphydryl compound which forms a disulphide with cystine. decreased cystine excretion related to treatment with captopril does occur but no therapeutic use has yet been established for it. Similarly, decreasing sodium intake and excretion reduces cystine excretion but a therapeutic role has not been accepted.

Cystine stones are not easily broken by lithotripsy, but it may still be helpful. Percutaneous removal may have its place for smaller stones, particularly in those who cannot take penicillamine and who are unable to regulate their drinking adequately.

Lysinuric protein intolerance

Clinical

Defective ornithine, lysine, and arginine transport affect the renal tubule and intestine with only minor defects of cystine transport. Stones do not form. At weaning, vomiting and diarrhoea begin. There is nutritional deficiency. failure to thrive, poor appetite, and poor growth are common. Occasional intermittent hyperammonaemic encephalopathy occurs. Osteoporosis is an important part of the clinical picture, with vertebral collapse. Interstitial lung disease causes breathlessness, cough, fever, and reduced arterial PO_2. Intellect is normal or mildly impaired. Pregnancy is associated with haemorrhage during labour. Immunological abnormalities have been reported.

Biochemistry

Plasma concentrations of arginine, ornithine, and lysine are low but citrulline, alanine, and glutamine are increased. Renal clearance values for lysine are 20 to 30 times normal and renal losses may be up to 1 g/day. Less marked increases of orthinine and arginine excretion are found but cystine increases are minor.

Plasma lysine values fail to rise after oral lysine loads or the ingestion of lysyl peptides. Intracellular peptide hydrolysis liberates lysine, which cannot be transported across the basolateral membrane, the site of the transport defect. There is also evidence of a transport defect in cultured fibroblasts but not in red cells. A deficiency of intramitochondrial ornithine due to a transport defect across the mitochondrial membrane may impair the urea cycle, causing hyperammonaemia and orotic aciduria (see below).

Genetics

The disease is an autosomal recessive with a relatively high incidence in Finland (1 in 60 000) compared with the rest of the world. The gene has been ocalized to chromosome 14q coding for a permease-related protein.

Prenatal diagnosis

This is possible with molecular techniques.

Treatment

Hyperammonaemia can be largely prevented by a low-protein diet. However, adequate calorie intake is difficult to sustain in infancy and appetite often remains poor. Protein restriction does not correct lysine deficiency and oral lysine supplementation causes diarrhoea. Oral citrulline (2.5 to 8.5 g/day), absorbed via a different transport system, corrects ornithine and arginine deficiency and lowers plasma ammonia by priming the urea cycle. Acute hyperammonaemic crises are managed with intravenous glucose and intravenous or oral sodium benzoate or phenylbutyrate (see below). Citrulline treatment should be maintained but intravenous citrulline is not readily available. Intravenous ornithine and arginine have been tried.

e-*N*-acetyl lysine has been used in the attempt to overcome lysine deficiency, which may be a factor in the osteoporosis and other problems. Plasma lysine concentrations rise but there is no agreement on its use, and cost and availability are a problem.

The cause of the serious interstitial pneumonia is not clear. It has not apparently responded to antibiotics given for the possibility of pneumocystis infection. Successful treatment with prednisolone has been reported.

Neutral amino aciduria: the Hartnup syndrome

This is an autosomal recessive disorder of neutral amino acid transport across the luminal brush border membrane of kidney and intestine. It does not involve cystine and the basic amino acids, the acidic acids, glycine, or the iminoacids (see Fig. 3). Clinical effects may include a light-sensitive rash on exposed skin, cerebellar ataxia, and mental disturbance, but patients with this disorder frequently remain normal. Affected individuals may respond to nicotinamide, but this does not change the amino acid transport defect. The relative deficiency of nicotinamide is attributed to the losses of the precursor amino acid tryptophan and its impaired intestinal absorption. Bacterial action on unabsorbed tryptophan generates indoles, which appear in the stools and urine and are characteristic of the disorder.

Familial renal iminoglycinuria

The excretion of glycine, proline, and hydroxyproline is raised in the Fanconi syndrome and in the inborn errors of proline or hydroxyproline metabolism when plasma concentrations of these amino acids are raised. Transient raised excretion of the three amino acids is usual in neonates, which reflects the ontogeny of one shared transport system. Genetic iminoglycinuria is an autosomal recessive defect of another transport system. The evidence supports several allelic mutations in the genetic defect with some heterozygotes having raised glycine excretion and some normal amino acid excretion. Familial iminoglycinuria is the consequence of a well worked out transport defect which is clinically harmless.

The g-glutamyl cycle

A possible amino acid transport system

Six enzyme-catalysed reactions link the steps for the synthesis of glutathione and its metabolism (Fig. 5). Glutathione is believed to be transported to the cell membrane, where its antioxidant properties may be important in preventing lipid peroxidation. Tissues with low g-glutamyl transpeptidase levels in the cell membrane transport glutathione into the body fluids and circulation. Some is filtered at the glomerulus. g-glutamyl transpeptidase, bound to the cell membrane of transport epithelia such as the choroid plexus, ciliary body, nephron, and jejunum, has been assigned a role in the membrane transport of amino acids via the formation of g-glutamyl amino acid peptides, which is quite different from free amino acid transport. The peptides are cleaved by g-glutamyl cyclotransferase to free the transported amino acid and the g-glutamyl moiety, which cyclizes to 5-oxoproline (pyroglutamic acid). Cystine is among the amino acids transported in this way and one function of the cycle may be to conserve cystine and, indirectly, cysteine. There is no suggestion of any defect in the cycle in cystinuria. The inherited defects of the g-glutamyl cycle are summarized in Table 6. Some of the links between biochemical defects and clinical manifestations are tentative.

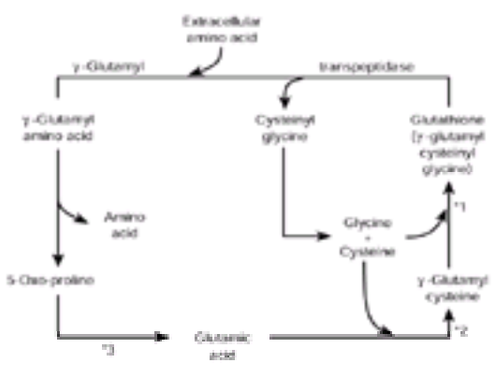

Fig. 5 The g-glutamyl cycle synthesizes glutathione and may play a role in amino acid transport. Asterisked enzymes are: 1, glutathione synthetase; 2, g-glutamyl cysteine synthetase; and 3, 5-oxoprolinase.

Defects of the urea cycle

Amino acids taken in excess of synthetic need are catabolized and the amino group converted to urea. Hyperammonaemia is one of the major metabolic abnormalities in urea cycle defects but is not unique to them (Table 7).

The formation of urea

Nearly all waste nitrogen disposal—10 to 12 g/day—is in the form of urea synthesized in the liver from ammonium ions (NH_4^+) and the a-amino nitrogen of aspartic acid (see Fig. 1). The ammonium nitrogen is incorporated into the first committed synthetic step to urea formation—the production of carbamyl phosphate for which

N-acetyl glutamine is believed to be regulatory. The a-amino nitrogen of aspartic acid comes from many amino acids during their transamination reactions with oxaloacetic acid. It is incorporated during the formation of argininosuccinic acid. Ornithine nitrogen is not incorporated into urea. Bicarbonate provides the carbon moiety of urea but this is not generally regarded as important in acid–base balance.

The source of ammonium ions (NH_4^+) for the generation of carbamyl phosphate is less clear. Glutamine synthesized in skeletal muscle is extensively taken up by the intestine. Glutamine nitrogen is released into the portal blood as alanine, ammonium ions, and citrulline. Apart from these urea precursors, ammonium ions are released into the renal vein by the action of renal glutaminase on glutamine. The generation of ammonium ions within the liver had been attributed to the deamination of glutamate by glutamate dehydrogenase. Transamination reactions involving glutamate are probably more important in linking glutamate to the urea cycle. Within the liver a number of other amino acids are deaminated and may be a source of ammonium for urea synthesis.

The extrahepatic urea cycle enzymes

The urea cycle synthesizes arginine but it has been noted that hepatic transplantation for urea cycle defects does not correct previously low plasma concentrations of citrulline and arginine. The intestine can also synthesize citrulline with the mitochondrial parts of the cycle. Other tissues contain only some of the urea cycle enzymes. Citrulline transported to a variety of tissues with the cytosolic components of the cycle can be used to synthesize arginine via argininosuccinic acid. This extrahepatic synthesis of arginine may be crucial to the body's needs.

The inherited defects of the urea cycle

Four of five inherited defects of the urea cycle (see Fig. 1) have common clinical features but arginase deficiency is different. Quite separately the activity of carbamyl phosphate synthetase can be impaired by a rare genetic defect in *N*-acetylglutamine formation which is not considered here. Ornithine transcarbamylase deficiency is the most common of the defects.

Clinical features of carbamyl phosphate synthetase deficiency, ornithine transcarbamylase deficiency, argininosuccinic acid synthetase deficiency, and argininosuccinic acid lyase deficiency

The neonatal presentation of these conditions is identical. After a brief normal period of 24 to 72 h, poor feeding, lethargy, and vomiting precede the descent to unresponsiveness and hyperammonaemic coma. Argininosuccinic acid lyase deficiency may be less acute and severe than carbamyl phosphate synthetase deficiency, ornithine transcarbamylase deficiency, or argininosuccinic acid synthetase deficiency because argininosuccinic acid excreted at the glomerular filtration rate (there being no tubular reabsorption) is a means of nitrogen excretion, and hyperammonaemia tends to be less severe. In males, ornithine transcarbamylase deficiency is usually fatal, but survival in the other conditions is more likely. Survivors may suffer intellectual impairment and other neurological damage. Only one of the four is X linked (ornithine transcarbamylase deficiency) and female carriers may sometimes present clinically in the neonatal period, presumably because of preponderant inactivation of the X chromosome with a normal gene.

Later presentations come in two broad clinical forms. Mental retardation and epilepsy without any clear neonatal history are well described in argininosuccinic acid lyase deficiency and also in carbamyl phosphate synthetase deficiency, ornithine transcarbamylase deficiency, and argininosuccinic acid synthetase deficiency. Children with argininosuccinic acid lyase deficiency may also show the hair defect of trichorrhexis nodosa, which is not shared by the other urea cycle defects. Another late presentation is with intermittent encephalopathy. This is seen in females who are carriers for ornithine transcarbamylase deficiency, including presentation in the puerperium after a symptomless pregnancy, and males hemizygous for ornithine transcarbamylase deficiency with less severe mutations who have presented in late childhood or the teenage years. Death has been recorded in these late onset encephalopathies. Carbamyl phosphate synthetase deficiency and argininosuccinic acid synthetase deficiency may also present in this way.

Clinical features of arginase deficiency

There is a progressive spastic quadriparesis, most marked in the legs, with psychomotor retardation, epilepsy, and poor growth. Obvious manifestations present in early childhood. Hyperammonaemic coma occurs but hyperammonaemia is less marked than in the other disorders.

Biochemistry

These defects are summarized in Table 8. Hyperammonaemia is preceded by raised plasma alanine and glutamine concentrations and may be accompanied by a rise in transaminases and prolongation of the prothrombin time. The raised excretion of orotic acid in some defects is caused by the accumulation of carbamyl phosphate, which is directed to pyrimidine synthesis (see Fig. 1).

Experimental hyperammonaemia in primates initially causes decreased activity, lethargy, and vomiting, and then hyperventilation and respiratory alkalosis, which have also been recorded in humans. Seizures and coma follow with progressive rise of intracranial pressure and cerebral oedema. The astrocytes, which occupy one-quarter to one-third of brain volume, exhibit marked swelling and mitochondrial change. High astrocyte glutamine concentrations may act osmotically to cause cerebral oedema. Many metabolic changes in hyperammonaemia are secondary to cerebral oedema. Glutamine concentrations ten times normal have been recorded in the cerebrospinal fluid in ornithine transcarbamylase deficiency and argininosuccinic acid lyase deficiency. Other amino acid abnormalities in the cerebrospinal fluid have been described in arginase deficiency. An early effect of hyperammonaemia on amino acid transport across the blood–brain barrier has been described, with tryptophan transport being regarded as particularly important.

Diagnosis

The biochemical defects are diagnostically important (see Table 8). Carbamyl phosphate synthetase deficiency can only be diagnosed when hyperammonaemia is not associated with the biochemical changes of the other urea cycle defects, although a low plasma citrulline value gives a clue. Other causes of hyperammonaemia must be excluded (see Table 7), which requires urinary organic acid analysis, consideration of Reye's syndrome, and acute valproate encephalopathy. Confirmatory enzyme assays on liver biopsy samples may be needed in carbamyl phosphate synthetase deficiency and ornithine transcarbamylase deficiency. Liver function and clotting tests should be checked.

Genetics

With the exception of ornithine transcarbamylase deficiency, the diseases are autosomal recessive. The gene for carbamyl phosphate synthetase is on the short arm of chromosome 2. Inherited deficiency is rare, with 14 mutations described. The enzyme protein may be targeted to the mitochondria by a leader peptide and the mature enzyme constitutes a relatively high proportion of mitochondrial protein. The gene for ornithine transcarbamylase is on the short arm of the X chromosome and its product targeted to mitochondria in a manner similar to carbamyl phosphate synthetase. Functional catalytic trimers form within the mitochondrial matrix. Ornithine transcarbamylase deficiency is associated with a variety of gene defects—insertions, deletions, and point mutations; about 140 have been described.

Argininosuccinic acid synthetase, argininosuccinic acid lyase, and arginase are cytoplasmic enzymes. Argininosuccinic acid synthetase catalyses the synthesis of argininosuccinic acid from citrulline and aspartic acid, requires adenosine triphosphate and magnesium ions, and functions as a tetramer of about 185 000 Da. The gene is on the long arm of chromosome 9. Argininosuccinic acid lyase, which cleaves argininosuccinic acid, functions as a tetramer of about 173 000 Da and the coding gene is on the short arm of chromosome 7. About 12 mutations have been described. Fibroblast studies of argininosuccinic acid lyase indicate that crossreacting material is usually present and correlates poorly with residual enyzyme activity. There are multiple complementation groups and, by implication, multiple alleles at the structural gene locus.

Hepatic arginase, a trimer of submit size around 35 000 Da, cleaving arginine to urea and ornithine, has a locus on the long arm of chromosome 6. A separate mitochondrial arginase is present in kidney.

Antenatal diagnosis

A restriction fragment length polymorphism has been helpful in diagnosis of carbamyl phosphate synthetase deficiency, with fetal liver biopsy and enzyme assay the

only alternatives. Antenatal diagnosis in ornithine transcarbamylase deficiency is complex. If the mother is known to be a carrier from pedigree analysis or biochemical testing, three approaches are possible:

1. If the mutation is known within the family then direct examination of the fetal genotype is possible using appropriate probes, but this occurs in a minority of cases.
2. If a restriction fragment polymorphism is linked to the mutant gene in the family then this approach may be possible.
3. If no such information is available then sexing the fetus followed by fetal liver biopsy and enzyme assay in the male is the only approach left.

Antenatal diagnosis for argininosuccinic acid synthetase deficiency is also difficult. The enzyme can be assayed in amniocytes and placental villus material, but it is more reliable to culture amniocytes with radioactive citrulline and measure the incorporation of the radioactive products into cell protein. Amniotic fluid citrulline concentrations may help. Molecular analysis is possible in argininosuccinic acid lyase deficiency. analysis of amniotic fluid for argininosuccinic acid or enzyme assay on cultured amniocytes have been used successfully. Arginase deficiency has been detected on fetal red cells and a number of mutations have now been identified.

Heterozygote detection in ornithine transcarbamylase deficiency

Because of its X-linked inheritance carrier detection is particularly important. Pedigree analysis including DNA studies where necessary, or investigation of frank symptomatic episodes may settle the issue. The symptomless female can be a problem, however. Protein loading with serial measurements of plasma ammonia and urinary orotic acid may reveal the biochemical defect but may also cause serious symptoms. Allopurinol causes a greater excretion of orotic acid and orotidine in carrier females than in normals and forms the basis of an acceptable safe test of heterozygosity. It may fail to identify some carriers.

Treatment and prognosis

The management of acute encephalopathy involves reducing the need to synthesize urea. Dietary protein is stopped and endogenous protein breakdown suppressed by a high oral carbohydrate intake or using intravenous 10 to 20 per cent dextrose and insulin if needed to control blood glucose concentrations. The blood ammonia is lowered in the neonatal period by peritoneal dialysis or haemodialysis (more effective). Slower methods useful in carbamyl phosphate synthetase deficiency and ornithine transcarbamylase deficiency include the use of intravenous or oral sodium benzoate, which is excreted as its glycine conjugate hippuric acid, so raising nitrogen excretion. The use of sodium phenylbutyrate, which is excreted as phenyl acetylglutamine, is more effective. Serious toxicity from either benzoate or phenylbutyrate overdose is possible. in argininosuccinic acid synthetase and argininosuccinic acid lyase deficiencies, oral or intravenous arginine is an urgent and important therapy to remedy deficiency. In argininosuccinic acid lyase deficiency in particular, plasma ammonia levels fall when arginine is administered. The prognosis for severe neonatal illness is poor (see above) especially if plasma ammonia concentrations are over 1000 µmol/litre.

Maintenance treatment of all urea cycle defects (including arginase deficiency) between encephalopathic episodes involves protein restriction to the minimum required for growth and development and supplementation with arginine in argininosuccinic acid synthetase deficiency and argininosuccinic acid lyase deficiency. The continuous use of oral sodium benzoate or sodium phenylbutyrate in carbamyl phosphate synthetase deficiency and ornithine transcarbamylase deficiency may be needed to maintain low plasma ammonia concentrations. Late onset forms of the urea cycle diseases carry a better prognosis, but arginase deficiency seems relentlessly progressive. Babies with argininosuccinic acid lyase deficiency picked up by neonatal screening but who have not developed early clinical illness are reported to develop with normal IQ on large arginine supplements and a low protein intake. Others do less well and urea cycle defects generally have a poor prognosis.

Valproate should be avoided in the treatment of seizures in urea cycle defects and ornithine transcarbamylase carriers because it may precipitate coma.

Liver transplantation has sometimes been carried out for urea cycle defects. Selecting patients and balancing the risks is extremely difficult. Gene transfer therapy has been attempted but the problems of suitably safe vectors and stable expression remain.

The disorders of carbon chain metabolism

The classification in Table 2 is a useful approach, but many different catabolic pathways and associated clinical abnormalities necessitate separate consideration of individual amino acids (or groups of them) with their relevant vitamin coenzymes. Pyridoxine, because of its central and varied roles, is considered separately below. The relatively 'non-specific' nature of some biochemical abnormalities is stressed again.

Pyridoxine

Pyridoxal phosphate is the coenzyme in amino acid transaminations, decarboxylations, and deaminations. Considerable molecular detail of its role in transamination has been worked out. It is also the coenzyme in the synthesis and breakdown of cystathionine in the trans-sulphuration pathway. The normal dietary pyridoxine intake is 2 to 3 mg/day but a number of diseases respond to doses of 10 to 500 mg/day. These include deficiencies of ornithine aminotransferase, cystathionine b synthase, cystathionase, hyperoxaluria due to peroxisomal glyoxylate aminotransferase deficiency, and some neonates with seizures considered due to defective glutamine decarboxylase, the enzyme which generates g-aminobutyric acid (see later).

'Non-specific' biochemical defects

The multiple causes of hyperammonaemia have been listed (see Table 7). Elevations of plasma glycine may also be non-specific and not necessarily a result of primary enzyme defects in glycine metabolism. Increases of glutamine and alanine in plasma are common in the early stages of ammonia accumulation. Hypoglycaemia is frequent in the organic acidurias as well as in specific defects of gluconeogenesis or glycogen metabolism. Alanine concentrations rise in lactic acidosis.

Defects of ornithine metabolism

P>Ornithine is a non-protein amino acid upon which the synthesis of urea takes place (see Fig. 1) and which is regenerated once the urea moiety is split off. It is also produced when arginine reacts with glycine to produce guanidinoacetate, the precursor of creatine. Ornithine-†-amino transferase produces glutamic semialdehyde, which cyclizes to pyrroline-5-carboxyllic acid, and is also produced from proline. The decarboxylation of ornithine produces the diamine putrescine.

Deficiency of ornithine-†-aminotransferase: gyrate atrophy

Clinical

The major abnormality is an atrophy of choroid and retina, beginning as a small yellowish spot and increasing to a circular lesion edged with pigment giving an 'atypical retinitis pigmentosa' appearance. Children present with myopia and decreased night vision progressing to blindness in middle life. Cataracts also develop but optic discs, cornea, and iris remain normal. A few patients develop mild proximal muscle weakness. Microscopic abnormalities of skeletal muscle fibres are found. Magnetic resonance imaging shows changes in the central nervous system, but the longer-term clinical implications are uncertain.

Biochemistry

Plasma ornithine values range from 400 to 1000 µmol/litre (normal 75 µmol/litre) with high concentrations in cerebrospinal fluid and aqueous humour. 400 to 900 mg/day is excreted with increased amounts of arginine and lysine (competitive inhibition of reabsorption).

The activity of ornithine-†-aminotransferase is low in liver and skeletal muscle. Most affected patients have less than 1 per cent of normal activity in fibroblasts. Some have values up to 5 to 6 per cent and some enzyme-deficient lines show marked increase of activity with very high concentrations of pyridoxal phosphate.

Diagnosis

The clinical picture and the amino acid defects are adequate means of diagnosis. Enzyme assays can be used to confirm it.

Genetics

It is an autosomal recessive with the highest incidence in Finland, (where it may be as high as 1 in 50 000). There are several mutants, as evidenced by complementation studies. The gene has been mapped to chromosome 10q. Two pseudogenes exist on the X chromosome. Different mis-sense mutations have been described in pyridoxine responsive and non-responsive forms. Splicing defects have also been described. Over 50 mutations have been described in gyrate atrophy.

Treatment

Despite encouraging therapeutic studies on a mouse model there are no reports of clinical improvement in humans but deterioration may be slower in patients whose plasma ornithine levels fall with pyridoxine treatment (500 mg/day or less). Low-arginine diets may reduce plasma ornithine concentrations as do large doses of lysine given to augment renal ornithine excretion. Creatine has been given and has been reported to improve muscle histology, but ocular deterioration continues. Local proline deficiency in the retina has been suggested as a cause of the retinal degeneration. Proline supplementation does not stop disease progression. The best approach if patients do not respond to pyridoxine maybe a combination of diet and high lysine doses. Studies on siblings in affected families indicate that the development of retinal changes is at least delayed by control of the plasma ornithine concentration.

Hyperornithinaemia with hyperammonaemia and homocitrillinuria

Clinical

Hyperornithinaemia with hyperammonaemia and homocitrillinuria is referred to as the **HHH** syndrome. Intermittent hyperammonaemic encephalopathy with vomiting, drowsiness, and coma may date back to infancy, or patients may present much later. Impairment of IQ from low normal to more severe retardation, with epilepsy and frank neurological features, is another form of presentation. Growth tends to be poor. Chorioretinal atrophy has been reported in one patient but to date has not been commonly seen.

Biochemistry

Intermittent hyperammonaemia, with plasma ornithine values three to ten times normal and increased excretion of orotic acid are believed to result from impaired transport of ornithine into the mitochondria which leads to the accumulation of carbamylphosphate. This increases orotic acid formation and the production of homocitrulline by the transcarbamoylation of lysine.

Genetics

It is an autosomal recessive. A gene for an ornithine transporter across the mitrochondial membrane (*ORNT1*) has been mapped to chromosome 13q. It has been reported that three mutant alleles in this gene account for a high proportion of HHH patients in North America.

Treatment

Moderate protein reduction (1 g/kg/day) reduces plasma ammonia and ornithine concentration. Ornithine supplementation may then lower plasma ammonia further by raising intracellular ornithine concentrations, which may induce entry of more ornithine into the mitochondria. In siblings presenting as adults, treatment with citrulline and sodium phenylbutyrate has decreased plasma ammonia, increased plasma ornithine, and relieved episodic confusional episodes. The outcome of treatment in the longer term is not known.

Defects of phenylalanine metabolism

The importance of tetrahydrobiopterin

The hyperphenylalaninaemias are a group of disorders characterized by defective hydroxylation of phenylalanine to tyrosine and plasma phenylalanine values above the normal fasting range of 40 to 80 µmol/litre. Tetrahydrobiopterin is the required coenzyme for this hydroxylation and high phenylalanine values may be due to defects in the apoenzyme or the generation of tetrahydrobiopterin.

An adult phenylalanine intake is about 3 to 4 g/day, one-quarter of which is incorporated into protein and three-quarters hydroxylated to tyrosine (Fig. 6). Adults need about 1 g/day, but in classic severe phenylketonuria health is maintained on half this. Transamination to phenylpyruvic acid and decarboxylation to phenylethylamine assume much greater importance in phenylketonuria because they occur only at elevated phenylalanine concentrations.

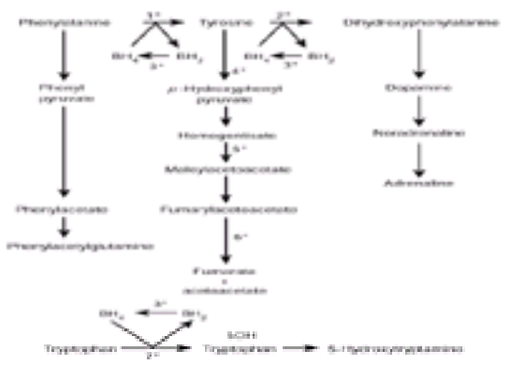

Fig. 6 The metabolism of phenylalanine and tyrosine and the role of tetrahydrobiopterin. The asterisked enzymes are: 1, phenylalanine hydroxylase; 2, tyrosine hydroxylase; 3, dihydrobiopterin reductase; 4, tyrosine aminotransferase; 5, homogentisic acid oxidase; 6, fumaryl acetoacetate hydrolyase; and 7, tryptophan hydroxylase.

Classic phenylketonuria

Clinical

Phenylalanine values are higher than 1200 µmol/litre (sometimes much higher). Untreated, phenylketonuria almost invariably causes severe mental retardation, with IQ values only occasionally above 60, and most often well below. a few patients have normal IQ values despite the biochemical defect; some female patients have been discovered only because of abnormalities in their offspring (see below). Brain phenylalanine concentrations measured by magnetic resonance spectroscopy have been lower than expected in some of these patients probably accounting for the preservation of IQ. Both microcephaly and epilepsy are common. About one in 20 untreated patients develop neurological problems in adult life, usually spastic paraparesis but sometimes extrapyramidal features. Pigmentary deficiency in the iris and hair are features of the untreated disease and so is eczema.

Milder variants

Mutations with greater residual enzyme activity produce phenylalanine values of 300 to 1200 µmol/litre. Those over 480 µmol/litre should be treated: some were not

with variable outcome for IQ.

Biochemistry

Plasma phenylalanine concentrations are elevated to 20 to 60 times, being highest in babies. Phenyl pyruvic acid which is converted to phenyl lactic acid, phenylacetic acid, and phenylacetyl glutamine accumulates with phenylethylamine. The ketone phenylpyruvic acid in the urine gives the disease its name and a green colour in the ferric chloride test. The defective enzyme phenylalanine hydroxylase, which requires tetrahydrobiopterin as a cofactor, has been found only in the liver in humans. It has never been found in the brain of any species. Phenylalanine hydroxylase may be tetrameric or trimeric with units of molecular weight between 50 000 and 60 000.

Pathology

The pathology of phenylketonuria is not clear. Phenylalanine itself is probably the damaging agent but there is controversy about the mechanism: relative tyrosine deficiency may also be important, reflected in the pigment deficiency and changes in neurotransmitters. High phenylalanine concentrations are associated with impaired brain growth and probably fewer nerve cells. Phenylalanine inhibits an enzyme important in sulphation of myelin intermediates and myelin formation is abnormal. In animal experiments high phenylalanine concentrations reduce transport of other amino acids at the blood–brain barrier and at the placenta. In addition, many *in vitro* biochemical processes (e.g. protein synthesis) are impaired by high phenylalanine concentrations. Patients with classic phenylketonuria also have low concentrations of homovanillic acid and 5-hydroxyindoleacetic acid in the cerebrospinal fluid, indicative of possible deficiency of the neurotransmitters dopamine, noradrenaline, and 5-hydroxytryptophan. Dietary treatment restores normal concentrations in the cerebrospinal fluid.

Diagnosis

All newborns in the United Kingdom should be screened for raised phenylalanine values between the sixth and tenth day of life, either by Guthrie's bacterial inhibition assay, chromatography, or tandem mass spectometry. Phenylalanine values greater than 240 µmol/litre are rechecked and, if confirmed, are investigated. Raised phenylalanine values are seen in the important variants due to defects in tetrahydrobiopterin synthesis and these must be excluded as they require specific treatment. Transient neonatal hyperphenylalaninaemia is probably less common now that cows' milk, with its relatively high protein content, is used less in infancy, but it must be distinguished from permanent forms. Liver disease must be excluded.

Genetics

The disease is autosomal recessive, with an incidence in Western countries of 1 in 8000 to 12 000 live births. It is rare in Finland and Japan. One in 50 people carry a mutant gene. These include splicing mutations, deletions, and mis-sense mutations. The location on chromosome 12 has been confirmed. The majority of patients are compound heterozygotes rather than being homozygous for a single mutation. Residual enzyme activity in liver biopsies has correlated fairly well with *in vivo* studies on the conversion of deuterated phenylalanine to tyrosine and there is growing information on which genotypes cause the most severe functional defects in the enzyme. Over 400 mutations have been described. The contribution which other genes (e.g. for amino acid transport into the central nervous system) may make to the disease manifestations may, however, become clearer.

Antenatal diagnosis

Restriction fragment polymorphisms in linkage disequilibrium with these mutations have been useful in some families for antenatal diagnosis. Patient demand for antenatal diagnosis has been relatively low.

Treatment

Natural protein intake is reduced to provide just what is necessary for growth and development while keeping the plasma phenylalanine between 120 and 360 µmol/litre using the Guthrie test or other technique for regular monitoring. These are lower phenylalanine values than were once recommended because outcome in terms of IQ is closely related to the control of abnormally high values. Persistently low values may also adversely affect outcome. Despite normal or near normal IQ results, more subtle neuropsychological defects have been described in well-treated phenylketonuria patients and may be very important scholastically.

In infancy, milk restriction with supplements is relatively easy. Later it is necessary to introduce other foods on an exchange basis using tables that define the weight of the food containing 1 g of protein (roughly 50 mg phenylalanine). Fruits and some vegetables very low in protein are allowed freely. Adults with classic phenylketonuria tolerate only three to four exchanges, which provide about the same amount of phenylalanine as the free foods. These diets are supplemented with phenylalanine-free amino acid mixtures, minerals, and vitamins. Specially produced low-protein products make the diet more palatable.

Regression of IQ when diets were stopped in later childhood has led to continuation of dietary treatment into the teenage years. Patients generally have not suffered when diets have stopped at 15 or 16 years of age. However, there is no follow-up of a substantial number with respect to IQ change who have been off diet for 20 years or more, and there is concern about possible neurological deterioration.

High plasma phenylalanine concentrations may produce a pharmacological impairment of mental function revealed by psychological tests in short-term studies, which improve when concentrations fall. Long-term damage to intellect or neurological function is another issue. A small number of patients who were not on diet in adult life have developed spastic paraparesis, epilepsy, or extrapyramidal features. These may improve on diet. All these have cerebral changes on magnetic resonance imaging, as do an appreciable proportion of those off diet without neurological manifestations. The imaging changes also improve on diet regardless of whether there were clinical manifestations or not. Together with the known neurotransmitter defects there is a genuine concern for the long-term welfare of patients. Diet for life is restricting and costs £7000 to £8000 annually for the diet alone. There is an urgent need for more information.

Maternal phenylketonuria

The retrospective review of Lenke and Levy in 1980 did much to emphasize the adverse fetal effects of maternal hyperphenylalaninaemia (Table 9). Experience in other centres with large clinics broadly supports these figures. Microcephaly and congenital heart disease in the offspring of mothers returning to diet at the seventh or eighth week emphasizes the need for preconception diet. This is the best policy. Starting dietary measures very early in the first trimester (5 to 6 weeks) lowers the incidence of impaired brain development, but an increased risk certainly remains to the face and heart.

The ratio of fetal to maternal phenylalanine plasma levels is around 1.5 to 1.7 because of active placental transport. Maternal values should be controlled at between 100 and 250 µmol/litre, which requires very careful monitoring twice weekly. Some values will rise above this in the critical first trimester when tolerance is very low and nausea restricts calorie intake. Dietary tolerance in the mother increases from about week 18 due to increased requirement for growth by the fetus and uterus, but also probably because phenylalanine hydroxylase in the fetal liver can be detected early in the second trimester (Fig. 7). There is already clear evidence that lower maternal phenylalanine values result in neonates of higher birth weight and larger head circumference. Dietary control before conception prevents congenital heart disease.

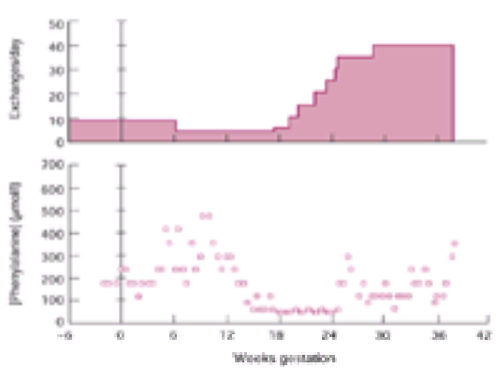

Fig. 7 Diet for a phenylketonuric mother illustrating the marked rise in phenylalanine tolerance in the second half of the pregnancy. (From Fernandes *et al*. (1990) with permission of Springer.)

Defects of biopterin metabolism

In the hydroxylation of phenylalanine the cofactor tetrahydrobiopterin is consumed and must be regenerated. A deficiency of tetrahydrobiopterin adversely affects the function not only of phenylalanine hydroxylase, but also of tyrosine hydroxylase and tryptophan hydroxylase (Fig. 7). Tyrosine hydroxylation is needed for the synthesis of noradrenaline and dopamine, and tryptophan hydroxylation for the production of 5-hydroxytryptophan. Tetrahydrobiopterin is therefore crucial to the production of neurotransmitters. The supply of this coenzyme is impaired in several enzyme defects. All produce hyperphenylalaninaemia, which may not be marked, and all produce progressive neurological disability despite a low-phenylalanine diet. About 1 to 2 per cent of newborns with abnormally raised phenylalanine values have a deficiency of tetrahydrobiopterin.

Dihydropteridine reductase deficiency

Clinical

Progressive neurological deterioration occurs with psychomotor retardation, epilepsy, pyramidal, and extrapyramidal features, especially the latter. Calcification occurs in the cerebral hemispheres.

Biochemistry

Plasma phenylalanine values are elevated. The enzyme dihydropteridine reductase is a dimer or tetramer of four units, each 25 000 Da. It has a wide tissue distribution.

Diagnosis

The most reliable test is an enzyme assay on red cells. It can be carried out on dried blood spots. Oral loading tests with tetrahydrobiopterin may be useful as the plasma phenylalanine may then fall, but as it is not regenerated when the enzyme is deficient the results may be equivocal. Urinary biopterin analyses are needed in the differential diagnosis of these defects.

Genetics and prenatal diagnosis

The disease is an autosomal recessive and the enzyme assay can be carried out on cultured anmiocytes. There are crossreacting material-positive and -negative forms. The gene is on chromosome 4p encoding a protein of 244 amino acids functioning as a homodimer with over 20 described mutations.

Treatment

A low-phenylalanine diet is combined with the administration of L-dopa, 5-hydroxytryptophan, and, in some cases, folinic acid. Early treatment has been reported to give good results. Monitoring of neurotransmitters and folate in the cerebrospinal fluid may help treatment.

Guanosine triphosphate cyclohydrolase deficiency and 6-pyruvoyltetrahydrobiopterin synthase deficiency

The clinical features are similar to those of dihydropteridine reductase deficiency. Intermittent hyperthermia has been described. All urinary biopterin and neopterin values are low in the cyclohydrolase deficiency whereas 6-pyruvoyltetrahydrobiopterin deficiency has high neopterin values and low biopterin values. Tetrahydrobiopterin is used in treatment because, in the presence of dihydropteridine reductase, it can be regenerated from dihydrobiopterin. However, the clinical outcome is not assured and there is concern that tetrahydrobiopterin does not easily enter the central nervous system. Treatment, therefore, is also being attempted with low-phenylalanine diet, L-dopa, and in addition, 5-hydroxytryptophan. From reports on Saudi Arabian families with a high incidence of 6-pyruvoyltetrahydrobiopterin synthase deficiency, tetrahydrobiopterin is said to produce a good outcome if started very early in life.

Disorders of tyrosine metabolism

The steps in tyrosine metabolism starting with the rate-limiting step—the conversion to *p*-hydroxyphenyl pyruvic acid by tyrosine amino-transferase—are outlined in Fig. 6. They are the means of production of the catecholamines, dopamine, and the principal pigments of hair and skin. Diagnosing a specific disorder of tyrosine metabolism needs consideration of the non-specific elevations of plasma tyrosine and methionine seen in liver disorders of various aetiologies and the frequency of transient neonatal tyrosinaemia.

Neonatal tyrosinaemia

An increase of plasma tyrosine concentration and excretion of tyrosine and phenolic acids was commonly seen in premature infants given cows' milk feeds. Lower-protein infant feeds approximating to breast milk have reduced the incidence greatly. Transient deficiency of *p*-hydroxyphenylpyruvate oxidase is considered the unproven cause and appears to be harmless. It responds to reducing any high protein intake and sometimes to ascorbic acid. A repeat tyrosine measurement is indicated to exclude other persistent causes of a raised tyrosine.

Tyrosinaemia type I

Clinical

An acute presentation occurs in the early weeks of life with failure to thrive, vomiting, hepatomegaly, fever, oedema, and epistaxis. Death from hepatic failure occurs within the first year. A milder more chronic presentation is compatible with survival for several years with chronic liver disease, a renal tubular Fanconi syndrome with hypophosphataemic rickets, and sometimes abdominal pain and neuropathy suggestive of acute porphyria (see below). Hypertrophic obstructive cardiomyopathy has been described. One-third of patients progress to hepatocellular carcinoma of the liver.

Biochemistry

Deficiency of fumarylacetoacetate hydrolyase (see Fig. 6) is the cause. A raised plasma tyrosine (and often a raised methionine) result. Succinyl acetone is excreted, formed from fumarylacetoacetate, which also inhibits porphobilinogen synthesis so that †-amino laevulinic acid increases in the urine. Human fumarylacetoacetate hydrolyase is a dimer with a monomer molecular weight of 43 000. Activity is found in liver, kidney, fibroblasts, lymphocytes, and amniocytes.

Diagnosis

Raised plasma tyrosine, succinyl acetone, and †-aminolaevulinic acid excretion and a Fanconi syndrome are the biochemical markers. Fumarylacetoacetate hydrolyase can be assayed in lymphocytes or fibroblasts. It is non-specifically depressed in the liver in a variety of liver diseases. A pseudodeficiency gene in the general population causes low '*in vitro*' assay results for fumarylacetoacetate hydrolyase but no clinical illness. Untreated plasma tyrosine values in proven tyrosinaemia type I may be normal, creating another diagnostic problem. Liver function tests are abnormal.

Genetics

The disease is an autosomal recessive. The acute neonatal form lacks immunologically detectable enzyme protein in contrast to the more chronic form. The fumarylacetoacetate hydrolyase gene has been localized to chromosome 15 and a variety of mutations identified.

Prenatal diagnosis and carrier detection

The measurement of succinyl acetone in amniotic fluid and fumarylacetoacetate hydrolyase in cultured amniocytes or chorionic villus samples forms the basis of prenatal diagnosis. In approximately 5 per cent of families one parent carries both a true mutant allele and the pseudogene, which lowers the parental enzyme activity into the homozygous disease state and causes confusion in prenatal diagnosis. The pseudogene also makes the detection of carriers less certain. Where the mutation is known molecular prenatal diagnosis should be possible and preferable.

Treatment

Restricted intake of tyrosine and phenylalanine may reduce the excretion of succinyl acetone and produce regression of the Fanconi tubular defects. Rickets may require treatment however. The liver disease is not cured. The risk of hepatocellular carcinoma remains. Therapeutic trials are in progress using a metabolic inhibitor, NTBC, which blocks the pathway before homogentisic acid thus reducing the production of toxic metabolites. The results are encouraging, with over 200 patients under follow-up and a greatly reduced incidence of liver damage and hepatic carcinoma since NTBC was introduced in 1991.

Liver transplantation remains the treatment of choice for some who do not respond to NTBC which may also improve renal function, although some succinyl acetone continues to be excreted. transplant timing is immensely problematic. Neither a-fetoprotein nor ultrasound are totally reliable at detecting early malignant change. After liver transplantation the future is uncertain. Chronic renal failure has occurred.

Tyrosinaemia type II

Clinical

Corneal erosions and dendritric ulcers may form within a few months of birth with later scarring, nystagmus, and glaucoma. Corneal transplants can be valuable. The skin lesions may begin after the eye lesions with blistering, painful palms and soles, and hyperkeratosis. Tongue changes have been described. Mental retardation is an inconstant feature but language defects may be more common with possible impaired co-ordination and self-mutilation. The pathology is considered secondary to the deposition of tyrosine crystals in cells precipitating an inflammatory response.

Biochemistry

Tyrosine aminotransferase, which is deficient, catalyses the formation of *p*-hydroxyphenylpyruvic acid (see Fig. 8) and requires pyridoxal phosphate and a-ketobutyrate. It is a liver enzyme, absent from brain, heart, and kidney, with a subunit size of 49 000 which forms dimers. The enzyme is synthesized rapidly, induced by steroids, and has a short half-life. The gene has been mapped to chromosome 16.

Plasma tyrosine values reach 20 times normal (normal 40 to 100 µmol/litre) in younger patients and 10 times normal in others. There is increased excretion of tyrosine, *N*-acetyl tyrosine, and tyramine; there is no Fanconi syndrome. Excreted phenolic acids come from phenylalanine or tyrosine metabolized at high concentrations by other enzymes.

Diagnosis

The clinical features and amino acid analyses are usually sufficient.

Treatment

A low-tyrosine, low-phenylalanine diet has been used to produce rapid improvement of skin and eye manifestations. There is little information on the neurological results of treatment and little on the degree of dietary control needed to sustain clinical improvement.

Alcaptonuria

Clinical

Presentation in infancy occurs only if discoloration of the urine is noticed. It is usually normal when passed, but darkens on standing (more rapidly at alkaline pH) to deep brown or almost black. Back pain begins in the second and third decade with increasing stiffness due to intervertebral disc degeneration. Involvement of the hips, knees, and shoulders follows. Greyish discoloration of cartilage is seen in the pinna, and pigment is deposited in the sclera. Abnormal pigmentation is seen in the heart valves and pigmented stones are common in the prostate. Discoloration of cartilage, tendons, and ligaments is more orange when seen microscopically (ochronosis). The prognosis for the joints is poor. By the fifth decade the lumbar spine is likely to be rigid and other joints will be seriously affected.

Pathology

The pigment is assumed to be a polymer derived from homogentisic acid after enzymatic conversion to the corresponding quinone (homogentisic acid polyphenol oxidase). Virchow described the internally pigmented cartilages including the larynx, tracheal rings, and ribs. The joint cartilages become thinned and fragmented. The intervertebral discs calcify.

Biochemistry

Homogentisic acid oxidase contains ferrous iron and several –SH groups. Molecular oxygen is consumed in splitting the ring to convert homogentisic acid to maleylacetoacetic acid. Homogentisic acid produces a false positive for glucose in the 'Clinitest' reaction but the reaction mixture quickly darkens because of the alkaline pH. There is no reaction with glucose in standard dipstick tests for glucose. Affected individuals excrete 4 to 8 g of homogentisic acid per day.

Diagnosis

In the presence of the clinical symptoms simple urine tests virtually make the diagnosis secure. The homogentisic acid can be demonstrated on thin-layer chromatography and quantitated by gas–liquid chromatography or high-pressure liquid chromatography.

Genetics

It is an autosomal recessive with an incidence of only 1 in 200 000 but small populations of very high incidence exist, especially in the former Czechoslovakia and the Dominican Republic. The gene has been localized to chromosome 3q and a variety of mutations described.

Antenatal diagnosis

This has not been required but is theoretically possible.

Treatment

The amount of homogentisic acid produced is decreased by a low-protein diet. It is very probable that specifically designed low-phenylalanine and low-tyrosine diets would lower the production still further. There seems to be no demand for such a restricting diet to deal with an arthritis which begins only in adult life and progresses slowly over many years. Ascorbic acid may slow the rate of oxidation of homogentisic acid to pigment precursors but there are no data on its clinical usefulness. Theoretically NTBC may be beneficial, but its current high cost would discourage trials and the longer-term toxicity not known.

Albinism

Tyrosinase deficiency in melanocytes prevents the conversion of *p*-hydroxyphenylalanine to dihydroxyphenylalanine and thence to dopaquinone, the precursor for pigment formation in the skin, the iris, the fundus, and the inner ear. The absence of pigment is the characteristic of the group of disorders referred to together as albinism. It is a complex group of ten or more types. The manifestations are primarily in the skin and eye.

The three main types are compared in Table 10. However, two points worth noting are: oculocutaneous albinism may also occur in association with a bleeding tendency—the Hermansky Pudlak syndrome—and in association with the leucocyte killing defect—the Chédiak–Higashi syndrome. Ocular albinism, too, in some genetic forms, occurs in association with nerve deafness.

Oculocutaneous albinism is characterized by structural optic tract defects. All the fibres at the optic chiasma cross over so there are no ipsilateral fibres and no binocular vision. The geniculate bodies and the radiation onwards to the cortex are also structurally abnormal. The inner ear lacks pigment that is normally said to be protective against noise trauma. The predisposition to squamous carcinoma of the skin is important. Further details are given in Table 10.

Disorders of sulphur amino acid metabolism

The trans-sulphuration pathway transfers the sulphur of methionine to serine to produce cysteine (Fig. 8). Methionine adenosyltransferase, with widely distributed isoenzyme forms, produces *S*-adenosylmethionine, the donor in a variety of methylation reactions. In creatine formation alone adult males may utilize more methyl groups than provided by dietary methionine. *S*-adenosyl homocysteine is cleaved to homocysteine, the sulphhydryl compound which exists in reversible equilibrium with its disulphide homocystine. Half of the homocysteine formed goes through the trans-sulphuration pathway and the other half takes a methyl group from betaine (betaine methyltransferase) or 5-methyltetrahydrofolic acid (methionine synthase). The latter is a cobalamin-dependent enzyme which is functionally impaired in defects of vitamin B_{12} metabolism. The remethylation of homocysteine is also impaired if the activity of the reductase that generates 5-methyltetrahydrofolate is inadequate.

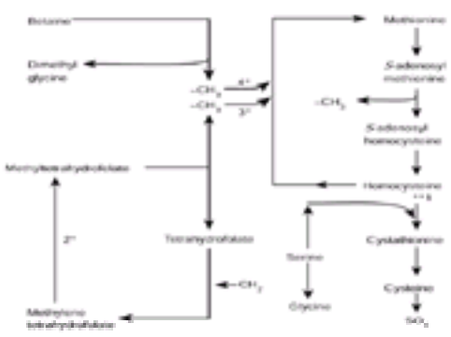

Fig. 8 The trans-sulphuration pathway from methionine to cysteine is shown on the right and the remethylation of homocysteine on the left. Asterisked enzymes are: 1, cystathionine synthase; 2, methylene tetrahydrofolate reductase, 3, methionine synthase; and 4, betaine methyltransferase.

When accumulation of homocystine results from defects of homocysteine remethylation plasma methionine concentrations are low. They are high when homocystine accumulates from impaired activity of cystathionine synthase, which forms the thioether cystathionine, an intermediate subsequently cleaved to produce the sulphydryl compound cysteine. Further metabolism of cysteine produces inorganic sulphate for excretion.

Cystathionine b synthase deficiency (homocystinuria)

Clinical

The classic clinical features in the older child and adult are mental retardation, lens dislocation, a thrombotic tendency, and skeletal abnormalities. Mental retardation, affecting two-thirds of patients, is sometimes gross but more commonly IQ values are around 65. Others are in the normal range with a few high values. Patients responsive to pyridoxine (vitamin B_6) (see below) have generally higher IQ values than non-responsive patients. Seizures affect about one-fifth and a few patients show extrapyramidal features, sometimes with severe involuntary movements. Psychiatric disturbances have been described but an increased frequency of schizophrenia is unproven.

Lens dislocation is acquired, usually in the preschool years, but later dislocation is well recognized especially in pyridoxine-responsive patients, and a few have not developed it even in adult life. Monocular and binocular blindness has been relatively frequent due to secondary glaucoma, staphyloma formation, buphthalmos, and retinal detachment.

The skeletal abnormalities include osteoporosis and spontaneous crush vertebral fractures. The common abnormalities seen in Marfan's syndrome—high arched palate, pectus excavatum or carinatum, genu valgum, pes cavus or planus, scoliosis—are all well recognized in homocystinuria. Arachnodactyly is less common and the fingers not infrequently (and elbows occasionally) show mild flexion contractures. Skeletal disproportion with a crown pubis length less than the pubis heel length is usual (Fig. 9).

Fig. 9 Child with cystathionine synthase deficiency. Note the kyphosis and short trunk.

Pathology

Thromboembolism is a major cause of morbidity and the main cause of the relatively high premature mortality. Thromboses have been described in a wide variety of arteries and veins: cerebral, coronary, mesenteric, renal, and peripheral. About 50 per cent are in peripheral veins with associated pulmonary emboli in many. Postoperative and postpartum thrombotic risks are high. Premature atheromatous vascular degeneration has been described, as has arterial aneurysm formation.

Homocysteine may interfere with crosslinking in collagen. Degeneration of zonular fibres around the lens causes the lens dislocation but these fibres are not collagen. Recent work on fibrillin in Marfan's syndrome suggests that defects in this protein may be important in cystathionine b synthase deficiency. There is still no accepted explanation for the relationship of homocystine/homocysteine to endothelial damage, platelet abnormalities, thromboses, and vascular change. Heterozygotes for the enzyme defect may be disposed to premature vascular disease and thrombosis. Finally, although the cerebral hemispheres normally have a high concentration of cystathionine, which is reduced in cystathionine b synthase deficiency, this is not considered a cause of the mental deficiency, and neither does diffuse vascular disease seem relevant to this problem.

Biochemistry

Elevated plasma methionine values between 100 and 500 µmol/litre (sometimes higher) are seen with plasma homocystine values of 50 to 200 µmol/litre (Fig. 8). A mixed disulphide (half homocysteine, half cysteine) is always present at concentrations somewhat below homocystine. Total homocysteine measured by high-performance liquid chromatography is used by some laboratories for diagnosis and monitoring treatment. This includes both homocysteine moieties of homocystine, the homocysteine moiety of the mixed disulphide, and the homocysteine bound to plasma proteins. The urinary excretion of homocystine is usually 250 to 1000 µmol/day, which accounts for only about 10 to 20 per cent of ingested methionine sulphur. The active cystathionine b synthase apoenzyme, which requires pyridoxal phosphate, is a tetramer of 63 kDa units found predominantly in liver but also in brain and intestinal mucosa. Much lower levels of activity can be found in cultured fibroblasts and stimulated lymphocytes. Residual hepatic activity of 1 to 2 per cent occurs in affected patients, this may increase two- to fourfold in pyridoxine-responsive cases. In some patients higher residual activities up to 9 to 10 per cent have been found. Heterozygotes have 25 to 45 per cent of normal activity. *In vitro* responsiveness to pyridoxal phosphate can also be detected in cultured fibroblasts.

Diagnosis

The urine gives a positive nitroprusside test (it is also positive in cystinuria). The amino acid defects are diagnostic if the plasma is deproteinized promptly to minimize binding of homocystine to protein. Plasma methionine concentrations are usually well above the normal values of 15 to 30 µmol/litre and homocystine is present in plasma and urine.

Genetics

The disease is an autosomal recessive with a birth incidence of about 1 in 40 000. The gene is on chromosome 21 with over 50 mutations already described.

Antenatal diagnosis

This has so far rested on enzyme assays on cultured amniotic cells. It is likely that work on the mutant gene will supersede this.

Treatment

Oral pyridoxine may rapidly reduce methionine and homocystine to near normal values. It should be the first treatment to try using 150 to 300 mg/day in the older child or adult and reducing the dose if a response is achieved. Very large sustained doses (1000 mg/day or more) in adults cause peripheral neuropathy. A very low-protein diet with a system of exchanges is appropriate for those not responding to pyridoxine and requires a methionine-free amino acid supplement, minerals, and vitamins. Biochemical control may only be achieved in older children and adults on natural protein intakes of 5 to 10 g/day. Cystine supplementation of diets should be considered in patients partially responsive to pyridoxine. Both folic acid (5 to 10 mg/day) and betaine (up to 12 g/day) can further reduce plasma homocystine levels but may produce large elevations of plasma methionine. Low red cell folate values occur and even megaloblastic anaemia. Low serum vitamin B_{12} values have also been found. The relationships between homocystine, the mixed disulphide, and total homocyteine values are not linear, making target values for treatment difficult to establish. Effective treatment lowers the incidence of vascular events.

Defects of homocysteine remethylation

Two defects have been described: a deficiency of methylene tetrahydrofolate reductase and a deficiency of methionine synthase (methyltetrahydrofolate homocysteine methyltransferase). The latter requires methylcobalamin as coenzyme.

Methylene tetrahydrofolate reductase deficiency

Clinical

Neurological features predominate with psychomotor retardation, seizures, abnormalities of gait, and psychiatric disturbance. Presentation occurs from early to late childhood. The risk of vascular disease is high.

Pathology

At autopsy dilated ventricles and low brain weight have been seen; thromboses may be present in arteries and veins. Demyelination occurs and the changes may resemble the classic findings of subacute combined degeneration seen in vitamin B_{12} deficiency. Calcification of the basal ganglia occurs.

Biochemistry

Plasma methionine concentrations are below normal and plasma homocystine concentrations in the range 20 to 200 µmol/litre with an excretion of 15 to 600 µmol/day.

Diagnosis

Homocystine is easily missed at low concentrations but is the important clue. The enzyme can be assayed in liver or fibroblasts.

Genetics and prenatal diagnosis

It is an autosomal recessive and enzyme assays on cultured amniocytes have been used for prenatal diagnosis. Several mutations have already been described.

Treatment

Betaine in large doses lowers plasma homocystine and raises plasma methionine. Other treatments tried alone or in combination include folinic acid, vitamin B_{12}, pyridoxine, and methionine. Some have suggested a 'cocktail' of all these treatments. It is difficult to be sure of clinical success.

Methionine synthase deficiency

The enzyme transfers a methyl group from methyltetrahydrofolate to homocysteine. Methyl cobalamin is the required coenzyme. This metabolic step may be impaired

by an apoenzyme defect or defects in cobalamin metabolism, some of which limit only the formation of methyl cobalamin. Other cobalamin defects are considered under methyl malonic acidaemia.

Clinical

The characteristic findings are developmental delay and megaloblastic anaemia, but the onset may be in later in childhood with dementia and spasticity. Retinal degeneration, cardiac defects, and haemolysis have been described.

Biochemistry and diagnosis

The findings include low plasma methionine and raised homocystine in plasma and urine. Methylmalonic acid should be measured in urine to exclude other cobalamin defects (see methylmalonic aciduria). Methione synthase can be assayed in liver or fibroblasts and antenatal diagnosis has been carried out on cultured amniocytes.

Treatment

This may involve large doses of hydroxocobalamin with betaine and possibly folinic acid.

Other defects of sulphur amino acid metabolism

Among several known defects, cystathioninuria due to cystathionase deficiency is probably clinically harmless. Cystathionine in excess of 1 g/day may be excreted at clearance values close to the glomerular filtration rate.

Methionine adenosyl transferase deficiency causes raised plasma methionine levels (up to 1200 µmol/litre; normal 15 to 30 µmol/litre) which seems to be harmless. The enzyme defect is partial.

Neither of these defects is considered further but sulphite oxidase deficiency is clinically important.

Sulphite oxidase deficiency

Most cases are due to abnormalities of the molybdenum cofactor, which therefore also affects the action of xanthine oxidase and aldehyde oxidase.

Clinical

Lens dislocation occurs, with severe neurological abnormalities, delayed psychomotor development, and xanthinuria. The neurological defects include seizures and axial hypotonia with increased limb tone. The disease is fatal.

Biochemistry

Sulphite concentrations are raised and sulphite is excreted in the urine. Direct reaction in the body between sulphite and cysteine yields sulphocysteine. Plasma urate levels are low and urine xanthine is increased when the disease is due to cofactor abnormalities but not if the defect is in the apoenzyme of sulphite oxidase.

Diagnosis

There is a dipstick test for sulphite which must be applied to fresh urine. *S*-sulphocysteine can be detected on an amino acid analyser. Sulphite oxidase can be measured in fibroblasts or liver.

Genetics and prenatal diagnosis

It is an autosomal recessive disorder. Prenatal diagnosis has been carried out on cultured amniocytes by enzyme assay.

Treatment

No effective treatment is known. Some damage may be prenatal. Measures that could be considered include diets low in methionine and cystine. Penicillamine might lower sulphite concentrations by binding with it. The nature of the molybdenum-containing cofactor is not well enough understood to be a useful therapeutic approach.

Defects of glycine metabolism

Folate and activated 1-carbon units

Tetrahydrofolate carries 1-carbon units—methyl, methylene, methenyl, formyl, or forminino—bonded to the N-5 or N-10 nitrogen atoms and the units are interconvertible. One-carbon units are donated from the tetrahydrofolate derivatives in a variety of syntheses. New 1-carbon units are accepted by tetrahydrofolate in degradative reactions, of which the most important is the conversion of serine to glycine. As serine can be formed from 3-phosphoglycerate, carbohydrates are the ultimate source of 1-carbon units (Fig. 10).

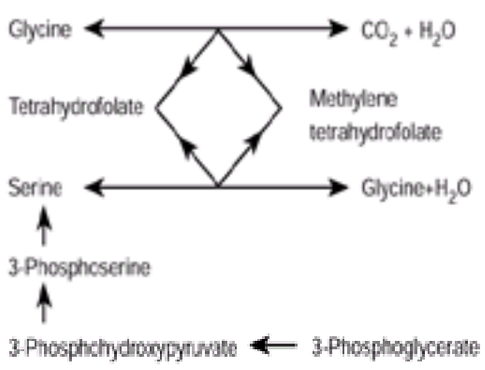

Fig. 10 Reversible glycine cleavage to carbon dioxide and water is illustrated together with reversible interconversion of serine and glycine. These reactions also serve to generate 1-carbon units. 3-phosphoglycerate (glycolysis) is the ultimate source.

The glycine cleavage system

This system, which generates methylene tetrahydrofolate from carbon-2 of glycine, and carbon dioxide from carbon-1, consists of four mitochondrial proteins. The P protein is a decarboxylase requiring pyridoxal phosphate. The heat-resistant H protein contains lipoic acid and carries the aminomethyl moiety. Both proteins are needed to generate carbon dioxide from the carbon-1 of glycine. The T protein requires tetrahydrofolate and produces methylene tetrahydrofolate from carbon-2 of glycine. The fourth protein (L protein) is needed to transfer hydrogen from the lipoic acid moiety of the H protein to nictotinamide adenine diphosphate. Reversal of the

sequence synthesizes glycine. Glycine can be converted to glyoxylate and to †-aminolaevulinic acid for porphyrin synthesis.

Non-ketotic hyperglycinaemia

Clinical

Twenty four to 48 h after birth, lethargy, convulsions, anorexia, poor feeding, and vomiting progress to coma and unresponsiveness. Apnoea may require ventilation at least temporarily. The mortality at this stage is high. Intellectual development does not occur in survivors, seizures persist, and tendon reflexes are increased. Microcephaly, poor head control, profound etardation, and a picture of spastic cerebral palsy result. Hiccupping *in utero* maybe recognized retrospectively.

There is a later childhood form presenting with spastic paraparesis, clonus, and extensor plantar responses with modestly raised plasma and cerebrospinal fluid glycine values. Optic atrophy with cerebellar signs has also been described.

Biochemistry

The defect is in the glycine cleavage system with plasma glycine values of 600 to 1200 µmol/litre. Normal values for cerebrospinal fluid levels of glycine are around 4 to 5 µmol/litre, the cerebrospinal fluid plasma ratio being around 0.02. Cerebrospinal fluid values are greatly increased in patients, raising the cerebrospinal fluid:plasma ratio to between 0.07 and 0.30. Large quantities of glycine appear in the urine, but this is not accompanied by proline or hydroxyproline.

Diagnosis

This rests on the analysis of glycine concentrations in plasma and cerebrospinal fluid. Activity of the glycine cleavage system can be measured on liver biopsies and in a few laboratories in leucocytes.

Genetics

The variant forms are autosomal recessives. The P protein is absent in classic phenotypes. T protein defects have been found in different phenotypes and H protein defects in later onset degenerative forms. Hyperglycinaemia seems to be commoner in Japan and Finland. Different mutations in these two populations affect the P protein.

Antenatal diagnosis

The enzyme system is unstable and not present in fibroblasts or cultured amniotic cells. Chorionic villi are being used for enzyme assay in prenatal diagnosis combined with amniotic fluid glycine:serine ratios. Increasing information on causative mutations will facilitate antenatal diagnosis.

Treatment

This is very unsatisfactory. Some damage to the central nervous system may be prenatal. Plasma glycine levels can be lowered by exchange transfusion or peritoneal dialysis but without clinical improvement. Low-protein diets have only a limited effect on decreasing plasma glycine concentrations. Supplying 1-carbon units in the form of methionine or *N*-formyltetrahydrofolate has not helped. The combination of sodium benzoate to increase glycine excretion and diazepines, which compete for inhibitoryglycine receptors in the central nervous system, has lowered plasma and cerebrospinal fluid levels of glycine and reduced seizures without clearly improving prognosis. Glycine is also a coagonist at the excitatory *N*-methyl-D-aspartate (NMDA) receptor blockage which has been attempted with several agents. Success has been absent or very limited. Imipramine may warrant further trial.

Defects in branched chain amino acid (leucine, isoleucine, and valine) metabolism

These essential amino acids, with a branched carbon chain structure, collectively make up 10 to 15 per cent of animal protein and are catabolized by transamination to the corresponding keto acids, 2-keto-isocaproic, 2-keto-3-methylvaleric, and 2-keto-isovaleric acids (Fig. 11). In all tissues except the liver aminotransferase activity exceeds a-ketodehydrogenase activity. Peripheral tissues, notably muscle, predominantly transaminate but the keto acids are largely transported back to the liver for subsequent metabolism.

Fig. 11 Branched chain amino acid metabolism. Transamination produces the keto acids (top) all of which are metabolized by the branched chain a-ketodehydrogenase complex (asterisked) 1. 2, Propionyl coenzyme A carboxylase; and 3, methylmalonyl coenzyme A mutase.

Branched chain a-ketodehydrogenase: the role of thiamine

The oxidative decarboxylation of branched chain keto acids is analogous to the oxidative decarboxylation of pyruvate and a-ketoglutarate to acetyl coenzyme A and succinyl coenzyme A, respectively. All are three-subunit mitochondrial enzymes, the first part of which, E_1, uses thiamine pyrophosphate as a coenzyme. The thiamine moiety is crucial to the decarboxylase function of branched chain a-ketodehydrogenase (E_1) and the release of carbon dioxide. Branched chain a-ketodehydrogenase (E_2) is the core protein of the complex, the acyl transferase that generates acyl coenzyme A while its lipoate moiety is reduced. The third part (E_3) regenerates the oxidized lipoate and is actually shared by all three dehydrogenase complexes. Branched chain a-ketodehydrogenase (E_1) is active in a dephosphorylated form and inactivated by phosphorylation, which provides a control mechanism. Branched chain ketoaciduria (maple syrup urine disease) arises from defects in the branched chain a-ketodehydrogenase complex. Some patients have a thiamine responsive form of this disease (see below).

Branched chain ketoaciduria

Clinical

In the classic disease the baby is well for 2 to 3 days and then poor feeding and sleepiness progress to coma and apnoea. Vomiting is inconstant. The mortality is high and survivors show dystonia, psychomotor retardation, spastic quadriplegia, and other neurological abnormalities.

Milder forms of the disease are described, sometimes with later presentation and intermittent forms where patients may be biochemically normal between attacks but succumb during intercurrent infection or illness or excessive protein intake.

Pathology

Myelin abnormalities that occur in patients dying of branched chain ketoaciduria are also found in Poll-Hereford calves with the same genetic defect, and in other experimental animal models.

Biochemistry

In the acute stage, hypoglycaemia and hyperammonaemia may occur. Leucine values may be as high as 4000 to 5000 µmol/litre. Isoleucine and valine are also much increased in plasma and urine (see Table 1 for normal values.) The three keto acids cause mild metabolic acidosis and the sweetish smell of maple syrup in urine. Residual enzyme activity in fibroblasts is 1 to 2 per cent for the classic severe disease but 20 to 40 per cent of normal in mild variants.

Diagnosis

The plasma amino acids and urine keto acids are diagnostic. Diagnosis before 6 days of age carries a better prognosis than later diagnosis with patients discovered by neonatal screening doing best of all.

Genetics

This is an autosomal recessive disorder. Screening is possible by bacterial assay but the disease is too rare to justify the cost. The incidence is about 1 in 120 000 in Europe but 1 in 200 000 in most of the United States, although an incidence of more than 1 in 1000 has been recorded in a Mennonite community. As the E_1 component of the branched chain a-ketodehydrogenase is subdivided further into E_{1a} and E_{1b} at least four genes code for the complex, plus two genes for the controlling phosphatase and kinase. Enzyme assays and immunological and complementation studies have already revealed genetic defects in E_{1a}, E_{1b} and E_2 in different families. The Mennonite mutation is an asparagine substitution for tyrosine in the E_{1a} subunit.

Prenatal diagnosis

This has been based on enzyme assays in cultured amniocytes or chorionic villus samples.

Treatment

A high calorie intake, given parenterally as 10 to 20 per cent dextrose if necessary, is needed to suppress nitrogen catabolism in the acutely ill. An amino acid mixture excluding leucine, isoleucine, and valine can be introduced by nasogastric tube to provide 2 g protein/kg/day. Normal protein sources (milk, etc.) are omitted until the branched chain amino acid concentrations fall towards normal. Both exchange transfusion and peritoneal dialysis have been used to speed biochemical recovery but haemofiltration is thought to be better. Hypoglycaemia, sepsis, and hypotension need intensive care and monitoring. Dietary treatment is lifelong but needs frequent adjustments. The aim is to keep plasma leucine, isoleucine, and valine concentrations close to their normal values (see Table 1). Coma carries a poor prognosis for subsequent development and function of the central nervous system. The incidence of impaired intellect and neurological handicap is high and special schooling will be necessary.

Responsiveness to thiamine(10 to 20 mg/day) has also been described in a few patients. It is claimed that large doses up to 500 mg/day improve some cases of classic branched chain ketoaciduria. *In vitro* evidence indicates that the E_{1a} subunit is stabilized by thiamine supplements, which may saturate all subunits. An increase in enzyme activity has even been described in normal subjects on thiamine treatment.

Other defects of branched chain amino acid metabolism

Rare cases of defective deamination have been described causing isolated hypervalinaemia or hyperleucinaemia–isoleucinaemia, indicating either separate amino transferases in humans or different mutations affecting different substrate binding sites in a common enzyme.

The organic acidaemias in branched chain amino acid metabolism

The catabolic steps outlined in Fig. 11 illustrate the formation of isovaleric acid, propionic acid, and methylmalonic acid, each of which accumulates in one of the three more common organic acidaemias. In the further metabolism of two of these acids there are important vitamin coenzymes—biotin for priopionyl coenzyme A carboxylase and cobalamin for methylmalonyl coenzyme A mutase. Biotin metabolism is considered under multiple carboxylase deficiency later and cobalamin metabolism immediately below. A range of other organic acidaemias have been described after discovery by gas–liquid chromatography with mass spectroscopy; their diagnosis may beome more frequent with the wider diagnostic use of tandem mass spectroscopy. They have been reported only rarely to date and are not considered further.

Vitamin B_{12} metabolism

Vitamin B_{12} has a complex metabolism but is required in only two metabolic steps—the remethylation of homocysteine to methionine and the conversion of methylmalonyl coenzyme A to succinyl coenzyme A. An outline of cobalamin metabolism in the body is shown in Fig. 12. In the cytosol hydroxocobalamin may become the coenzyme methyl cobalamin, which is required by methionine synthase, or be transported into the mitochondria to be metabolized to adenosyl cobalamin, the coenzyme of methylmalonyl coenzyme A mutase.

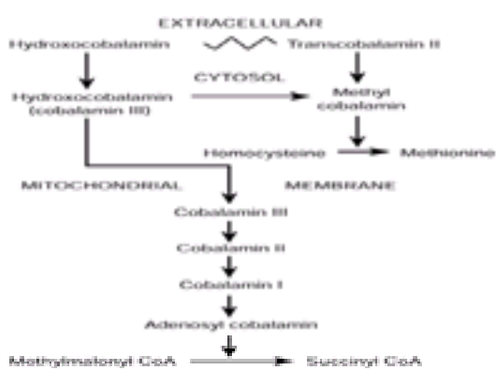

Fig. 12 Naturally occurring cobalamin is converted in the cytosol to methyl cobalamin, or adenosyl cobalamin is eventually formed by successive valency reductions of the cobalt moiety within the mitchondria.

Isovaleric, propionic, and methylmalonic acidaemias

Clinical

One to several days after a normal pregnancy and delivery the child stops feeding. Respiratory problems ensue with varying tonal change, both axial hypotonia and episodes of generalized hypertonia and myoclonic jerking. Apnoea, coma, and death supervene. Characteristically the child is acidotic, possibly ketotic, and non-specific increases of ammonia and glycine may occur. Both hypoglycaemia and hyperglycaemia have been described, the latter causing confusion with diabetic

ketoacidosis. Hypocalcaemia is also found. Early mortality is high and patients are often difficult to treat. Survivors have recurrent episodes of decompensation. There is an abnormal body odour likened to sweaty feet in isovaleric aciduria.

A more chronic form of these diseases is recognized, with anorexia, failure to thrive, psychomotor retardation, hypotonia, and weakness. Cardiomyopathy has been reported as a late complication. Damage to the basal ganglia with movement disorders is common and chronic renal failure may develop in survivors with methylmalonic aciduria.

The intermittent clinical forms present as recurrent attacks of encephalopathy and ataxia with normality between attacks. Changes in blood glucose may again be confusing (see above). Acute attacks may be followed by neurological abnormalities of a pyramidal or extrapyramidal nature. Leucopenia and thrombocytopenia sometimes occur.

Biochemistry

Isovaleric acidaemia is due to a deficiency of isovaleryl coenzyme A dehydrogenase and is characterized by the excretion in the urine of isovaleric acid, isovalerylglycine, 3-hydroxy isovaleric acid, and isovalerylcarnitine.

Isolated propionic acidaemia is due to a deficiency of the apoenzyme for propionyl coenzyme A carboxylase, a biotin-requiring enzyme. The enzyme converts proprionyl coenzyme A to methylmalonyl coenzyme A. Characteristically, plasma and urine propionate values are raised with the formation of methylcitrate from the condensation of propionyl coenzyme A with oxaloacetate (Fig. 13). Propionylcarnitine excretion is increased.

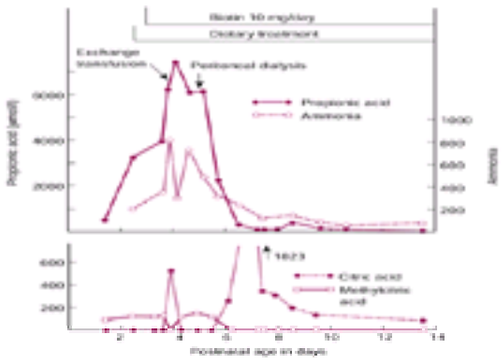

Fig. 13 Neonatal propionic acidaemia with hyperammonaemia, raised plasma methylcitrate levels, and low levels of citrate (µmol/litre). Treated by diet, exchange transfusion, and peritoneal dialysis. (From Brenton and Krywawych, unpublished data.)

Methylmalonic acidaemia is due to deficient activity of methylmalonyl coenzyme A mutase, the enzyme converting methylmalonyl coenzyme A to succinyl coenzyme A, which requires adenosyl cobalamin. Two apoenzyme defects are described, one with virtually zero activity and one with residual activity of 2 to 75 per cent of normal. Two genetic defects in the formation of adenosyl cobalamin have been described. One affects the formation of both adenosyl and methyl cobalamin, resulting in methylmalonic aciduria and homocystinuria. The other affects only adenosyl cobalamin, and only methylmalonic aciduria occurs. Patients with severe apoenzyme defects excrete up to 5 to 6 g/day of methylmalonic acid with high blood concentrations up to 6 mmol/litre (Fig. 14). Propionate also accumulates in the blood and is excreted together with methylcitrate.

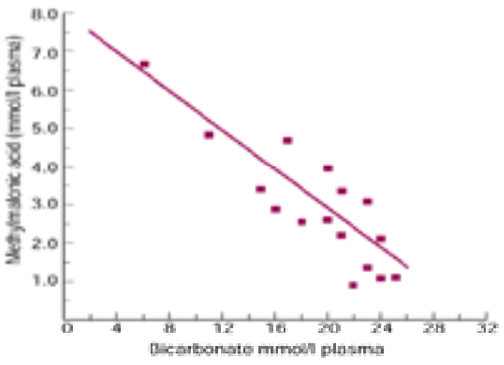

Fig. 14 Plasma concentrations of methylmalonate (a dicarboxylic acid) and bicarbonate in an affected teenage girl indicating that the acidosis is due almost entirely to the methymalonate. (From Brenton and Krywawych, unpublished data.)

Diagnosis

Diagnosis rests upon the detection of the relevant organic acids, their conjugates, or their carnitine esters in blood and urine.

Genetics

All three diseases are autosomal recessive. Isovaleryl coenzyme A dehydrogenase is a four-unit homopolymer with a single locus on the long arm of chromosome 15. Different enzyme variants cause phenotypic variation but severe neonatal and intermittent forms have been described in the same family.

Propionyl coenzyme A carboxylase has the subunit structure a_6/b_6. The a subunit gene is on chromosome 13 and the b subunit gene is on chromosome 3. Defects in the a chain (which binds the biotin) are associated with 50 per cent enzyme activity in heterozygotes and 1 to 5 per cent activity in homozygotes. Homozygous b-chain defects are similarly severe but heterozygotes have near normal activity. b chains are produced in half-normal amounts. b chains are normally produced in excess of a chains.

Methyl malonyl coenzyme A mutase is a dimer of subunit size 75 000 with adenosyl cobalamin bound to each subunit. The gene locus is on chromosome 6. The mutant mutase with no residual enzyme activity has no detectable enzyme protein, either because none is made or because it is highly unstable.

There is now considerable information on the causal mutations in all three diseases.

Prenatal diagnosis

Isovaleric acid in amniotic fluid is measured reliably by stable isotope dilution analysis, and isovaleryl coenzyme A dehydrogenase can be measured in cultured amniocytes. The measurement of methylcitrate in amniotic fluid and enzyme assay in cultured amniocytes has been used for diagnosis of propionic acidaemia. Similar approaches to prenatal diagnosis in isolated methylmalonic aciduria have used the measurement of methylmalonate acid in amniotic fluid and enzyme assays or studies of adenosyl vitamin B_{12} metabolism in cultured amniocytes. Molecular prenatal diagnosis will be increasingly used in families where the genotype is known.

Treatment

In the severe neonatal form of these diseases the initial treatment is concerned with removal of toxic organic acids by exchange transfusion (as urinary excretion of propionate is poor this may be followed in propionic acidaemia by peritoneal dialysis) and encouraging anabolism by the provision of calories as 10 to 20 per cent glucose and electrolyte solutions intravenously with or without insulin. Enteral feeding should be started by nasogastric tube as soon as possible (after 24 to 48 h); initially this should be with protein-free feeds, but soon changing to a low-protein feed (0.5 g/kg/day) and later increasing to tolerance and supplemented with amino acid mixtures that omit the amino acids whose metabolism is impaired. The requirements of these amino acids for growth are provided by the natural protein, whose intake must be adjusted accordingly. L-glycine supplements of 0.25 to 0.5 g/kg/day are helpful in isovaleric acidaemia because it increases the formation of the non-toxic isovalerylglycine. L-carnitine 100 mg/kg/day may help in all three diseases by replenishing carnitine and increasing the excretion of non-toxic carnitine acyl esters. Both insulin and growth hormone have been used to try and produce positive nitrogen balance and hasten recovery in catabolic states.

No true *in vivo* responsiveness to biotin has been demonstrated in isolated propionic acidaemia. However, *in vivo* response to hydroxocobalamin therapy in methylmalonic acidaemia occurs and should be tested in all such patients and continued long term if response occurs. Diet is needed long term in all three disorders; this is relatively easy in isovaleric acidaemia where a low-protein diet may suffice. A low-protein diet may also suffice in some patients with methylmalonic acidaemia, combined with regular oral sodium bicarbonate to control residual acidosis. Patients with propionic acidaemia are more difficult to manage and require a low-protein diet with more frequent supplements of amino acids. Chronic nasogastric feeding may be needed for anorexia. Oral metronizanole may reduce propionate production by gut bacteria in the intestine in propionic and methylmalonic acidaemia but therapeutic usefulness is not yet clear. Similarly, the use of L-carnitine on a chronic basis may help in all diseases but it is not proven. Patients with methyl malonic aciduria and renal failure may require renal transplantation. combined hepatic and renal transplantation carried out to cure the underlying metabolic defect has also had very variable outcome.

Disorders of g-aminobutyric acid metabolism

g-aminobutyric acid is formed from glutamate in the brain by the cytosolic enzyme glutamate decarboxylase, which requires pyridoxal phosphate. Pyridoxine-dependent seizures in neonates are postulated to be due to a deficiency of this enzyme, which is difficult to prove because other tissues have a genetically different mitochondrial glutamate decarboxylase. Glutamate can be regenerated from g-aminobutyric acid by transamination with ketoglutarate (g-aminobutyric acid transaminase), which is also pyridoxal phosphate dependent. The other product is succinic semialdehyde, which is dehydrogenated to succinate, which enters the citric acid cycle. Deficiency of succinic semialdehyde dehydrogenase leads to the excretion of 4-hydroxybutyric acid. Some more details of disordered g-aminobutyric acid metabolism are given in Table 11.

Defects of lysine metabolism

Lysine catabolism

The main pathway is via saccharopine to acetyl coenzyme A (Fig. 15); there are other less important pathways. Glutaryl coenzyme A dehydrogenase catalyses the conversion of glutaryl coenzyme A to crotonyl coenzyme A. Deficiency of this enzyme causes glutaric aciduria type I, a serious disorder. Other lysine degradation defects are of uncertain clinical consequence.

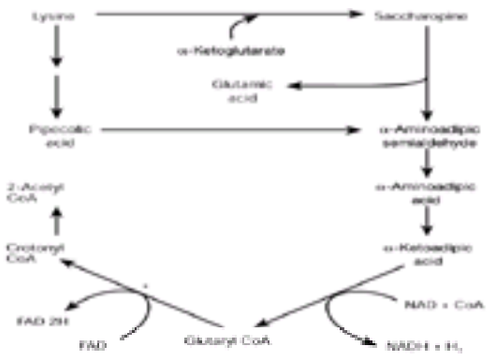

Fig. 15 The metabolism of lysine. The enzyme glutaryl coenzyme A dehydrogenase is asterisked.

Glutaric aciduria type I

Clinical

Abnormalities of development of the central nervous system begin before birth with macrocephaly and defective frontal and temporal lobe development, although early clinical development is often considered normal. Delayed motor development in the early years of life with hypotonia is followed by encephalopathic episodes precipitated by intercurrent illness with ataxia, athetosis, and other involuntary movements. Severe dystonia, pyramidal defects with extensor or flexor spasms, and severe dysarthria may follow. Intercurrent infection can also precipitate acidosis, seizures, coma, and paralysis, from which recovery is incomplete. The overall picture then resembles dystonic cerebral palsy. Computed tomography and magnetic resonance imaging have revealed progressive cerebral atrophy and hyperlucency of the caudate nucleus due to striatal necrosis. Even if the diagnosis is made in asymptomatic patients, acquired motor skills such as walking and writing may be slowly lost in the childhood years.

Biochemistry

Glutaryl coenzyme A dehydrogenase deficiency causes an accumulation of glutaryl coenzyme A (also derived from tryotophan degradation), increasing glutaric acid concentrations in plasma and urine, and increasing concentrations of 3-hydroxyglutarate and glutaconic acid. These are all inhibitors of glutamic acid decarboxylase, which may explain the low g-aminobutyric acid concentrations in the central nervous system. Neurodegeneration probably results from excessive stimulation of NMDA receptors by 3-hydroxyglutaric acid. Glutaryl carnitine is excreted in the urine even when free glutaric acid is absent. Systemic acidosis occurs in acute attacks with ketosis and hypoglycaemia.

Diagnosis

This cause of progressive dystonic cerebral palsy is usually indicated by the organic acids in plasma and urine. Sometimes the organic acids have not been detected, particularly between acute attacks. Enzyme assays on leucocytes or fibroblasts are then indicated.

Prenatal diagnosis

This has been carried out by finding glutaric acid in the amniotic fluid and enzyme assay on cultured amniocytes. Where the mutation in the family is known molecular prenatal diagnosis would be more accurate.

Genetics

The disease is an autosomal recessive. The glutaryl coenzyme A dehydrogenase gene is on chromosome 19p and over 70 mutations have been described.

Treatment

Low-protein diets reduce glutaric acid excretion. Carnitine supplementation corrects low plasma levels which are secondary to losses from glutaryl carnitine excretion. Riboflavin has been reported to diminish glutaric acid excretion in some patients, the treatment rationale being that increased flavine adenine dinucleotide might stabilize the enzyme. Baclofen has also been studied because it activates g-aminobutyric acid receptors. When treatment is started very early in life brain degeneration may be preventable. Delay results in irreversible damage to the caudate and putamen.

Defects in the final stages of carbon chain metabolism

Biotin-dependent carboxylation

Biotin is important in transferring a 1-carbon unit (carbon dioxide) to acceptor molecules. Defects in biotin metabolism disturb the function of four enzymes—pyruvate carboxylase, acetyl coenzyme A carboxylase, propionyl coenzyme A carboxylase, and 3-methylcrotonyl coenzyme A carboxylase (Fig. 16). These apoenzymes are converted to holoenzymes by the attachment of biotin, which needs the catalytic activity of an enzyme, holocarboxylase synthetase (Fig. 17). When the holoenzymes are themselves biologically degraded the biotin is initially released still attached to lysine peptides. The enzyme biotinidase frees biotin from these peptides. It also liberates dietary biotin from proteins in the gastrointestinal tract. In its absence biotin peptides are excreted, dietary biotin is not absorbed, and biotin deficiency occurs. Biotinidase is widely distributed throughout the body.

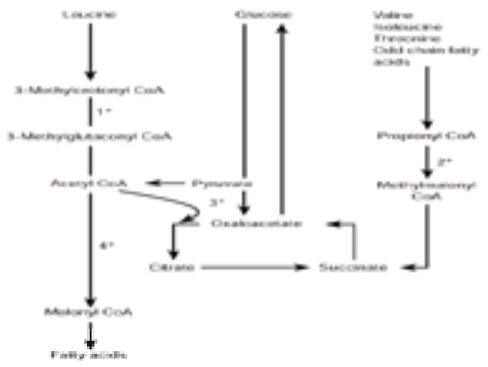

Fig. 16 Important carboxylases in amino acid metabolism. Asterisked enzymes are: 1, 3-methylcrotonyl coenzyme A carboxylase; 2, propionyl coenzyme A carboxylase; 3, pyruvate carboxylase; and 4, acetyl coenzyme A carboxylase.

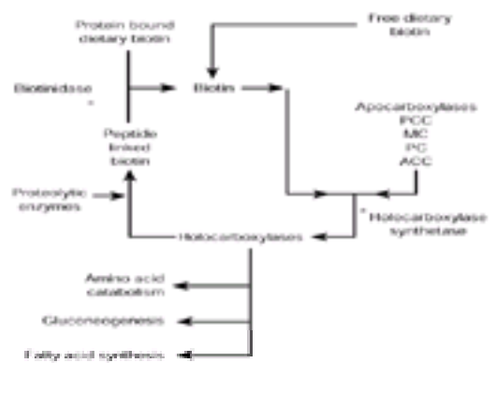

Fig. 17 The metabolism of biotin. MCC (3-methylcrotonyl coenzyme A) and PCC (propionyl coenzyme A carboxylase) are important in amino acid catabolism, PC (pyruvate carboxylase) is important in gluconeogenesis, and ACC (acetyl coenzyme A carboxylase) in fatty acid synthesis. Important enzymes are asterisked.

Electron transport and the acyl coenzyme A dehydrogenases

The electrons accumulating during oxidation in the citric acid cycle are carried by reduced nicotinamide adenine dinucleotide and reduced flavine adenine dinucleotide to be transferred along the electron transporting chain to molecular oxygen, with the generation of adenosine triphosphate and water. Transfer from reduced nicotinamide adenine dinucleotide takes place sequentially across four multienzyme complexes (I to IV), which are part of the structure of the inner mitochondrial membrane. The flavin-containing acyl coenzyme A dehydrogenases transfer electrons differently to an intermediate electron transferring flavoprotein and from there to ubiquinone catalysed by the enzyme electron transferring flavoprotein ubiquinone oxidoreductase (Fig. 18).

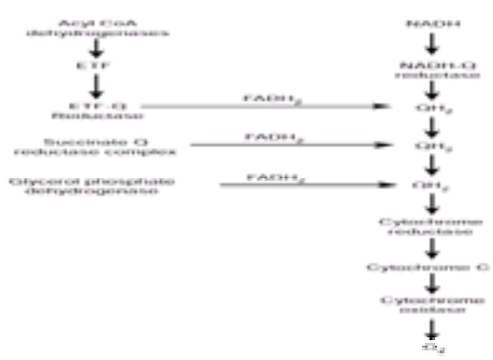

Fig. 18 The main electron transporting chain from reduced nicotinamide adenine dinucleotide (NADH) to oxygen is shown on the right, with other entry points for the flow of electrons coming from the left. ETF, electron transporting flavoprotein; $FADH_2$, reduced flavin adenine dinucleotide; QH_2, reduced ubiquinone.

Defects at this level affect not only amino acid catabolism but fatty acid oxidation, and the organic acid defects are complex. The affected acyl coenzyme A dehydrogenases include glutaryl coenzyme A dehydrogenase and defects in electron transport at this point in metabolism are labelled glutaric aciduria type II.

Multiple carboxylase deficiency

Clinical

Holocarboxylase synthetase deficiency causes neonatal acidosis with seizures, skin rash, and alopecia; it progresses to coma and death. Vomiting and ketosis are present. Biotinidase deficiency has a more variable clinical picture with progressive neurological deterioration including ataxia and seizures, developmental delay, and hypotonia. Other features of the neonatal form such as skin rash, alopecia, acidosis, and organic aciduria may not be prominent. Hearing loss and optic atrophy have

been described. Keratoconjunctivitis occurs.

Biochemistry

The carboxylase deficiencies cause a complex organic aciduria. Isovaleric acid (which imparts an unpleasant odour to the patient), 3-hydroxyisovaleric acid, methylcrotonic acid, and methylcrotonyl glycine result from the impaired activity of 3-methylcrotonyl coenzyme A carboxylase. Lactic acidosis, with more marked increases in cerebrospinal fluid levels of lactate, reflects defective pyruvate carboxylase activity. Impaired propionate metabolism also increases 3-hydroxypropionate and propionylglycine excretion. The accumulating acetyl coenzyme A results in ketosis.

Diagnosis

Apart from organic acid analyses biotinidase activity in plasma is reduced to 0 to 5 per cent of normal in genetic deficiency. Biotin itself can be measured in plasma and urine. The assay of holocarboxylase synthetase is difficult and possible in only a few places. The therapeutic response to biotin does not distinguish between the two defects.

Genetics

Both are recessive disorders and biotinidase deficiency seems to be more common than holocarboxylase synthetase deficiency. The gene for the latter has been assigned to chromosone 21 and several mutations described.

Prenatal diagnosis

This is only required in holocarboxylase synthetase deficiency and depends on amniotic fluid analysis for organic acids and enzyme assay in cultured amniotic cells.

Treatment

Biotinidase deficiency responds well, often dramatically, to 5 to 10 mg/day of oral biotin. Deficiency develops in a few days if biotin is stopped. Pre-existing neurological damage may not reverse. Most patients with holocarboxylase deficiency respond well to 10 mg daily, but larger doses may be needed and some have not fully responded to doses as high as 100 mg/day.

Glutaric acidaemia type II

Clinical

The most severe neonatal presentation, with associated congenital abnormalities, often leads to premature birth, metabolic acidosis, hypoglycaemia, hepatomegaly, and hypotonia. Severe cystic dysplasia of the kidneys is common; the kidneys may be palpable. Other defects include facial dysmorphism, 'rocker-bottom' feet, anterior abdominal wall defects, and defects of the external genitalia. Death usually occurs in the first week of life. Some affected neonates, without congenital defects, have the other clinical abnormalities of metabolic acidosis, hypoglycaemia, hypotonia, and hepatomegaly. The prognosis remains poor, with death in the early days or weeks of life, often with severe cardiomyopathy.

Milder forms presenting after the neonatal period, or survivors of early illness, may suffer recurrent encephalopathic episodes similar to Reye's syndrome. Cases with a predominantly late clinical presentation of lipid storage myopathy have been described. Adult presentation has been recorded. From their predominant organic acid pattern, some of these clinically milder patients are given the diagnosis of ethylmalonic-adipicaciduria.

Biochemistry

Glutaric aciduria type II is due to deficiency of electron transferring flavoprotein or electron transferring flavoprotein–ubiquinone oxidoreductase, the latter causing the severest neonatal form with congenital defects. The flavin-containing acyl coenzyme A dehydrogenases affected include glutaryl coenzyme A dehydrogenase, isovaleryl coenzyme A dehydrogenase, the long, medium, and short chain dehydrogenases used in fatty acid oxidation, and the dehydrogenases involved in sarcosine synthesis and breakdown. The organic acids found in urine as a consequence include short chain acids—isovaleric, 3-hydroxy isovaleric, glutaric, 2-hydroxyglutaric—the oxidation products of medium chain fatty acids—adipic, suberic and sebacic acids—ethylmalonic acid, 5-hydroxy hexanoic acid, and glycine conjugates of a variety of these. Carnitine concentrations in plasma are low and a range of acyl carnitines are found in urine and increased by carnitine therapy. Hypoglycaemia is very common.

Diagnosis

The florid organic acid pattern in severe patients is characteristic but in those more mildly affected it is less marked. Acyl carnitines are now well demonstrated by tandem mass spectrometry. Hepatomegaly and hypoglycaemia in older patients raise the diagnosis of glycogen storage diseases, but ketonaemia does not occur in glutaric aciduria type II. Electron transferring flavoprotein and electron transferring flavoprotein–ubiquinone oxidoreductase can be assayed in some centres using cultured fibroblasts.

Genetics

Both of the basic defects are autosomal recessive with assays of electron transferring flavoprotein and the electron transferring flavoprotein–ubiquinone oxidoreductase showing variable residual activity. The electron transferring flavoprotein protein has a and b subunits. The relevant genes have been localized to chromosomes 15 and 19 and mutations in both have been described.

Prenatal diagnosis

This has been carried out using amniotic fluid analysis and cultured amniocytes for electron transferring flavoprotein and oxidoreductase assays.

Treatment

Nothing has influenced severe early cases. Diets low in fats and protein reduce organic acid accumulation in milder cases and carnitine supplements increase the formation of the less toxic carnitine acyl esters. Oral riboflavin 100 to 300 mg/day has apparently been beneficial in some older patients, perhaps by stabilizing electron transferring flavoprotein or the oxidoreductase. Milder cases are helped by a high energy intake during intercurrent illness, which may need to to be intravenous.

Other defects of amino acid and organic acid metabolism

Many are not covered in the text because their rarity does not really justify it. Information is available in specialized texts.

11.3.1 Glycogen storage diseases

T. M. Cox

Glycogen, the main energy store in liver and muscle, is configured for the compact storage of glucose in a form that has a minimal osmotic effect but which is readily accessible and metabolically active. The molecule contains polymerized a- D-glucose units anchored covalently at their reducing termini to a small protein, glycogenin. The structure of glycogen is elaborate: its extensively arborized macromolecular arrangement is linked by a-1,4 glycosidic bonds with a-1,6 bonds at the branch points. These branch points are arranged in several tiers with increasingly long outer chains that terminate in non-reducing glucose residues. Thus the complex branched structure of glycogen also promotes its ready access to the enzymes of biosynthesis and degradation.

The liver and muscles contain between 200 and 300 g of glycogen and its polymerized structure can be seen with the electron microscope: liver glycogen consists mainly of a-aggregates or rosettes of smaller particles (b-particles) that are principally found in muscle cytoplasm. The molecular weight of glycogen in these tissues is several million daltons. Each b-particle contains up to 60 000 glucose residues, but despite its size the glycogen molecule undergoes remodelling as a result of constant breakdown and synthesis. Defects in the enzymatic steps for the synthesis, utilization, or degradation of glycogen lead to its pathological storage. Accumulation of glycogen may be generalized or involve certain tissues selectively; the stored glycogen may have a normal or aberrant structure.

Glycogen metabolism

The individual enzymatic steps for the formation and breakdown of glycogen are summarized in Fig. 1.

Fig. 1 The synthesis and degradation of glycogen.

Glycogen biosynthesis

The immediate precursor for glycogen synthesis is uridine diphosphoglucose (**UDPG**), which is formed from glucose 1-phosphate by UDPG pyrophosphorylase. This enzyme has a high affinity for its substrates and is abundant—no deficiencies have been recorded. In contrast, glycogen synthase is a highly regulated enzyme complex that exists in distinct isoforms in muscle and liver: the enzyme catalyses the transfer of UDP glucose units to glucose residues already covalently attached to a tyrosine residue of glycogenin, which acts as a primer. The tyrosine glucosyltransferase activity has not been identified but the glycogenin adduct possesses an intrinsic glucosyltransferase activity. Initially, one molecule each of glycogen synthase and glycogenin occur as a complex in each b-glycogen particle. After elongation, branching of the molecule is catalysed by amylo (1,4 ® 1,6) transglucosidase, 'branching enzyme'.

Glycogen synthase is subject to phosphorylation control that inhibits its activity: this inhibition is overcome by the allosteric activator, glucose 6-phosphate. The phosphorylation of at least nine serine residues is brought about by protein kinases. Glucagon and adrenaline, while stimulating phosphorylase via phosphorylase kinase, indirectly inhibit glycogen synthase by maintaining protein phosphatase I in its inactive configuration. Insulin stimulates glycogen synthase by promoting its dephosphorylation through the action of this same phosphatase: protein phosphatase I is activated by a cascade of protein kinases whose phosphorylation is initiated by the insulin receptor tyrosine kinase. Inherited deficiency of glycogen synthase activity is associated with reduced storage of liver glycogen and fasting hypoglycaemia. Branching-enzyme activity is essential for the formation of the compact spherical molecules of glycogen, especially in liver. It transfers a minimum of six a-1,4-linked glucose units from the distal ends of glycogen chains to a 1,6 position on the same or a neighbouring chain. Deficiency of branching enzyme leads to the accumulation of abnormal molecules that are partially resistant to degradation.

Glycogen breakdown

Glycogen is degraded by three enzymes: phosphorylase, debranching enzyme and acid a-glucosidase. Phosphorylase brings about the sequential release of glucose units from the a-1,4-linked chains of glycogen to liberate glucose 1-phosphate. After conversion to glucose 6-phosphate by phosphoglucomutase, free glucose is formed by the action of glucose 6-phosphatase. Debranching enzyme possesses transferase and a-1,6-glucosidase activities. When phosphorylase has degraded glycogen chains to within four a-1,4-glucosyl units of an a-1,6 linkage, three glucose residues are transferred to the end of another chain by the glycosyltransferase activity. Debranching enzyme then hydrolyses the remaining a-1,6 bond to release free glucose using its amylo-1,6-glucosidase activity. Debranching enzyme also cleaves the unique glucosyl–tyrosine linkage that anchors the terminal reducing glucose unit to glycogenin. Deficiency of debranching enzyme leads to the storage of glycogen that possesses short outer chains, 'limit dextrin'.

The main product of glycogen breakdown in muscle and liver is glucose 1-phosphate, which is produced by the sequential action of phosphorylase on a-1,4 glycosidic bonds. Glucose 1-phosphate is a key intermediate of glycolysis, gluconeogenesis, glycogenolysis, and the pentose-phosphate pathway, but, by virtue of phosphoglucomutase, the hepatic glucose 6-phosphatase system is the predominant metabolic source of blood glucose. Glucose 6-phosphatase exists as a multicomponent complex in the endoplasmic reticulum of hepatocytes and, to a lesser extent, in renal tubular cells—it is not found in muscle. The system contains glucose 6-phosphatase, several proteins that facilitate the transport of glucose, glucose 6-phosphate, and phosphate, as well as other stabilizing and regulatory moieties. Several genetic defects in this compartmentalized system are recognized to affect overall glucose 6-phosphatase activity: they are associated with severe

hypoglycaemia, metabolic acidosis, and hepatic disease.

Glucose 6-phosphate obtained from the breakdown of glycogen in skeletal muscle is used directly in glycolysis. Defects of muscle phosphorylase lead to a defective supply of adenosine triphosphate (**ATP**), especially during ischaemic exercise. There is a failure of conversion of glycogen to lactate, and exercise-induced muscle cramps reflect mild muscle necrosis with increased accumulation of glycogen. Phosphofructokinase-1 catalyses an irreversible step in the glycolytic pathway and is a key regulatory enzyme. Inherited defects that render it inactive or affect its positive allosteric regulation by the effectors adenosine monophosphate (**AMP**) and fructose 2,6-diphosphate resemble muscle phosphorylase deficiency. Because deficiency of phosphofructokinase affects the metabolism of endogenous glycogen as well as carbon units derived from extracellular glucose, the symptoms of phosphofructokinase-1 deficiency are more severe and of earlier onset than muscle phosphorylase deficiency. As expected, glucose 6-phosphate, fructose 6-phosphate, and glycogen, accumulate in the muscle cells.

Breakdown of glycogen in liver and skeletal muscle is brought about by the concerted activities of phosphorylase and debranching enzyme in the cytoplasm. Phosphorylase, which requires pyridoxal-5-phosphate, is activated by phosphorylation in response to hormonal or neural stimulation—a complex process that is mediated by phosphorylase kinases. Phosphorylase kinase is a multisubunit protein with regulatory, catalytic, and calcium-binding subunits that are encoded on separate genes. Separate isoforms are found in liver and muscle. The final common pathways for the regulation of phosphorylase kinase involve protein kinase A (cAMP-dependent protein kinase), calcium and kinase activation of calmodulin, and protein phosphatases 1 and 2A.

Another enzyme, acid a-1,4-glucosidase (otherwise known as acid maltase), has an important role in the metabolism of glycogen. This lysosomal hydrolase is present in all cells except erythrocytes and, although it has no relation to glycolysis, its deficiency causes a generalized disorder in which muscle disease, especially of the heart, is usually severe. Deficiency of acid a-glucosidase is associated with rapidly progressive cardiac hypertrophy with hepatic enlargement and generalized muscle weakness. Skeletal muscle symptoms may be prominent in patients with the infantile or late-onset forms of this condition but disease progression is usually rapid. Acid a-1,4-glucosidase deficiency was the first inborn lysosomal disease to be clearly recognized and represents a prototype for the other storage diseases: intracellular vesicles containing glycogen represent lysosomes distended by an undegradable substrate that accumulates as a result of autophagy. The accumulation of glycogen in lysosomes indicates that glycogen fragments are constantly being taken up for partial degradation and macromolecular remodelling.

Clinical features

The principal features of the different glycogen storage diseases are set out in Table 1, which also gives the primary enzymatic (or translocator) defect and chromosomal locus of the cognate human gene in each case.

Many of the manifestations of the glycogen storage disorders are common to several of these diseases and correlate with the main site of storage. However, in those disorders that affect the liver, the consequential effects of the primary metabolic lesions are often far-reaching and the function of many different tissues may be impaired as part of a pleiotropic disturbance of biochemical homeostasis. In several instances, for example glycogen storage diseases types III and IV, pathological storage affects both liver and muscle tissue (including cardiac muscle) (Table 2).

An additional set of clinical features is observed in the enzymatic defects that affect glycolysis: typically, these are associated with acute exercise-induced muscle symptoms and signs of rhabdomyolysis. These defects are usually restricted to those tissues with a high glycolytic capacity or dependence, such as muscle and red cells; mild haemolysis results from the impaired supply of ATP to the membrane sodium–potassium ATPase of the erythrocyte.

Several unusual features of the glycogen storage diseases have been reported that remain unexplained. These include the development of hepatic adenomas (which presage malignant transformation); leucocytes and macrophages in the translocator deficiencies (types 1b, c, and d) that predispose to microbial infections and granulomatous colitis, and vasoconstrictive pulmonary hypertension. Typically, the renal disease is preceded by a hyperfiltration syndrome and mild proteinuria. An unusual feature of late-onset glycogen storage disease type II due to acid maltase deficiency, has been the association with intracerebral arterial aneurysms; glycogen storage in arterial smooth muscle with prominent vacuolation has been documented.

Clinical genetics of the glycogenoses

The genes encoding the human enzymes that are defective in the individual glycogen storage diseases have been identified and mapped to their respective chromosomal loci, as indicated in Table 1. The individual disorders are inherited as autosomal recessive traits, with the exception of liver phosphorylase b kinase deficiency (type VIII) and Danon's disease (type IIb) which are X-linked diseases.

Diagnosis of glycogen storage diseases

Affecting the liver

The diagnosis may be suspected in infants and children with hepatomegaly, growth retardation, and hypoglycaemia, which is not invariable. Review of a previous biopsy may indicate glycogen deposition; glycogen deposits stain strongly within hepatocytes with the Periodic acid–Schiff reagent and the reaction characteristically is abolished by prior treatment with diastase. In many cases, a glucagon stimulation test (20 µg/kg intramuscularly) fails to induce the normal (>2 mmol/l) rise in blood glucose; however, definitive diagnosis by biopsy is warranted for prognosis, future antenatal diagnosis, and to direct treatment. Direct assay of liver tissue for glycogen and fat content as well as enzymatic analysis is desirable. Histochemical and electron microscopic study of glycogen structure provides useful additional information. Where possible, open wedge-biopsy of the liver should be carried out to obtain sufficient material for diagnosis and ensure haemostasis under direct vision; appropriate provision of platelets and blood coagulation factors should be made to correct the haemorrhagic diathesis before biopsy is carried out. However, the procedure is hazardous for young infants with acidosis or a bleeding tendency and close attention should be given to prevention of hypoglycaemia.

A particular difficulty arises in the diagnosis of certain variants of type I glycogen storage disease. The glucose 6-phosphatase system is uniquely incorporated into the endoplasmic reticulum: latency of its membrane-bound components renders diagnosis of specific lesions affecting the transport of substrates or products impossible when frozen tissue is thawed for analysis. Types 1B and 1C glycogen storage disease (in which glucose 6-phosphate translocation is defective) is an example where the study of fresh tissue is essential for establishing a diagnosis, since analysis of freeze–thawed material disrupts the integrity of the microsomal enzyme system and—by rendering it permeable to phosphate, pyrophosphate, and glucose 6-phosphate—overcomes the transport defect. Thus, where defects of glycogen storage are suspected, it is essential to seek the prior advice of a laboratory that is competent to carry out the appropriate investigations using fresh and deep-frozen biopsy material.

In muscle

Forearm exercise tests are useful for detecting defects in skeletal muscles that interfere with the supply of chemical energy in the form of ATP by the metabolic pathway that breaks down glucose and glycogen to lactate. In the absence of oxygen, glycolysis is the sole means by which ATP may be generated: the preferred energy source being glucosyl units derived from glycogen, rather than glucose obtained from the plasma. Defects in glycolysis (glycogenosis type VII and other enzyme deficiencies) cause similar symptoms. Exercise-induced cramps may occur in patients with the purine pathway disorder, myoadenylate deaminase deficiency, which may also be safely diagnosed by exercise testing. Unlike the earlier test devised by McArdle (1951), these provocative tests do not induce rhabdomyolysis accompanied by raised creatine kinase activity in the serum with acute myoglobinuric renal failure—features in the history that may indicate muscle glycogenosis.

After a 30-min rest, blood is taken from the antecubital vein of the non-exercising arm and a small sphygmomanometer cuff placed around the other wrist is inflated to 200 mmHg. A second standard cuff around the upper arm to be tested is inflated to mean arterial pressure and the patient squeezes as powerfully as possible 120 times over 2 min. Immediately afterwards, the second cuff is inflated to 200 mmHg. Blood is drawn through a needle placed in the antecubital vein of the exercising arm 2 min after completing the exercise and the upper cuff is released. To complete the test, five further samples are drawn at 1-min intervals. The samples are transported rapidly to the laboratory for analysis of lactate and ammonia. Reduced or absent generation of lactate is characteristic of glycogenolytic and glycolytic defects that affect muscle; in contrast, plasma levels of ammonia (as well as inosine and hypoxanthine) increase greatly in patients with glycogenosis types III, V, and VIII. These abnormalities reflect the excessive degradation of purines that occurs in the exercising muscles of patients in whom there is a disturbance of ATP generation. Measurement of ammonia release as well as lactate production also adds discriminatory value to the exercise test, as it controls for low levels of lactate release that result merely from inadequate exercise during performance of the test. The test may also identify myoadenylate kinase deficiency: in such patients lactate production is normal, but the failure to utilize the purine cycle to conserve intracellular nucleotides and provide alternative substrates for energy production is shown

by the failure of venous ammonia concentrations to rise.

Pompe's disease due to acid maltase deficiency is a generalized disorder that predominantly affects skeletal and cardiac muscle. Carbohydrate metabolism is otherwise normal, and phosphorylysis of cytosolic glycogen in the liver is sufficient to maintain euglycaemia. The diagnosis of infantile disease may be suspected on the basis of cardiac and liver enlargement in an infant with respiratory distress and hypotonia. Macroglossia is frequent and the electrocardiogram shows left axis deviation, a short P–R interval and broad QRS complexes. In the juvenile- and adult-onset forms of acid maltase deficiency the disease resembles limb-girdle and other myopathies as well as polymyositis; some patients have been reported with myotonic features. The activity of skeletal muscle creatine kinase (**CK**) in this variant (non-CK MB fraction) is elevated in the serum and may be the first sign of intrinsic muscle disease, especially in adult patients complaining of non-specific fatiguability and weakness. Myopathic changes—occasionally with pseudomyotonic discharges—are observed on electromyography and the diagnosis is revealed by biopsy, which shows vacuolar myopathy: massive deposits of glycogen in and between myofibrils. Under the electron microscope, free and lysosomal a-glycogen particles are observed. Enzymatic deficiency of acid a-1,4-glucosidase is readily confirmed in cultured amniocytes and all tissues except erythrocytes.

Recently, the molecular basis for an unusually perplexing vacuolar cardiomyopathy associated with glycogen storage has been identified (Danon's disease). This X-linked disorder has been principally reported in male infants, boys, and men with proximal muscle weakness and prominent hypertrophic cardiomyopathy including cardiac conduction defects. Although the ultrastructural studies revealed membrane-bound inclusions of glycogen resembling Pompe's disease, acid maltase (a-1,4-glucosidase) activity was normal. In those cases with normal phosphorylase kinase activity (an enzyme that also maps to the X-chromosome), no cause for the severe cardioskeletal myopathy was apparent until it was shown to be associated with mutations in the lysosomal membrane protein, LAMP2. Families with probable Danon's disease have been reported with mild mental intellectual impairment and systemic manifestations. Clinical expression has been reported in obligate carrier female subjects in affected pedigrees showing inheritance patterns typical of an X-linked trait; the severity of the storage disease appears to be highly variable in female heterozygotes, consistent with patterns of random X-inactivation. Danon's disease can be diagnosed by molecular analysis of the *LAMP-2* gene that maps to human chromosome Xq24, and thus represents the first example of a disease due to a structural protein of the lysosomal membrane.

Definitive diagnosis of muscle glycogenoses depends on biopsy with histochemical, ultrastructural, and biochemical analyses. Biopsy should be carried out after liaison with the laboratory so that, if necessary, tissue can be stored frozen for further study and enzymatic analysis. Biopsy and electromyography may be needed to differentiate suspected glycogen storage diseases from other myopathies, including Duchenne's dystrophy, Kugelberg–Welander disease, dystrophia myotonica, and mitochondrial and secondary disorders of muscle such as polymyositis.

Individual glycogen storage diseases

The main features of these disorders are surveyed and summarized in Table 1. Brief accounts of selected conditions are set out below.

Classical type I glycogen storage disease (von Gierke's disease)

In this disease, glucose formation from glycogen and gluconeogenesis is defective and affected infants develop hypoglycaemia on fasting or as a result of intercurrent infection or other stress. The liver is enlarged at birth. It contains excess glycogen and shows gross infiltration with fat but cirrhosis and portal hypertension are rare. In contrast, growth retardation, often combined with obesity, is common. The kidneys are enlarged by glycogen deposition. Progressive focal glomerulosclerosis and proximal tubular failure with a secondary Fanconi syndrome may also occur. Stress and starvation provoke acidotic attacks with marked lactic acidaemia. Poor metabolic control causes: growth arrest; hyperuricaemia and gout; marked hypertriglyceridaemia and hypercholesterolaemia with raised very low-density lipoprotein (**VLDL**) and normal low-density lipoprotein (**LDL**) cholesterol concentrations in the plasma (skin and retinal xanthomas accompany these findings); and prolonged bleeding time related to an acquired von Willebrand-like defect affecting the platelet. Patients with defects of the glucose 6-phosphate translocase system (type 1B) are prone to bacterial infection: there is neutropenia, and neutrophil migration and chemotaxis are impaired. These patients may develop episodes of severe diarrhoea in association with granulomatous infiltration of the colonic mucosa. Partial deficiencies of the glucose 6-phosphatase system lead to variable clinical expression, and subtypes of type I glycogen storage disease have been convincingly demonstrated in patients presenting with glucagon-unresponsive hypoglycaemia with or without liver enlargement in adult life. Adult patients or children with uncontrolled disease develop hepatic adenomas; frank hepatocellular carcinomas occur.

Metabolic disturbance

The metabolic disturbance in classical type I glycogen storage serves as a paradigm for the hepatic glycogenoses.

Hypoglycaemia in von Gierke's disease is often asymptomatic and tolerance of it improves with increasing age. The primary defect leads to a profound reduction in the supply of glucose from glucose 6-phosphate in the liver leading to marked substrate-cycling. Lactate delivered from extrahepatic sources is converted to glucose 6-phosphate, which is metabolized by the pentose-phosphate shunt or transferred back into glycogen. The pentose pathway supplies precursors for purine synthesis and reducing equivalents. Residual production of glucose probably occurs by lysosomal hydrolysis of glycogen and recycling through the glycogen synthase-debranching enzyme pathway, but metabolic adaptation of the brain, which can use lactate as an alternative substrate, is very important.

Failure to dephosphorylate glucose 6-phosphate stimulates substrate cycling and increases the activity of the pentose-phosphate pathway, with enhanced production of reduced NADP (**NADPH**, reduced form of nicotinamide-adenine dinucleotide phosphate), ribose 5-phosphate, and purines—this latter ultimately leads to the overproduction of uric acid through the action of xanthine oxidase. Increased delivery of fructose 6-phosphate from the pentose-phosphate pathway leads to the excess formation of lactate as a result of phosphohexosisomerase activity. Enhanced cycling of UDPG and the glycogen synthase reaction promotes glycogen accumulation. However, small quantities of free glucose can be liberated by the a-1,6-glucosidase activity of the secondary action of debranching enzyme but the co-ordinated action of glucosyltransferase and phosphorylase releases additional glucose 1-phosphate residues for recycling. An additional (fractional) degradation of the intracellular glycogen store is probably contributed by the a-1,4-glucosidase activity of lysosomal acid maltase.

Hypertriglyceridaemia is induced by the increased provision of reduced nicotinamide-adenine dinucleotide (**NADH**) and NADPH, glycerol, and acetyl-coenzyme A (**acetyl-CoA**) because of enhanced flux through glycolysis and underutilization of gluconeogenic precursors. Malonyl-coenzyme A, derived from acetyl-CoA, inhibits the carnitine acyltransferase system and blocks the oxidation of fatty acids; thus marked ketosis does not usually develop. Lactic acidaemia results from stimulation of glycolysis at the level of phosphofructokinase by high concentrations of glucose 6-phosphate (and hence fructose 6-phosphate); lactate cannot be recycled in the liver to form new glucose and lactic acidosis results. Lactate competes with urate for excretory pathways in the kidney and thus contributes to the hyperuricaemia. Uric acid is also overproduced in the liver: it arises from the degradation of purine nucleotides by AMP-deaminase and the co-ordinated action of xanthine oxidase on inosine phosphate and hypoxanthine. The deaminase is activated when the concentration of free phosphate falls as a result of sequestration in sugar phosphate esters.

Treatment

The main objective is to maintain euglycaemia: most of the other metabolic abnormalities are thereby corrected and the prognosis improves.

In infants, normoglycaemia is maintained throughout 24 h by intravenous alimentation at 0.25 to 0.5 g/kg per hour and, later by continuous nasogastric administration at night together with glucose supplements at intervals of 1 to 2 h during the day. These intensive regimens correct acidosis, hyperuricaemia, and hyperlipidaemia; they also promote normal development and allow catch-up growth to occur in stunted infants and children. After growth in later childhood and in adult patients, metabolic control can be maintained by the use of raw cornstarch, which serves as a source of glucose that is slowly released by hydrolysis: 1 to 2 g/kg is given orally every 4 to 6 h as a suspension in water.

In type Ib glycogen storage disease it is vital to avoid intercurrent infection, and prophylactic antimicrobial drugs may therefore be necessary. In several instances, infusions of granulocyte-colony-stimulating factor has been strikingly effective in reducing the rate of infection and controlling granulomatous colitis. Patients with type Ia disease may also require treatment for their bleeding tendency. The bleeding diathesis is associated with a qualitative defect of platelet function, prolonged bleeding time, and reduced factor VIIIc and von Willebrand factor activities. These abnormalities and the haemorrhagic tendency respond to the administration of 1-deamino-8-D-arginine vasopressin (**DDAVP**) at 0.3 µg/kg infused in 50 ml of saline over 30 min intravenously. Correction of the bleeding disorder lasts for several hours and is useful for the treatment of bleeding after trauma or surgery.

Failure of metabolic control in type I glycogen storage disease appears to be associated with tissue complications: hepatic adenomas or malignant transformation, renal disease due to hyperfiltration, focal glomerulosclerosis, and postinfective scarring. Lately, an inflammatory disorder of the colon, resembling granulomatous colitis, has been recognized in type Ib disease. Type Ic disease, characterized by the increased latency of hepatic microsomal inorganic pyrophosphatase activity has

now been reported. Phagocytic defects are not prominent in this disease subtype. Defective function of the microsomal glucose transporter has been reported and is designated type Id glycogen storage disease. Long-term, follow-up care with monitoring of biochemical parameters of kidney function and periodic ultrasonic examination of the liver is necessary. Continuing failure of growth, enlarging hepatic adenomas or progressive renal failure raise the question of organ transplantation. Transportal hepatocyte transplantation has been successfully achieved in this disease with correction of hypoglycaemia and lactic acidosis. Several successful renal, as well as hepatic, allografts have been carried out in patients with this condition using DDVAP infusions to control haemorrhagic manifestations. However, as regression of most complications, including hepatic adenomas, can be achieved by strict dietary measures, transplantation should be reserved for patients in whom nutritional treatment has failed. Survival into adult life (and parenthood) can be now expected.

Type II glycogen storage disease

Pompe's disease caused by acid maltase deficiency is usually a rapidly progressive disorder with effects on the heart, skeletal muscle, and nervous system. Affected children usually die within the first year or two of life, and until recently no measures other than supportive therapy and ventilatory assistance have been beneficial. Late-onset disease, usually without cardiomyopathy, occurs in juvenile and adult patients in whom it typically presents with skeletal myopathy affecting the proximal muscles. Ultimately, respiratory failure results from paralysis of the muscles of ventilation, including the diaphragm; voluntary muscles of deglutition may also be paralysed. Occasionally the disease resembles polymyositis or limb-girdle muscular dystrophy. Given that enzyme-replacement therapy is theoretically possible for lysosomal storage diseases, administration of purified acid a-1,4-glucosidase (acid maltase) has been attempted. Early trials of recombinant human acid maltase harbouring mannose 6-phosphate residues, to mediate targeting to cell-surface receptors for lysosomal uptake by skeletal myocytes, have been reported in infants with classical Pompe's disease. Two preparations (from the milk of lactating rabbits and from genetically engineered rodent cells) have been studied. Limited success was obtained in both trials, with improved muscle strength and transient mobility as well as delayed progression of myopathy. The long-term outcome is rendered uncertain by the development of neutralizing antibodies in many recipients and by the ability to manufacture sufficient enzyme. Bone marrow transplantation does not appear to be beneficial. In juvenile and adult acid maltase deficiency, muscle wasting may be arrested with improved or maintained function by institution of a high-protein, restricted-carbohydrate diet. Enzyme-replacement trials using recombinant human acid maltase have yet to be conducted in late-onset type II disease, although this treatment is likely to be more successful than in infantile disease where enzyme antigen is usually completely absent.

Type III glycogen storage disease

The clinical manifestations of Forbes–Cori's disease resemble those of type I glycogenosis, especially in infants, who present with hypoglycaemia, short stature, and hepatomegaly. Mild progressive myopathy, occasionally with signs of hypertrophic cardiomyopathy, may occur. The disorder is characterized by marked clinical variability. Generally the signs of liver disease regress during maturation and myopathy also improves with nutritional therapy as outlined for von Gierke's disease. Protein supplements, which may provide additional sources of energy, appear to benefit the muscle disorder.

Type IV glycogen storage disease

This disorder is one of the more severe glycogenoses because the deficiency of branching enzyme in Anderson's disease gives rise to the deposition of an abnormal glycogen in many tissues. Severe inflammation occurs in the liver, resulting in early cirrhosis, with splenomegaly due to portal hypertension. This fatal disorder is characterized by failure to thrive, hepatosplenomegaly, jaundice, and hypotonia. The myopathy is often prominent with a lordotic posture and waddling gait due to limb-girdle weakness. Cardiomyopathy leading to cardiac failure develops in severely affected infants and children. Diagnosis is based on the appearances of the liver biopsy and abnormal glycogen structure shown by histochemical and biochemical analysis. Deficiency of branching enzyme is demonstrable in leucocytes. No definitive therapy is available, but a few patients have survived hepatic transplantation without the development of neuromuscular or cardiac complications up to 7 years after the procedure. Generally the prognosis is poor: without transplantation most patients die before the age of 4 years with liver failure, variceal bleeding, and intercurrent infection. Prenatal diagnosis of branching enzyme can be conducted by enzymatic analysis of amniotic cells or chorionic villi; DNA analysis of the human branching enzyme on chromosome 3p12 may also be possible for at-risk families.

Type V glycogen storage disease (McArdle's disease)

This disorder is characterized by the late onset of muscle fatigue and cramps during adolescence or early adult life. Hepatomegaly is absent. Strenuous exercise may induce episodic myoglobinuria and biochemical evidence of rhabdomyolysis. A characteristic feature is the occurrence of the 'second wind' phenomenon: progressive weakness and fatigue develop during the first 10 to 15 min of exercise, with a rapid recovery that is complete on resting; after this adaptation phase, patients are often able to continue exercise without difficulty. The mechanisms involved in this adaptive phenomenon are not clear but include increased cardiac output, blood flow to the muscles, and metabolic changes, probably including different patterns of fibre recruitment and the use of oxidative pathways. Occasionally, acute myoglobinuric renal failure may result. Muscle biopsy may show abnormal muscle fibres with necrosis, atrophy, and hypertrophied fibres alongside. The course of this disease is benign; ingestion of glucose or pre-exercise administration of glucagon may partially ameliorate the symptoms but avoidance of strenuous exercise is advisable. The muscle phosphorylase gene maps to chromosome 11q13 and sequence analysis has identified common mutations in this glycogenosis; one mutation, involving formation of a stop codon within exon 1 at position 49 (arginine) is sufficiently common to be of diagnostic value.

Type VI glycogen storage disease and phosphorylase b kinase deficiency

These disorders cause hepatomegaly, intermittent hypoglycaemia, and markedly increased liver glycogen content. Although many polypeptides constitute the intact phosphorylase b kinase complex (encoded on autosomes and the X-chromosome), glycogen mobilization is usually only partially defective. X-linked phosphorylase b kinase deficiency is the most frequent variant and is associated with growth retardation, mild ketosis, and hyperlipidaemia in childhood. The symptoms improve with age and the disorder is compatible with a normal life expectancy. Cirrhosis of the liver is very rare, and the incompleteness of the defect is shown by almost normal hyperglycaemic responses to glucagon administration. Rare autosomal variants of phosphorylase kinase deficiency affecting liver and muscle or restricted to skeletal or cardiac muscle have been documented. These subtypes are associated with hypotonia or cardiac failure, respectively. Treatment of liver phosphorylase or kinase deficiency with frequent feeding to avoid hypoglycaemia may be needed, but intensive nutritional therapy is rarely indicated since the general prognosis is good. No specific treatment for the isolated cardiac form of kinase deficiency is known but cardiac transplantation could be considered if the diagnosis can be established.

Type VII glycogen storage disease (Tarui's disease)

This disorder, which is most frequent in patients of Japanese or Russian Ashkenazi ancestry, closely resembles type V muscle glycogenosis but severe symptoms usually come to light in childhood. There may be hyperuricaemia which is aggravated by exercise. Deficiency of red cell phosphofructokinase leads to chronic haemolysis; there is mild jaundice and a strong association with pigment-type gallstones. Decreased 2,3-diphosphoglycerate synthesis resulting from the metabolic block has been noted and probably contributes to exercise-induced symptoms by reducing oxygen delivery. Phosphofructokinase I catalyses an irreversible step in glycolysis and is an important regulatory enzyme, especially in muscle. Deficiency of phosphofructokinase I renders the pathway insensitive to positive allosteric regulation by the key effector molecules, fructose 2,6-diphosphate and AMP; hence myophosphorylase activity remains depressed. For this reason, Tarui's disease resembles a severe form of McCardle's disease. No specific therapy for this disorder is known—in contrast to McArdle's disease, neither glucagon nor glucose infusions improve exercise tolerance. Indeed, carbohydrate-rich meals aggravate the symptoms, presumably by diminishing the concentration of non-esterified fatty acids in the plasma, which serve as the alternative source of muscle energy production. Several very rare variants of phosphofructokinase deficiency are known: a severe infantile form with progressive and fatal myopathy and a late-onset form that causes fixed muscle weakness in middle-aged subjects are both clearly recognized. Approximately 15 mutations have been identified in the human muscle phosphofructokinase gene in patients with Tarui's disease; the three subunits encoding this isozyme originate from a locus on chromosome 12q13.3.

Glycogen synthase deficiency

Although glycogen synthase deficiency is very rare, it causes deficiency of glycogen formation in the liver. Most cases have been reported in infants and young children. It is, therefore, a disorder of storage rather than a true glycogenosis. The condition causes severe interprandial hypoglycaemia and marked ketosis; a notable feature is the rapid development of hyperglycaemia and lactic acidaemia on feeding. The disorder resembles fructose 1,6-bisphosphatase deficiency, but mutations in the liver glycogen synthetase gene II on chromosome 12p12.2 have been identified. Biopsy examination of the liver shows fatty infiltration and depletion of glycogen: uridine diphosphate-pyrophosphorylase, phosphorylase, glucose 6-phosphatase activities are normal but glycogen synthase is absent. Glucose polymers and uncooked cornstarch are effective therapy.

11.3.2 Inborn errors of fructose metabolism

T. M. Cox

There are three inborn errors of fructose metabolism recognized: (1) essential or benign fructosuria due to fructokinase deficiency; (2) fructose 1,6-diphosphatase deficiency; and (3) hereditary fructose intolerance (fructosaemia). There are discussed in relation to the overall metabolism of fructose, a major nutrient.

Metabolism of fructose

Phosphorylated forms of fructose are critical intermediates in the glycolytic and gluconeogenic metabolic pathways in all cells. Fructose is also an important component of the diet: it occurs as a free monosaccharide in fruit, nuts, honey, and some vegetables. Free fructose is released from sucrose in the gut lumen by sucrase–isomaltase in the brush-border membrane of the mucosal epithelium. Finally, the sugar alcohol, sorbitol (a constituent of medicines and tablets, as well as some foods for diabetics), is converted quantitatively to fructose in the liver and intestine. Most individuals in developed countries ingest 50 to 150 g fructose equivalents daily in the diet.

The pathways of fructose metabolism are summarized in Fig. 1. Fructose is absorbed rapidly by a carrier mechanism that facilitates transport across the intestinal epithelium; this process is mediated by the glucose transporter isoforms, GLUT5 and GLUT2, the latter probably contributing to efflux across the basolateral membrane of the enterocyte.

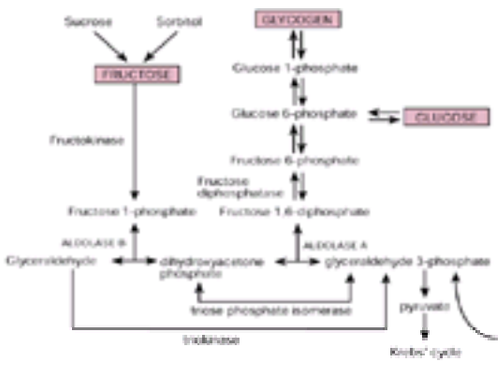

Fig. 1 Fructose metabolism.

It is then conveyed via the portal bloodstream to the liver, where it is assimilated. The jejunal mucosa and proximal tubule of the kidney are subsidiary sites of fructose metabolism. Assimilation of fructose depends on the concerted activities of the enzymes ketohexokinase (fructokinase), aldolase B, and triokinase, which are expressed specifically in these tissues. Uptake of fructose occurs independently of insulin and its incorporation into intermediary metabolism bypasses the regulation of glycolysis at the level of phosphofructokinase-1. For these reasons, solutions of fructose or sorbitol were advocated and, in the past, extensively used for parenteral nutrition. However, the occurrence of lactic acidosis, hyperuricaemia and other serious consequences have led to their withdrawal from hyperalimentation regimens in most, if not all, countries.

Fructokinase rapidly phosphorylates fructose at the 1-carbon position. This enzyme has a high affinity for its substrates and the intestinal mucosa and liver rapidly convert fructose to fructose 1-phosphate: in other tissues, the capacity of hexokinase to phosphorylate fructose at the 6-carbon position is limited. Similarly, the fate of fructose 1-phosphate in the fructose-metabolizing tissues is dependent on a specific isozyme of aldolase, aldolase B. This has greater activity towards fructose 1-phosphate than does its ubiquitous counterpart, aldolase A, the natural substrate of which is fructose 1,6-diphosphate. Cleavage of fructose 1-phosphate generates glyceraldehyde and dihydroxyacetone phosphate. These trioses enter the intermediary pools of carbohydrate metabolism, and, as a result of triokinase activity, glyceraldehyde is phosphorylated so that the two triose phosphates may be condensed by aldolase A to form the glycolytic and gluconeogenic intermediate, fructose 1,6-diphosphate.

Gluconeogenesis from triose phosphates, lactate, glycerol, amino acids, and Krebs cycle intermediates such as oxaloacetate, requires reversal of the committed reactions of glycolysis. It is the enzyme fructose 1,6-diphosphatase that releases the glucose precursor fructose 6-phosphate from fructose 1,6-diphosphate. Thus, when the remaining reactions of glycolysis are reversed, exogenous fructose provides a source of glucose or glycogen. Fructose 1,6-diphosphatase is active in the liver, kidney, and intestine; it is a key enzyme of gluconeogenesis.

Fructose malabsorption

Incomplete absorption of fructose with abdominal symptoms and diarrhoea reminiscent of intestinal disaccharidase deficiency is well recognized by gastroenterologists. The symptoms occur in adults and children after ingestion of fructose- or sorbitol-rich foods and drinks such as apple juice, and usually recede when these sugars are excluded from the diet. Many such individuals, as well as a high proportion of healthy control subjects, have suggestive evidence of fructose malabsorption based on breath-hydrogen tests. Unfortunately, the molecular basis of this syndrome and of the wide variation of tolerance to dietary fructose and its congeners is not known. Moreover, molecular analysis of the human *GLUT5* gene in several patients complaining of fructose-related intestinal symptoms, has hitherto failed to implicate this candidate sugar transporter. Preliminary studies suggest that lower intestines and colons of many patients who experience abdominal flatulence and diarrhoea after ingesting fructose-containing foods contain a bacterial population showing enhanced uptake and anaerobic metabolism of fructose. No conclusive evidence has yet been provided to support these observations and more fructose transport studies are needed on the mucosal epithelium of patients who complain of symptoms that indicate an intestinal malabsorption of this sugar.

Essential (benign) fructosuria (Mendelian inheritance in man (MIM) 229800)

This is a rare disorder (estimated frequency 1 in 130 000) of little clinical consequence. The abnormality is transmitted as an autosomal recessive condition and manifests itself by the presence of a reducing sugar in the blood and urine, especially after meals rich in fructose. The abnormality results from the deficiency of

fructokinase activity in the liver and intestine, significantly reducing the capacity to assimilate this sugar. Mutations in the human ketohexokinase gene on chromosome 2p23.3–p23.2 have been identified in patients with essential fructosuria, thus confirming the suspected molecular defect in this condition. Fructose metabolism occurs slowly in essential fructosuria as a result of conversion to fructose 6-phosphate by hexokinase in adipose tissue and muscle, but, while plasma concentrations remain high postprandially, large amounts of fructose appear in the urine. Essential fructosuria may be confused with diabetes mellitus if the nature of the mellituria is not defined with the use of glucose oxidase strips in preference to the older chemical methods for urinalysis, such confusion is now unlikely. No treatment beyond recognition and explanation appears to be necessary.

Fructose diphosphatase deficiency (MIM 229700)

Description

This very rare, recessively inherited disorder presents with hypoglycaemia, ketosis, and lactic acidosis in early infancy. Fewer than 30 cases have been reported since its original description in 1970. Severe, sometimes fatal, acidosis is associated with infection and starvation and most cases have presented within the first few days of life or in the neonatal period. Onset during the first year of life is the rule.

In newborn infants, the severe metabolic disturbance shows itself by acidotic hyperventilation, which may be accompanied by irritability, disturbed consciousness, seizures, or coma. The unusual combination of ketonaemia, lactic acidaemia, and hypoglycaemia is induced by fasting, the administration of fructose, sorbitol, and glycerol, and by ingestion of a diet rich in fat. Episodes in the neonatal period respond well to infusions of glucose and bicarbonate but, after an interval, further attacks occur, often provoked by intercurrent infection. Lethargy accompanied by hyperventilation is followed abruptly by prostration, coma, and seizures. Investigations reveal hypoglycaemia, ketosis, and profound lactic acidosis; there is hyperuricaemia, amino aciduria, and ketonuria. If the infant survives, hepatomegaly due to fatty infiltration may be detected but overt clinical disturbances of hepatic or renal tubular function are not seen. The untreated disease is associated with growth retardation.

The first infant to be affected by fructose diphosphatase deficiency in a given family may succumb before the diagnosis is established and in any case fares worse than siblings for whom the appropriate diet and prompt control of the condition are instituted. The response to treatment is favourable, however, and fructose diphosphatase deficiency is ultimately compatible with a benign course and with normal growth and development.

Metabolic defect

Deficiency of fructose 1,6-diphosphatase causes failure of gluconeogenesis in the liver—although the abnormality may be detected in intestinal mucosa, kidney, and in cultured mononuclear cells from peripheral blood. The muscle isozyme of fructose 1,6-diphosphatase is not affected.

Between meals, blood glucose is maintained by glucogenolysis and hence the onset of disturbed metabolism in fructose diphosphatase deficiency depends on the availability of hepatic glycogen. Since febrile illnesses accelerate the consumption of liver glycogen, the accompanying anorexia with or without vomiting may deplete glycogen stores critically. Acidosis results from the accumulation of gluconeogenic precursors including lactate, pyruvate, and alanine as well as ketone bodies, which cannot be utilized. Hypoglycaemia, which is unresponsive to glucagon and associated with exhaustion of glycogen stores, occurs: this does not respond to normal gluconeogenic substrates (for example, glycerol, amino acid solutions, dihydroxyacetone, sorbitol, or fructose), indeed administration of these aggravates the metabolic disturbance.

The pathogenesis of hypoglycaemia and accompanying disturbances in fructose diphosphatase deficiency is complex and not completely explained by exhaustion of hepatic glycogen stores. Well-fed patients have a normal response to glucagon but are intolerant of high-fat diets, as well as of fructose, sorbitol, alanine, glycerol, and dihydroxyacetone administration. Challenge with these nutrients induces hypoglycaemia, hyperuricaemia, and hypophosphataemia, accompanied by an exaggerated rise in blood lactate levels. The hypoglycaemia is then unresponsive to glucagon, indicating a secondary inhibition of phosphorylase activity in the liver, which results from the build-up of phosphorylated sugar intermediates that cannot be further metabolized in the context of reduced intracellular free inorganic phosphate. Adenosine deaminase is activated primarily because of reduced phosphate concentrations, so that purine nucleotides are broken down to uric acid. Failure to utilize glucogenic amino acids and metabolites such as dihydroxyacetone and glycerol appears to stimulate triglyceride formation in the liver, which induces steatosis. Unlike hereditary fructose intolerance (see below), high concentrations of hepatic fructose 1-phosphate do not occur, and profound disturbances of blood coagulation or hepatic or renal tubule function with progressive structural damage are absent in fructose diphosphatase deficiency. Similarly, aversion to foods that aggravate the disorder does not develop in affected infants and children; this may be explained by the absence of pain and abdominal symptoms in the condition.

Diagnosis

The importance of establishing the diagnosis of fructose diphosphatase deficiency cannot be overemphasized: proper dietary control and protocols for the institution of appropriate therapy depend upon recognizing the complex disturbance that underlies this disease.

Fructose diphosphatase deficiency should be considered in otherwise normal infants who develop unexplained severe acidosis or hypoglycaemia associated with episodes of infection. The combination of ketosis and lactic acidosis with hypoglycaemia is highly suggestive of a disorder affecting the gluconeogenic pathway, including deficiency of glucose 6-phosphatase, pyruvate carboxylase, pyruvate dehydrogenase, and phosphoenolpyruvate carboxykinase. The absence of abdominal distress, haemolysis, jaundice, coagulopathy, and disturbances of the proximal renal tubule differentiate the condition from hereditary fructose intolerance, tyrosinosis, and Wilson's disease. Confusion may arise with disorders associated with secondary defects in gluconeogenesis, especially the Reye-like syndrome caused by deficiencies of long-, medium- and short-chain acyl coenzyme A dehydrogenase activities, as well as defects of carnitine metabolism. Organic acidaemias are also readily distinguished by biochemical screening methods.

Provocative tests using food deprivation and the administration of infusions of fructose, sorbitol, or glycerol should be avoided in the acutely ill infant or child with suspected deficiency of fructose 1,6-diphosphatase (or fructose intolerance). The definitive diagnosis depends on the demonstration of selectively decreased fructose diphosphatase activity in tissue samples. Most frequently, the enzymatic defect will be identified by biochemical assay of a freshly obtained liver biopsy specimen, which allows other metabolic disorders and gluconeogenic defects to be confidently excluded. The defect may also be demonstrated in biopsy samples of jejunal mucosa and in cultured monocyte-derived macrophages obtained from peripheral blood. However, the presence of fructose 1,6-diphosphatase in these tissues is metabolically inconsequential and, although useful for confirmation of the diagnosis where it is strongly suspected, in practice decisive identification of this disorder normally depends on a systematic biochemical analysis of liver tissue in an experienced laboratory. The human fructose 1,6-diphosphatase (**FBP1**) gene maps to chromosome 9q22.2–q22.3 and inactivating mutations have been identified in the disease. Unlike fructose intolerance however, these mutations tend to be private and thus individually of less diagnostic significance for routine laboratory use in this disorder since mutational heterogeneity appears to be the rule. However, a minor exception to this occurs in the Japanese population, where one mutation (960–961 ins G) appears to account for almost one-half of mutant *FBPI* alleles.

Treatment

Dietary control and avoidance of starvation with rapid control of febrile illnesses is the mainstay of treatment. Minor infections and injuries require prompt attention, and intravenous glucose therapy should be instituted early in acute episodes to avoid hypoglycaemia and acidosis. Fasting should be avoided as far as possible, while night-time feeding may be needed in infants during recovery from injuries or infections and after strenuous exercise in older children. The habit of taking meals at regular 4-hourly intervals is best inculcated when the patient is young. The diet should exclude excess fat; sorbitol, sucrose, and fructose must be strictly avoided. Breast milk is rich in lactose, which is readily assimilated, but difficulties arise on transfer to artificial feeds during weaning. In addition, medications and syrups containing fructose, sucrose, or sorbitol present a special danger to patients with deficiency of fructose diphosphatase activity. A diet excluding these sugars but containing 56 per cent calories as carbohydrate with 32 per cent calories as fat and 12 per cent as protein has produced normal growth and development. Acute episodes of acidosis or hypoglycaemia are controlled rapidly by intravenous administration of glucose with or without bicarbonate as required.

Hereditary fructose intolerance (fructosaemia) (MIM 229600)

This disorder, first recognized in 1956, is the most common inherited defect of fructose metabolism with an estimated frequency of 1 in 20 000 births. The condition is transmitted as an autosomal recessive abnormality and, although it manifests itself first in early infancy, the effects of clinical disease may not be recognized until late childhood or adult life. Provided the diagnosis is made before visceral damage occurs, hereditary fructose intolerance responds completely to an exclusion diet.

The cardinal features of the illness are vomiting, diarrhoea, abdominal pain, and hypoglycaemia, which are induced by the consumption of foods, drinks, or medicines that contain fructose seizures, or the related sugars, sucrose or sorbitol. There is a generalized metabolic disturbance with lactic acidosis, hyperuricaemia, and hyperphosphataemia. Hypoglycaemia causes trembling, irritability, and cognitive impairment. Attacks are associated with pallor, sweating, and, when severe, loss of consciousness—sometimes accompanied by generalized seizures. These episodes usually occur within 30 min of feeds that contain large quantities of fructose or sucrose. Continued ingestion of noxious sugars is associated with renal tubular disease, liver damage with jaundice, and defective blood coagulation. There is failure to thrive and growth retardation. Persistent exposure to fructose in infants leads to structural liver injury with cirrhosis, amino aciduria, coagulopathy, and coma leading to death. The infant is first exposed to the offending sugars at weaning or upon transfer from breast milk to artificial feeds: survival is dependent on recognition of the effects of fruit and sugar by the mother or, especially in older infants, by vomiting or forcible rejection of food.

Infants who survive the stormy period of weaning, develop a strong aversion to sweet-tasting foods, vegetables, and fruits. This usually affords protection against the worst effects of fructose and sucrose, but abdominal symptoms with bouts of tremulousness, irritability, and altered consciousness due to hypoglycaemia usually continue. It has become clear that many cases escape diagnosis in infancy and childhood, but that the risk of illness, related to dietary indiscretion, remains throughout life. Characteristically, children and adults with hereditary fructose intolerance show a striking reduction in, or absence of dental caries.

Recently, a syndrome of chronic sugar intoxication has been recognized in older children and adolescents with hereditary fructose intolerance. General lack of vigour and developmental retardation are prominent features. Hypoglycaemia, though obvious after heavy fructose loading, may be insignificant after chronic low-level exposure in older children. Similarly, tests of hepatic and renal function may be only mildly abnormal. Persistent ingestion of fructose and sucrose is toxic to the kidney and liver, so that renal tubular acidosis (occasionally with calculi) as well as hepatosplenomegaly are frequently detectable in the younger patients. Severe growth retardation may be accompanied by rachitic bone disease that complicates the Fanconi-like syndrome of proximal renal tubular disturbance. Growth retardation responds to dietary treatment and is usually accompanied by regression of the other disease manifestations.

Provided that organ failure and serious tissue injury do not supervene, patients with hereditary fructose intolerance recover rapidly when the offending sugars are withdrawn. Children who survive by acquiring the protective eating-behaviour pattern avoid foods that they associate with abdominal symptoms. The aversion extends to most sweet-tasting items of food and drink as well as fruits and vegetables—it remains lifelong and consumption of fructose is usually reduced to less than 5 g daily. It has been shown that normal growth and development can be secured in children if less than 40 mg/kg fructose equivalents are ingested daily.

Metabolic defect

Hereditary fructose intolerance is caused by a deficiency of aldolase B in the liver, small intestine, and proximal renal tubule. These tissues suffer injury as a result of persistent exposure to fructose in patients affected by the disorder. In the absence of the fructose 1-phosphate splitting activity of aldolase B, the intracellular pool of inorganic phosphate is depleted. Studies *in vivo* by ^{31}P magnetic resonance spectroscopy show that 80 per cent of hepatic free phosphate is sequestrated as sugar phosphates after the infusion of small quantities of fructose (250 mg/kg body weight). The secondary metabolic disturbances are initiated by the accumulation of fructose 1-phosphate in a milieu where free inorganic phosphate is reduced: there is competitive inhibition of aldolase A and inhibition of phosphorylase activity so that glycogenolysis and gluconeogenesis are impaired. Thus challenge with fructose leads to hypophosphataemia and hypoglycaemia that is refractory to glucagon or the infusion of gluconeogenic metabolites such as glycerol or dihydroxyacetone. During challenge with fructose, high concentrations of fructose 1-phosphate cause feedback inhibition of fructokinase, thereby limiting the incorporation of fructose in the liver. As a result, fructosaemia occurs and when the concentration exceeds about 2 mmol/l in peripheral blood, fructosuria becomes apparent. Although the assimilation of fructose by the specialized pathway is blocked, only a small fraction of the fructose load is recovered in the urine. Studies show that 80 to 90 per cent of the fructose is taken up under these circumstances by adipose tissue and muscle, where it can be alternatively metabolized by phosphorylation to fructose 6-phosphate.

Electrolytic disturbances occur during challenge with fructose. Hypokalaemia results from acute renal impairment with defective urinary acidification. There is a defect of proximal tubule function with bicarbonate wasting and acidosis. Occasionally, acute flaccid weakness due to hypokalaemia accompanies the other effects of fructose exposure. In patients with hereditary fructose intolerance, the administration of fructose reproducibly increases serum magnesium concentrations. This is probably explained by the breakdown of magnesium–adenosine triphosphate (**ATP**) complexes, releasing intracellular magnesium ions as a result of nucleotide degradation by adenosine deaminase. Significant ingestion of fructose is thus also accompanied by marked hyperuricaemia in patients with hereditary fructose intolerance.

Pathology and molecular genetics

Chronic ingestion of fructose in hereditary fructose intolerance causes hepatic injury: there is diffuse fatty change and increased glycogen deposition. Hepatocyte necrosis with intralobular and periportal fibrosis occurs and fully developed cirrhosis results from continued exposure to fructose. After acute experimental challenge, electron microscopy has shown irregular electron-dense material surrounded by membranous structures, suggesting a florid lysosomal reaction to intracellular deposits of fructose 1-phosphate. Fatal administration of fructose or sorbitol parenterally is associated with the abrupt onset of hepatorenal failure associated with bleeding. Histological examination shows hepatic necrosis in these cases (Fig. 2). Loss of cellular functions, for example in the proximal renal tubule, is probably caused by depletion of ATP resulting from the arrested metabolism of fructose by the specialized pathway. The source of the severe abdominal pain that follows ingestion of fructose is unknown, but stimulation of visceral afferent nerves by the local release of purine nucleotides or lactate may be responsible.

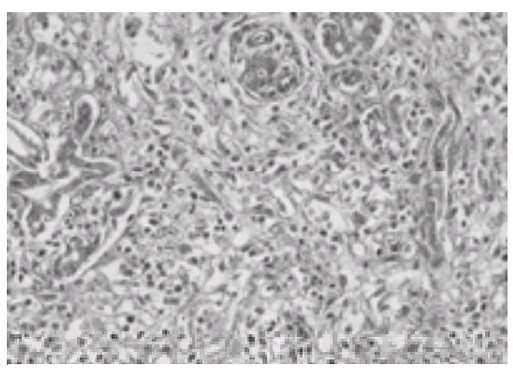

Fig. 2 The effects of fatal infusions of fructose in a young Italian girl.

The genetic basis of aldolase B deficiency has been studied intensively. The human aldolase B gene maps to chromosome 9q22.3. Several point mutations affecting the function of the enzyme are sufficiently widespread in patients of European origin to merit diagnostic investigation. One particular mutation, Ala ^{149}®Pro, which disrupts residues in a substrate-binding domain of aldolase B, is prevalent in Europe. This mutation accounts for most alleles responsible for fructose intolerance, but others, including Ala^{174}®Asp, Asn^{334}®Lys and a four-base deletion in exon 4, are sufficiently frequent and widespread to merit examination in the diagnostic laboratory (see below).

Diagnosis

In infancy and childhood, hereditary fructose intolerance most characteristically causes persistent vomiting, with failure to thrive, acidosis, hypoglycaemia, and jaundice. Clearly in very young infants there is a wide differential diagnosis, but fructose intolerance may be indicated by the nutritional history and feeding difficulties. The presence of reducing sugar in the urine may indicate that fructosuria and amino acids may also be present. Older children and adults report food aversion and may show a striking absence of dental caries. If fructose intolerance is considered, then sucrose, sorbitol, and fructose should be excluded completely before definitive tests can be carried out. Striking improvement, suggestive of hereditary fructose intolerance, may be seen within a few days. The differential diagnosis includes pyloric stenosis, galactosaemia, hepatitis, renal tubular disease, Wilson's disease, and tyrosinosis.

Since the prompt institution of strict dietary treatment has beneficial and, in infants and children, life-saving effects in those with fructose intolerance, every

reasonable effort should be undertaken to make a definitive diagnosis. This will have important consequences for relatives of the propositus and will provide information critical for the introduction of a rigorous and life-long exclusion diet.

The intravenous fructose tolerance test is often useful for diagnosis, particularly in adults: 0.25 g/kg (0.2 g/kg in infants) of D(+)-fructose is infused as a 20 per cent solution over a few minutes and blood samples for potassium ions, magnesium ions, phosphate ions, and glucose are taken at regular intervals over a 2-h period. Epigastric and loin pain accompany the infusion, and hypoglycaemic coma may occur. The hypoglycaemia does not respond to glucagon, therefore glucose for parenteral injection must be available. The test should be carried out under controlled conditions with medical personnel at hand: oral challenge with fructose or sucrose may produce severe pain and shock and is best avoided. Responses differ between individuals and hypoglycaemia is usually milder in adults, but typical responses in hereditary fructose intolerance and a control subject are depicted in Fig. 3. The tolerance test should not be carried out in patients with overt signs of liver disease where it may occasionally yield misleading results, particularly in infants and children.

Fig. 3 (a) Intravenous fructose tolerance tests in a 39-year-old woman with hereditary fructose intolerance proven by fructaldolase essay and DNA analysis. (b) An age- and sex-matched control subject with alcohol-related episodic hypoglycaemia.

Aldolase B deficiency is demonstrated definitively by enzymatic analysis of biopsy samples obtained from the liver or small intestinal mucosa. Biochemical assay of fructaldolases characteristically demonstrates reduced or absent fructose 1-phosphate cleavage activity with a partial deficiency of fructose 1,6-diphosphate aldolase. Since fructaldolase deficiency may accompany other parenchymal disease of the liver, these assays are of limited value in the acutely ill or jaundiced patient.

Recently, a direct diagnosis of hereditary fructose intolerance has been possible, particularly in patients of European ancestry: examination of aldolase B genes for the presence of common mutations responsible for the disease can be carried out by laboratories that specialize in the molecular analysis of genomic DNA. The ability to identify disease alleles by analysing tiny samples of blood or tissue may be beneficial for the investigation of infants with this disorder and, eventually, for postnatal screening before dietary exposure occurs. Tests for fructose intolerance based on the analysis of DNA may avoid the need for invasive or hazardous investigations using tissue biopsy procedures or challenge with parenteral sugar solutions.

Treatment

Dietary treatment of fructose intolerance alleviates the disorder but requires the almost complete exclusion of sucrose, fructose, and sorbitol. The daily consumption of sugar should be reduced to less than 40 mg of fructose equivalents per kilogram body weight (that is, 2–3 g for an adult) in order to reverse the disease manifestations and establish normal development in affected infants and children. The ubiquity of fructose and its congeners in the Western diet presents serious difficulties. Adult patients have usually restricted their consumption of fructose to less than 20 g daily and the source of the residual sugar may be difficult to establish. For this reason, the advice of an experienced dietitian should be sought (Table 1). Particular care needs to be taken with sugar-coated pills and, especially, liquid medications for paediatric use, as large amounts of fructose, sucrose, and sorbitol are frequently present. Children and adults with hereditary fructose intolerance may tolerate the taste of confectionery that contains large quantities of noxious sugars but in which the sweetness is masked by other flavours such as peppermint, which they enjoy. This behaviour may lead to unexplained hypoglycaemic symptoms and other signs of sugar toxicity. Occasionally, patients are unable to tolerate certain foods that are permitted on their diet sheets—in doubtful cases it is advisable to avoid the offending item or to have it analysed. Patients with hereditary fructose intolerance may lack folic acid and vitamin C. Supplements of these vitamins in particular are recommended, especially during pregnancy, but, as with other medicines, care has to be taken to avoid harmful sugars contained in the preparation: Ketovite®; (Paines and Byrne, Ltd, Surrey, England) is a satisfactory source of these vitamins.

Prognosis

Untreated hereditary fructose intolerance is a fatal disease in infants and young children in whom it generally causes irreversible liver disease and episodic, life-threatening, hypoglycaemia. Occasionally, adolescents and adult patients may succumb to the inadvertent use of parenteral fructose or sorbitol but, except in Germany, this practice is now obsolete. With the introduction of a strict exclusion diet, the disorder is compatible with a normal life expectancy.

11.3.3 Disorders of galactose, pentose, and pyruvate metabolism

T. M. Cox

Inborn errors of galactose metabolism

Galactose is derived principally from the milk sugar, lactose, in the diet by the action of mucosal lactase in the small intestine. The concentration of lactose in human breast milk is approximately 200 millimoles per litre. Newborn infants normally receive about one-fifth of their dietary energy supply in the form of galactose, which is derived from the breakdown of this lactose to galactose and glucose in equimolar amounts. After absorption, galactose serves as a source of glucose. Galactose is a component of many membrane glycoproteins and glycolipids; galactosylated lipids are abundant in nervous tissue.

The conversion of galactose to glucose involves reactions that lead to the formation of glucose 1-phosphate, which can enter the main pathways of carbohydrate metabolism, directly (Fig. 1). The first step involves phosphorylation to form galactose 1-phosphate, which is converted to glucose 1-phosphate and uridine diphosphate-galactose after reaction with the nucleoside diphosphate sugar, uridine diphosphoglucose. Uridine diphosphoglucose is regenerated by the action of uridine diphosphate-galactose-4-epimerase. The presence of this epimerase enables galactose to be produced from glucose for the synthesis of complex glycoconjugates and renders the individual potentially independent of exogenous galactose. Enzymatic defects in the interconversion of these metabolites lead to increased blood and tissue concentrations of galactose, especially after meals containing milk or dairy products. There are three inborn errors of galactose metabolism recognized: (1) galactokinase deficiency; (2) galactose 1-phosphate uridylyltransferase deficiency; and (3) uridine diphosphate-4-epimerase deficiency.

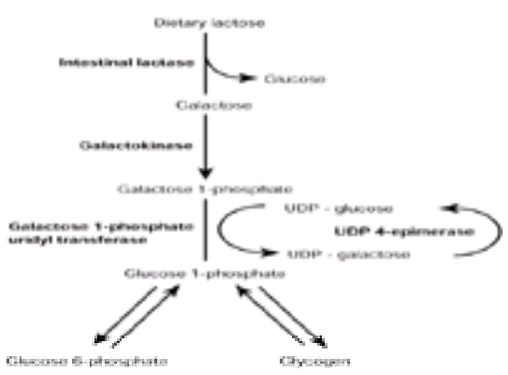

Fig. 1 Galactose metabolism.

Galactokinase deficiency: 'galactose diabetes'

Failure to phosphorylate galactose in the liver and other tissues impairs its clearance from the blood so that the free sugar and its metabolites, galactonic acid and galactitol, appear in the urine. Homozygous deficiency of galactokinase occurs with an approximate frequency of 1 in 100 000 live births.

Clinical features

Precocious formation of cataracts in infants and children is characteristic, with some heterozygotes developing cataracts before the age of 40 years. When blood concentrations are high, galactose is taken up by the lens and converted to the end-product galactitol by the action of aldose reductase: subsequent toxic or osmotic effects lead to swelling and irreversible damage to lens fibres. Patients with galactokinase deficiency persistently excrete reducing sugar in their urine but, apart from possible confusion with diabetes mellitus, this has no apparent significance.

Diagnosis and treatment

Galactokinase deficiency should be suspected in infants or children with cataracts and reducing sugar should be sought in the urine. This sugar will not react with glucose oxidase test strips. Definitive diagnosis by enzymatic assay of galactokinase in erythrocytes or cultured fibroblasts differentiates the disorder from classic galactosaemia and hypergalactosaemia due to vascular disease in the liver. Treatment with a strict lactose and galactose exclusion diet prevents cataract formation. The human gene for galactokinase maps to chromosome 17q24, with a putative second locus on chromosome 15. Several mutations responsible for galactokinase deficiency have been identified in the *GALK1* gene at the chromosome 17 locus.

Galactose 1-phosphate uridylyltransferase deficiency: galactosaemia

Unlike individuals in whom galactokinase is deficient, when patients who lack uridylyltransferase activity ingest lactose, there is a significant rise in intracellular galactose 1-phosphate as well as in the blood galactose concentration. The severe consequences of classical galactosaemia thus result from the toxic effects of galactose 1-phosphate principally in cells of the liver, proximal renal tubule, and brain. Although the exact mechanism of toxicity is unknown, as in hereditary fructose intolerance, the accumulated metabolite probably inhibits other enzymatic reactions involving phosphorylated intermediates and may lead to purine nucleotide depletion.

Recognition of galactosaemia in early infancy is of paramount importance since the acute effects of galactose poisoning may be reversed by institution of a lactose exclusion diet. However, the ability of dietary therapy to promote a completely healthy long-term outcome has now been questioned by follow-up studies in large cohorts of patients with classical galactosaemia and therefore more research is needed to improve our understanding about the pathogenesis of tissue injury in this nutritional disease.

Clinical and pathological features

The affected infant appears normal at birth, but vomiting or diarrhoea, jaundice, and hepatomegaly usually occur in the first few weeks. There is failure to gain weight, subcutaneous bruising, and progressive enlargement of the liver. Cataracts may be apparent at 1 month of age, by which time abdominal distension with ascites has developed. Mental retardation does not become manifest until later in the first year of life and varies greatly in severity. Many patients suffering from galactosaemia develop severe infections with *Escherichia coli* during the neonatal period, and Gram-negative bacterial sepsis may be the first indication of this disorder in young infants. A bactericidal defect in circulating leucocytes has been postulated. In adult patients after reversal of the acute galactose toxicity syndrome, the most obvious sequelae are growth failure, neurological deficit, and primary ovarian failure with infertility.

Occasional patients with galactosaemia remain asymptomatic while ingesting milk but gradually fail to gain weight. Such patients may come to light during childhood or even adult life, because of varying degrees of mental retardation and cataracts. Hepatomegaly and intermittent galactosuria are usually present, and often there is a history of feeding difficulties on institution of modified formula feeds during the neonatal period.

The neurological manifestations of classical galactosaemia are highly variable but, despite prompt institution of dietary therapy, a degree of mental retardation is common in affected children and adults. Characteristic learning difficulties in mathematics and spatial relationships with behavioural deficits have been observed. It appears that the galactose-free diet fails to confer benefit on mental development when instituted beyond the age of 2 years. In follow-up studies of galactosaemic children and adults, a range of neurological deficits, including seizures, apraxia, extrapyramidal disorders, and cerebellar signs, have been documented despite strict dietary measures.

Serum tests of liver function are non-specifically deranged: histological examination shows lobular fibrosis, fatty change, bile ductular proliferation and progression to frank cirrhosis. A haemorrhagic tendency is an early feature of galactosaemia and the diagnosis should be considered in jaundiced infants with signs of a bleeding diathesis. Involvement of the proximal renal tubule is shown by generalized aminoaciduria and occasionally a full-blown Fanconi syndrome with vacuolation of tubular epithelial cells. Histological examination of the brain shows non-specific signs of injury with gliosis and Purkinje cell loss in the cerebellum. Follow-up studies of female patients with galactosaemia has shown a high incidence of gonadal failure with ovarian atrophy: although this complication appears to be more common in patients in whom dietary therapy was delayed, no clear cause-and-effect relationship has been established. A toxic effect on the fetal ovary due to maternal hypergalactosaemia has been postulated to account for the hypergonadotrophic hypogonadism in affected women and girls. No evidence of gonadal failure has been found in male patients.

Genetic studies

Galactosaemia is transmitted as an autosomal recessive trait with an overall estimated frequency of 1 in 62 000. Classical galactosaemia is rare in Japan but frequent in some isolated groups, most notably in the modern Traveller population of Ireland. In this group, screening methods indicate a birth frequency of 1 in 480 compared with 1 in 30 000 in the non-Traveller Irish population. In Black patients from the United States a relatively mild disorder as been reported that is probably due to an unstable enzyme variant; uridylyltransferase activity is absent from their red cells but amounts to some 10 per cent of normal in samples of liver and small intestinal tissue. Individuals with the so-called 'Duarte variant' possess about half the normal enzyme activity in erythrocytes but remain asymptomatic.

The human galactosyl-1-phosphate uridylyltransferase gene maps to human chromosome 9p13 and encodes a protein of molecular weight 43 000 Da, which exists as a functional homodimer. Molecular analysis of the transferase gene indicates that most patients with classical galactosaemia harbour missense-type mutations and are compound heterozygotes. Several variant transferase enzymes have been described. Molecular analysis of the transferase gene has identified several widespread mutations; for example one mutant allele (Q188R) is in linkage disequilibrium with a restriction fragment-length polymorphism flanking exon 6 of the gene sequence in multiple populations worldwide, including the Irish Travellers – galactosaemic patients amongst whom, are all homozygous for Q188R. A less frequent mutation of diagnostic significance in White populations is designated R333W; the Duarte transferase mutation has been identified as N314D. Molecular analysis of the transferase gene now renders prenatal diagnosis of at-risk pregnancies possible.

Diagnosis

Galactosaemia may be suspected in an infant with growth failure, cataracts, liver disease, aminoaciduria, mental retardation, and especially where reducing sugar is present in the urine. The occurrence of unexplained bacterial sepsis, especially if due to *E. coli* infection in a newborn infant, may indicate galactosaemia. Cataracts may be detected by slit-lamp examination in the first few days of life.

The finding of hypergalactosaemia is not specific for those hereditary galactosaemias due to inherited deficiences of galactose-metabolizing enzymes. Recent studies show that persistent hypergalactosaemia may be commonly due to portosystemic venous shunts in infants that are often associated with patent ductus venosus or other congenital vascular abnormalities in the liver. Doppler ultrasonography is a convenient non-invasive investigation to search for such shunts in young infants.

Definitive diagnosis of hereditary galactosaemia is mandatory, and relies on the determination of galactose 1-phosphate uridylyltransferase activity and other galactose-metabolizing enzymes in red cells or leucocytes by means of a specific enzymatic assay. Reliable enzymatic or genetic testing for heterozygotes can be carried out in the parents of a child who died before the diagnosis was confirmed. In particular populations, neonatal screening for elevated blood galactose and galactose 1-phosphate concentrations is carried out routinely. Molecular analysis of the gene for galactose 1-phosphate uridylyltransferase deficiency in at-risk pregnancies has been requested by some affected families.

Treatment

Without strict dietary treatment, most patients with galactosaemia die in early infancy, although some may survive with liver disease and mental retardation beyond childhood. The course of galactosaemia is altered strikingly upon withdrawal of lactose (and galactose), although the outcome of neurological disease is often disappointing. However, lactose is present in many non-dairy foods and advice from an experienced dietician, as well as meticulous attention to detail, is required to eliminate it completely. In infants, soybean milks or commercial casein hydrolysates, 'Nutramigen', are used as milk substitutes and therapy is monitored by periodic assay of red cell galactose 1-phosphate concentrations. Despite reports that galactose may be reintroduced as the patient develops, lifelong strict adherence to the exclusion diet should be advocated. In subsequent pregnancies of heterozygous mothers who have had affected children, there is evidence that premature cataracts can be avoided in the fetus if the maternal intake of lactose is restricted. In late pregnancy, lactosaemia and lactosuria are common findings and result from the physiological induction of lactose biosynthesis in mammary tissue. In rare cases (see below) there is a risk of self-intoxication when women with homozygous deficiency of the transferase become pregnant and breast feed, so that additional dietary precautions are needed to maintain metabolic control during lactation.

Prognosis

The acute manifestations of galactosaemia and growth failure respond quickly to dietary therapy and cataract formation is prevented. Unfortunately, a proportion of patients have significant neurological deficits despite prompt and conscientious treatment. An international survey of the long-term outcome in 350 patients receiving dietary therapy has been published by Waggoner and colleagues. The presence of ovarian failure and elevated galactose 1-phosphate concentrations in patients apparently ingesting no lactose or galactose raises the possibility that an endogenous pathway of galactose 1-phosphate formation from the pyrophosphorylysis of uridine diphosphate-galactose may occur. This may also explain the late emergence of neurological disease in treated patients. Long-term follow-up and periodic neuropsychiatric, as well as physical, monitoring is recommended. Recently, several pregnancies have been reported in women suffering from classical galactosaemia, including subjects homozygous for the *Q188R* mutation. In such pregnancies, high concentrations of galactitol are found in amniotic fluid but cord blood values have been determined to be within the range found in galactosaemic patients receiving strict dietary therapy. Thus, although maternal galactitol traverses the placenta, it probably does not harm the heterozygous fetus.

Uridine diphosphate-4-epimerase deficiency

Epimerase deficiency is very rare but may be identified during screening for classic galactosaemia. In most cases no symptoms attributable to galactosaemia are apparent and follow-up studies have confirmed the usually benign nature of this anomaly. However, a few cases of marked deficiency of uridine diphosphate-4-epimerase have been discovered in patients otherwise manifesting the classic features of galactosaemia. In the absence of epimerase activity, the individual is dependent on exogenous sources of galactose, since this cannot be derived from glucose. The autosomal recessive nature of this inherited disorder has been confirmed by demonstrating a partial epimerase deficiency in the healthy parents of an affected infant. As a complete deficiency of the epimerase would lead to an absolute lack of uridine diphosphate (**UDP**)-galactose for glycosphingolipid synthesis, the ingestion of very small quantities of galactose has been recommended in this unusual disorder so that brain development and biosynthesis of essential galactosides can proceed. Because of the dual activity of the epimerase towards UDP-acetyl glucosamine as well as UDP-glucose, it has been suggested that small supplements of the aminoacetyl galactosamine should also be provided in the diets of patients with UDP galactose-4-epimerase deficiency. This condition may be contrasted with the transferase deficiency that allows the formation of small amounts of endogenous galactose in the presence of an intact epimerase. The gene for human UDP-galactose-4-epimerase has been mapped to chromosome 1p36–p35, and several mutant alleles has been identified.

Pentosuria

Pentosuria is caused by the excessive renal excretion of L-xylulose: this has no clinical significance, except that it may lead to the incorrect diagnosis of diabetes mellitus should tests for reducing sugar be carried out on the urine. Xylulose does not react with urinary test strips based on the glucose oxidase method.

Although pentosuria is a rare autosomal recessive trait, its frequency in Ashkenazi Jews may be as high as 0.05 per cent. It is caused by enzymatic deficiency of L-xylulose reductase in the oxidative pathway of glucuronate metabolism, which results in 1 to 4 g of xylulose and L-arabitol continuously appearing in the urine: output is greatly enhanced by the ingestion of glucuronic acid or drugs that are excreted as glucuronides.

Inborn errors of pyruvate metabolism

Pyruvate dehydrogenase

Deficiency of pyruvate dehydrogenase is the most common cause of lactic acidosis in newborn infants and children, but it is also associated with neurodegenerative syndromes in later life. Pyruvate dehydrogenase exists as a multienzyme complex representing the products of 10 distinct genes. However, defects in one subunit of pyruvate dehydrogenase itself (E1a) account for most patients so far investigated, although defects in dihydrolipoyl dehydrogenase (E3) are also described.

Biochemical defect

The pyruvate dehydrogenase (**PDH**) complex catalyses the conversion of pyruvate to acetyl-coenzyme A within mitochondria and operates at about 10, 40, and 70 per cent of capacity in the liver, heart, and brain, respectively. The PDH complex is critical for brain metabolism since this is normally entirely dependent on the oxidative breakdown of glucose. There are three main activities associated in the complex: (1) pyruvate dehydrogenase, a thiamine-dependent moiety (E1); (2) dihydrolipoyl transacetylase (E2); and (3) dihydrolipoyl dehydrogenase (E3). Also associated are a pyruvate dehydrogenase-specific kinase and phosphatase (both involved in overall metabolic regulation of the complex) as well as an essential lipoic acid moiety.

The accumulated pyruvate may either be reduced to lactate or transaminated to alanine, so that hyperalaninaemia and varying degrees of lactic acidaemia occur. Very rare defects in dihydrolipoyl dehydrogenase are associated with deficiency of branched-chain keto-acid dehydrogenase. Failure to carry out oxidative reactions in regions of the cortex and midbrain causes neuronal death, and deficiency of 4-carbon intermediates may critically impair neurotransmitter synthesis.

Clinical features and prognosis

Severe deficiency of pyruvate dehydrogenase affects intrauterine development and causes marked acidosis (blood lactate >10 mmol/l) at birth with early death. The clinical presentation of pyruvate dehydrogenase deficiency is strikingly heterogeneous. Many victims do not show clinically significant metabolic acidosis and come to light because of intrauterine growth failure, neonatal hypotonia asphyxia, and feeding difficulty. In some affected individuals the enzyme deficiency is responsible for a slowly progressive neurodegeneration associated with dysgenesis and other structural abnormalities in the olivopontocerebellar tract and periventricular grey matter. Cortical atrophy and agenesis of the corpus callosum have also been reported in association with spastic quadriplegia. In those with neurological manifestations, blood lactate concentrations do not exceed 10 mmol/l. Should feeding by gavage be instituted, there is a protracted course with failure of neurological development, microcephaly, quadriplegia, seizures, and blindness. Intermittent cerebellar ataxia or torsion dystonia has been recorded and choreoathetoid movements occur. Involuntary eye movements in children are associated with a progressively deteriorating course. In a few patients with intermittent cerebellar ataxia, hereditary spinocerebellar degeneration appearing in early adult life has been attributed to the deficiency of pyruvate dehydrogenase but there is no direct relationship to Friedreich's ataxia. In patients who present with severe acidosis at birth, subacute necrotizing encephalomyelopathy of the Leigh's type has been confirmed at necropsy and deficiency of pyruvate dehydrogenase activity has been demonstrated.

Genetics

The most common cause of pyruvate dehydrogenase deficiency is due to a defect in the E1a subunit—a protein encoded on the X chromosome. Although the disease is characteristically more severe in males, manifestations in the heterozygous female are unusually frequent for an X-linked disease and probably reflect the low functional reserve of the enzyme complex in the brain. Neonatal lactic acidosis is more frequent in males. An auxiliary gene for the E1a subunit is localized as a result of retroposition from the X-chromosome to the long arm of chromosome 4, but is expressed only during spermatogenesis; its presence, however, indicates the critical need for activity of the complex in nearly all tissues. Causal mutations in the *E1a* gene on the X chromosome have been described—most appear to be short deletions or duplications and, at present, are not generally applicable for diagnosis. However, analysis of X-chromosome inactivation patterns, by determination of methylation status, has proved useful for the evaluation of enzymatic assays of fibroblasts obtained from obligate carriers or female patients in whom the diagnosis is suspected.

Diagnosis and treatment

The diagnosis is suspected from the presence of severe acidosis at birth. It may also emerge during the investigation of neurological deficits, especially where they are associated with intrauterine growth failure. Routine screening of urine samples for organic acids may identify excessive pyruvate, lactate, and alanine excretion. In patients without clinically evident acidosis, cerebral disease is accompanied by striking elevations of lactate and pyruvate in the cerebrospinal fluid. Mutation analysis of the X-linked *PDH* gene and determination of the abundance of immunoreactive PDH protein now permits decisive diagnosis of this disease.

Neuroradiological procedures, including cerebral ultrasonography and computed tomography, reveal ventricular dilatation and cerebral atrophy. In several infant girls with PDH deficiency, magnetic resonance imaging showed hypoplasia of the corpus callosum as well as loss of normal white matter signal intensity. Proton magnetic resonance spectroscopy (**MRS**) revealed high-abundance signals for brain lactate with decreased intensity of *N*-acetylaspartate, while phosphorus MRS of skeletal muscle showed abnormally low muscle phosphorylation potentials, in keeping with the predicted biochemical disturbance. Pathological examination of previously affected siblings shows shrinkage of gyri, with involvement of the medulla shown by loss or hypoplasia of the pyramids. The pathological features of Wernicke's encephalopathy may be present. The corpus callosum may be absent. Definitive diagnosis, however, depends on genetic and enzymatic studies in skin fibroblasts or blood leucocyte samples.

Institution of a high-fat, low-carbohydrate, ketogenic diet may ameliorate the biochemical abnormalities, but, given the degree of neurological impairment that is normally present at diagnosis, little clinical improvement can be expected. Therapeutic responses to the administration of high-dose thiamine have been reported in patients with partial enzymatic deficiency, notably where ataxia and abnormal eye movements reminiscent of Wernicke's encephalopathy were conspicuous. In rare patients with the autosomally recessive condition due to dihydrolipoyl dehydrogenase deficiency, oral administration of lipoic acid has been reported to correct the organic acidaemia with clinical improvement.

Pyruvate carboxylase deficiency

Inborn defects in pyruvate carboxylase, a key gluconeogeneic enzyme, cause hypoglycaemia or profound metabolic acidosis with neurological disease. The manifestations of this latter syndrome closely resemble those caused by deficiencies of pyruvate dehydrogenase activity. A severe form associated with hyperammonaemia and citrullinaemia is also recognized, particularly in patients of French descent.

Metabolic defect

Pyruvate decarboxylase is a biotin-dependent enzyme that catalyses the first step in the formation of oxaloacetate from pyruvate and is activated allosterically by acetyl-coenzyme A. Thus, hypoglycaemia would be expected only after glycogen stores had been depleted. Krebs cycle intermediates may become depleted so that there is an insufficient synthesis of neurotransmitters. There may also be a reduced supply of aspartate for the arginosuccinate synthase reaction of the urea cycle.

Clinical features

Patients with severe deficiency of pyruvate carboxylase may present with the Leigh syndrome (necrotizing encephalomyopathy with lactate/pyruvate acidosis) or

hypotonia and neurological retardation. The presence of ataxia and abnormal ocular movements in life suggest the occurrence of midbrain disease resembling Wernicke's encephalopathy. Hypoglycaemia frequently occurs during intercurrent infection or during starvation and acidosis, requiring bicarbonate therapy. The most severe form, originally reported from France, progresses rapidly with evidence of liver damage, hyperammonaemia, and citrullinaemia.

Genetics

This disorder is transmitted as an autosomal recessive trait. In severely affected patients with hyperammonaemia, pyruvate carboxylase protein and its mRNA are absent in the liver. A partially inactive variant enzyme is detectable in other patients.

Diagnosis and treatment

The condition is suspected when acidosis and neurological disease occur in infants, especially in the presence of hypoglycaemia. Specific diagnosis requires enzymatic assay in fibroblasts, which can also be used for carrier detection. Disorders of pyruvate metabolism may be mimicked biochemically by mitochondrial diseases and acquired deficiencies of thiamine or biotin. Although biotin therapy has been disappointing in pyruvate carboxylase deficiency, occasional responses to high-dose lipoic acid and thiamine treatment, which may stimulate the pyruvate metabolism by the dehydrogenase complex, have been recorded.

Therapy

Episodes of acidosis are treated with intravenous sodium bicarbonate, and glucose may be required for hypoglycaemia. There is evidence that ketogenic diets containing 50 per cent fat and 20 per cent carbohydrate ameliorate the biochemical disturbance and delay the onset of neurological disease: the administration of glutamate and aspartate, which may act as a source of oxaloacetate, appear to have been beneficial in some patients.

11.4 Disorders of purine and pyrimidine metabolism

*Richard W. E. Watts**

These disorders are due to abnormalities in the biosynthesis, interconversion, and degradation of the purines, adenine and guanine and of the pyrimidines, cytosine, thymine, and uracil. All these compounds are heterocyclic bases which exist as tri-, di-, and monophosphorylated either deoxyribosylated or ribosylated derivatives (deoxyribose and ribose are pentose carbohydrates). The phosphorylated deoxyribosylated and ribosylated derivatives are termed 'nucleotides', while the purely ribosylated derivatives, which lack the phosphate group, are termed 'nucleosides'.

The polynucleotide deoxyribonucleic acid (**DNA**) contains equimolar amounts of adenylic acid (adenosine monophosphate, **AMP**), guanylic acid (guanosine monophosphate, **GMP**), thymidylic acid (thymidine monophosphate, **TMP**), and cytidylic acid (cytidine monophosphate, **CMP**). Uridylic acid (uridine monophosphate, **UMP**) replaces TMP in the polynucleotide ribonucleic acid (**RNA**).

DNA encodes, stores, and ultimately hands on genetic information. RNA transcribes and translates the genetic information so that the corresponding polypeptide strand emerges from its site of synthesis on the ribosome.

The purine nucleotides, their cyclic derivatives (CAMP and CGMP), and their more highly phosphorylated derivatives have functions in many aspects of intermediary metabolism. Purine compounds also function as signal transducers, neurotransmitters, vasodilators, and mediators of platelet aggregation.

Disorders of purine metabolism

The purine nucleotides are built up in a step-wise manner (*de novo* synthesis), undergo a series of interconversion and salvage reactions, and a final degradative process to yield uric acid, as shown in Fig. 1. Most human morbidity connected with diseases of purine metabolism is due to sodium urate monohydrate and to uric acid. The dietary intake of nucleoproteins is also an important factor in diseases due to sodium urate and uric acid. Ingested adenine and guanine nucleotides are degraded to free purine bases and, hence, to uric acid by enzymes in the intestinal juices and small-intestine mucosa so that the products of their metabolism do not mix with the corresponding endogenous metabolic pools except at the final uric acid stage.

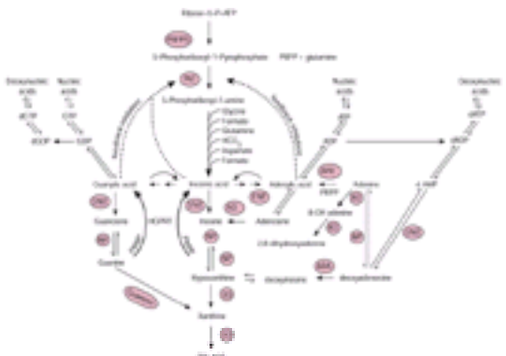

Fig. 1 Pathways of purine metabolism in humans. **ADA**, adenosine deaminase; **APRT**, adenine phosphoribosyltransferase; **HPRT**, hypoxanthine–guanine phosphoribosyltransferase; **5-NP**, nucleoside phosphorylase; **5'-NP**, 5'-nucleotidase; **PAT**, phosphoribosyl pyrophosphate amidotransferase; **PRPPS**, phosphoribosyl pyrophosphate synthetase; **XO**, xanthine oxidase.

De novo synthesis contributes about 300 to 600 mg (1.8–3.6 mmol/day) and dietary purines about 600 to 700 mg (3.6–4.2 mmol/day) to the dynamic urate metabolic pool of about 1200 mg (7.2 mmol) expressed as uric acid. Each day, about two-thirds of uric acid are excreted in the urine and about one-third is destroyed, mainly by bacterial uricolysis in the gut.

The urate anion is freely filterable at the renal glomerulus, only 5 to 10 per cent being very loosely bound to the plasma proteins (a $_{1–2}$-globulin fraction). The physiologically important p*K*a value of uric acid is 5.75, so that it exists mainly as the monovalent urate anion in plasma (pH 7.4) and assumes more of the free acid form when it passes into regions of the renal tubule, the contents of which are at lower pH values.

The kidney handles urate by:

1. glomerular filtration of virtually 100 per cent of the filtered load;

2. proximal tubular reabsorption by a urate/chloride exchanger in the endothelial brush border (99 per cent of the filtered load);
3. tubular secretion (equivalent to about 50 per cent of the filtered load);
4. postsecretory reabsorption (equivalent to about 40 per cent of the filtered load).

Thus, the net renal clearance of uric acid is approximately 10 per cent of the filtered load and is in the range of 6 to 11 ml/min per 1.73m ^{2} (1.73m^2 = average body surface area of an adult). The exact location of the reabsorptive, secretory, and postsecretory reabsorptive processes within the distal nephron is unclear.

Plasma urate levels

The currently quoted overall reference range for plasma urate (expressed as uric acid) in adults is 3.5 to 8.1 mg/dl (210–480 µmol/l) for men and 2.5 to 6.5 mg/dl (150–390 µmol/l) for women. The corresponding value for children is 1.0 to 4.0 mg/dl (60–240 µmol/l). It rises at puberty with female values being lower than those in men until the menopause, after which it gradually rises to the male value. Extrinsic factors, particularly diet, plumbism, the prevalence of a high ethanol intake in the community, and the prevalence of diseases such as malaria and thalassaemia, which lead indirectly to either increased purine biosynthesis or decreased excretion (Table 1), affect the plasma urate distribution in different populations.

The plasma urate concentration decreases during pregnancy, the reference range being 1.7 to 4.5 mg/dl (100–270 µmol/l). Hyperuricaemia is a characteristic and often an early feature of pre-eclampsia, preceding the proteinuria and hypertension, and is a diagnostically valuable parameter. It results from a reduced renal urate clearance and tends to be associated with hypocalciuria.

Epidemiological studies show significant variations in plasma urate concentrations between different ethnic groups: for example, Maoris and Polynesians have higher values than Western Europeans and Americans. This illustrates the genetic, presumably, polygenic aspects in the control of serum uric acid. Other epidemiological studies emphasize the importance of the environmental factors of purine, protein, and alcohol intake. For example, Gresser and Zöllner showed that the cumulated frequency of plasma urate, expressed as uric acid, rose from approximately 6.2 mg/dl (370 µmol/l) to about 9.0 mg/dl (536 µmol/l) between 1962 and 1971 in association with the improved nutritional state of the Bavarian population from the near-starvation conditions following the Second World War (Fig. 2).

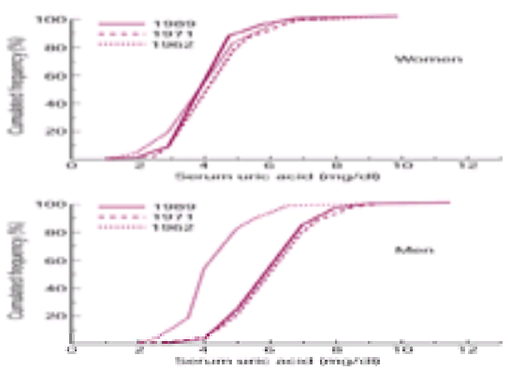

Fig. 2 Differences in the cumulated frequencies in urate levels in female and male blood donors in Bavaria between 1962 and 1989. (Reproduced with permission from Gresser and Zollner 1991.)

Similarly, the plasma urate levels in immigrant communities with low values in their home lands, move towards the values prevailing in the host country as they adopt the lifestyle and dietary habits of that country: for example, Filipinos migrating to the United States. Similarly, migrants with genetically determined high urate levels become even more hyperuricaemic.

The frequency distribution of plasma urate values based on asymptomatic populations is only approximately Gaussian, with an excess of higher values due to the inclusion of some asymptomatic hyperuricaemic subjects. Although plasma is saturated with monosodium urate at a concentration of 7.0 mg/dl (420 µmol/l), higher concentrations of urate can remain in a stable supersaturated solution in plasma without producing any symptoms. Ignoring the slight asymmetry of the frequency distribution and defining normality as the mean value ± 2 standard deviations about the mean, normal values of 7.0 mg/dl (420 µmol/l) for men and 6.0 mg/dl (360 µmol/l) for women have been widely adopted. This has led to considerable overtreatment of patients who have quite innocuous plasma urate concentrations.

Gout and hyperuricaemia

Gout is a classic example of a multifactorial disease in which there is an interplay of genetic and environmental factors. The overall effects of this interplay are wide, extending from cases where there is a clear-cut family history with autosomal dominant inheritance (Fig. 3) to those where environmental factors are the determinants, although often against a genetic background that may be either unifactorial or multifactorial. Gout *per se*, does not shorten life, although some of its complications may do so in the absence of treatment.

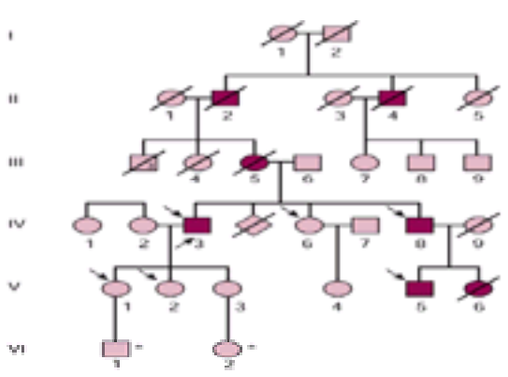

Fig. 3 Pedigree chart of a family showing autosomal dominant inheritance of gout complicated in some cases by renal failure (hyperuricaemia nephropathy). n • male and female subjects, respectively, with hyperuricaemia and renal failure; male and female subjects not known to be affected; Š; deceased male and female subjects, propositus; ¯ subjects whose rates of mononuclear cell *de novo* purine synthesis was measured and shown to be normal; * babies who were examined clinically but not further investigated. (Reproduced with permission from McDermott, *et al.* (1984). *Clinical Science* **67**, 249-58. ©Biochemical Society and Medical Research Society.)

Gout is defined as a syndrome brought about by the crystallization of monosodium urate monohydrate *in vivo* from body fluids supersaturated with this salt. The supersaturation results from either the overproduction or underexcretion of urate, or from a combination of these defects. The underlying causes of hyperuricaemia and gout are:

1. *Decreased net tubular urate secretion*: this is the major factor in the aetiology of the majority of those cases of gout previously described as being idiopathic (or primary), the hereditary predisposition to which is often compounded by environmental factors (e.g. high dietary purine intake and alcoholism).
2. *Identifiable enzymatic defects that accelerate urate* de novo *synthesis*: these are a hypoxanthine–guanine phosphoribosyltransferase (**HPRT**) deficiency which causes the Lesch–Nyhan syndrome and, in milder degrees of HPRT deficiency, some cases of the X-linked recessive hyperuricaemia, gout, and uric acid stone syndrome;
3. *Phosphoribosyl pyrophosphate (PRPPS) synthetase superactivity*: this also presents as X-linked recessive hyperuricaemia, gout, and uric acid stones and, in

some cases, neurological manifestations (e.g. deafness and autism).

Secondary causes of hyperuricaemia and gout are shown in Table 1.

The following abnormalities are commonly associated with, but not causally related to hyperuricaemia and gout:

1. obesity;
2. dyslipidaemia (usually type 4) with raised very low-density (**VLD**) lipoproteins and normal cholesterol levels, and sometimes hypercholesterolaemia with elevated low-density lipoprotein (**LDL**)-cholesterol and low high-density lipoprotein (**HDL**)-cholesterol levels;
3. hypertension;
4. insulin resistance with hyperinsulinaemia and impaired glucose tolerance;
5. ischaemic heart disease.

Thus, these patients may display the features of the 'metabolic syndrome X'.

There is no evidence that uric acid is toxic to the myocardium. Hyperuricaemia may be a marker of coincident cardiac disease, but **not** a causal risk factor. The elevated plasma uric acid concentrations observed in patients with ischaemic heart disease could arise from upregulated vascular adenosine synthesis associated with ischaemia and the subsequent degradation of adenosine to uric acid. However, the relationship of urate to endothelial function is complex. Plasma uric acid accounts for 60 per cent of the free-radical scavenging activity in human plasma: it interacts with peroxynitrile to form a stable nitric oxide donor, so promoting vasodilatation and reducing the potential for peroxynitrile-induced oxidative damage. Conversely, it could have an adverse effect on endothelial function by promoting leucocyte adhesion to the endothelium. However, there is no clear evidence that these actions are significant at the clinical level.

The fractional excretion of urate is the ratio of urate clearance to the glomerular filtration rate (**GFR**). In the presence of normal overall renal function, this can be measured on a random urine sample and a simultaneous plasma sample. The equation simplifies to:

$$\text{Fractional clearance of urate} = U_{\text{urate}} \times P_{\text{creatinine}} / P_{\text{urate}} \times U_{\text{creatinine}}$$

where '*U*' and '*P*' represent the urine and plasma concentrations. The fractional clearance can be used to assess the role of renal tubular dysfunction in the production of hyperuricaemia, provided that the overall renal function is normal.

Acute gouty arthritis

Acute gout is a sodium urate monohydrate-induced crystal inflammation of joints, bursas, and tendon sheaths. Clinically, the affected structures—classically, the first metatarsophalangeal joint is the first joint affected—become acutely inflamed, exquisitely tender, warm to the touch, and the overlying skin becomes red, shiny, and itchy and may desquamate as the inflammation subsides spontaneously over 5 to 15 days in the absence of treatment. Inflammation is usually maximal within 24 h of onset and is accompanied by pyrexia and malaise.

Joint aspiration yields a fluid containing polymorphonuclear leucocytes and negatively birefringent sodium urate monohydrate crystals. The attacks occur most frequently when the plasma urate level is rising or falling. Monosodium urate crystals may be found within monocytes in asymptomatic joints; it has recently been proposed that the inflammatory response to monosodium urate is influenced by the state of monocyte to macrophage differentiation, the balance being tipped towards acute inflammation by the recruitment of undifferentiated monocytes and neutrophils from the bloodstream by one of the precipitants for acute gout. At the beginning of an acute gouty attack, monocyte/macrophage activation leads to the production of inflammatory cytokines (interleukines, tumour necrosis factor (TNF-a)) and the activation of cyclo-oxygenase (**Cox**)-2. Apoptotic neutrophils and crystals are removed by activated macrophages as the inflammation subsides spontaneously.

The American College of Rheumatology criteria for the clinical diagnosis of acute gout are shown in Table 2. The presence of 6 of the 11 criteria has a 95 per cent specificity in differentiating gout from pseudogout (calcium pyrophosphate gout) and an overall sensitivity of 85 per cent. The final confirmation is the demonstration of negatively birefringent sodium urate monohydrate crystals as opposed to the positively birefringent crystals of calcium pyrophosphate.

Although acute gouty arthritis is typically a monoarthritis, some patients have short, recurrent, mild attacks of discomfort and swelling of affected joints. Some 10 per cent of attacks affect more than one joint and typical attacks may provoke migratory attacks in other joints. Multiple, simultaneous attacks are rare. Some attacks are triggered by trauma, intercurrent illness, surgery, alcohol, dietary excess, diuretics, and other medications (see Table 1). An acute septic arthritis is the most important differential diagnosis of acute gouty arthritis.

Chronic tophaceous gout

Large deposits (tophi) containing monosodium urate monohydrate crystals produce firm nodules over affected joints on the extensor surfaces of the fingers, hands, olecranon bursas (commonly bilateral), extensor surfaces of the forearm, Achilles tendon, the helix of the ear, and in the renal parenchyma. Tophi may discharge white chalky material, containing sodium urate monohydrate. They cause the bone erosions and joint destruction with secondary degenerative arthritis seen on radiographs. Tophus formation can be regarded as an attempted, but disordered, healing process in response to the presence of sodium urate monohydrate crystals in tissues.

Treatment of gout

The acute attack

Full doses of any of the non-steroidal anti-inflammatory drugs are effective in terminating attacks of acute gout. Indomethacin is particularly favoured by some clinicians. Colchicine remains a very effective remedy—an initial dose of 1.0 mg followed by 0.5 mg every 6 hours until either the attack subsides or a total dose of 6.0 mg has been achieved, or symptoms of toxicity (nausea, vomiting, and diarrhoea) occur. More frequent doses of colchicine, 0.5 mg every 2 to 3 h, deliberately inducing symptoms of toxicity was previously recommended. This is unnecessary now that the non-steroidal anti-inflammatory drugs are available. Heavy dosage with colchicine can also cause gastrointestinal haemorrhage and favour the development of other severe side-effects, including profuse diarrhoea, rashes, renal and hepatic damage, more rarely peripheral neuropathy, myopathy, and alopecia in the long-term. Intravenous colchicine is no longer recommended.

An attack of acute gout can be effectively terminated by the adrenocorticotropin analogue, tetracosactrin, or by a single intravenous dose of hydrocortisone. Rebound attacks of acute gout tend to occur unless the situation is covered by either colchicine or a non-steroidal anti-inflammatory drug.

Pharmacologically, colchicine disrupts the cellular microtubular architecture in the inflammatory cells. This mode of action gives it the potential to do more widespread damage and presumably underlies its inhibitory effects on mitosis, neutrophil migration, and phagocytosis. Short intensive courses of colchicine should not be repeated at less than 3-day intervals, although lower doses (0.5 mg-2 mg per day) can be used for longer periods, as in the treatment of familial Mediterranean fever.

Interval treatment

Asymptomatic hyperuricaemia should not be treated with urate-lowering drugs unless the patient experiences more than one acute attack of gout per year (Table 3). Allopurinol, a xanthine oxidate inhibitor, is effective in preventing acute gout; it acts by reducing the serum urate concentration to a value below the solubility of sodium urate monohydrate in plasma so that tophaceous deposits are mobilized and healing occurs. This applies to the tophi in bones as well as elsewhere. The drug should be introduced at a low level (e.g. 100–200 mg daily) and increased under cover of either colchicine or a non-steroidal anti-inflammatory drug, which should be continued until the serum urate concentration has stabilized at a normal level. Allopurinol is then continued indefinitely.

Initiating allopurinol without cover may cause attacks of acute gout as the serum urate concentration falls. Moderately severe gout may require as much as 300 to 600 mg of allopurinol daily, and occasionally as much as 700 to 900 mg per day given in divided doses. Between 10 and 20 mg/kg body weight per day is an appropriate

dose for children.

The incidence of adverse reactions to allopurinol is low but they can be severe and occasionally fatal. Reactions include erythema multiforme progressing to the Stevens–Johnson syndrome and toxic epidermal necrolysis, exfoliative dermatitis, vasculitis, interstitial nephritis, eosinophilia, hepatocellular damage, polyneuropathy, bone marrow depression, disturbances of vision and taste, as well as gastroenteropathy. Allopurinol potentiates the effect of coumarin anticoagulants (for example, warfarin), azathioprine, and 6-mercaptopurine, and predisposes to an ampicillin or amoxicillin rash. At high dosage and in the presence of greatly increased purine synthesis it may cause xanthine and oxipurinol urinary stones. There is also increased risk of toxicity with captopril (especially in the presence of renal failure) and with ciclosporin.

Much of the overall toxicity of allopurinol is due to the metabolite oxipurinol, which has a much longer half-life *in vivo* than the parent compound. Special care is necessary in the presence of renal failure, when a dose of 100 to 150 mg is usually sufficient. Patients with hyperuricaemia due to renal failure rarely develop gout, possibly due to immunoparesis.

Patients in whom allopurinol produces adverse reactions

Patients for whom the treatment of hyperuricaemia and gout is essential and who have developed severe adverse reactions to allopurinol present a special problem, especially if they have impaired overall renal function. The uricosuric drugs sulfinpyrazone, probenecid, and benzbromarone, together with a sufficiently high fluid intake to provide a measured urine output of at least 3 litres per 24 h and alkalization of the urine with sodium or potassium bicarbonate or sodium or potassium citrate, represent an approach to this problem, but may be inappropriate in the overall clinical context, for example in patients with cardiac or renal failure. Only sulfinpyrazone is readily available in the United Kingdom. Uricosuric drugs may be inefficient in the presence of renal failure and are contraindicated in the presence of uric acid urinary stones.

The use of recombinant uricase—either in its unmodified form or linked to polyethylene glycol (PEG) in order to reduce its immunogenicity—remains experimental, and is unlikely to be applied except in patients at risk of developing acute hyperuricaemic nephropathy and who cannot be given allopurinol.

The uricosuric agent benzbromarone is sometimes effective in patients with renal failure when other uricosuric agents have lost their efficacy. The use of oxipurinol (in low dosage) has also been proposed. Protocols are also available for the desensitization of patients who have experienced adverse reactions to allopurinol, and in whom the risk of uric acid stone formation with the potential for further reduction of renal function presents a problem.

Asymptomatic hyperuricaemia

Routine biochemical screening frequently identifies patients with hyperuricaemia. Guidance on their management is given in Table 3.

Acute uric acid nephropathy

This complicates the treatment of widespread malignant disease, particularly chemo- and/or radiotherapy of leukaemias and lymphomas. The nephropathy is of multifactorial origin and may form part of the acute tumour-lysis syndrome with accompanying tubular necrosis. These patients are usually underhydrated and acidotic and have high rates of uric acid production from nucleoprotein degradation in the apoptotic tumours. Acute uric acid nephropathy has occasionally been reported after extremely severe muscular exercise, after severe epileptic seizures, and in patients with gout and grossly increased rates of *de novo* purine synthesis.

The renal lesion is the intratubular precipitation of uric acid crystals. In addition, the renal pelvis and ureters may also be blocked by crystal aggregates and/or uric acid stones. Acute uric acid nephropathy can be avoided by giving allopurinol for several days before starting chemotherapy or radiotherapy. The condition presents as acute oliguric renal failure. Imaging techniques should be used to exclude the presence of bilateral ureteric obstruction by radiotranslucent uric acid stones. Treatment is by:

1. induction of an alkaline diuresis;
2. haemo- or peritoneal dialysis or haemofiltration;
3. percutaneous nephrostomy and/or ureteric catheterization may be needed if there is an element of postrenal obstruction due to impacted aggregates of sodium urate crystals or uric acid stones;
4. disruption or removal of impacted stones.

Chronic sodium urate nephropathy

Between 20 and 30 per cent of patients with untreated chronic tophaceous gout die from renal failure. These patients form an identifiable subgroup of the gouty population and an autosomal dominant inheritance is sometimes clearly apparent (Fig. 3). The term 'familial juvenile gouty nephropathy' is sometimes used for patients presenting in early life. Environmental factors exacerbate this hereditary predisposition. Such patients must be differentiated from another group of gout patients (20–30 per cent) with mild intermittent proteinuria and a good prognosis. Significant renal disease due to sodium urate deposition is very rare in asymptomatic hyperuricaemia. Patients with chronic sodium urate nephropathy have shrunken kidneys containing interstitial monosodium urate microtophi and show segmental destruction of the renal parenchyma due to tubular blockage by aggregates of uric acid crystals (microcalculi). These areas of segmental destruction have been referred to, inappropriately, as 'uric acid infarcts'.

Polycystic renal disease

Hyperuricaemia and gout may precede the onset of renal failure in patients with polycystic renal disease and about one-third of patients with polycystic renal disease develop gouty arthritis. This may be due to abnormal renal tubular handling of urate. A similar mechanism may operate in patients with medullary sponge kidney disease.

Ethanol and hyperuricaemia

Ethanol is oxidized to acetaldehyde by the liver. This raises the ratio of **NADH**:**NAD** (reduced nicotinamide–adenine dinucleotide:nicotinamide-adenine dinucleotide), which in turn promotes the reduction of pyruvate to lactate in the hepatocytes. Lactate competes with urate in the renal tubular excretory mechanisms and thereby promotes urate retention. There is also an element of starvation ketoacidosis in chronic alcoholics, with acetoacetate and betahydroxybutyrate also competing for the renal tubular excretory mechanisms which subserve urate tubular secretion. In addition, there is increased urate production associated with ethanol intake: first due to the high purine content of some alcoholic beverages (for example, beer) and second, the metabolism of alcohol involves increased dephosphorylation and degradation of adenine nucleotides in the liver. The free adenine produced is further metabolized to urate.

Uric acid urolithiasis

Pure uric acid stones account for 5 per cent of all urinary stones in patients in the United Kingdom. There is a much higher incidence elsewhere, for example in the Middle East. Uric acid urolithiasis occurs in 10 per cent of patients with gout. In Israel, about 40 per cent urinary calculi are composed of uric acid and 75 per cent of patients with primary gout develop renal calculus disease. Uric acid stones are more common in secondary than in primary gout and are sometimes associated with an impaired ability to alkalinize the urine. Ileostomy predisposes to uric acid urolithiasis because of (1) chronic bicarbonate loss, which leads to a persistent acidification of the urine and (2) a concentrated urine due to excessive water loss. Urinary uric acid concentrations close to, or greater than, those at which spontaneous crystallization begins are frequent in these circumstances. The genetic causes of uric acid urolithiasis are rare: (1) **HPRT** deficiency; (2) phosphoribosylpyrophosphate synthetase (**PRPPS**) superactivity; and (3) congenital renal hypouricaemia (congenital failure of the renal tubular reabsorption of urate). Renal hypouricaemia may be due to renal tubular damage by other genetic diseases or by toxic damage (Table 4) and this may be associated with other features of the Fanconi syndrome.

The urinary uric acid concentration is the main determinant of uric acid stone formation. The concentration depends on the state of hydration, the rate of purine *de novo* synthesis, the rate of metabolic turnover of purine compounds, the dietary intake of purines and alcohol, and the action of uricosuric drugs (for example,

sulfinpyrazone). Calcium oxalate stone formation is increased 30-fold in patients with gout and hyperuricosuria is common in non-gouty stone formers. Uric acid micro crystals may act as epitaxial nucleation sites for calcium oxalate crystallization. It is also possible that colloidal uric acid adsorbs urinary glycosaminoglycan inhibitors of crystallization and crystal growth.

Uric acid stone disease is treated by hydration to maintain a urine volume of at least 3 litres per 24 h, alkalization of the urine, and allopurinol if there is hyperuricosuria. The use of sodium and potassium salts for alkalization has to be carefully reviewed in the light of concurrent diseases, particularly impaired renal and cardiac function. The standard imaging techniques (particularly ultrasonography) are required for the diagnosis of these radiotranslucent stones. They can be fragmented or removed by standard procedures.

Congenital renal hypouricaemia and uric acid stones

Reduced net tubular reabsorption of urate occurs either as an isolated renal tubular reabsorption defect due to mutations in the gene directing the synthesis of the putative urate carrier protein, or in association with other inherited and acquired renal tubule transport defects (Table 4).

Isolated reduced net tubular reabsorption of urate (hereditary renal hypouricaemia) is inherited in an autosomal recessive manner. The hyperuricosuria may amount to 1000 mg (5.9 mmol) per 24 h in the homozygote. Lesser degrees of hyperuricosuria occur in heterozygotes. About 30 per cent of the homozygotes have an associated hypercalciuria. Uric acid urolithiasis occurs in about 25 per cent of the homozygotes, most commonly in patients with combined hyperuricosuria and hypercalciuria. Only two patients with hereditary renal hypouricaemia were found by searching the clinical biochemical data on 47 420 patients in a general hospital. The causes of hypouricaemia are summarized in Table 4.

The Lesch–Nyhan syndrome and variants

The Lesch–Nyhan syndrome results from mutations in the gene that directs the synthesis of hypoxanthine–guanine phosphoribosyltransferase (**HPRT**), an enzyme which normally catalyses the salvage of hypoxanthine and guanine to inosinic and guanylic acids (inosine monophosphate, **IMP**; and guanosine monophosphate, **GMP**), respectively, as shown in Fig. 1. The clinical spectrum extends from hyperuricaemia alone to hyperuricaemia with profound neurological and behavioural dysfunction. The biochemistry and molecular genetics of this disorder have been studied extensively. A recent survey of a database of 271 cases showed that mutation analysis does not provide precise information for predicting disease severity, but that it is a valuable tool for genetic counselling in terms of confirming diagnosis, the identification of carriers, and for prenatal diagnosis.

The clinical features of the most severely affected patients who are correctly referred to as having the 'Lesch–Nyhan syndrome' or as having 'complete or virtually complete HPRT deficiency', are summarized in Table 5.

Infants affected by HRPT deficiency have a lower than average birth weight, indicating some degree of intrauterine growth retardation (Fig. 4). The first clinical sign may be the presence of red grit (uric acid crystals with adsorbed urinary pigments) on the nappy. Affected infants are hypotonic from birth, although this is frequently not remarked upon before poor head control becomes apparent at the age of about 3 months.

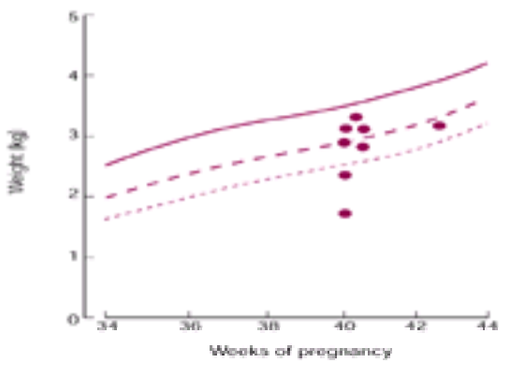

Fig. 4 Birth weight in eight boys who later developed the Lesch–Nyhan syndrome: the 50th (bold), 10th, and 3rd (interrupted) centiles are shown as lines. (Reproduced from Watts *et al.* 1987, with kind permission from Kluwer Academic Publishers.)

Postnatal growth, which becomes more marked after the second year of life, is also subnormal (Fig. 5) as indicated by sequential measurement of body weight, accurate assessment of body length being impossible due to the dystonic posturing. The overall pattern of weight growth follows centile lines for the first 2 years of life and thereafter slows to about 1 kg per year, or about half normal, a pubertal growth spurt is not observed. Head growth and bone development are less affected than weight. The poor weight gain cannot be attributed to either renal failure or malnutrition.

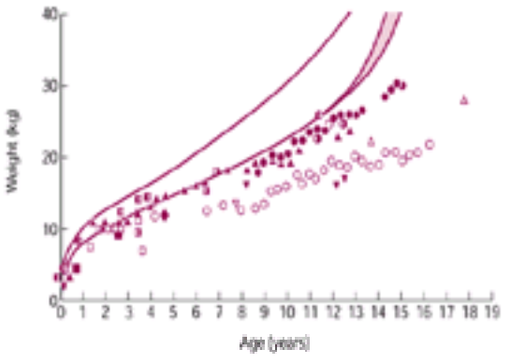

Fig. 5 Patterns of growth in weight of 13 boys with the Lesch–Nyhan syndrome: each patient is shown by a different symbol. The 50th and 3rd centiles are shown. (Reproduced from Watts, *et al.* 1987, with kind permission from Kluwer Academic Publishers.)

Torsion dystonia, with its two components of abnormal posturing and episodic rigidity, is superimposed on the basic hypotonia that is present between the dystonic episodes. Severe dysarthria is associated with dyskinesia of the face, mouth, pharynx, and the larynx, which greatly limits communication and even the ability to point accurately, thus leading to great frustration. The self-injurious behaviour and dyskinesia are eliminated or much reduced when the child is concentrating on a self-selected activity, such as watching an interesting television programme. Self-injury and dyskinesia are exacerbated by excitement such as the arrival of a visitor, fear, frustration, and unsuccessful attempts at volitional motor activity. The children also appear to be aware of the value of this behaviour as an attention-seeking manoeuvre, and sometimes appear to use it in a manipulative manner. This mixture of involuntary and volitional involuntary abnormal motor activity with an apparent interplay of unconscious and consciously meditated behaviour patterns should be common ground for behavioural scientists, neurochemists, and neuropharmacologists.

Although mental handicap has been stressed as a feature of the Lesch–Nyhan syndrome, it is of inconstant severity, and is neither marked nor specific. The apparent degree of mental handicap may be affected by the extensive disorder of expressive motor functions that exceeds the comprehension defect, by the lack of basic social and educational opportunities, and by the lack of intelligence tests for older children who have lacked these opportunities. However, for whatever combination of reasons, there does appear to be a decline of intellect from the age of 8 to 10 years.

Self-injurious behaviour usually begins at about 2 years of age. Its severity and the ingenuity with which the patients exploit new ways of self-injury exceeds that encountered in any other clinical situation. It is not a constant feature and some patients never show it; in the majority its severity waxes and wanes. Self-injury can produce very severe damage, such as complete destruction of the lower lip or traumatic amputation of a fingertip. The patients feel pain normally and are aware of their compulsion; they are afraid of it but are unable to control it. Nyhan and his colleagues consider it to be the hallmark of complete HPRT deficiency, as opposed to those patients with some residual enzyme activity (which may or may not be measurable in erythrocyte lysates).

There are no structural or ultrastructural changes in the brain as judged by light and electron microscopy. Computed tomography and electroencephalography also show no abnormality during life. MRI and PET scanning have not yet been applied to this problem.

Both the purine *de novo* synthesis and the HPRT-catalysed purine salvage pathways are present in all parts of the normal brain. HPRT activity is absent, but the *de novo* synthesis pathway remains active in patients with the Lesch–Nyhan syndrome. It has been suggested that the bone marrow and brain have particular requirements for the purine salvage pathway and that HPRT deficiency might constrain brain development. If this is so, it is not explained by particularly low activity of purine *de novo* synthesis activity in the brain. Indeed, demonstrable structural and ultrastructural changes in patients with the Lesch–Nyhan syndrome are also lacking, suggesting that the inability to salvage hypoxanthine and guanine in the Lesch–Nyhan syndrome causes a 'functional' aberration. Such a derangement could derive from either a postulated postsynaptic transmitter function for cyclic GMP (**cGMP**), or a related compound, or a consequential effect on the availability of synaptic neurotransmitters. So far, further studies have not supported the cGMP postsynaptic neurotransmitter hypothesis. The levels of HPRT activities are approximately uniform in a normal human brain. Purine salvage as well as purine *de novo* synthesis activity is also uniformly distributed in the different gross anatomical regions of the rat brain.

Evidence has been advanced for some aspects of the Lesch–Nyhan phenotype being related to dysfunction of the small central, but widely projecting, aminergic pathways involved in learning. Thus it has been suggested that self-injurious behaviour in the Lesch–Nyhan syndrome is due to an imbalance between the activities of catecholaminergic neurones and 5-hydroxytryptaminergic neurones. The catecholaminergic neurones are largely concerned with learning by reward, and the 5-hydroxy-tryptaminergic pathways with learning by punishment. Patients with the Lesch–Nyhan syndrome are insensitive to punishing stimuli and do not learn when such stimuli are used to reinforce the desired behaviour, which in this case is non-self injury. The ability to learn from rewarding stimuli is impaired. Psychotherapeutic techniques that are effective in eliminating self-injurious behaviour in other situations fail in patients with the Lesch–Nyhan syndrome. Thus, although the self-injurious behaviour in the Lesch–Nyhan syndrome could be modified by a programme of positive reinforcement of non-self injury and 'time out', this has proved difficult to achieve in the long term. The reinforcement strategy was found to be unsuitable for use at home because it involved apparently ignoring the self-injury and only paying attention to the child during periods of non-self injury. This was misinterpreted by friends and relations as unkindness or indifference.

The present view is that the neurological manifestations are brought about by a neurotransmitter imbalance (probably mainly in the basal ganglia). This imbalance is possibly due to a deficient supply of metabolic energy resulting from the non-salvage of hypoxanthine and guanine, thus causing a deficiency of adenine nucleotides that provide energy for short bursts of neurotransmitter synthesis.

Failure of pubertal development and testicular atrophy in HPRT deficiency are attributed to an inadequate supply of purine nucleotides to meet the increased metabolic energy requirement in the testis at this time. A similar inability to meet energy requirements may underlie the neurological manifestations. A partial defect in adrenocortical 11b-hydroxylation of steroids is demonstrable in patients with the Lesch–Nyhan syndrome after ACTH stimulation, and is thought to be linked with a failure to modulate mitochondrial function for this hydroxylation due to a deficiency of purine nucleotides.

Patients with Lesch–Nyhan syndrome whose hyperuricaemia has been controlled and who have not suffered renal damage, die in their teenage years, often with postmortem evidence of gastric aspiration during sleep. Less severe degrees of HPRT deficiency lead to the X-linked recessive hyperuricaemia gout and urolithiasis syndrome, which may also be associated with minor neurological abnormalities.

Treatment

Sufficient allopurinol should be administered to reduce the plasma urate and urine uric acid concentrations to normal in order to prevent gouty arthritis, urate nephropathy, and renal calculi. Relatively large doses of allopurinol are needed and the patient should be kept well hydrated to minimize the risk of xanthine and/or oxipurinol (the metabolic oxidation product of allopurinol) stones developing. Both types of stone are, like uric acid stones, radiotranslucent. Allopurinol treatment from birth does not prevent the behavioural phenotype. All therapeutic attempts at neuropharmacological manipulation have been unsuccessful.

Dental extraction, physical restraints with splints and bandages, and strapping the patient into a specially designed padded wheelchair fitted with a padded firm head support to prevent cervical spine injury during violent opisthotonic spasms, are usually needed to limit the effects of compulsive self-mutilation.

Children whose restraints have been temporarily released ask or indicate their wish for the bandages, straps, etc. to be replaced so that they are less able to damage themselves. Every effort should be made to exploit these patients' intellect and to keep them in a stimulating environment.

Clinical genetic aspects

The Lesch–Nyhan syndrome and its variants are inherited in a sex-linked recessive manner with no clinical manifestations in the female carriers. However, subtle alterations in purine metabolism, with small increases in the rates of *de novo* purine synthesis and increased uric acid excretion and occasionally mild asymptomatic hyperuricaemia, have been reported in females. Affected male hemizygotes are identified biochemically by HPRT assays on red cell haemolysates, the lack of HPRT being accompanied by an elevated level of phosphoribosylpyrophosphate. Genomic analysis is also possible. Carrier females are identified by the demonstration of mosaicism with respect to *HPRT*+ and *HPRT*– hair roots due to random inactivation of the X-chromosome, the hair roots being clonal in origin. Autoradiographic techniques can be used to demonstrate two cell populations (*HPRT*+ and $HPRT^{-}$) in fibroblast cultures.

Early prenatal diagnosis is possible using chorionic villus samples obtained during the ninth week of pregnancy, this permits elective abortion of an affected fetus before the end of the first trimester of pregnancy. *In vitro* fertilization with enzymatic assay on a cell removed at the four-cell stage to ensure that only unaffected embryos are implanted is theoretically possible.

Phosphoribosylpyrophosphate synthetase superactivity

This enzyme catalyses the production of phosphoribosylpyrophosphate, which is required for the first specific and rate-limiting reaction on the *de novo* pathway of purine synthesis. It is subject to feedback inhibition by purine nucleotides. The known mutations in the gene regulating the synthesis of phosphoribosylpyrophosphate synthetase diminish its sensitivity to this feedback inhibition, thereby leading to hyperuricaemia, hyperuricosuria, and gout. The condition is inherited in an X-linked recessive fashion.

Affected males develop uric acid lithiasis or gouty arthritis in childhood or early adult life. Hyperuricaemia is often severe and in the range 0.5 to 1 mmol/l, with uric acid excretion of 5 to 15 mmol/24 h. Heterozygotes remain asymptomatic, although some degree of increased purine synthesis *de novo* has been demonstrated.

In some families, the disorder presents in childhood with associated neurological features such as motor and mental retardation, ataxia, deafness, hypotonia, disturbed speech, and the development of polyneuropathy, intracerebral calcifications, and dysmorphic facial features. The constellation of associated disorders varies in different families.

Heterozygotes can be identified by studies in cultured skin fibroblasts. Amniocentesis, prenatal diagnosis, and preventive abortion are not justified in this condition unless one of the unusually severe phenotypes is known to be segregating in the family. The hyperuricaemia, primary purine overproduction, and uricosuria can be well controlled with allopurinol.

2,8-Dihydroxyadeninuria

These patients lack adenine phosphoribosyltransferase activity, adenine accumulates behind the metabolic block and is oxidized under the catalytic influence of

xanthine oxidase to the very insoluble compound, 2,8-dihydroxyadenine. This compound is excreted in the urine along with adenine itself, where it forms radiotranslucent stones that are white or pale fawn in colour. These rough and friable calculi have, in the past, been widely misdiagnosed as uric acid stones because 2,8-dihydroxyadenine reacts as if it were uric acid in colorimetric assays. The use of enzymatic uric acid assays has obviated this confusion.

Adenine phosphoribosyltransferase deficiency has an autosomal recessive pattern of inheritance and is clinically silent in heterozygotes. There are two subtypes (I and II). Type I patients have no detectable enzyme activity, being homozygotes or compound heterozygotes for null alleles. Type II patients have between 5 and 25 per cent residual enzyme activity. Whereas type I patients are encountered in many racial groups, the type II subtype has so far only been identified in the Japanese population. Heterozygotes for type I and type II can only be distinguished from one another by enzyme assays on extracts from cultured peripheral blood lymphocytes, both types show no activity in the red cell lysates that are generally used diagnostically.

Because of the extremely low solubility of 2,8-dihydroxyadenine in renal tubule fluid and urine, this condition often presents in early life. Severe obstructive uropathy and renal failure may occur in infancy.

Treatment is by hydration and xanthine oxidase inhibition with allopurinol, and with standard measures to disrupt or remove the stones and to manage urinary infections and renal failure.

Type I lycogenosis

Type I glycogenosis (hereditary glucose 6-phosphatase deficiency) is associated with hyperuricaemia. This is due to chronic hyperlacticacidaemia which leads to urate retention, and to increased urate production due to reduced serum phosphate concentrations. The phosphate ion inhibits AMP deaminase: the enzyme that catalyses the rate-limiting step in the metabolic pathway for the conversion of adenine nucleotides to uric acid. Thus, hypophosphataemia increases adenine nucleotide degradation to uric acid and adds to the accumulating urate burden; gouty arthritis may develop in childhood.

Treatment is by maintaining the blood glucose level in the normal range with frequent small meals and intragastric glucose infusion at night. Gout is treated in the standard manner with colchicine and/or non-steroidal anti-inflammatory drugs for the acute attacks, and with long-term allopurinol.

Xanthinuria

Xanthine stones occur in patients with xanthinuria (congenital xanthine oxidase/reductase deficiency) and occasionally in those who are being treated with the xanthine oxidase inhibitor, allopurinol. The latter is particularly likely in patients with accelerated purine *de novo* synthesis (for example, in patients with the Lesch–Nyhan syndrome). Xanthinuria is inherited in an autosomal recessive manner, and hypoxanthine and xanthine accumulate behind the metabolic block. The plasma urate concentration and urine uric acid excretion are less than about 0.06 mmol/l (1.0 mg/dl) and 0.30 mmol/24 h (50 mg/24 h), respectively, when the patient is taking an unrestricted diet. A search of general hospital clinical data on 47 420 unselected patients yielded no cases of xanthinuria. The plasma and urine 'oxypurines' (hypoxanthine plus xanthine) concentrations are characteristically elevated. Normal subjects have plasma levels between 0.00 and 0.15 mmol/l (0.00–0.25 mg/dl) and urine levels of 0.07 to 0.13 mmol/24h (11–22 mg/24 h); patients with xanthinuria have plasma levels between 0.03 and 0.05 mmol/l (0.05–0.9 mg/dl) and urine levels of 0.60 to 3.5 mmol/24 h (100–600 mg/24 h). Xanthine accounts for 60 to 90 per cent of the total xanthine plus hypoxanthine excreted, presumably reflecting the more active metabolic turnover of hypoxanthine and its efficient salvage by hypoxanthine phosphoribosyltransferase. Hypoxanthine and xanthine are mainly derived from adenine and guanine nucleotides, respectively (see Fig. 1). Hypoxanthine has a relatively high solubility and causes no problems.

At any age, about one-third of cases present with radiotranslucent xanthine stones. These stones are usually smooth, soft, and yellow–brown. Xanthinuric myopathy is a rare complication.

Xanthine stones also occur when there is a combined deficiency of the three molybdoflavoprotein enzymes—xanthine oxidase, sulphite oxidase, and aldehyde oxidase—because of defective molybdopterin cofactor synthesis. The clinical picture in these patients is overshadowed by the sulphite oxidase deficiency that produces severe brain damage and dislocation of the ocular lenses. Another subgoup of patients with xanthinuria only lack xanthine oxidase and aldehyde oxidase activity. These patients present with xanthine stones and are detected by their inability to convert allopurinol to oxipurinol, a reaction normally catalysed by aldehyde oxidase.

Adenylosuccinase deficiency

Adenylosuccinase (adenylate succinate lyase) catalyses the eighth step on the 10-step *de novo* purine synthesis pathway and the second step on one of the purine nucleotide interconversion pathways, the formation of ATP from IMP.

The patients present in infancy with severe psychomotor retardation, autism, and axial hypotonia with normal tendon reflexes. Self-mutilation has been recorded in some cases and cerebellar hypoplasia is present on computed tomographic (**CT**) scanning.

The presence of aspartic acid and glycine in body fluids suggests the diagnosis, and this is confirmed by finding succinyladenosine and succinylaminoimidazole carboxamide riboside in plasma, cerebrospinal fluid, and urine. There is gross purine overproduction with high levels of nucleosides in the urine. Urine and plasma uric acid levels are normal. Partial enzyme deficiencies have been demonstrated in liver, kidney, muscle, lymphocytes, and fibroblasts.

Adenylosuccinase deficiency is inherited as an autosomal recessive. The growth retardation has been improved by adenine (10 mg/day) and allopurinol. The latter promotes purine conservation by blocking hypoxanthine oxidation to xanthine and uric acid, and prevents the oxidation of administered adenine to 2,8-dihydroxyadenine.

Myoadenylate deaminase deficiency

Myoadenylate deaminase is the muscle-specific isoenzyme of adenylate deaminase which catalyses the deamination of adenylic acid to inosinic acid during muscle contraction. This reaction is necessary for normal muscle function. Myoadenylate deaminase deficiency may be congenital, due to a mutation in the gene directing the synthesis of the protein, or associated with a wide range of muscle diseases including the muscular dystrophies, polymyositis, and dermatomyositis.

Patients with congenital myoadenylate deaminase deficiency present at any age, including early childhood, with a syndrome of muscle weakness and muscle cramps during and after exertion. There is some decrease in muscle mass, some hypotonia, and a little muscle weakness. There may be a modest rise in plasma creatine phosphokinase levels and non-specific electromyographic changes. The lack of ammonia in the venous outflow from the affected muscles during exercise and the enzyme deficiency can be demonstrated histochemically. The pattern of inheritance is autosomal recessive, not all homozygotes have clinical symptoms and heterozygous carriers are clinically silent. A single mutant allele contains a non-sense mutation that leads to the production of a severely truncated enzyme. The acquired disorder may be due to the coincidental disease arising in a patient whose inherited myoadenylate deaminase deficiency would be otherwise silent. Genetic testing for the mutant allele can be utilized to determine whether congenital myoadenylate deaminase could be contributing to the patient's clinical presentation.

Oral ribose (2–60 g/day, or taking a dose before vigorous exercise) has been reported to produce symptomatic improvement. The risk of rhabdomyolysis has led some authors to recommend the avoidance of vigorous exercise, myoglobinuria following strenuous exercise having been reported in a few cases. Such advice is appropriate if exertion-related myoglobinuria has occurred or been suspected.

Inborn errors of purine metabolism and immunodeficiency

Adenosine deaminase (**ADA**) and purine nucleoside phosphorylase (**PNP**) catalyse sequential steps in the metabolism of purine ribonucleosides and deoxyribonucleosides (Fig. 6). These enzymes are highly expressed in lymphoid cells and their deficiency, which causes the lymphotoxic substrates 2'-deoxyadenosine (**dAdo**) and 2'-deoxyguanosine (**dGuo**) to accumulate (see Fig. 6), leads to lymphopenia and immunodeficiency.

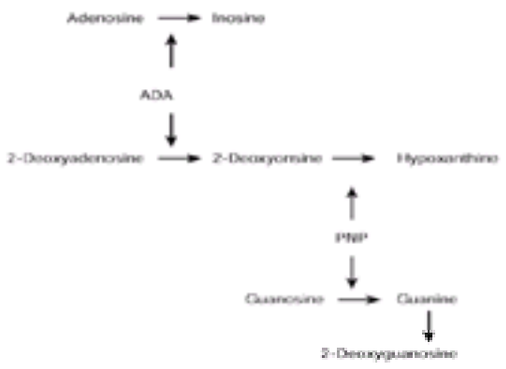

Fig. 6 Metabolic steps catalysed by adenosine deaminase (ADA) and by purine nucleoside phosphorylase (PNA).

Most patients with ADA deficiency lack both cell- (T cell) and humoral (B cell)-mediated immunity, resulting in severe combined immunodeficiency disease (**SCID**). Although PNP deficiency causes defective T-cell mediated immunity, these patients may possess either normal, hyperactive, or reduced humoral immunity. Most patients with these enzyme deficiencies present in infancy or early childhood with severe infections caused by pathogens or opportunistic organisms. About 50 per cent of patients with SCID have X-linked agammaglobulinaemia (Bruton's disease), a disease that is unrelated to ADA and PNP deficiencies and which displays an autosomal recessive pattern of inheritance.

Adenosine deaminase deficiency

About 85 per cent of patients with ADA deficiency are infants with SCID. In all patients with SCID, ADA deficiency accounts for a minority, possibly about 15 per cent. Although adenosine deaminase deficiency classically presents during infancy, a minority of patients have a clinically less severe variant and are diagnosed later. The prevalence of ADA deficiency has been estimated at between less than 1 in 10^6 and 1 in 2×10^5 live births.

ADA deficiency is inherited in an autosomal recessive fashion, the gene having been mapped to chromosome 20q13.11. The diagnosis is made by measuring ADA activity in erythrocytes. Heterozygote detection and prenatal diagnosis are best done using molecular probes for the ADA gene.

In addition to immunoparesis, about one-third of cases have multiple skeletal abnormalities, including fraying of the long bones, abnormally thick growth-arrest lines, and chondro-osseous dysphasia at the costochondral junctions. Other occasionally reported comorbidities are renal tubular acidosis, choreoathetosis, spasticity, and fine sparse hair.

The prognosis for patients with untreated adenosine deaminase-deficient SCID is very poor, with death due to multiple recurrent infections during the first year of life.

Adenosine and dAdo, derived from the breakdown of DNA due to cell death, accumulate proximal to the metabolic block—dAdo is the primary lymphotoxic precursor in adenosine deaminase deficiency, elevated levels of which are present in plasma and urine. Erythrocytes contain markedly raised levels of deoxyadenosine triphosphate (**dATP**) and reduced *S*-adenosylhomocysteine (**AdoHcy**) hydrolase activity due to inactivation by dAdo; erythrocyte ATP is reduced. The level of dATP in erythrocytes correlates with clinical expression and with the level of ADA activity expressed in *Escherichia coli* by mutant ADA alleles.

There are several mechanisms by which adenosine deaminase deficiency can impair immune function. Thus, accumulation of dATP can induce apoptosis in lymphoid cells, which may be related to dATP-induced inhibition of ribonucleotide reductase blocking DNA replication in dividing cells, and to dATP-induced DNA strand breaks in non-dividing lymphocytes. dATP also activates the protease (caspase 9) involved in apoptosis. AdoHcy also blocks *S*-adenosylmethionine (**AdoMet**)-mediated transmethylation reactions. The formation of dATP from dAdo activates IMP dephosphorylation, thereby leading to the depletion of cellular ATP. It has also been suggested that lymphocyte function may be impaired by aberrant signal transduction mediated by Ado acting through G-protein-associated receptors, or from an altered co-stimulatory function of T-cell associated ADA-complexing protein CD26/dipeptidyl peptidase IV.

Treatment

This is by bone marrow transplantation from a histocompatible donor. Repeated blood transfusions can provide temporary benefit, although repeated transfusion leads to iron overload. More sustained clinical improvement follows the weekly or twice-weekly administration of polyethylene glycol-modified bovine adenosine deaminase. The use of ADA-loaded erythrocytes membranes is also being explored.

Transplantation of T-cell-depleted marrow from an HLA-haploidentical donor has been tried, but it is associated with greater morbidity and is less effective than bone marrow transplantation in restoring immune function.

The *ex vivo* retrovirus-mediated transfer of ADA cDNA is the first attempt at somatic-cell gene therapy in humans. The efficacy of transducing stem cells has been low, but persistence of the vector myeloid cells and T lymphocytes has been demonstrated. The long-term evaluation of this approach is still awaited.

Purine nucleoside phosphorylase deficiency

PNP deficiency occurs less frequently than ADA deficiency. In addition to the clinical results of immunoparesis, more than 50 per cent of these patients have neurological abnormalities including disorders of muscle tone, delayed motor and intellectual development, ataxias, tremors, spastic tetraparesis, behavioural difficulties, and varying degrees of mental handicap. Autoimmune haemolytic anaemia and megaloblastic bone marrow have been occasional associations.

There appears to be a particular susceptibility to virus infections such as varicella, vaccinia, and cytomegalovirus. The tonsils and the thymus are small or absent and the lymph nodes are deficient in the thymus-dependent areas. Circulating lymphocyte counts are usually very low, with a low percentage of T lymphocytes and depressed or absent responsiveness to mitogen-induced transformation. Serum immunoglobulin levels and antibody responses to pneumococcal polysaccharide and keyhole limpet haemocyanin are typically increased in children with PNP deficiency, and the occasional finding of monoclonal IgG paraprotein strongly suggests that the changes in antibody production are the result of T-cell defects.

PNP deficiency is associated with the accumulation and excretion of dGuo and deoxyinosine, as well as guanosine and inosine. Paradoxically, there is massive purine overproduction and excretion, although all patients are severely hypouricaemic. Erythrocyte concentrations of dGTP are markedly raised in PNP-deficient cells. T cells, but not B cells, appear to be particularly susceptible to dGuo toxicity, probably as a result of the accumulation of dGTP, inhibition of ribonucleotide reductase, impairment of DNA synthesis, and, eventually, cell death.

The prognosis in children with PNP deficiency is often much better than that in adenosine deaminase deficiency. Since some children have remained healthy and free from viral infection until the age of 6 years, high-risk procedures such as bone marrow transplantation are currently not thought to be justified in all cases. Conservative treatment with gammaglobulin replacement and attempts at enzyme replacement with red cell transfusions in children with recurrent infections are the current approach to management.

Purine 5'-nucleotidase deficiency

Deficiency of the ecto enzyme 5'-nucleotidase is found in some patients with X-linked and 'acquired' adult-onset hypogammaglobulinaemia. There is no evidence that the enzyme deficiency causes the immunodeficiency in either case. It is currently thought much more likely to simply reflect an arrested stage of lymphocyte development in these patients.

Other disorders of purine metabolism

There are two unrelated conditions: (1) a regulatory mutation in liver adenylic deaminase as a cause of uric acid overproduction and gout in a single patient; and (2) erythrocyte adenylic acid deaminase deficiency in Japanese and Chinese peoples, which has no clinical phenotype.

Disorders of pyrimidine metabolism

The pathways of pyrimidine biosynthesis interconversion and degradation are shown in Fig. 7.

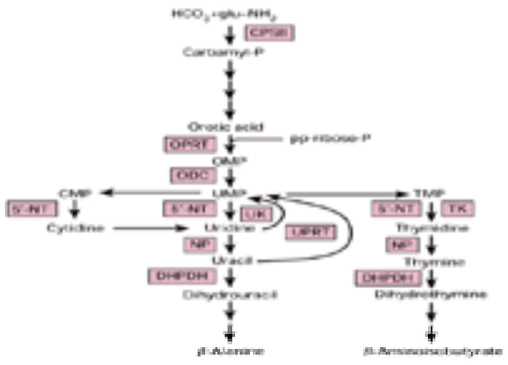

Fig. 7 Pathways of pyrimidine metabolism in humans. CPSH, carbamyl phosphate synthetase II; OPRT, orotate phosphoribosyltransferase; ODC, orotidine decarboxylase (OPRT + ODC from UMP synthase; 5'-NT, pyrimidine 5'-nucleotidase; NP, pyrimidine nucleoside phosphorylase; DHPD, dihydropyrimidine dehydrogenase; UK, uridine kinase; UPRT, uracil phosphoribosyltransferase; TK, thymidine kinase.

The *de novo* synthesis of pyrimidine nucleotides involves a series of six reactions beginning with the formation of carbamyl phosphate and concluding with orotidylic acid (**OMP**), which then undergoes a series of interconversion and salvage reactions as summarized in Fig. 7. The first three steps on the *de novo* synthesis pathway are catalysed by the multifunctional protein that encompasses carbamyl phosphate synthetase, aspartate transaminase, and dihydro-orotase. The fourth step is catalysed by dihydro-orotate dehydrogenase. The fifth and sixth steps are catalysed by the bifunctional protein encoding orotate phosphoribosyltransferase (**ORPT**) and orotidine-5'-monophosphate dehydrogenase (**OMPD**) activities. The pyrimidines are degraded to b-alanine and b-aminobutyrate (Fig. 7).

The inherited disorders of pyrimidine metabolism are much less common, or possibly much less easily recognized, than disorders of purine metabolism.

Orotic aciduria

Orotic aciduria is due to a deficiency of the bifunctional protein that encodes both OMP dehydrogenase and OPRT activities. There is massive overproduction of orotic acid due to loss of feed-back inhibition of carbamyl phosphate synthase, which is the first and rate-limiting step on the metabolic pathway.

Orotic aciduria presents during infancy with severe megaloblastic anaemia, orotic acid crystalluria, and, occasionally, radiotranslucent orotic acid urinary stones. Cardiac malformations, mild intellectual impairment, and strabismus have been reported. Orotic aciduria is inherited as an autosomal recessive.

Enzyme assays on erythrocyte lysates show either low levels of OPRT and OMPD (type 1 orotic aciduria) or a deficiency of ODC only (type 2 orotic aciduria). Administration of uridine (100–150 mg/kg per day), which is converted to UMP (Fig. 7), produces a prompt haematological response. Treatment needs to be started as soon as the diagnosis is made during infancy in order to minimize the possibility of persistent neurological deficits.

Some degree of orotic aciduria has been found in urea cycle defects, lysinuric protein intolerance, PNP-deficiency, normal pregnancy, and during allopurinol administration.

Pyrimidine 5'-nucleotidase deficiency

This autosomal recessive disorder leads to non-spherocytic haemolytic anaemia. Uridine triphosphate (**UTP**) and cytidine triphosphate (**CTP**) accumulate in the red cells, which show basophilic stippling. The enzyme is assayed in erythrocytes and activities between 0 and 30 per cent of normal have been reported. There is no effective treatment. Lead poisoning can also be associated with acquired erythrocyte pyrimidine 5_-nucleotidase deficiency.

Pyrimidine 5'-nucleotidase superactivity

Pyrimidine 5'-nucleotidase superactivity has been reported in four unrelated families with developmental delay and neurological abnormalities. Treatment with uridine is said to have been beneficial.

Deficiency of dihydropyrimidine dehydrogenase (DHPDH)

This autosomal recessive disorder presents with variable degrees of hypertonia, epilepsy, and autism. Some cases have only presented during adult life, when they have developed severe adverse side-effects following cancer chemotherapy with 5-fluorouracil. Uracil and thymine are elevated in the body fluids, including urine. Absent enzyme activities have been demonstrated in blood, cerebrospinal fluid, leucocytes, liver, and fibroblasts. There is no effective treatment for this condition and the prognosis for life is very variable.

N-Carbamyl-b-aminoaciduria

To date, just one patient has been detected with ureidopropionase deficiency causing *N*-carbamyl-b-aminoaciduria. This patient presented with choreoathetosis, hypotonia, and microcephaly.

11.5 The porphyrias

T. M. Cox

The haem biosynthetic pathway holds great fascination for biochemists who marvel at the evolution of ancient enzymes which interact to bring about the formation of the pigments of life—haemoglobin, the cytochromes, chlorophyll, and the cobalamins (vitamin B_{12}). It is unfortunate that, because of complexities in their chemical structure and ambiguities in their technical nomenclature, the terminology of the porphyrin pigments and the diseases associated with their disturbed metabolism are perceived to be confusing and intimidating. These considerations apply particularly to the acute porphyrias which are rare but distressing syndromes that mimic other acute illnesses but for which recognition may be critical for the patient's survival; too often the diagnosis is not established until permanent disability or even death supervenes.

The porphyrias are caused by disturbances in the multistep pathway for the formation of haem—a pigment essential for oxygen transfer and the energy-yielding reactions of electron transport. The formation of haem is tightly regulated so that acquired or hereditary defects of any of its component reactions lead to the overproduction of haem precursors. Potentially photoactive macrocyclic compounds and toxic precursors of pyrroles thus accumulate. Most of the human porphyria syndromes result from uncommon genetically determined deficiencies of unitary enzymes of the haem biosynthetic pathway; but certain toxins including lead, iron, and hydrocarbons influence the pathway and cause porphyria in susceptible individuals. Similarly the metabolism of endogenous molecules, including steroid hormones, and xenobiotics such as alcohol and many therapeutic drugs, may disturb the delicate equilibrium that is achieved in asymptomatic patients with latent porphyria. Thus gene–environment interactions in previously fit individuals may precipitate sporadic attacks of acute porphyria.

Classification: types of porphyria

The porphyrias are disorders of metabolism characterized by overproduction of the precursors of haem synthesized principally in the liver and bone marrow. About 15 per cent of *de novo* haem biosynthesis occurs in the liver and about 80 per cent in the erythroid marrow. Hepatic synthesis of haem is subject to rapid and wide oscillations in flux; haem biosynthesis in the erythropoietic bone marrow is under most circumstances constitutive and stable. However, haem synthesis may be increased as the erythron expands and proliferates to meet the demands of blood loss or haemolysis, including ineffective erythropoiesis.

Hitherto the porphyrias have been classified into the hepatic and erythropoietic types depending on the principal location at which overproduction of haem precursors occurs. For clinical purposes, however, an operational definition of the porphyric syndromes is more usefully presented as the acute and the non-acute porphyrias. The acute porphyrias cause life-threatening neurovisceral manifestations typically precipitated by environmental factors that occur sporadically. The non-acute porphyrias are characterized by photosensitivity syndromes resulting from the overproduction of macrocyclic porphyrins which cause light-induced skin injury. Several of the acute porphyrias may be associated also with the overproduction of porphyrin intermediates and so may be accompanied at times by long-term photosensitivity which is often exacerbated during the acute attacks. In all instances it is the overproduction of haem precursors that characterizes the condition biochemically: this is the principal means by which a diagnosis can be made of the underlying enzymatic defect during the acute attack. Table 1, Table 2, and Table 3 set out the individual defects that characterize the clinical porphyrias and summarize the clinical features of these hereditary syndromes.

Formation of haem

Haem biosynthesis is catalysed by eight enzymes and is co-ordinated between mitochondrial and cytoplasmic compartments in the cell (Fig. 1). The first committed precursor, 5-aminolaevulinate, is formed in the mitochondria from glycine and the Krebs' cycle intermediate, succinyl-CoA, by one or other of the two isozymes of 5-aminolaevulinate synthetase. Precursor 5-aminolaevulinate is then exported to the cytoplasm where it undergoes condensation to form the monopyrrole, porphobilinogen, four molecules of which are then condensed to yield the macrocyclic tetrapyrrole, uroporphyrinogen III. This reaction is brought about by porphobilinogen deaminase and uroporphyrinogen III synthetase acting co-ordinately to reverse the orientation of one porphobilinogen molecule to yield the uroporphyrinogen III isoform that is the sole precursor of biological haem. Porphyrins of the I series do not serve as biological intermediates in the formation of protoporphyrin IX or haem.

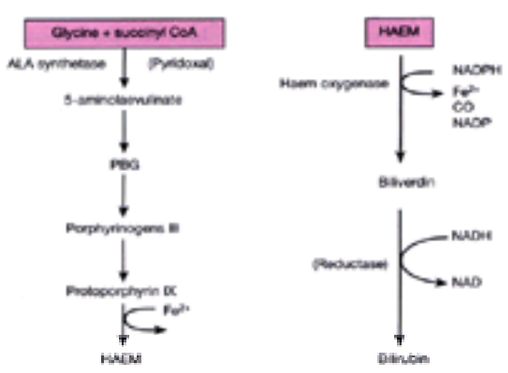

Fig. 1 Main pathways for haem biosynthesis and degradation in humans.

The cytoplasmic enzyme, uroporphyrinogen III decarboxylase decarboxylates the four acetate substituent side-chains to yield coproporphyrinogen III, which is then reimported into the mitochondrion for further oxidative decarboxylation. Coproporphyrinogen III oxidase modifies the two propionate side-chains to vinyl groups yielding protoporphyrinogen IX, the penultimate precursor of haem. Protoporphyrinogen oxidase removes six hydrogen atoms to yield protoporphyrin IX, which is the substrate for the final step in haem biosynthesis. The insertion of ferrous ions into the porphyrin macrocycle to form ferroprotohaem (haem) is catalysed by the mitochondrial enzyme ferrochelatase.

Haem serves as a key prosthetic group in haem proteins including cytochromes, myoglobin, and haemoglobin by which it fulfills its essential biological roles as a transporter of oxygen and electrons in the respiratory chain and in the metabolism of xenobiotics. The two isozymes (constitutive erythroid and the inducible hepatic isozyme) of 5-aminolaevulinate synthetase catalyse the rate-limiting step of haem biosynthesis. The hepatic isozyme maps to the autosome, chromosome 3, but the

erythroid isozyme of 5-aminolaevulinate synthetase (ALAS-2) maps to the X chromosome. These enzymes are subject to differential regulation principally involving transcriptional control in the liver and translational and post-translational control mechanisms in the erythroid cell by the end product, haem. These mechanisms regulate the activity of the whole biosynthetic pathway. Pyridoxal 5-phosphate (derived from vitamin B_6) is an essential cofactor for 5-aminolaevulinate synthetase isozymes. Deficiency of pyridoxine or interference with its metabolism leads to sideroblastic anaemia.

The second enzyme of the haem biosynthetic pathway, 5-aminolaevulinate dehydratase, is a multimeric enzyme with reactive sulphydryl groups that are particularly sensitive to the toxic effects of heavy metals, especially lead, so that 5-aminolaevulinate dehydratase activity is a sensitive measure of environmental and industrial toxicity. Moreover, 5-amino-laevulinate dehydratase is inhibited competitively by the metabolite succinyl acetone, concentrations of which rise to inhibitory levels in patients suffering from the defect of aromatic amino-acid degradation, tyrosinaemia type I. Patients with tyrosinaemia type I and lead poisoning suffer neurovisceral manifestations that resemble the acute porphyrias and it appears likely that overproduction of aminolaevulinate, as a result of arrest at the 5-aminolaevulinate dehydratase reaction, contributes to this effect.

In living cells most of the macrocyclic precursors of the haem biosynthetic pathway are present as their reduced porphyrinogen precursors which are not themselves photoreactive. However, when these tetrapyrroles (uroporphyrinogen, coproporphyrinogen, and protoporphyrinogen) are produced in excess, they diffuse into plasma and tissues where they react with ambient oxygen to form their parent porphyrins, which are spectacularly fluorescent. The double-bond resonance structure of these macrocyclic compounds promotes the formation of singlet oxygen by the transfer of absorbed energy to ground-state oxygen through light activation. It appears that generation of singlet oxygen brings about the photodermatoses associated with the porphyrias; these are characterized by photosensitization of the skin and tissues exposed to light in a broad region of the spectrum including the visible range (350 to 430 nm). Porphyrias associated with overproduction of formed macocyclic haem precursors are thus associated with photosensitivity; the particular skin reactions that develop differ between the particular enzyme defects. This may be explained principally by the degree of hydrophobicity of the overproduced porphyrins and their solubility in cellular membranes.

The first tetrapyrrole that serves as an immediate precursor to haem is uroporphyrinogen III, formation of which requires co-ordinated action of the two cytoplasmic enzymes, uroporphyrinogen I synthase (porphobilinogen deaminase) and uroporphyrinogen III cosynthase. In the absence of adequate cosynthase activity, there is a marked overproduction of porphyrins of the I series, which do not form biologically active ferroprotohaem. Deficiency of uroporphyrinogen III cosynthase leads to the very rare but disabling syndrome of Gunther's disease (congenital erythropoietic porphyria). This disorder is characterized by extreme photosensitivity, haemolysis, and the passage of pink urine containing abundant porphyrins of the I isoform. Persistently high concentrations of these toxic molecules in body fluids leads to staining of the teeth and bones and extreme photosensitive damage, often with cruel and painful skin disfigurement and hair loss.

Porphyria cutanea tarda is caused by deficiency of uroporphyrinogen decarboxylase, defects of which involve complex interactions between heredity and environmental factors. The enzyme activity is markedly decreased in the presence of excess tissue iron and, although rare familial cases of porphyria cutanea tarda occur, most patients have a sporadic disease which is provoked by exposure to environmental toxins such as alcohol, oestrogens, hydrocarbons, iron (often associated with mutations in the haemochromatosis gene, *HFE*), and hepatitis C. At the time of writing, the pathogenic relationship between these external factors and the manifestations of uroporphyrinogen decarboxylase deficiency is unclear.

The final step in the haem biosynthetic pathway involves insertion of ferrous iron into the protoporphyrin nucleus generated enzymatically from protoporphyrinogen IX by protoporphyrinogen IX oxidase. This latter step occurs in the mitochondrion. Ferrochelatase depends on the iron–transferrin cycle for the delivery of iron from plasma transferrin. In the bone marrow, when the iron supply is deficient, freely available zinc may be preferentially converted to zinc protoporphyrin rather than ferroprotohaem thus offering a convenient means to monitor iron-deficient erythropoiesis. Similarly, industrial lead exposure that inhibits both iron delivery and the activity of the sulphydryl enzyme ferrochelatase causes accumulation of zinc protoporphyrin and free protoporphyrin in erythroid precursors and reticulocytes. Deficiency of ferrochelatase leads to the accumulation of free protoporphyrin in liver tissue, plasma, and the skin, where it induces marked photosensitivity. The accumulation of excess protoporphyrin in red cell precursors leads to the characteristic fluorocytes (young red cells containing excess free protoporphyrin) that are the easily recognized hallmark of patients with burning photosensitivity caused by protoporphyria.

The highly regulated control mechanism of haem biosynthesis ensures that the free concentrations of the toxic intermediates involved in the pathway are kept low unless there is a metabolic arrest at one of the biosynthetic reactions; under these circumstances an overproduction of the intermediate compounds occurs which can be used for diagnosis. This overproduction predisposes to the development of the particular clinical porphyric syndrome. A knowledge of the enzymatic steps and of the differential solubility of the haem precursors facilitates appropriate diagnostic testing for the precise identification of suspected porphyria. In principle, overproduction of the early precursors such as aminolaevulinic acid is a common feature of those syndromes associated with neurovisceral manifestations or acute attacks of porphyria. Aminolaevulinate, in particular, represents a common biochemical marker of such attacks and those syndromes that mimic the porphyrias such as hereditary tyrosinaemia type I and lead poisoning. In patients with cutaneous photosensitivity, overproduction of the formed porphyrin macrocycles can be detected also in plasma, urine, and faeces in which they are distributed according to their aqueous solubility (Table 4).

The profile of molecules that are overproduced in a given syndrome may be predicted from the level at which the enzymatic arrest occurs as flux through the pathway is stimulated by diminished negative feedback. In those porphyrias where the principal site of production appears to be in the liver, including the acute porphyrias and porphyria cutanea tarda, oscillations in the flux through the biosynthetic pathway as a result of regulatory effects from environmental or endogenous factors can occur very rapidly; indeed minute-to-minute oscillations in biosynthetic haem fluxes have been recorded in the liver. Thus in starvation and on challenge with xenobiotic reagents (which place a demand for the production of haem to meet the needs for new cytochrome formation), as well as with endogenous hormonal changes, enhanced flux through the pathway leads to toxic overproduction of 5-aminolaevulinic acid. By the same token, rapid repression of the haem biosynthetic pathway in the liver can be induced by the administration of exogenous haem—a useful agent in the control of acute attacks and which rapidly corrects the disturbed metabolism (see below).

Haem formation in the erythron is more rapid than that in the liver but is not subject to sudden oscillations in synthetic rates. Nonetheless in patients with erythropoietic porphyrias, such as congenital porphyria, enhanced rates of red cell destruction when hypersplenism supervenes or in response to light exposure greatly exacerbate the overproduction of porphyrin intermediates and aggravate photosensitivity due to increased porphyrin release. Short-term experiments indicate that exogenous haem may partially repress the endogenous haem biosynthetic pathway in erythroid tissue but this has not proved to be useful for long-term relief in the erythropoietic porphyrias. Blood transfusion to suppress erythropoiesis or definitive replacement of bone marrow by transplantation has, however, proved to be successful in controlling the devastating manifestations of congenital erythropoietic porphyria.

Pathogenesis

The individual porphyria syndromes are described briefly below but the main manifestations (neurovisceral or phototoxic) remain the subject of further clinical research.

Acute neurovisceral attacks

These attacks occur in four of the porphyrias indicated in Table 1, Table 2 and Table 3. In all but one, Doss porphyria (aminolaevulinate dehydratase deficiency), the inheritance is as an autosomal dominant disease. 5-Aminolaevulinate dehydratase deficiency is inherited as an extremely rare recessive condition. Clinical expression is characterized by acute, life-threatening attacks of neuropathy that include abdominal pain, psychiatric symptoms, signs of sympathetic and hypothalamic autonomic overactivity, sometimes accompanied by convulsions and motor and sensory deficits. The syndrome is characteristically precipitated by drugs that induce hepatic haem formation and are metabolized by the hepatic cytochrome P-450 system. Neuropathological examination shows axonal degeneration and central chromatolysis in anterior horn cells and in the brain. Electromyography may reveal denervation compatible with a primary axonal neuropathy of peripheral nerves.

Although this acute porphyria is associated with lone overproduction of 5-aminolaevulinic acid, common to all those associated with acute manifestations, a toxic effect of this precursor is not the only potential mechanism of injury. The structure of aminolaevulinate is analagous to the inhibitory neurotransmitters g-aminobutyric acid and L-glutamate. It seems likely that 5-aminolaevulinate may interfere with the action of the GABA-ergic system—the best evidence for which appears to be its ability to inhibit melatonin production in the rat pineal gland *in vivo*, as has been described in patients with recurrent acute porphyric attacks. It has been further postulated that under the conditions of the acute attack there may be a deficiency of essential haem proteins, such as the cytochrome P-450 isozymes in the liver, with further disturbances in secondary metabolism; other possibilities include a decrease in the activity of hepatic tryptophan dioxygenase, leading to increased formation of 5-hydroxytryptamine (serotonin).

At present there is no clear resolution between combined or individual effects of acute porphyria on the production of neurotoxic pseudotransmitters

(aminolaevulinate) or secondary local deficiency of haem. However, early unpublished but apparently beneficial results of liver transplantation in patients with disabling recurrent attacks of acute intermittent porphyria indicate that the principal cause of the acute syndrome is the hepatic overproduction of toxic haem precursors. In any event, there is convincing evidence of abnormal neurotransmitter function and increased serotonin production—as well as direct interference of GABA receptors by toxic concentrations of 5-aminolaevulinate. Supplying exogenous haem during the acute attack, however, would be expected to correct both arms of this disturbed metabolism, which may account for the beneficial biochemical and clinical effects observed with its use. The recent development of a mouse model of porphyrinogen deaminase deficiency showing sensitivity to barbiturates serves as an authentic model of the biochemical and neuropathological manifestations of acute porphyria and may clarify much about the pathogenesis of this disturbing clinical syndrome. Detailed observations of the effects of hepatic transplantation in acute human porphyrias are also eagerly awaited.

Photosensitivity

Porphyrins absorb light maximally in the Soret region (400 to 420 nm) and in the visible wavelength region (between 500 and 600 nm); they re-emit this light energy at lower wavelengths to give pink, orange, or red fluorescence. This fluorescence is associated with the photodynamic effects and excitation to form triplet states; in the presence of oxygen in biological tissues, transfer of electronic energy leads to the generation of reactive oxygen species, including singlet oxygen, leading to complement activation and cutaneous toxicity. Careful studies examining the photoactive spectrum of skin from patients with various porphyrias has confirmed a cause-and-effect relationship between irradiance within the absorbing wavelength range of the given porphyrin and the development of weal-and-flare and other cutaneous phototoxic responses.

Distinct porphyric syndromes are associated with the accumulation of a particular formed macrocyclic porphyrin, each with its particular solubility properties in plasma and in cell membranes. In porphyria cutanea tarda, skin biopsies show subepidermal bullas and electron microscopy reveals vacuoles in the cells of the superficial dermal epithelium. In this disease, as in protoporphyria, the endothelium of the dermal capillary is thickened and the vessels are surrounded by complement and mucopolysaccharide deposits. In protoporphyria, an adequate oxygen supply has been shown to be critical for the development of experimental phototoxicity *in vivo.* Singlet oxygen and other radicals may lead to lipid peroxidation and cross-linking of membrane proteins with activation of late complement components. In the more severe disease, congenital erythropoietic porphyria, egress of uroporphyrin I from circulating erythrocytes, which may be destroyed within capillaries, leads to gross accumulation of porphyrin in dermal tissue and juxtaposed epithelium. Exposure to light is known to promote photohaemolysis indicating that light of the visible wavelength can penetrate the skin sufficiently to induce porphyrin photoactivation *in situ*.

Induction of acute porphyric attacks

Acute attacks of porphyria may be life-threatening illnesses which occur in genetically predisposed individuals who usually remain asymptomatic. The acute episodes develop on exposure to environmental or endogenous factors that place a demand for hepatic haem biosynthesis which leads to the overproduction of porphyrin intermediates and pyrrole precursors. The most frequent precipitating factors are changes in reproductive steroid hormones either due to natural hormone cycles or the administration of exogenous gonadal steroids. Starvation, including that associated with surgical procedures and anaesthesia, intercurrent infections, and many xenobiotics including alcohol as well as prescription drugs, over-the-counter agents, and chemicals present in health foods can precipitate acute porphyria.

Table 5 and Table 6 list drugs that have been classified as unsafe in the porphyrias either because they have been shown to be porphyrinogenic in animals or *in vitro* studies, or have been associated with acute attacks in patients with porphyria. The table is taken from the British National Formulary published by the British Medical Association and the Royal Pharmaceutical Society of Great Britain. It is pointed out in this publication that slight changes in the chemical structure can lead to marked differences in the ability of the drug to induce attacks of porphyria. A more complete list of drugs is provided in a review by Anderson *et al*. (2001) in the Further reading section.

Acute attacks of porphyria occur in the four conditions known as the hepatic porphyrias and particularly occur for the first time in latent carriers who are aged between 15 and 40 years. Attacks have been recorded in children before puberty but are extremely rare and usually occur during febrile illnesses precipitated by the use of porphyrinogenic cough medicines. Although the porphyrias occur in a latent state in men with a frequency that is equal to that in women, women suffering from acute porphyria outnumber men by at least 2:1.

Clinical features of acute porphyria

The clinical manifestations of an acute attack are very diverse and the condition may be indistinguishable from many other disorders. In Table 7 are listed common neurovisceral symptoms of acute porphyric attacks and of these abdominal pain is the most common, but not invariable, presenting symptom. The pain itself may be difficult to identify since it is usually constant but poorly localized and usually unassociated with tenderness. There may be an associated colicky component and later ileus with abdominal distension which may mimic a surgical emergency. Characteristically, constipation occurs but diarrhoea with increased borborygmi may develop. The patient often becomes very distressed and tachycardia is common.

A frequent feature is the development of pain in the limbs, particularly in the upper thighs, but also in any of the somatic muscles of the chest, lumbar region, shoulders, and neck. Ultimately, muscle weakness and respiratory paralysis may occur. The patient becomes restless or frankly disturbed and deluded as in a toxic confusional state. The inability of attending medical personnel to identify the cause of the pain and the distress associated with it often leads to alienation and an exaggeration of the patient's complaints which may be difficult to diagnose: often a suggestion of hysterical conversion syndrome or worse, malingering, is made by attending staff. Hypertension, sweating, and tremor together with tachycardia indicate marked sympathetic overactivity and cardiac arrythmias may ensue. In about 10 per cent of severe attacks, grand mal seizures develop; treatment of which may prolong the attack, since many anticonvulsants are porphyrinogenic. With sustained attacks there may be signs of a peripheral neuropathy which is related to axonal degeneration, principally affecting motor nerves. Peripheral neuropathy in its early stages may not affect the limb and tendon reflexes but with time these will be decreased or absent. Ultimately, progressive muscle weakness affecting the respiratory muscles, diaphragm, and swallowing may lead to paralysis and death in prolonged attacks in which the institution of lifesaving cardiorespiratory resuscitation measures and intensive care assessment is delayed.

In a full-blown attack, mental symptoms including anxiety, sleeplessness, and depression may be prominent. If the porphyric attack is sustained as a result of inadequate management or diagnosis, progressive alienation, visual and auditory hallucinations, and frank paranoia with progressive and homicidal outbursts may occur. These are extremely difficult to contain within the routine environment of the busy acute hospital. Although seizures may be a presenting sign of the acute attack, they are commonly attributable to marked hyponatraemia resulting from the inappropriate secretion of antidiuretic hormone that itself originates from hypothalamic sympathetic overactivity. Treatment of hyponatraemia due to this cause in the acute attack poses special difficulties (see below). The use of large volumes of hypotonic dextrose has in the past often aggravated the hyponatraemia and seizures—as well as cerebral odema.

Diagnosis of the acute attack is suspected on the basis of the past history including photosensitivity or the intermittent discoloration of urine. There may be a history of abdominal pain in first-degree family members, with or without photosensitivity. Confirmation of an acute attack of porphyria requires the demonstration of increased porphyrin precursors in the urine. Most commonly, increased excretion of the monopyrrole, porphobilinogen, is accompanied by increased excretion of urinary 5-aminolaevulinate. However, porphobilinogen excretion is not increased in the rare aminolaevulinate dehydratase deficiency nor in the pseudoporphyria of lead poisoning.

Acute attacks of porphyria appear to be more common in women as a result of changes in reproductive steroid hormones and many women who suffer from periodic attacks do so in the 1 or 2 days before onset of menstrual bleeding; usually as the menopause approaches, the pattern of these attacks may change or worsen, but with the onset of amenorrhoea, severe attacks of porphyria almost invariably cease. Sometimes, acute attacks lasting a day or two may have their onset in the mid-menstrual period around the time of ovulation. Many mild attacks of porphyria resolve spontaneously within a few days, either as a result of withdrawal of the precipitating factor or of natural hormonal rhythms. Prolonged attacks usually result from the interaction of adverse exogenous and endogenous cofactors and may last for many weeks or even months. The ensuing neurological injury, accompanied in severe attacks by bulbar and respiratory paralysis, may lead to prolonged or even permanent disability. Experience shows that in many such cases inappropriate drugs have been given to counter the early manifestations of the condition, for example analgesics, psychotropic drugs, and anticonvulsants. Thus the initiating medical interventions ultimately prove to be critical determinants of outcome where the diagnosis is not suspected or, if known, is ignored.

Outcome

An early series showed that during the first acute attack of porphyria half the patients died. However, perhaps as a result of better hospital facilities to deal with severe

or adverse outcomes, the mortality and effects of the disease in patients with acute attacks has improved. Reports from a single centre reported that about three-quarters of patients with acute intermittent porphyria or variegate porphyria were able to lead normal lives after an acute attack. Recurrent attacks of pain occurred only in a minority during a period of prolonged follow-up; these recurrent attacks were most likely to occur in the first 3 years.

The development of national centres for the treatment of porphyria, the early detection of genetic predisposition in at-risk first-degree relatives, and the dramatic reduction in prescriptions of porphyrinogenic drugs such as barbiturates and sulphonamides, together with better treatment of acute attack, are all responsible for the improved outcome. Nonetheless, acute porphyria remains life-threatening and deaths or marked disability due to prolonged, mismanaged, or undiagnosed attacks are all too frequent. Rapidly recurrent attacks of porphyria may be associated with severe motor neuropathy and sustained hypertension; postural hypotension may result from autonomic neuropathy. In severe cases, cranial nerve palsies, typically affecting the facial nerve and the vagus nerve, occur. Ischaemia of the occipital cortex during acute attacks has been associated in a number of instances with failed recognition of colours or of human faces (aprosopagnosis) and cortical blindness.

Although it appears that progestogens are principally responsible for cyclical or periodic attacks in women because they are more porphyrinogenic than oestrogens, pregnancy itself is not usually associated with adverse outcomes in women at risk from acute attacks. However, drugs such as metoclopramide that provoke attacks may be used mistakenly to control gastrointestinal symptoms in pregnancy and thus place the woman and her unborn infant at risk.

Individual porphyrias

Acute porphyrias

These are, in a descending order of frequency: acute intermittent porphyria, variegate porphyria, hereditary coproporphyria, and Doss porphyria (aminolaevulinate dehydratase deficiency). The first three of these disorders occur in at-risk heterozygotes for a single mutant allele in the cognate gene as autosomal dominant traits; 5-aminolaevulinate dehydratase deficiency is inherited as a very rare autosomal recessive trait.

The overall frequency of heterozygosity for acute porphyrias is estimated to be 1 in 10 000 of the population, of whom only 1 in 5 to 10 will develop an acute attack. In certain populations (South Africa and in the Lapps of Northern Sweden) the frequency rises to 1 in 1000 of the population. In South Africa, a high gene frequency results from the founder effects of the migration of a Dutch settler in the seventeenth century. Variegate porphyria has thus spread to all ethnic groups within the South African population, molecular analysis of which confirms the presence of a single dominant mutant allele of the protoporphyrinogen IX oxidase gene.

In the last decade or so there has been much interest in the identification of very rare homozygous forms of porphyria where the presence of two mutant alleles of the causative gene are generally responsible for severe clinical disease. In most instances, the condition is not truly homozygous since those individuals affected prove to be compound heterozygotes for two mutant alleles of the cognate gene rather than true homozygotes for the many discrete but rare mutations that occur in porphyria but which would only be expected to occur in consanguineous pedigrees.

Acute intermittent porphyria

This, the most frequent of the acute porphyrias, is caused by mutations in the porphobilinogen deaminase gene that maps to human chromosome 11q23 in which well over 100 mutations have been identified. Several widespread mutations have been identified in certain populations but the majority are reported in only one or two pedigrees.

Two isozymes of the human porphobilinogen deaminase enzyme occur in the tissues: an erythroid mRNA variant and a non-erythroid transcript that encodes 17 additional amino-acid residues in its N-terminus lead to synthesis of housekeeping ubiquitous isozyme and an erythroid-specific isozyme. Most mutations cause a decrease in the abundance as well as the activity of the porphobilinogen deaminase enzyme in all tissues. A small proportion of mutations associated with lack of the detectable protein product from the mutant allele are associated with reduction of the housekeeping isozyme but normal enzymatic activity of the erythroid-specific isozyme. Thus in such patients hepatic porphobilinogen deaminase activity may be reduced to approximately half normal values while the activity of the easily accessed red-cell enzyme is within the normal range.

A few mutations lead to the synthesis of a catalytically impaired but stable porphobilinogen deaminase protein from the cognate mutant allele but these appear to be in a minority. Molecular analysis of the porphobilinogen deaminase gene in patients with acute intermittent porphyria has been very valuable in establishing diagnosis of latent heterozygotes at risk in the affected family, for the provision of appropriate counselling and for the introduction of preventative strategies (see below).

Acute intermittent porphyria is characterized solely by acute porphyric attacks and cutaneous photosensitivity does not occur. In most instances the patients do not notice any change in their urine, although on standing, the increased excretion of pyrroles leads to the formation of coloured oxidation products of porphobilinogen (loosely called porphobilin) which may lead to obvious discoloration (Fig. 2 and Plate 1). During the increased excretion of porphyrin precursors, water-soluble porphyrins form as a result of non-enzymatic photochemical reactions induce a pink discoloration. During acute attacks, copious excretion of pyrrole precursors, including porphobilin, may occasionally give the urine a striking appearance resembling blackcurrant juice or strong solutions of potassium permanganate.

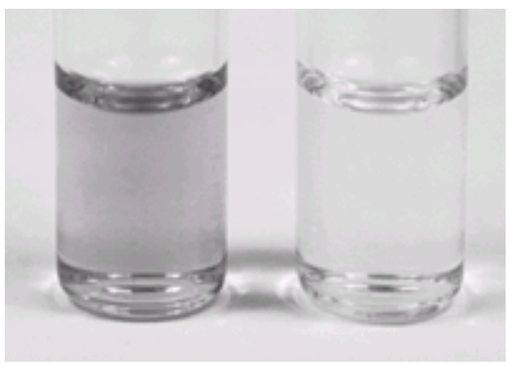

Fig. 2 Urine from a patient with acute intermittent porphyria around the time of an acute attack (left); control urine (right). A positive reaction with Ehrlich's diazo reagent is shown in the patient following the addition of 50 µl of urine to 1 ml of 2 per cent acidic dimethyl benzaldehyde. Subsequent tests showed that the pink diazo adduct was insoluble in chloroform and other organic solvents indicating the presence of excess porphobilinogen. (Urobilinogen in excess may give a positive reaction with the diazo reagent but the product is readily extracted into organic solvents.) (See also Plate 1.)

The incidence and severity of acute attacks in acute intermittent porphyria and variegate porphyria are generally greater than in hereditary coproporphyria. Various estimates indicate between 1 in 10 to 1 in 5 of heterozygotes experience acute attacks of porphyria during their lifetime. However, increasing use of molecular diagnostic methods for screening at-risk families, institution of appropriate avoidance, and the careful dissemination of information to family members and their medical advisers will further reduce the likelihood of disease in latent gene carriers. Latent carriers of acute intermittent porphyria have a high frequency of hypertension and although this should be treated, the potential for inducing attacks is increased by the uninformed prescription of antihypertensive drugs. A proportion of subjects appear to suffer depression and other chronic mental symptoms and at least one survey has reported an increased prevalence of acute intermittent porphyria in patients attending long-stay psychiatric facilities—again putting them at risk from the ill-considered use of porphyrinogenic neuroleptic and other psychoactive drugs.

Variegate porphyria

Variegate porphyria is particularly frequent amongst South African white people and other ethnic groups within that country. The condition is associated with typical acute attacks of porphyria as well as skin manifestations (the van Rooten skin). Acute attacks of porphyria occur very much as in acute intermittent porphyria. More than half the patients come to medical attention with skin lesions alone; in the same series only one-fifth of patients had acute neurovisceral disease and a similar

proportion had acute attacks as well as cutaneous disease.

Cutaneous photosensitivity resembles that seen in porphyria cutanea tarda and hereditary coproporphyria (see below) with fragility, milia, hyperpigmentation, and hairiness of light-exposed skin. During acute sunlight exposure, vesicles and even large bullas may form. Microscopic examination of the affected skin shows deposits of immunoglobulin and hyaline material that stains positively with the periodic acid–Schiff reagent in the dermal capillaries with proliferation of the basal lamina. As with porphyria cutanea tarda, ingestion of reproductive steroid, for example the oral contraceptive pill, may induce the cutaneous manifestations of variegate porphyria in otherwise latent heterozygotes.

A few severely affected patients with variegate porphyria have inherited mutations of the protoporphyrinogen oxidase gene (that maps to chromosome 1q22 to 1q23) from each parent, leading to homozygous 'dominant' variegate porphyria. These individuals present in childhood with a severe phenotype associated with marked photosensitivity, convulsions, and developmental delay; they have several skeletal abnormalities including medially deviated and shortened fifth digits. Developmental retardation is prominent, but surprisingly such patients appear to have few if any attacks of acute porphyria.

Hereditary coproporphyria

This condition is an infrequent and often mild form of acute porphyria which may be associated with cutaneous manifestations. It is due to mutations in the coproporphyrinogen III oxidase gene that maps to chromsome 3q12 and is transmitted as an autosomal dominant trait of low penetrance. The condition usually presents with acute attacks of abdominal pain as with the other acute porphyrias and about 30 per cent of patients develop cutaneous photosensitivity. As with several other porphyrias, several children presenting with marked photosensitivity in childhood have been shown to have inherited a mutant allele of the coproporphyrinogen III oxidase gene from each parent giving rise to so-called homozygous dominant hereditary coproporphyria. Particular mutations in the gene are usually restricted to individually infected pedigrees. As with the other acute porphyrias, molecular analysis of the coproporphyrinogen III oxidase gene may be of value in identifying at-risk heterozygotes for genetic counselling and provision of appropriate advice about the prevention and management of symptomatic disease.

5-Aminolaevulinate dehydratase deficiency (Doss porphyria)

Only a few affected homozygotes for this condition have been identified. Molecular analysis of the cognate gene has revealed the presence of compound heterozygosity and homozygosity for point mutations in the gene which maps to chromosome 9q34. As with the porphobilinogen deaminase gene, there are two promoter regions and alternative non-coding exons that allow for the synthesis of housekeeping and erythroid-specific transcripts. Less than 10 cases of this porphyria have been reported but it seems likely from the individual case histories of those identified that the disease will be underrecognized as the cause of acute abdominal crises usually presenting shortly after puberty and associated with neurological symptoms, including respiratory paralysis. The condition resembles acute lead poisoning. The urine contains an excess of 5-aminolaevulinate but excretion of porphobilinogen and tetrapyrrolic haem precursors is normal. Heterozygotes for aminolaevulinate dehydratase deficiency have been reported in at least one lead worker in whom peripheral neuropathy was ascribed to simple lead poisoning but it may have resulted from the susceptibility of the residual 5-aminolaevulinate dehydratase to inhibition by environmental lead.

Cutaneous porphyrias

Congenital erythropoietic porphyria is a classic but very rare syndrome now known to have an astonishing range of presentation from severe haemolytic anaemia *in utero*, severe photosensitivity presenting soon after birth (with excess porphyrins staining the teeth and urine), to mild late-onset forms presenting with skin lesions in adult life. Most patients have a mild to severe haemolysis with increased reticulocytosis, circulating normoblasts, decreased serum haptoglobin, and increased unconjugated bilirubin concentrations. Inclusion bodies are often seen in marrow, erythroid cells, and circulating normoblasts. Splenomegaly develops in childhood, thereby causing pancytopenia as a result of hypersplenism; this accelerates the haemolysis and leads to compensatory erythropoiesis in the bone marrow. Under these circumstances, splenectomy may help to control the condition.

The classic skin manifestations are of severe blistering lesions on sun-exposed skin, particularly of the hands and face, with the formation of vesicles and bullas that may become infected. There are pigmentary changes with greatly increased skin fragility. Healing of the lesions with or without consequential infection often leads to cutaneous deformities with loss of digits, scarring of the eyelids, nose, lips, scalp, and occasionally blindness due to corneal scarring. Examination of the teeth shows erythrodontia and deformities; exposure to ultraviolet light may reveal striking dental fluorescence. The condition is associated with osteoporosis and resorption of long bones as a result of gross expansion of the erythroid bone marrow.

Mutations in the uroporphyrinogen III synthase gene that maps to chromosome 10q25.3 to q26.3 have been shown to be responsible for this disease and thus may assist in the prenatal diagnosis of mothers harbouring an at-risk pregnancy and who have previously given birth to an affected infant. Constitutive activation of the haem biosynthetic pathway in erythroid cells leads to persistent overproduction of uroporphyrinogen I and coproporphyrinogen I as byproducts of the defective synthesis of uroporphyrinogen III, the sole precursor of protoporphyrin IX and haem. These reduced and colourless metabolites become oxidized to the fluorescent tissue and urinary porphyrins associated with the passage of pink urine that characterizes this often devastating disease.

Porphyria cutanea tarda

This disease is the most common of the cutaneous porphyrias and, unlike other hepatic porphyrias, is never associated with acute porphyric crises. The disease is characterized by skin blistering which is related to sunlight exposure. It occurs in several forms. Porphyria cutanea tarda may result from environmental exposure to dioxin or to hexachlorobenzene, particularly after industrial accidents such as that which occurred in Turkey in the 1960s. Occasional cases have been reported after exposure to other hallogenated phenols but under these circumstances it appears simply to be an environmental toxic syndrome. Toxic cutaneous porphyria appears to be separate from the sporadic porphyria cutanea tarda which is precipitated by other specific environmental factors: increased hepatic storage iron, excess ethanol consumption, administration of oestrogens, hepatitis C virus infection, human immunodeficiency virus infection and possibly, nutritional deficiencies including antioxidants such as vitamin C.

Most individuals who develop sporadic porphyria cutanea tarda prove to have increased iron stores in association with the presence of one or more mutant alleles for the *HFE* gene that also predispose to the development of hereditary adult haemochromatosis. In addition, many patients with sporadic porphyria cutanea tarda consume excess alcohol and smoke. There is a clear association between porphyria cutanea tarda and renal impairment in which the development of disease can be explained by the presence of iron overload (as a result of defective iron utilization with or without routine iron supplementation, particularly in patients on haemodialysis) and failure to excrete excess plasma porphyrins that do not readily diffuse through the peritoneal cavity or haemodialysis membranes. In sporadic porphyria cutanea tarda there is a partial deficiency of uroporphyrinogen III decarboxylase activity in the liver and no family history of the condition. The sequencing of the human uroporphyrinogen decarboxylase gene that maps to human chromosome 1p34 has not provided any evidence of mutations to account for the tissue-specific enzyme deficiency and no isoforms of the enzyme have yet been identified. At the time of writing the molecular pathogenesis of sporadic porphyria cutanea tarda is unknown, but it is also clear that iron and other environmental influences inactivate hepatic uroporphyrinogen decarboxylase. The relationship between regulators of iron homeostasis and the demand for haem biosynthesis in the hepatocytes of affected individuals is not understood but it appears likely from studies in experimental animals that genetic variation in the expression and activity of cytochrome isozymes such as P-450 IA2 may be critical for disease expression. Irreversible inhibition of hepatic uroporphyrinogen decarboxylase may also explain the occurrence of toxic porphyria cutanea tarda after exposure to halogenated hydrocarbons, metabolites of which cause experimental uroporphyria in animals.

Less than one-quarter of patients who suffer from porphyria cutanea tarda show a familial susceptibility to the condition. In these cases, mutations occur in one allele of the human uroporphyrinogen decarboxylase gene leading to catalytic deficiency of the enzyme in all cells, including erythrocytes. In most instances the genetic defect leads to partial reduction of the enzyme protein encoded by the mutant allele. Studies of pedigrees affected by familial porphyria cutanea tarda indicate that expressivity of the trait is very low: less than 10 per cent of heterozygotes develop clinical disease. Conversely, a very few patients present with a syndrome that closely resembles congenital erythropoietic porphyria with marked blistering skin lesions, excess hair growth, and cutaneous scarring in association with the excretion of pink or red urine. These individuals represent a homozygous form of uroporphyrinogen decarboxylase deficiency, termed hepato-erythropoietic porphyria, associated with a variety of mutations in the uroporphyrinogen III decarboxylase gene.

In hepato-erythropoietic porphyria, the activity of uroporphyrinogen decarboxylase is markedly deficient although residual activity remains to preserve essential haem biosynthesis in the erythron and liver. Most patients with hepato-erythropoietic porphyria ultimately develop splenomegaly with accelerated haemolysis closely resembling congenital erythropoietic porphyria. Molecular analysis of the human uroporphyrinogen decarboxylase gene may assist the prenatal diagnosis of at-risk

pregnancies in women who have already given birth to an affected infant.

The clinical features of porphyria cutanea tarda of whatever form are very characteristic and are confined to light-exposed skin (Fig. 3 and Plate 2). Most often, the only signs are of erosions resulting from minor trauma in skin with increased fragility as a result of light exposure, typically on the dorsum of the hands. Other changes include the development of large subepidermal bullae after exposure to light, which may burst leaving ulcerated lesions that are slow to heal. Increased, often accompanied by areas of decreased, pigmentation is a common feature combined with increased hair growth, particularly on the face.

Fig. 3 Porphyria cutanea tarda in a 60-year-old heterozygote for the *HFE* C282Y mutation. This man, a taxi driver, had noticed irritation after exposure of his hands to light transmitted through the windscreen. He had noticed fragility and blistering combined with pigmentary changes typical of this disorder. After treatment by controlled phlebotomy his skin complaint has regressed. (See also Plate 2.)

Patients with porphyria cutanea tarda do not always notice the photosensitivity and rarely experience marked pain unless exposed to brilliant sunlight. Occasionally there is evidence of dermal injury and loss of nails, damage to the conjunctivae, and hair loss. Careful examination of the affected areas shows small depigmented cutaneous scars and the formation of milia. If bacterial infection occurs and there is repeated exposure to sunlight, then severe and permanent scarring may result. Typically, porphyria cutanea occurs in middle-aged men with a history of alcohol use and in women after institution of oestrogen replacement therapy: in young persons, infection with hepatitis C or the immunodeficiency virus may precipitate the disease expression. Frank signs of hepatomegaly or iron overload are rare in porphyria cutanea tarda but have been noted; as with adult haemochromatosis, there is a significantly increased frequency of hepatocellular carcinoma.

Occasional patients with porphyria cutanea tarda may notice an increase in urine excretion of formed porphyrins which, especially after concentration overnight, may resemble the colour of tea or cola. The stool and urine contains large quantities of copro-and uroporphyrins that fluoresce intensely on exposure to long-wavelength ultraviolet light when placed in a suitable vessel for its transmission (namely silica rather than standard glass). Similarly, examination of liver biopsy specimens under ultraviolet light reveals bright red/orange fluorescence; microscopical examination may also show coincidental hepatitis with or without excess deposits of stainable tissue iron reflecting the increased iron storage of this disease. In sporadic porphyria cutanea tarda, increased storage iron is reflected by modest elevations of serum ferritin that often occur in association with the presence of one or more copies of the C282Y allele of the *HFE* gene that maps to human chromosome 6 and which is associated with adult haemochromatosis.

Treatment

Sunlight exposure should be avoided as much as possible until the porphyrin abnormality is corrected. Care is needed to protect fragile skin from mechanical injury and from infection; sunblock creams may also be useful until the metabolic disturbance is controlled.

Patients with porphyria cutanea tarda should moderate or stop their intake of alcohol and avoid the use of iron tonics and sex hormones, especially oestrogens. Screening should be undertaken for chronic infection with human immunodeficiency virus and hepatitis viruses, especially hepatitis C. Management should include imaging or biopsy of the liver if serum liver-related tests are abnormal as well as measurement of a-fetoprotein, since there is a risk of hepatocellular carcinoma in this disease.

Most patients with porphyria cutanea tarda respond to iron depletion by phlebotomy and initial iron status should be determined by measuring serum ferritin concentrations. Weekly or fortnightly removal of 500 ml of blood will usually correct the abnormal urine and plasma porphyrin profile within a few months but maintenance phlebotomy will be required, usually amounting to the removal of 2 to 4 units of blood at intervals each year. Successful therapy reduces the urinary excretion of porphyrins to normal. Patients with porphyria complicating renal failure should be treated with recombinant human erythropoietin and depleted of iron by gentle phlebotomy or parenteral desferrioxamine, if necessary.

The cutaneous manifestations of porphyria cutanea tarda respond rapidly to low-dose chloroquine treatment, which should be considered in patients with persistent symptoms or at the outset before iron storage has been fully corrected. This action of chloroquine was discovered empirically but the agent forms complexes with uroporphyrin deposits and promotes their external cellular disposal. Chloroquine promotes excretion of uroporphyrin from the liver and induces marked, but transient, porphyrinuria. Although chloroquine usually provides rapid relief from the cutaneous disease and photosensitivity, it does not correct the underlying metabolic defect in the liver; its long-term use is not recommended unless the other provocative factors in porphyria cutanea tarda have been removed. The usual effective dose of chloroquine is 100 to 200 mg once or twice weekly; larger doses are associated with marked hepatic toxicity in porphyria cutanea tarda. The drug is reported to have no therapeutic effect on other photosensitive porphyrias.

(Erythropoietic) protoporphyria

Protoporphyria is caused by the overproduction of the immediate precursor of haem, protoporphyrin IX, principally in the bone marrow. Protoporphyria causes an unusual cutaneous photosensitivity syndrome that presents in infancy. Protoporphyria is also a neglected cause of fatal hepatobiliary disease in about 5 per cent of those affected.

Recent studies indicate that protoporphyria is inherited as a recessive condition. Inheritance of mutations in the coding region of the ferrochelatase gene that partially inactivate the enzyme are coinherited in *trans* with a low-expression allele that occurs at polymorphic frequency in the population. Parent-to-offspring transmission of protoporphyria occurs in less than 10 per cent of cases but in all instances of the disease there is a marked deficiency of the enzyme ferrochelatase (less than 50 per cent of control values). The asymptomatic carrier parent shows only mild ferrochelatase deficiency. The gene for human ferrochelatase maps to chromosome 18q.

Protoporphyria characteristically presents with severe burning pain and cutaneous irritation on exposure to visible light and is usually obvious in infancy or early childhood. Erythema and diffuse oedema may follow marked light exposure but vesicles, blistering, and altered skin fragility are most unusual. After several years, increased pigmentation and thickening of the skin (lichenification) occur, especially over the knuckles. A typical feature is of shallow scarring in the malar regions of the cheeks and at the angle of the lips, where scarring is termed ragades. Overt scarring is unusual. There are no changes in urine colour. Protoporphyria is often the subject of delayed diagnosis because of the marked disparity between the severity of the symptoms and the development of physical signs in the skin.

The cutaneous pathology results from photoactivation of red-cell and plasma-derived protoporphyrin IX in skin capillaries (Fig. 4, Fig. 5 and Plate 3 and Plate 4). Protoporphyrin IX is a hydrophobic molecule that dissolves in cell membranes; it has a photoactivation spectrum in the Soret region with subsidiary activation by green and yellow light. Photoinjury is associated with complement activation and release of vasoactive factors; there is intracellular epidermal oedema accompanied by acute inflammatory changes and extravasated red cells. Deposits of hyaline material are found in superficial capillaries with thickening of the basement membranes. A supply of oxygenated blood appears to be essential for the development of photosensitive damage in protoporphyria.

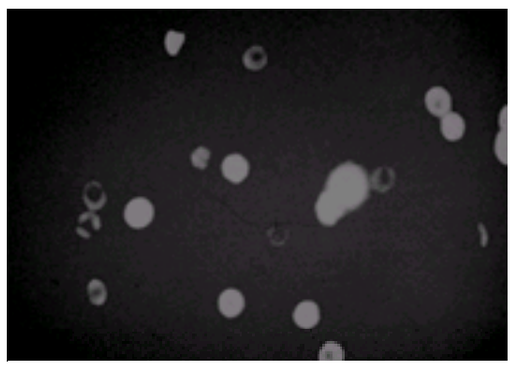

Fig. 4 Fluorescent microscopy of an unstained blood film from a patient with erythropoietic protoporphyria. Note the fluorescence of increased free protoporphyrin within individual young erythrocytes and reticulocytes. (See also Plate 3.)

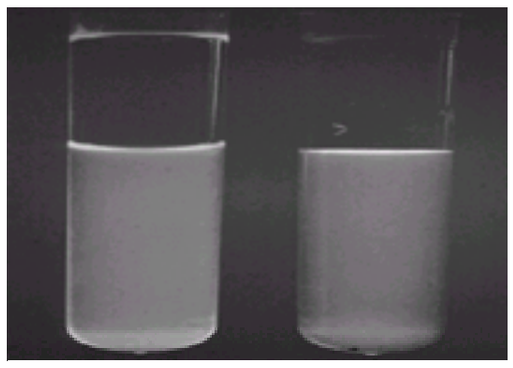

Fig. 5 Examination of human plasma under long-wave ultraviolet light. Plasma on the left was obtained from a patient with protoporphyrin hepatopathy and greatly increased photosensitivity and is compared with plasma obtained from a healthy subject on the right. Note the bright red fluorescence due to the presence of high concentrations of free protoporphyrin. Maximum fluorescence was obtained by exposure to visible light in the violet and green–yellow spectral regions corresponding to the absorbance bands of protoporphyrin.

Mild hypochromic microcytic changes with mild anaemia are usually the only manifestation of disturbed haem biosynthesis and iron metabolism in the bone marrow, although examination of the marrow may reveal occasional sideroblasts with intramitochondrial iron deposits. Haemolysis is usually clinically insignificant until severe cholestatic hepatic disease occurs when splenomegaly and hypersplenism aggravate haemolysis. The photosensitivity worsens under these circumstances and there is upper abdominal pain with splenic enlargement, jaundice, and extreme photosensitivity as concentrations of free protoporphyrin in the plasma rise (Fig. 5). A vicious cycle of decompensation is established with either fulminant hepatic failure associated with cholestasis due to protoporphyrin deposits within biliary radicals, or the development of cirrhosis. Without treatment, the prognosis is dismal and hepatic transplantation is required (see below).

Protoporphyric hepatic disease

Protoporphyria is normally associated with trivial abnormalities of serum liver-related tests but in a small proportion of patients micronodular cirrhosis with pigment deposition occurs. Examination of the liver under polarized light shows birefringent crystals with a characteristic Maltese cross appearance and examination under long-wave ultraviolet light reveals bright fluorescence. Gallstones containing precipitated protoporphyrin occur frequently in protoporphyria but cholestasis results principally from intracellular and cannalicular precipitation of protoporphyrin.

The principal source of protoporphyrin in protoporphyria is the erythron and although under emergency conditions hepatic transplantation may be effective, recurrence of protoporphyrin deposition with injury to the hepatic graft has been reported. The occurrence of this phenomenon, however, is not a contraindication to the use of hepatic transplantation when the illness requires it. Deteriorating hepatic disease is heralded by generalized abdominal pain, splenic enlargement, worsening jaundice, and haemolysis. Interruption of the enterohepatic circulation of protoporphyrin with charcoal or polymeric cationic resins such as cholestyramine may arrest the early downhill course by binding protoporphyrin or promoting hepatic bile acid secretion. However, once established, hepatic decompensation and accelerating photosensitivity is rapid.

Surgical management

Severe protoporphyrin hepatotoxicity is an indication for liver transplantation, preferably carried out by an experienced surgical team with the assistance of an informed anaesthetist and expert physicians in attendance. Consideration should be given to the simultaneous removal of the enlarged spleen at the time of the transplant procedure; there is evidence that splenectomy may reduced the haemolytic component of endstage protoporphyria.

In some patients with endstage liver disease due to protoporphyria, a bizarre neurological syndrome has been identified. In the perioperative period, axonal neuropathies requiring mechanical ventilation and cranial nerve palsies have been reported. Under these circumstances, coproporphyrin and uroporphyrins appear in the urine and may account for a blistering photosensitivity in endstage protoporphyric liver disease.

Operative treatment in patients with protoporphyria can be very dangerous as a result of phototoxic injury to visceral tissues and mucous membranes exposed to brilliant vertical lighting in the operating theatre. Surgical lights are best attenuated by the use of filters that reduce spectral power output below 530 nm; such precautions should be used throughout the perioperative period to reduce overall phototoxicity in the clinical environment. Theoretically, the definitive therapy of protoporphyria will require restoration of erythroid cell ferrocheletase activity in bone marrow. There is a single report of successful marrow transplantation in protoporphyria with coincidental myeloid leukaemia. This procedure cured the symptomatic protoporphyria. In future, either bone marrow transplantation or erythroid progenitor gene therapy will be used to correct this disease in patients suffering from life-threatening liver sequelae. Ancillary treatment by blood transfusion or red cell exchange transfusion will reduce the immediate source of plasma and red cell protoporphyrin, and in the immediate preoperative period plasmapheresis may also reduce phototoxicity. Neurological complications of fulminant protoporphyria may necessitate prolonged ventilatory support in the postoperative period.

Treatment of photosensitivity

Photosensitivity is managed by avoiding excessive light exposure, remembering that visible light of exciting green and violet wavelengths traverses ordinary window glass. Effective sunscreen preparations may assist management, especially in young children at risk. For many years b-carotene has been given to patients with protoporphyria. b-Carotene may absorb light energy at the appropriate wavelengths and also serve as a free-radical quenching agent. The preparation Lumitene (Hoffmann-LaRoche) at a dose of 120 to 180 mg/day is normally used. This causes orange staining of the skin due to carotenaemia but is otherwise well tolerated. It may improve tolerance to sunlight when plasma carotene concentrations between 10 and 15 µmol/l are achieved.

Treatment of an acute porphyric attack

It is essential to establish that the symptoms complained of are caused by an acute attack of porphyria. Of key importance is the careful laboratory analysis of urine and blood early in the course of the illness. This demonstrates elevated concentrations of porphyrins and haem precursors typified by elevated urinary 5-aminolaevulinate and porphobilinogen, which should be high in an attack of acute porphyria. The urine sample should be taken freshly from the patient and protected from light before analysis to avoid non-enzymatic conversion of the porphyrin precursors to porphyrins and hence misdiagnosis.

The immediate management of the acute attack of porphyria

This should involve scrupulous review of avoidable factors recently introduced that would have precipitated an attack. The precipitating factors are usually drugs, alcohol, exogenous or endogenous hormonal changes, fasting (including that due to dieting), or recent surgical procedures. More than 100 drugs may induce attacks of porphyria. Particular care should be taken to exclude agents that are obtained over the counter as tonics or herbal remedies, some of which may induce attacks. Tolerance of alcohol varies greatly in patients with porphyria, many of whom appear to tolerate modest amounts of alcohol. Alcohol is, however, best avoided. At the same time it is wise not to implicate alcohol in an acute attack, unless other causes have been excluded.

Abdominal pain and distress, together with anxiety, require prompt treatment: opiates which are safe in porphyria may be useful, although they often exacerbate constipation. Opiates may be combined with the phenothiazine tranquillizers, such as chlorpromazine, which may potentiate their action usefully.

Since starvation induces attacks of porphyria and haem biosynthesis may be suppressed by the ingestion of carbohydrate, it is advised that patients with minor attacks should eat regular meals containing carbohydrate in a complex form such as starch for its slow release. One-half to two-thirds of the energy intake should be derived from ingested carbohydrate. The management of an acute attack should involve repeated monitoring for the development of hyponatraemia, which may be very severe as a result of inappropriate secretion of antidiuretic hormone. In the past, intravenous glucose or fructose solutions have been advocated as a means to suppress haem biosynthesis in the liver. Great caution is needed in the use of these agents either as 5 or 20 per cent solutions since they exacerbate hyponatraemia and may cause fatal cerebral oedema. In the author's view, if the patient is sufficiently unwell not to be able to control the attack with oral carbohydrate-rich food, parenteral preparations of haem, such as haem arginate, rather than glucose or other sugar solutions, should be administered.

Haem therapy

Haem arginate is administered by a short intravenous infusion in porphyric crises of sufficient severity to merit hospital admission or those associated with limiting pain or metabolic disturbance. Haem arginate (Normosang) supplied by Orphan Europe (see below) is provided as a stable 25 mg/ml concentrate and should be administered at a dose of 3 mg/kg body weight once daily for up to 4 days to a maximum dose of 250 mg in 100 ml of physiological saline infused through a large antebrachial vein over at least 30 min. Haem arginate, like all preparations of haem, tends to polymerize and is unstable; thus the administration should be completed within 1 h after diluting the concentrate. The shelf-life of the concentrate is about 2 years. In the United States, haematin is supplied by Abbott Laboratories and appears to be a comparable preparation for suppressing hepatic haem synthesis and correcting the metabolic disturbance of the acute attack. Haem arginate and a preparation of haem albumin are apparently somewhat more stable than haematin, which tends to produce phlebitis or interfere with the action of coagulant proteins.

Recovery from an acute attack depends on the degree of damage to the nervous system and may occur within 1 or 2 days if haem therapy is introduced at the outset. Cast-iron proof of clinical benefit of haem treatment is lacking, but there is sufficient evidence for the beneficial use of therapy for it to be licensed in 19 countries, including the United Kingdom. Haem arginate therapy has a rapid effect on the excretion of aminolaevulinate and porphobilinogen in acute porphyria and retrospective studies suggest that the outcome of this treatment is better than that in patients previously documented before the use of the agent. Moreover, the results of a double-blind study comparing placebo and haem therapy showed a trend in favour of haem arginate in terms of duration of hospital stay and the requirement for pain relief but the differences did not quite reach statistical significance in the limited study of 12 patients. On the balance of probabilities, however, the evidence for a beneficial effect of haem arginate therapy, particularly at the onset of a porphyric attack, is very strong.

Haem therapy should be used in any patient with significant hyponatraemia, incipient neuropathy, seizures, or bulbar paralysis and in any patient with severe symptoms, particularly of abdominal pain. It must be recognized that patients with established neuropathy may take many months or even years to recover from an attack and, if it is to be effective, haem therapy should be introduced sufficiently early to halt its progress. Where haem therapy is not available, parenteral carbohydrate loading is the only alternative treatment for the acute attack: 2 litres of a 20 per cent w/v glucose solution is recommended over a 24-h period administered through a central venous catheter. There are risks from giving such therapy as outlined above and in the author's opinion the treatment has been superceded by the introduction of stable preparations of haem. Hypersensitivity reactions to haem arginate are rare and the drug has been used during attacks in pregnant women without injury to either the mother or child. Haem contains 10 per cent by weight of iron and the maximum daily dose of haem arginate would contain only 23 mg of elemental iron; the development of iron storage disease is therefore unlikely, except in very rare instances where the patient receives numerous infusions of haematin over prolonged periods.

Occasional patients, usually women, are seen in whom repeated acute attacks occur irrespective of the use of one or two courses of haem arginate. The reason for this is unknown but it is possible that haem arginate therapy induces tachyphylaxis as a result of exaggerated oscillation of haem catabolism by the induction of haem oxygenase in the liver. For this reason tin-protoporphyrin, an inhibitor of haem oxygenase, has been considered. This agent is only available in specialist centres and, because it contains toxic heavy metal and itself may induce photosensitivity, is currently not recommended for routine use. Recently, the combination of recurrent life-threatening porphyric attacks and poor venous access for administration of therapeutic haem preparations has led to the use of liver transplantation in a few young women stricken by this disease. Early (unpublished) reports indicate that this approach may, under exceptional circumstances, be successful.

Young women with cyclical porphyric attacks may require hormonal intervention by the use of gonadotrophin-releasing hormone analogues such as goserelin or buserelin for the release of gonadotrophins. These agents inhibit androgen, oestrogen, and progestogen production—as a result they induce menopausal-like symptoms and depression, as well as rapid decreases in trabecular bone density. Doses sufficient to suppress luteinizing and follicule-stimulating hormone concentrations in serum are required. Their prolonged use for more than a few months is not recommended but buserelin may be used intranasally and may be more convenient. To avoid the worse aspects of hypogonadism in women, low-dose oestrogen therapy under appropriate gynaecological supervision may be coadministered, once cyclic porphyric attacks have come under control. Hypertension is frequent in porphyric attacks and may be very severe as a result of sympathetic overactivity; during the attack, sinus tachycardia is frequent. b-Blockers are effective in the control of the hypertension and propanolol is safe; it also provides effective relief of sinus tachycardia.

Hyponatraemia may be very severe and in acute porphyria progresses on a daily basis during the course of the acute attack in most patients. Its management is critical and the rapid onset of severe hyponatraemia clearly contributes to the confusion and other mental symptoms associated with a porphyric attack. Prompt treatment by careful adjustment of fluid balance and fluid restriction is needed. Great care should be exercised in the presence of hyponatraemia with the use of intravenous solutions whose prescription should be reviewed frequently. The temptation to place a patient with abdominal pain on a surgical ward and administer a dilute solution of glucose is very great in current hospital practice: in the porphyric attack such management may contribute to death as a result of cerebral oedema or the complications of rapid-onset hyponatraemia. Where hyponatraemia progresses rapidly despite fluid restriction, once the diagnosis of inappropriate secretion of antidiuretic hormone is confirmed by determining urine and plasma osmolalities, hypertonic saline solutions or fluid restriction may be required for its correction.

Grand mal seizures in acute porphyric attacks pose a particular problem for management; they are often precipitated by hyponatraemia that frequently complicates the acute attack. Clearly appropriate management of the electrolytic abnormality (with the potential for life-threatening cerebral oedema) is an essential element of treatment. Status epilepticus poses special difficulties but has been treated successfully with parenteral diazepam or the related benzodiazapine, temazepam. Carbamazepine, lorazepam, and midazolam are probably (but not definitely) safe in acute porphyria. Clonazepam or valproate have been used for seizure prevention; the generally outmoded therapy of bromide may also have a role. Acetazolamide, which has been used as a minor agent in seizure prophylaxis, has been used safely in acute porphyria but many first-line drugs such as carbamazepine, sodium valproate, phenytoin, and chloral hydrate have been classified as unsafe or are frankly porphyrinogenic. Primidone and phenobarbitone are absolutely forbidden.

Further problems arise in the management of acutely disturbed patients who are not responsive to the safe phenothiazine, chlorpromazine. Thioridazine is categorized as unsafe but parenteral haloperidol has been used with good effect in occasional patients with uncontrollable or life-threatening manic aggression and paranoid disturbance. In all instances, prescription of any agent to a patient who has suffered from or is suffering from an acute porphyric crisis must involve consultation with a reliable pharmacopoea with individual drugs categorized for safety.

The ability of most drugs to initiate attacks of porphyria appears in many instances to be related to their effects on the induction of haem biosynthesis in the liver and specifically for the formation of the relevant P-450 xenobiotic metabolizing isoforms. One key isoform involved in the induction of porphyria is inhibited, at least *in vitro*, by the H_2-antagonist, cimetidine. It has been reported that cimetidine at 400 to 800 mg daily is sufficient to inhibit induction of this P-450 isozyme in adult humans. Cimetidine has been administered with occasional success as a means to inhibit or control spontaneous porphyric crises and as a last resort it might be considered in patients with life-threatening, otherwise uncontrollable, disease.

There is particular difficulty in young or middle-aged women with cyclical premenstrual attacks. Treatment with high-dose gonadotrophins continued for 1 to 2 years is likely to abort the attacks, but given alone will cause distressing symptoms of hypogonadism with depression and osteoporosis. The worst symptoms of hypogonadism can be overcome by the use of low-dose oestrogen replacement, for example with oestrogen patches, which have a significantly lower risk of provoking an attack of porphyria than progestagen-only hormone preparations. Clearly there is a risk of unopposed oestrogen therapy in patients with an intact endometrium and monitoring for the effects in those receiving oestrogen will be needed.

Acute perimenstrual attacks can be controlled by the prompt administration of haem arginate for 1 to 2 days at the predicted time of susceptibility. Although tachyphylaxis has not been recorded, there may be difficulties in withdrawing the haem arginate because of its effect on inducing haem oxygenase and hence amplifying the potential oscillations of haem biosynthesis in the liver once the haem arginate is withdrawn. The potential for iron overload developing as a result of haem arginate is most unlikely owing to its low content of iron at the doses recommended. Some authors have suggested the use of the haem oxygenase inhibitor, tin-protoporphyrin as an adjunct to the use of haem arginate. Although this may induce a more prolonged biochemical remission of the abnormalities of an acute porphyric attack, it does not induce a more rapid depression of the biochemical abnormality. Experience with tin-protoporphyrin where tachyphylaxis of haem arginate is suspected has been favourable in a few patients, but the drug itself induces photosensitivity. Tin is also potentially toxic as a heavy metal of which only limited excretion occurs. At present the use of tin protoporphyrin or its cogener, zinc deuteroporphyrin must remain speculative and more experience is necessary before these agents can be recommended for safe use in the long-term management of patients with current porphyric crises. The role of liver transplantation and, ultimately corrective gene therapy directed to the liver in acute porphyrias, awaits fuller evaluation in animal models of these diseases and in the few porphyric recipients of hepatic allografts so far recorded.

11.6 Lipid and lipoprotein disorders

P. N. Durrington

Lipids are a heterogeneous group of substances, including oils and fats, that are distinguished by their low solubility in water and their high solubility in non-polar (organic) solvents. The difference between an oil and a fat lies in its melting point. Lipids are essential as energy stores and respiratory substrates, as structural components of cells, as vitamins, as hormones, for the protection of internal organs, for heat conservation, for digestion, and for lactation. Lipoproteins are macromolecular complexes of lipid and protein; their principal function is to transport lipids through the vascular and extravascular body fluids and they are also found as components of milk. Lipoproteins include apolipoproteins and enzymes. Increased concentration of a circulating lipoprotein is termed hyperlipoproteinaemia and a decreased concentration is termed hypolipoproteinaemia. Disturbed composition of circulating lipoproteins is termed dyslipoproteinaemia.

Atherosclerosis is the context in which lipid disorders most commonly present to clinicians and this will be the principal focus of this chapter; undoubtedly lipoproteins will ultimately be implicated in many pathological processes.

Lipid physiology

Triglycerides (triacylglycerols)

These are formed by the esterification of glycerol with fatty acids, which have a hydrocarbon group attached to a carboxyl group. Generally the hydrocarbon moiety is present in a long chain. Naturally occurring fatty acids usually have even numbers of carbon atoms, most of them linked by single bonds, but some contain double bonds. Those with double bonds are termed unsaturated, whereas those with only single bonds are the saturated fatty acids. Fatty acids with one double bond are termed monounsaturated and those with more, polyunsaturated. Each double bond creates the possibility of two stereoisomers according to whether the hydrogen atoms of the –CH=CH– are both on the same side of the double bond (*cis*) or on the opposite sides (*trans*). Naturally occurring fatty acids are mostly *cis* isomers. *Trans* isomers are, however, present in the milk of ruminants, such as the cow, and in margarines.

Triglycerides in adipose tissue provide our principal energy store. The body of a 70 kg man contains some 15 kg of stored triglycerides, representing 135 000 kcal (560 000 J) of energy, which would permit survival during total starvation for up to 3 months (compare this with the 225 g of stored glycogen, representing only 900 kcal (3800 J)). Obesity represents an excess of stored fat, and it is unfortunate for those wishing to slim that considerable and very prolonged dietary energy restriction is necessary to lose weight, given the large amount of energy stored in fat. Each gram of triglyceride produces 9 cal (38 J) of energy, whereas the same mass of carbohydrate or protein only produces 4 cal (17 J), and the latter are more difficult to store because they require an aqueous environment. Thus a muscle or liver cell can only store a minimal amount of glycogen. The adipocyte, on the other hand, contains a droplet of hydrophobic triglyceride surrounded by only a tiny rim of cytoplasm: about 85 per cent of the adipocyte is triglyceride. Thus each gram of adipose tissue yields almost 8 cal (33 J) of energy, whereas tissues containing cells packed to capacity with glycogen would not even approach a yield of 1 cal (4.2 J) for each gram.

For other organs to utilize the energy in adipose tissue the stored triglyceride must first be hydrolysed to its constituent glycerol and non-esterified fatty acids, a process known as lipolysis. This is accomplished by adipose tissue lipase, an intracellular enzyme which is inhibited by insulin (not to be confused with lipoprotein lipase, an extracellular enzyme located on the vascular endothelium of fat and muscle and which is activated by insulin (see below)).

The products of lipolysis are released into the circulation and non-esterified fatty acids bind to albumin. The normally circulating concentration of non-esterified fatty acids is 300 to 800 µmol/litre (8–23 mg/dl), but this falls when insulin is secreted following a meal and rises in starvation when insulin secretion is low. Their importance as a system for transporting lipid energy should not be underestimated, even at low concentrations, since their half-life in the circulation is only 2 to 3 min and their turnover is thus 100 to 200 g/day, and even more in starvation or uncontrolled diabetes.

Non-esterified fatty acids can be oxidized to acetyl-CoA by some tissues, such as muscle and liver, and then entered into the Krebs (carboxylic acid) cycle. Other tissues, which in the fed state rely on glucose as an oxidative substrate, cannot directly utilize non-esterified fatty acids. During starvation these tissues are supplied with water-soluble ketone bodies (acetone, acetoacetate, b-hydroxybutyrate), which the liver produces by partial oxidization (b-oxidation) of non-esterified fatty acids transported to it from adipose tissue. These ketone bodies, which can readily be entered into the Krebs cycle by tissues lacking the ability to oxidize fatty acids, constitute the second system for the transport of lipid energy. They are vital for survival when dietary energy is at a premium, but are also the cause of diabetic ketoacidosis when insulin production is insufficient to suppress the flux of non-esterified fatty acids from adipose tissue, so that the production of ketone bodies takes place at a faster rate than they can be respired. The amount of insulin required to decrease blood glucose increases in the presence of high levels of circulating non-esterified fatty acids. The higher flux of non-esterified fatty acids out of adipose tissue in diabetes thus contributes to insulin resistance. In the case of non-insulin-dependent diabetes a high rate of release of non-esterified fatty acids may have pre-dated the development of hyperglycaemia by many years because obesity, which is a common antecedent of this type of diabetes, is itself associated with an increased flux of non-esterified fatty acids through the circulation and with insulin resistance.

Phospholipids

These also have at least one fatty acyl group esterified to an alcohol and one phosphate group linked both to the alcohol and to another organic compound. The glycerolipids have glycerol as the alcohol. Examples of these are phosphatidylcholine (lecithin) and lysophosphatidylcholine (lysolecithin). Another abundant class of phospholipids are the sphingolipids, such as sphingyomyelin. Phospholipids are essential components of cell membranes and, because of the great diversity of physical properties permitted by their structure, are responsible for much of the variation in membrane structure.

Cholesterol

Cholesterol is also an essential component of cell membranes, where it allows the phospholipid molecules to pack more closely, increasing membrane rigidity. It is

also a precursor for the synthesis of steroid hormones, vitamin D, and bile acids. It is present in arterial fatty streaks and in atheromatous plaques (see below).

Cholesterol is an alcohol and may be unesterified as free cholesterol or esterified with a fatty acyl group (Fig. 1).

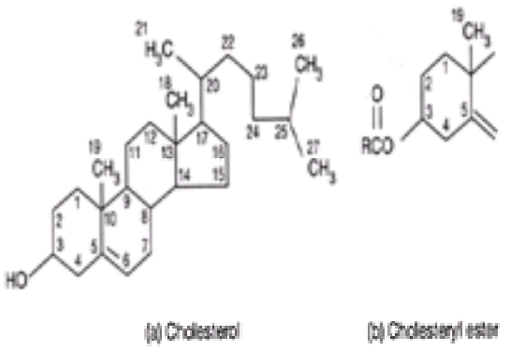

Fig. 1 The structure of free cholesterol and cholesteryl ester.

Lipoprotein physiology

Lipoprotein structure

The general structure of lipoprotein molecules is globular (Fig. 2). The physicochemical considerations, which govern the arrangement of their constituents, are similar to those involved in the formation of mixed micelles in the lumen of the intestine. Thus, within the outer part of the lipoprotein are found the more polar lipids, namely the phospholipids and free cholesterol, with their charged groups pointing out towards the water molecules. In physical terms, however, the role of bile salts, which are also in the outer layer in the mixed micelle, is assumed by proteins, so that the surface structure of a lipoprotein resembles the outer half of a cell membrane. Within the core of the lipoprotein particle are the more hydrophobic lipids, the esterified cholesterol and triglycerides. These form a central droplet to which are anchored, by their hydrophobic regions, the surface-coating molecules, phospholipids, free cholesterol, and proteins. The exception to this general structure is the newly formed or nascent high-density lipoprotein (**HDL**), which lacks the central lipid droplet and appears to exist as a disc-like bilayer consisting largely of phospholipids and proteins.

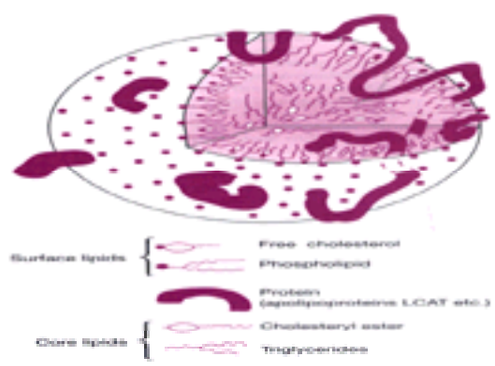

Fig. 2 Lipoprotein structure. The most hydrophobic lipids (triglycerides, cholesteryl esters) form a central droplet-like core, which is surrounded by more polar lipids (phospholipids, free cholesterol) at the water interface. Apolipoproteins are anchored by their more hydrophobic regions, with their more polar regions often exposed to the surface. (Reproduced from Durrington (2002) with permission.)

The protein components of lipoproteins are the apolipoproteins, a group of proteins of immense structural diversity, some of which have a largely structural role and others of which are important metabolic regulators. In addition, enzymes are found as components of lipoproteins. One example is lecithin:cholesterol acyltransferase which is located on HDLs, which are also its site of action.

Lipid transport from liver and gut to peripheral tissues

The products of fat digestion (fatty acids, monoglycerides, lysolecithin, and free cholesterol) enter the enterocytes from the mixed micelles. They are re-esterified in the smooth endoplasmic reticulum of these cells. Long-chain fatty acids (those with more than 14 carbon atoms) are esterified with monoglycerides to form triglycerides and with lysolecithin to form lecithin. Free cholesterol is esterified by the enzyme acyl-CoA:cholesterol *O*-acyltransferase.

The triglycerides, phospholipids, and cholesteryl esters are then combined with an apolipoprotein, known as apoB $_{48}$, in the enterocyte. The lipoproteins thus formed are secreted into the lymph (chyle) as chylomicrons. These are large (diameter > 75 nm; density < 950 g/litre) and are rich in triglycerides but contain only relatively small amounts of protein (Fig. 3). They travel through the lacteals to join lymph from other parts of the body and enter the blood circulation via the thoracic duct. In addition to cholesterol absorbed from the diet, the chylomicrons may also receive cholesterol that has been newly synthesized in the gut or transferred from other lipoproteins present in the lymph and plasma. The newly secreted, or nascent, chylomicrons receive C apolipoproteins from HDL, which in that respect appears to act as a circulating reservoir, since later in the course of the metabolism of the chylomicron, the C apolipoproteins are transferred back to the HDL pool. The chylomicrons also receive apolipoprotein E (**apoE**), although the manner in which they do so is unclear. Unlike other apolipoproteins, which are synthesized either in the liver or the gut or both, apoE is exceptional in that it is synthesized (and perhaps secreted) by a large number of tissues: liver, brain, spleen, kidney, lungs, and adrenal gland.

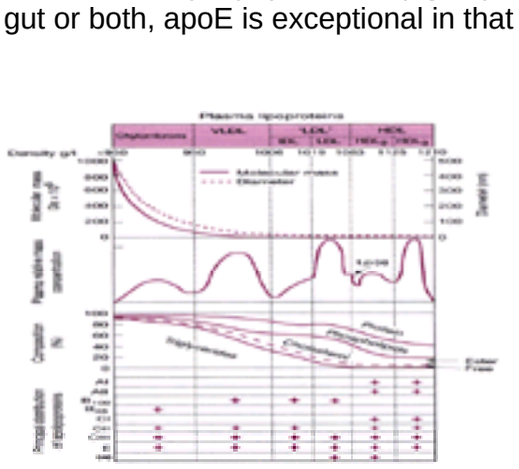

Fig. 3 The spectrum of plasma lipoprotein particles according to their hydrated density, molecular mass, molecular diameter, relative concentration, lipid composition, and apolipoprotein composition. (Reproduced from Durrington (2002) with permission.)

Once the chylomicron has acquired the apolipoprotein, apoC-II, it is capable of activating lipoprotein lipase (Fig. 4(a)). This enzyme is located on the vascular endothelium of tissues with a high requirement for triglycerides, such as skeletal and cardiac muscle (for energy), adipose tissue (for storage), and lactating mammary

gland (for milk). Lipoprotein lipase releases triglycerides from the core of the chylomicron by hydrolysing them to fatty acids and glycerol, which are taken up by the tissues locally. In this way the circulating chylomicron becomes progressively smaller. Its triglyceride content decreases and it becomes relatively richer in cholesterol and protein. As the core shrinks, its surface materials (phospholipids, free cholesterol, C apolipoproteins) become too crowded and they are transferred to HDL. The cholesteryl ester-enriched, triglyceride-depleted product of chylomicron metabolism is known as the chylomicron remnant. The apoB $_{48}$, present from the time of assembly, remains tightly anchored to the core throughout. The apoE also remains and regions of its structure are exposed, permitting chylomicron remnant catabolism via the 'remnant receptor' of the liver and also the low-density lipoprotein (**LDL**) receptors (also called apoB$_{100}$/E receptors), which can be expressed by virtually every cell in the body including the liver. Unlike the LDL receptor, which is discussed in more detail later, the 'remnant receptor' is not downregulated by intrahepatic cholesterol and involves the LDL receptor-related protein, LRP, which in addition to its binding site for apoB also has receptor sites for other proteins. ApoE is inhibited from binding to its receptors earlier in the metabolism of chylomicrons because its receptor-binding domain is blocked by the apolipoprotein, apoC-III. Remnants are largely removed from the circulation by the liver. Although the clearance of these particles by the LDL receptor is theoretically possible, this route is not likely to contribute greatly to remnant uptake in the adult, since the binding of remnant particles to the LRP is enhanced by a trapping mechanism in the space of Disse and elsewhere the remnant particles must compete for binding to the LDL receptor with LDL, the particle concentration of which is much higher than that of the chylomicron remnants (even more so in the tissue fluid than in the plasma). Also the LDL receptor is rapidly downregulated by the lysosomal release of free cholesterol into the cell, which follows the entry of lipoprotein–receptor complexes into the cell, whereas expression of the remnant clearance pathway is unaffected by entry of cholesterol into the liver.

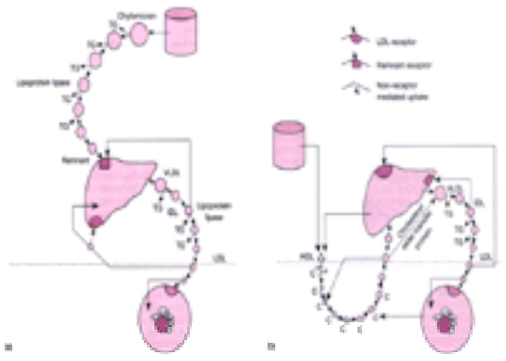

Fig. 4 Metabolism of (a) triglyceride-rich lipoproteins secreted by the gut and liver and (b) hepatic triglyceride-rich lipoproteins and lipoproteins transporting cholesterol to and from the tissues.

The liver itself secretes a triglyceride-rich lipoprotein known as very low-density lipoprotein (**VLDL**) which allows the supply of triglycerides to tissues in the fasting state as well as postprandially. Very low-density lipoprotein particles are somewhat smaller than the chylomicrons (diameter 30–75 nm, density < 1006 g/litre). Once secreted, they undergo exactly the same sequence of changes as chylomicrons; that is the acquisition of apolipoproteins and the progressive removal of triglycerides from their core by the enzyme, lipoprotein lipase. However, some additional transformations are involved in their metabolism in the human. In man, the liver, unlike the gut, does not esterify cholesterol before its secretion. This process differs in species such as the rat. In the human, most of the cholesterol released from the liver each day into the circulation is secreted in the VLDL as free cholesterol, and it undergoes esterification in the circulation. Free cholesterol is transferred to HDL along a concentration gradient. There it is esterified by the action of lecithin:cholesterol acyltransferase, which esterifies the hydroxyl group in the 3-position of cholesterol to a fatty acyl group. This it selectively removes from the 2-position of lecithin to give lysolecithin. The fatty acyl group in this position is generally unsaturated and the cholesteryl esters thus formed are frequently cholesteryl oleate or cholesteryl linoleate. Familial lecithin:cholesterol acyltransferase deficiency is a very rare disorder, in which HDL fails to mature and circulating free cholesterol levels increase. It leads to anaemia, corneal opacities, proteinuria, and renal failure.

Esterified cholesterol on HDL is transferred back to VLDL. This cannot take place by simple diffusion, because cholesteryl ester is intensely hydrophobic and because the concentration gradient is unfavourable. A special plasma protein, cholesteryl ester transfer protein or lipid transfer protein, transports cholesteryl ester from HDL to VLDL. It does this in exchange for triglycerides in VLDL and thus also contributes to the removal of core triglycerides from VLDL. The principal mechanism for the removal of triglycerides from VLDL is, however, lipolysis catalysed by lipoprotein lipase.

Another major difference between VLDL and chylomicrons is that the apolipoprotein B produced by the liver in man is not apoB $_{48}$ but is almost entirely apoB$_{100}$. As in the case of chylomicrons, the quantum of apoB packaged in the VLDL remains tightly associated with the particle until its final catabolism; its amount does not vary after secretion. It is probable that each molecule of VLDL contains one molecule of apoB $_{100}$. The apoB$_{100}$ produced in the liver contains the protein sequence necessary to bind to the LDL receptors, whereas that produced by the gut, although derived from the same gene, does not: a process of 'gene editing', which stops the ribosome translating the messenger RNA before the receptor-binding sequence, leads to an apoB with 48 per cent of the molecular mass of that from the liver. Microsomal triglyceride transfer protein is essential for the process by which both apoB $_{48}$ and apoB$_{100}$ are packaged with triglyceride in the enterocyte and hepatocyte to form chylomicrons or VLDL respectively; this is defective in abetalipoproteinaemia (see below).

The circulating VLDL particles become progressively smaller as their core is removed by lipolysis and surface materials are transferred to HDL. In normal man most of the VLDL is converted to smaller LDL particles through the intermediary of a lipoprotein known as intermediate density lipoprotein (**IDL**). This has a density of 1006 to 1019 g/litre and contains apoE. In this latter respect it is similar to chylomicron remnants. In some species, such as the rat, it is largely removed by the hepatic receptors, and LDL formation is thus bypassed. The enzyme hepatic lipase may be important in the conversion of IDL to LDL.

In man, LDL particles, which are relatively enriched in cholesterol but are small enough (diameter 18–25 nm, density 1019–1063 g/litre) to cross the vascular endothelium and enter the tissue fluid, serve to deliver cholesterol to the tissues. Their concentration in the extracellular fluid is probably about 10 per cent of that in the plasma. Cells require cholesterol for membrane repair and growth and, in the case of specialized tissues such as the adrenal gland, gonads, and skin, as a precursor for the syntheses of steroid hormones and vitamin D. Low-density lipoprotein is able to enter cells by two routes making a major contribution to its catabolism: one which is regulated according to the cholesterol requirement of each individual cell and one which appears to depend almost entirely on the extracellular concentrations of LDL.

The first of these two routes is by a cell-surface receptor, which specifically binds lipoproteins that contain apoB $_{100}$ or apoE. This is the LDL receptor. As mentioned previously, the receptor, although capable of binding apoE-containing lipoproteins, in practice binds mainly to the apoB $_{100}$-containing lipoproteins, of which LDL is the most widely distributed. After binding, the LDL–receptor complex is internalized and undergoes intracellular lysosomal degradation. The apoB moiety is hydrolysed to its constituent amino acids, and the cholesteryl ester is hydrolysed to free cholesterol. The release of this free cholesterol is the signal which regulates the cellular cholesterol content by three co-ordinated reactions. First the enzyme which is rate-limiting for cholesterol biosynthesis (3-hydroxy,3-methyl-glutaryl CoA reductase) is repressed, thus effectively centralizing cholesterol biosynthesis to organs such as the liver and gut. Secondly, the synthesis of the LDL receptor itself is suppressed. Thirdly, acyl-CoA:cholesterol *O*-acyltransferase is activated so that any cholesterol that is surplus to immediate requirements can be converted to cholesteryl ester, which, because of its hydrophobic nature, forms into droplets within the cytoplasm and is thus conveniently stored. The effect of the lysosomal release of free cholesterol on the expression of the LDL receptor contrasts with its effect on the hepatic remnant receptor, which is not subject to any similar downregulatory process. Free cholesterol released by lysosomal digestion of cholesteryl ester-rich, apoE-containing lipoproteins entering the hepatocyte via the 'remnant receptor' does not influence expression of this receptor mechanism; it will, nevertheless, downregulate the hepatic LDL receptors. Defective uptake of LDL by the LDL receptor is the basis of familial hypercholesterolaemia (see below).

The other quantitatively important mechanism by which LDL cholesterol may enter cells is by a non-receptor-mediated pathway: LDL binds to cell membranes at sites other than the LDL receptors and some of it passes through the membrane by pinocytosis. High-density lipoprotein is able to compete with LDL for this type of cell membrane association. The absence of a receptor means that the 'binding' is of low affinity and thus, at low concentrations, LDL entry by this route may have little significance. However, unlike receptor-mediated entry, non-receptor-mediated LDL uptake, is not saturable, but continues to increase with increasing extracellular LDL concentrations. When LDL levels are relatively high, entry of cholesterol into the cells by this route may thus assume greater quantitative importance than that via the LDL receptor, which will be both saturated and downregulated. This appears to be the situation in the typical adult consuming a high-fat diet whose LDL cholesterol is high compared with most animals and in whom only about one-third of LDL is catabolized by receptors and two-thirds by non-receptor-mediated pathways. In hypercholesterolaemia, an even greater proportion of LDL is catabolized via the non-receptor pathway (four-fifths in patients heterozygous for familial

hypercholesterolaemia, virtually all in homozygotes; see below).

Low-density lipoprotein may also be removed from the circulation by receptors other than the classical LDL receptor. These are probably responsible for the catabolism of only relatively minor amounts of LDL, but two groups of receptors present on the macrophage have excited considerable interest, because they are pertinent to atherogenesis. They are the b-VLDL receptor, a modified LDL receptor which allows the uptake of the b-VLDL from patients with type III hyperlipoproteinaemia (see below), and the scavenger receptors and oxidized LDL (**ox-LDL**) receptors, which permit the uptake of oxidized LDL by macrophages. Uptake by these receptors is so rapid that foam cells resembling those in arterial fatty streaks and atheromatous lesions are formed *in vitro*. On the other hand, uptake of unmodified LDL by the macrophage via the LDL receptor is too slow to allow foam cells to be formed. Oxidation of LDL may occur *in vivo* and is of potential relevance to atherogenesis (see below).

Lipoprotein (a)

Lipoprotein (a) (**Lp(a)**) is a lipoprotein first identified as a result of blood transfusion reactions occurring due to allotypic variation. Its exact location in the LDL and HDL_2 also varies from individual to individual, as does its serum concentration. It may be undetectable in some people or present at concentrations equalling those of LDL in others. The protein moiety of Lp(a), like that of LDL, contains $apoB_{100}$, but in addition apolipoprotein (a) (**apo(a)**) is also present. This contains homologous sequences of plasminogen, in which part of the plasminogen protein sequence (the kringle 4 domain) is repeated many times. The number of these repeats, which is determined at a genetic locus adjacent to the plasminogen gene, determines the molecular mass of apo(a), and individuals expressing polymorphisms with fewer kringle 4 repeats have the highest serum concentrations of Lp(a). Lp(a) is associated with the risk of coronary heart disease in people of European origin, particularly when serum cholesterol levels are also raised and when there is a family history of premature coronary heart disease. Lipoprotein (a) does not give rise to fibrinolytic activity because of a mutation in its activation site, and it may interfere with thrombolysis. Furthermore because Lp(a) binds to many different cells and connective tissue matrices, it is retained in the arterial wall longer than LDL and is thus more likely to be oxidized and taken up by macrophages, leading to atheroma (see below).

Transport of cholesterol from tissues back to liver

Cholesterol is exported by the gut and liver in quantities which greatly exceed its peripheral catabolism (largely conversion to steroid hormones and sebum). Therefore, except when the requirement for membrane synthesis is high, for example during growth or active tissue repair, the greater part of the cholesterol transported to the tissues (if it is not to accumulate there) must be returned to the liver for elimination in the bile, as bile acids and faecal sterols, or for reassembly into lipoproteins. The return of cholesterol from the tissues to the liver is termed 'reverse cholesterol transport'. It is less well understood than the pathways by which cholesterol reaches the tissues but it may well be critical to the development of atheroma. High-density lipoprotein has many features that make it very likely that it is directly involved in the reverse transport process.

The precursors of plasma HDL (nascent HDL) are disc-shaped bilayers composed largely of protein and phospholipid secreted mainly by the gut and liver (Fig. 4(b)). These are converted to the spherical, mature form of HDL by the action of lecithin:cholesterol acyltransferase. High-density lipoprotein components are also derived from surplus material (phospholipids, free cholesterol, and apoproteins) of triglyceride-rich lipoproteins released during lipolysis. ApoA-I and apoA-II, the major apolipoproteins of HDL, and apoE have been identified in nascent HDL. Other apolipoproteins and the bulk of its lipid are acquired as it circulates through the vascular and other extracellular fluids. In this respect the transformation of HDL from its lipid-depleted precursor to a relatively lipid-rich molecule is the inverse of that undergone by the other lipoproteins following their secretion.

High-density lipoprotein is a small particle compared with the other lipoproteins (diameter 5–12 nm, density 1063–1210 g/litre) and easily crosses the vascular endothelium, so that its concentration in the tissue fluids is much closer to its intravascular concentration than is the case for LDL. Because the serum HDL cholesterol concentration is only about one-quarter that of the LDL, it is often wrongly assumed that its particle concentration is lower. In fact, the particle concentrations of HDL and LDL in human plasma are often similar, and in the tissue fluids there are several times as many HDL molecules as those of other lipoproteins unless the capillary endothelium is fenestrated. Generally, therefore, cells are in contact with higher concentrations of HDL molecules than of any other lipoprotein. In man, unlike the rat, HDL serves no function in transporting cholesterol to cells.

Recently it has been suggested that cells express receptors for HDL, particularly HDL_3, which might permit the transfer of cholesterol out of the cell. Passage across the cell membrane depends on an ATP-binding cassette transporter, ABCA1, which has recently been identified as the cholesterol efflux regulatory protein. Homozygosity for mutations in the *ABCA1* gene cause analphalipoproteinaemia (Tangier disease, see below) in which nascent HDL disappears rapidly from the circulation without acquiring cholesterol. Heterozygotes for *ABCA1* mutations have low levels of HDL cholesterol and accelerated atherogenesis. Factors regulating the balance between intracellular cholesterol ester and free cholesterol (activities of acyl-CoA:cholesterol *O*-acyltransferase and cholesterol esterase) may also be important. Apolipoprotein E synthesized within certain cells may also mediate the egress of cholesterol to HDL. Once outside the cell, free cholesterol must be re-esterified in order that it can be transported in any quantity in the core of lipoproteins. Therefore, whether or not HDL is involved as the initial acceptor molecule, cholesterol must at some stage on its return journey to the liver reside on HDL, because it is the site of lecithin:cholesterol acyltransferase activity. However, once cholesterol has been esterified and packed into the core of HDL, simple clearance of the whole lipoprotein particle by the liver is not the route by which most cholesterol is returned to it. This is because LDL equivalent to 1500 mg of cholesterol is produced each day, whereas the rate of catabolism of the HDL apolipoproteins A-I and A-II would permit less than 200 mg of HDL cholesterol to be returned each day. Therefore:

1. the liver must be capable of selectively removing cholesterol from HDL and then returning the particle to the circulation with most of its apolipoproteins intact, or
2. the cholesterol in HDL must be transferred to another lipoprotein class which is capable of being cleared in quantity by the liver, or
3. a class of HDL, which contains little apoA-I or apoA-II, must be cleared by the liver at a much greater rate than the bulk of HDL.

In support of pathway (1), there is some evidence that hepatic lipase might act on the phospholipid envelope of HDL during its passage through hepatic sinusoids, and release the cholesteryl ester contained in its core, and that some hepatic trapping or even a receptor-mediated mechanism might enhance the process. On the other hand, in support of pathway (2) there is a well-established mechanism for the transfer of cholesteryl ester from HDL to VLDL through the agency of cholesteryl ester transfer protein. Once on VLDL, the conversion of this lipoprotein to IDL and then LDL means that the cholesteryl ester can then arrive at the liver via remnant receptors, LDL receptors, or by the non-receptor-mediated route for LDL uptake. Evidence for pathway (3), the return of cholesterol to the liver from HDL by a rapidly metabolized form of HDL present at low concentration in serum, is at present lacking in man, although it is possible that binding of the subclass of HDL containing apoE to hepatic remnant receptors permits the return of some cholesterol to the liver.

It is incorrect to regard HDL as a single homogeneous species, since it is known to be a mixture of particles differing in size, in lipid and apolipoprotein composition, and in function. Two main species can be resolved by ultracentrifugation, the less dense of which is designated HDL_2 (density 1063–1125 g/litre) and the more dense HDL_3 (density 1125–1210 g/litre). HDL_3 may be converted to HDL_2 by the acquisition of cholesterol, HDL_3 thus being a precursor of HDL_2. Whereas antisera to apoA-I precipitate virtually all of HDL, antisera to apoA-II do not, suggesting that some molecules of HDL contain apoA-I and apoA-II, whereas others contain only apoA-I. The apoA-I-only HDL molecules, which predominate in HDL_2, may arise from different metabolic channels than do the apoA-I/A-II particles. High-density lipoprotein containing apoE, as has previously been mentioned, may also have a different metabolic fate. Furthermore, HDL may contain other molecular species with overlapping density ranges, such as Lp(a); it is thus a highly diverse lipoprotein class.

Disorders produced by raised concentrations of lipoproteins

The incidence of coronary heart disease varies greatly in different parts of the world. Those countries with a Northern European culture (and in particular diet) have the highest rates, and places such as China, Japan, and rural Africa the lowest. Mediterranean countries are intermediate. There are, of course, many differences between these countries, but the variable that relates most closely to coronary heart disease is the median serum cholesterol of the middle-aged male population. It is of considerable interest that in a country such as Japan, where the average serum cholesterol is low, other coronary risk factors do not seem to operate. Thus in Japan coronary heart disease is comparatively uncommon, even in cigarette smokers and people with diabetes and hypertension.

Within populations there is an exponential relationship between serum cholesterol and the incidence of coronary heart disease (Fig. 5). This depends on the LDL cholesterol which comprises some 70 to 80 per cent of the total cholesterol in men and a little less in women. The greater part of the residual cholesterol in serum is on HDL, and the concentration of this HDL cholesterol is inversely related to the likelihood of developing coronary heart disease.

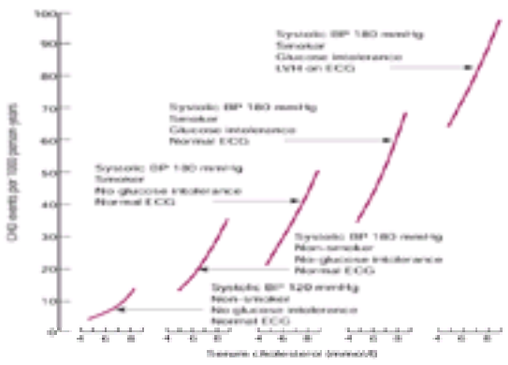

Fig. 5 The probability of 50-year-old men developing coronary heart disease each year as a function of serum cholesterol concentration, in the absence and in the presence of increasing numbers of risk factors. (Data from Kannel WB *et al.* (1973). The Framingham Study. An epidemiological investigation of cardiovascular disease. Section 28: the probability of developing certain cardiovascular diseases in eight years at specific values of some characteristis. Publication 74-618, US Department of Health Education and Welfare. Government Printing Office, Washington DC.)

In populations in which death from coronary heart disease is common, fatty streaks are evident in the arteries, such as the aorta, of men dying in their late teens of causes unrelated to cardiovascular disease. This was noted in American casualties of the Korean and Vietnam wars. The fatty streak is the precursor of atheroma (see Section 15). The epidemiological and histopatholgical evidence implicating LDL in atherogenesis seems overwhelming. Yet in tissue culture, LDL uptake by macrophages or smooth muscle cells proved disappointingly slow and foam cells were not formed. Subsequently, it was found that the macrophage has receptors which will allow the rapid uptake of LDL to form foam cells if the LDL has undergone some chemical modification. Initially these receptors were known as the acetyl-LDL receptors (after the first experimental chemical modification leading to their identification), but now scavenger receptors and another class of receptors, the ox-LDL receptors, are known to be responsible for the uptake of modified LDL by macrophages. It is likely that the chemical modification leading to LDL uptake in human atherogenesis is oxidation of the polyunsaturated fatty acyl groups of phospholipids of LDL which have crossed the arterial endothelium to enter the subintimal space. The lipid peroxides so formed break down to lysophospholipids and aldehydes, which directly damage the apoB of the LDL, which then binds to the scavenger and ox-LDL receptors. The same substances are directly cytotoxic and may further damage the overlying arterial endothelium, increasing its permeability. The oxidized LDL itself and the release of the cytokines it stimulates are chemotactic to blood monocytes (from which arterial wall macrophages are derived) and may thus recruit more inflammatory cells into the lesion. HDL may protect LDL against oxidative modification by a process which involves the enzyme paraoxonase, which is tightly bound to HDL. In addition to uptake of LDL through scavenger and ox-LDL receptors, macrophages phagocytose aggregated LDL to become foam cells and take up LDL–antibody complexes via Fc (immunoglobulin crystallizable fragment) receptors. Other lipoproteins can be taken up to form foam cells. In particular, the b-VLDL (a mixture of chylomicron remnants and IDL), which accumulates in the circulation in type III hyperlipoproteinaemias (see below), is rapidly taken up by a macrophage receptor.

Triglyceride-rich lipoproteins can also be taken up by macrophages by phagocytosis to form foam cells, although these large particles would not be expected to cross the vascular endothelium unless it is fenestrated. Thus in extreme hypertriglyceridaemia, lipid-engorged macrophages are present in the mononuclear phagocyte system. They may be observed on bone marrow biopsy, and are the cause of the hepatosplenomegaly associated with extreme hypertriglyceridaemia. When hypertriglyceridaemia occurs in association with elevated levels of LDL cholesterol, it increases the likelihood of atheroma developing still further, perhaps because this combination is associated with low serum HDL cholesterol, perhaps because of an increase in circulating IDL and delayed clearance of chylomicron remnants, perhaps because it is associated with smaller LDL particles, which are more readily oxidized, or perhaps because there are associated increases in the coagulability of blood due to increased plasma fibrinogen levels and factor VII activity. When, however, triglyceride-rich lipoproteins are increased without any increase in LDL, as in familial lipoprotein lipase deficiency (see below), there appears to be only a modest risk of atheroma. There is, however, an increased likelihood of acute pancreatitis in all types of severe hypertriglyceridaemia, both primary and secondary, particularly when serum triglyceride levels exceed 20 to 30 mmol/litre (2000–3000 mg/dl). The cause of this is not known for certain, but may be attributed to the release of fatty acids by lipolysis *in situ* due to pancreatic lipase.

Normal serum lipid concentrations

Whereas the average serum concentrations of most substances, for example sodium or fasting glucose, are much the same in all parts of the world, cholesterol displays considerable variation. In Britain the median serum cholesterol for a middle-aged man is 5.8 mmol/litre and deaths from coronary heart disease comprise around 40 per cent of total mortality at this age. In China the average for men of middle age is 2 mmol/litre less, and coronary heart disease accounts for less than 5 per cent of their deaths.

Conventionally, the normal range for a variable in a particular population is chosen to include values between the 2.5 and 97.5 percentiles, or sometimes the 1 and 99 percentiles, on the assumption that 19 out of 20 of the population, or 49 out of 50 respectively, are normal. To be rational, the implication in a medical context must also be that those people in the normal range are healthy. In the case of cholesterol, which is clearly linked to coronary heart disease, the healthy range would be more representative were it to include values from societies in which coronary heart disease is uncommon, such as China or Japan. This has led the National Institute of Health in the United States and the European Atherosclerosis Society to define healthy limits for serum cholesterol based on the risk of coronary heart disease. Thus an optimal serum cholesterol is 5.0 mmol/litre (200 mg/dl) or less. A level of 6.3 mmol/litre (250 mg/dl) (at the 75th percentile in the United States) is considered to indicate 'moderate risk' and 6.7 mmol/litre (270 mg/dl), which is the 90th percentile in the United States, 'high risk'. Some caution is required in using this concept. The risk of fatal coronary heart disease in an American middle-aged male population whose serum cholesterol is 5 mmol/litre (200 mg/dl) over the next 6 years is about 6 in 1000. At 6 mmol/litre (250 mg/dl) it is almost doubled, but that is only 10 in 1000, and at 7 mmol/litre (270 mg/dl) it is still less than 15 in 1000. Thus although these levels may be of great importance for public health initiatives aimed at reducing the cholesterol level in societies in which the risk of coronary heart disease is high, the clinician must be wary about overtreating men with cholesterol at these levels, if it is their only risk factor for coronary heart disease. The risk conferred by a particular level of cholesterol increases considerably when it is combined with another risk factor and this may considerably increase the benefits of treatment (Fig. 5). This is why there can be no single cholesterol level which demands a particular therapeutic response: the cholesterol value must always be viewed in the context of an individual's overall cardiovascular risk (see below).

An upper limit of normality for fasting serum triglycerides is often regarded as 2.2 mmol/litre (200 mg/dl). This is close to the 90th percentile for men and the 95th percentile for women. For serum HDL cholesterol a lower limit of normality of 0.9 mmol/litre (35 mg/dl) is frequently quoted, which is close to the 10th percentile for men and between the 5th and the 10th percentiles for women.

The Fredrickson/WHO classification

The concentration of four classes of serum lipoproteins when elevated can be regarded as pathological. These are chylomicrons, VLDL, LDL, and b-VLDL. The hyperlipoproteinaemias can be classified according to which of them is increased (Table 1).

The Fredrickson/WHO classification causes great confusion, largely because it is difficult to remember and is frequently wrongly regarded as a diagnostic classification when it is simply a way of reporting which of the serum lipoproteins is elevated. It is usually sufficient to remember that when cholesterol alone is elevated there is a type IIa hyperlipoproteinaemia. When both cholesterol and triglycerides are elevated the hyperlipoproteinaemia is generally type IIb, but occasionally it is type V (the serum will look milky if it is) and rarely type III. Type I is extraordinarily rare. An isolated increase in fasting serum triglycerides almost invariably signifies type IV hyperlipoproteinaemia.

All hospital laboratories, in addition to measuring cholesterol and triglyceride levels, should also measure HDL cholesterol in patients whose overall cardiovascular risk is being critically assessed when treatment of their hyperlipoproteinaemia with drugs is under consideration. Particularly in women, an elevated level of cholesterol may result from a relatively high HDL cholesterol concentration and thus not signify any increased risk of coronary heart disease. High serum HDL cholesterol does not have a Fredrickson/WHO class, but as evidence suggests it is associated with longevity, it cannot be regarded as hyperlipoproteinaemia in the pathological sense. It is low HDL cholesterol which is associated with an increased cardiovascular risk, particularly if total serum cholesterol and triglycerides are also elevated.

Primary hyperlipoproteinaemias

Primary hyperlipoproteinaemias in which there is hypercholesterolaemia (type IIa)

Serum cholesterol levels exceeding 5 mmol/litre are common in adults in Britain and much of Europe, the United States, Australia, and New Zealand. In Britain, for example, 80 per cent of middle-aged people have levels exceeding this, and the proportion in the United States is at least 50 per cent. Most of this hypercholesterolaemia does not represent the effect of any single cause, but is due to some combination of dietary fat, obesity, and individual susceptibility to develop hypercholesterolaemia. This susceptibility is partly genetic, probably involving more than one gene, and this common type of hypercholesterolaemia is usually referred to as polygenic hypercholesterolaemia. At the very top end of the cholesterol distribution are to be found individuals who have the less common monogenic condition, familial hypercholesterolaemia.

Familial hypercholesterolaemia

Heterozygous familial hypercholesterolaemia

Familial hypercholesterolaemia is dominantly inherited. The heterozygous form of the condition affects about 1 in 500 people in Britain and the United States, making it one of the most common genetic disorders in these countries. In some populations, such as the Lebanese Christians, the Afrikaner and Cape Coloured peoples of South Africa, and French Canadians, it is considerably more common. This is because such people have descended from a relatively small number of early settlers, a few of whom by chance had familial hypercholesterolaemia. This is known as a founder effect. In yet other populations, such as Africans who have not intermingled with Europeans, familial hypercholesterolaemia appears to be rare.

Typically, the serum cholesterol in adult heterozygotes is 9 to 11 mmol/litre (350–450 mg/dl). The condition is expressed regardless of diet or age, and elevated cholesterol levels are present throughout childhood. The lipoprotein phenotype is usually IIa, but occasionally there is a moderate increase in fasting serum triglycerides to produce a IIb pattern. There is a tendency for HDL cholesterol to be at the lower end of the range, particularly if triglycerides are elevated.

The clinical hallmark of familial hypercholesterolaemia is the presence of tendon xanthomas. These appear in heterozygotes from the age of 20 onwards. The most common sites for tendon xanthomas are in the tendons overlying the knuckles and in the Achilles tendons (Plate 1 and Plate 2). Less commonly, they may also be found in the extensor hallucis longus and triceps tendons, and occasionally other sites. It is also common to find subperiosteal xanthomas on the upper tibia where the patellar tendon inserts. The skin overlying tendon xanthomas is of normal colour and they do not appear yellow. The cholesteryl ester deposits are deep within the tendons. Tendon xanthomas feel hard because they are fibrotic. Indeed, it is not uncommon for those in the Achilles tendons to become inflamed from time to time, sometimes presenting as chronic Achilles tenosynovitis. More generalized tendinitis may follow rapid therapeutic reduction in serum cholesterol levels. Tendon xanthomas occur in only two disorders apart from familial hypercholesterolaemia, and these are so rare as not to pose any diagnostic difficulty. They are cerebrotendinous xanthomatosis, in which plasma cholestanol is elevated and deposited in tendons, and phytosterolaemia (b-sitosterolaemia), in which there is abnormal intestinal absorption of plant sterols, which are then deposited in tendons.

Corneal arcus is also a frequent occurrence in familial hypercholesterolaemia. When it occurs in adolescence or early adulthood it is more likely to be associated with familial hypercholesterolaemia than corneal arcus occurring in middle age or later. It is, however, not uncommon to encounter patients with familial hypercholesterolaemia who have florid tendon xanthomas but no arcus. It is thus not a very valuable physical sign. Xanthelasmata palpebrarum, although occurring with greater frequency and at a younger age in familial hypercholesterolaemia, affect only a minority of heterozygotes. Xanthelasmas are not specific for any particular type of hypercholesterolaemia and occur in polygenic hypercholesterolaemia, pregnancy, primary bilary cirrhosis, and hypothyroidism. They are also common in middle-aged women, often overweight, with no very marked increase in serum cholesterol, if any. They may run in families apparently independently of hypercholesterolaemia.

Identifying those heterozygous for familial hypercholesterolaemia as early as possible is important, because of their risk of coronary heart disease. Untreated, over half of affected men die before the age of 60 years. It is not uncommon for men to have their first myocardial infarction or develop angina in their thirties and occasionally even earlier. Some 15 per cent of women with familial hypercholesterolaemia die of coronary heart disease before the age of 60 years and the majority have symptomatic coronary disease by that age. Perhaps as many as 10 per cent of women have some evidence of cardiac ischaemia before their menopause. However, whereas it is exceptional for a man with familial hypercholesterolaemia to live to 70 without symptomatic coronary heart disease, almost a quarter of women do so. This largely explains why a family history of premature coronary heart disease is absent in as many as one-quarter of patients discovered to have familial hypercholesterolaemia on screening, or in men who are discovered to have familial hypercholesterolaemia when they present with a heart attack in early life: the condition has been inherited from their mother, who has herself not yet developed coronary symptoms. Most people with familial hypercholesterolaemia are not overweight and do not have risk factors for coronary heart disease other than hypercholesterolaemia and a family history of the premature disease. Those without a family history of premature coronary heart disease (approximately 25 per cent) will be missed in screening programmes for risk factors for coronary heart disease, in which cholesterol is only measured selectively.

Those patients with familial hypercholesterolaemia who develop coronary heart disease particularly early often come from families in which the affected members have all tended to develop coronary heart disease early. This may be because other genetic factors in the family predispose to coronary heart disease. Thus low serum HDL cholesterol and increased fasting triglycerides are associated with a worse prognosis. Serum lipoprotein (a) is increased in familial hypercholesterolaemia and any familial tendency to run a high level of Lp(a) is exacerbated in those members who also have familial hypercholesterolaemia. The apoE $_4$ genotype (see below) is also associated with more aggressive atheroma in familial hypercholesterolaemia. A knowledge of the average age at which affected members of a family developed coronary heart disease may be helpful in planning how actively to treat boys and young adult women.

There is an increased risk of atheroma in other parts of the arterial tree in heterozygous familial hypercholesterolaemia, but this is strikingly less so than in the coronary arteries. Some heterozygotes have aortic systolic cardiac murmurs due to deposits of atheroma in the aortic root, sometimes involving the aortic cusps.

Homozygous familial hypercholesterolaemia

Most cases of homozygous familial hypercholesterolaemia occur in societes in which consanguineous marriages and heterozygous familial hypercholesterolaemia are frequent. The chance of marriage between unrelated heterozygotes meeting by chance in countries such as the United Kingdom or United States is 1 in 500 ^{2}, and each of their children would stand a 1 in 4 chance of being homozygotes. Assuming no adverse effect on the survival of the conceptus, an incidence of homozygous familial hypercholesterolaemia of 1 in 10 ^{6} births would be predicted—a rare disorder.

Clinically, homozygous familial hypercholesterolaemia is characterized by the development of cutaneous xanthomas in childhood. These may be present in the first year of life or may not develop until late childhood. They are typically orange-yellow, subcutaneous, planar xanthomas, occurring on the buttocks, antecubital fossae, and the hands, frequently in the webs between the fingers. Tuberose subcutaneous xanthomas on the knees, elbows, and knuckles are also a feature. Serum cholesterol is typically greater than 15 mmol/litre (600 mg/dl). Myocardial infarction and angina frequently occur in childhood, sometimes even in infancy. Atheromatous deposits at the aortic root, invariably present by puberty, are so marked as to produce significant aortic stenosis, which contributes to the risk of sudden death. Death before the age of 30, and often considerably younger, was the rule before the advent of plasmapheresis and similar techniques for the extracorporeal removal of LDL (see below).

Polyarthritis, predominantly affecting the ankles, knees, wrists, and proximal interphalangeal joints, is common in homozygotes for familial hypercholesterolaemia.

The metabolic defect in familial hypercholesterolaemia

In familial hypercholesterolaemia there is decreased catabolism of LDL so that it remains for longer in the circulation. Normally the plasma half-life of LDL is 2.5 to 3 days, whereas in familial hypercholesterolaemia heterozygotes it is 4.5 to 5 days, and even longer in homozygotes. The molecular defect which causes this has been elucidated following the discovery of the LDL receptor (see above) by Goldstein and Brown, for which they received the Nobel prize for medicine in 1985. The gene encoding the LDL receptor protein is located on chromosome 19. Heterozygotes express only about half the LDL receptors of a normal person. Homozygotes have between none and 25 per cent of normal receptor activity. The mutations in the LDL receptor gene produce either receptors with no binding activity (receptor negative; because the receptor is not synthesized, is not transported to the cell surface, or, if it gets there, cannot be internalized after binding to LDL) or because, although the

mutation allows some LDL to be bound and to enter the cell, this occurs only slowly because the binding site is abnormal (receptor defective). Some 200 mutations have been described and undoubtedly more exist. In Afrikaners or French Canadians far fewer mutations are associated with familial hypercholesterolaemia. For example, three mutations account for 90 per cent of familial hypercholesterolaemia in Afrikaners. In societies such as Britain and the United States, however, the most frequent of these mutations is likely to occur in no more than 3 to 4 per cent of patients with familial hypercholesterolaemia. This means that the prospect of developing a DNA test for this condition in most countries is unrealistic. It also means that only patients in populations with a small number of mutations, or where intermarriage is common, are homozygous in the sense that both their LDL gene mutations are identical. Most will be compound heterozygotes. For clinical purposes it is reasonable to label as homozygotes patients who have the clinical syndrome. However, it is instructive to realize that some of the heterogeneity of the severity of the syndrome relates to the nature of the two LDL mutations present. Thus the worst prognosis is associated with inheritance of two receptor-negative mutations, and the best is with two receptor-defective mutations. The type of receptor mutation in heterozygotes is also probably of some importance, but here it is blurred against a background of other acquired or genetic factors, which can find expression over a much longer time than in homozygotes.

A small proportion (3 per cent) of patients who have the same clinical features as heterozygotes for familial hypercholesterolaemia do not have an LDL receptor defect but a mutation of apoB in which glutamine is substituted for arginine at amino acid residue 3500, which is part of the LDL receptor binding domain. This disorder has been termed familial defective apoB $_{100}$, and probably has a frequency of 1 in 500 to 600 in Britain and the United States. Only a minority of affected individuals have tendon xanthomas and typically the serum cholesterol associated with it is around 8.0 mmol/litre (310 mg/dl), which is less than in most heterozygotes for familial hypercholesterolaemia.

Common or polygenic hypercholesterolaemia

When a diagnosis of familial hypercholesterolaemia can be made, either because hypercholesterolaemia is present in childhood or an adult has the clinical features of the syndrome, a reasonably accurate estimate of clinical risk can be made and appropriate therapy given. In Britain, however, familial hypercholesterolaemia probably accounts for no more than 3 per cent of men dying of coronary heart disease before the age of 60. There is overlap between the range of LDL cholesterol levels encountered in familial hypercholesterolaemia and those due to the more common polygenic hypercholesterolaemia. Epidemiological studies have not included sufficient numbers of people with particularly high cholesterol levels to be certain, but it is probable that the risk in familial hypercholesterolaemia is greater than in polygenic hypercholesterolaemia. This may be because in the familial condition the hypercholesterolaemia has been present since birth, whereas polygenic hypercholesterolaemia is frequently not fully developed until the third or fourth decade. Furthermore familial hypercholesterolaemia, unlike many other types of hypercholesterolaemia, is associated with increased serum concentrations of Lp(a).

Estimates of how much different levels of cholesterol contribute to the overall cumulative male mortality from coronary heart disease by the age of 60 years are given in Table 2. The majority of such premature deaths come from the middle part of the cholesterol distribution, and therefore it has been argued that if a significant reduction in the incidence of coronary heart disease is to be achieved in countries such as the United Kingdom, efforts to lower cholesterol cannot simply be confined to those individuals whose plasma cholesterols lie at the upper end of the distribution. Nevertheless because the number of people in the middle range is so large (the vast majority of whom are not at increased risk of premature coronary heart disease), a different strategy must be applied to reducing their cholesterol from that applied to those in the upper part of the cholesterol distribution. This is the 'low-risk' or 'population' strategy, which aims to lower serum cholesterol by public health measures aimed at encouraging the adoption of a lower-fat diet and avoidance of obesity. Some patients from the middle range of serum cholesterol are, however, at much greater individual risk from their cholesterol level than the majority, because they have other risk factors for coronary heart disease which combine to increase their susceptibility. Probably the most potent of these is that the individual already has coronary heart disease.

In middle-aged survivors of myocardial infarction, serum cholesterol is an important indicator of cardiac prognosis (Fig. 6(a)), ranking after left ventricular function, but ahead of most of the other risk factors for coronary heart disease. Lipoproteins are also the most important risk factors for occlusion of coronary artery bypass grafts after the initial postoperative period. In people who have not yet developed coronary heart disease, the effect of risk factors such as cigarette smoking, hypertension, and diabetes synergizes with the risk from any given level of cholesterol (Fig. 5). A family history of coronary heart disease at an early age in a first-degree relative also increases the likelihood of coronary heart disease, and part of this effect is independent of other risk factors for coronary heart disease. The combination of all these factors with a relatively modestly increased serum cholesterol level can increase individual risk substantially to a level where clinical intervention is as justified as it is with more marked elevations in serum cholesterol. This is the 'high-risk' or clinical approach to prevention of coronary heart disease.

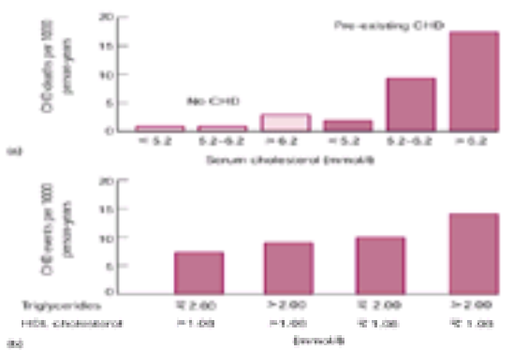

Fig. 6 (a) The risk of subsequent fatal myocardial infarction in survivors of myocardial infarction according to their serum cholesterol concentration. (Data from Pekkanan J *et al.* (1990) *New England Journal of Medicine* **322,** 1700–7.) (b) The likelihood of developing coronary heart disease in patients with moderately raised serum cholesterol concentrations (on average 6.9 mmol/litre) is increased when serum triglyceride levels are also raised and HDL cholesterol concentrations decreased. (Data from Manninen V *et al.* (1989).)

Metabolic defect in polygenic hypercholesterolaemia

In polygenic hypercholesterolaemia there is overproduction of VLDL by the liver. If this is rapidly converted to LDL there is no increase in serum triglyceride levels. The LDL receptor mechanism is probably overloaded in many individuals and in any case appears to catabolize only about one-third of LDL, so that the build-up of cholesterol in most patients is not due to any defect in the LDL receptor, but the inability of non-receptor-mediated catabolism to cope without a rise in the serum cholesterol concentration. Obesity and a high-fat diet (particularly saturated fat) are probably the major reasons for the enormous differences in the prevalence of polygenic hypercholesterolaemia in different parts of the world. Undoubtedly, however, individual responses to diet vary greatly and there is a complex interplay between dietetic and genetic factors in the genesis of polygenic hypercholesterolaemia. The rise in cholesterol with age, which occurs in both men and women until the climacteric, seems less evident in societies where the cholesterol level is, for nutritional reasons, lower. There is an impression that dietary modification aimed at lowering cholesterol in middle age in societies where serum cholesterol is high does not reduce it to the extent that might be anticipated from populations habitually consuming such a diet. Whether this is simply a matter of non-compliance with diet or represents some imprinted change in metabolism caused by a high-fat diet in early life is, at present, uncertain.

Primary hyperlipoproteinaemias in which there is hypercholesterolaemia combined with hypertriglyceridaemia

Type III hyperlipoproteinaemia

Type III hyperlipoproteinaemia has several synonyms: broad beta disease, floating beta disease, dysbetalipoproteinaemia, and remnant removal disease. It is rare, probably occurring in fewer than 1 in 5000 people. Type III hyperlipoproteinaemia has the distinction of being the first clinical syndrome associated with hyperlipoproteinaemia to be described (by Addison and Gull in 1851).

Type III hyperlipoproteinaemia is due to the presence in the circulation of increased amounts of chylomicron remnants and IDL, often collectively termed b-VLDL. This is the result of decreased clearance of these lipoproteins at the hepatic 'remnant' (or apoE) receptor. There is an increase in both the serum cholesterol and fasting triglyceride concentrations. Typical levels are 7 to 12 mmol/litre (270–470 mg/dl) for cholesterol and 5 to 20 mmol/l (450–1800 mg/dl) for triglycerides. Often the molar concentrations of cholesterol and triglycerides are similar, and this may be a clue that a patient has type III hyperlipoproteinaemia. Occasionally the condition is

associated with marked hypertriglyceridaemia due to overwhelming chylo-micronaemia.

Xanthomas are present in more than half of the patients who have the type III lipoprotein phenotype. Characteristic of the condition are striate palmar xanthomas and tuberoeruptive xanthomas. Striate palmar xanthomas may simply be an orange-yellow discoloration within the creases of the skin of the palms of the hands. They may, however, be more florid and appear as raised, seed-like lesions (sometimes even larger) in the skin creases of the palms, fingers, and flexor surfaces of the wrists. Tuberoeruptive xanthomas are raised yellow lesions, usually on the elbows and knees (Plate 3). They may be nodular or cauliflower like, often surrounded by smaller satellites. Sometimes they may be found over other tuberosities, such as the heels and dorsum of the interphalangeal joints of the fingers. They resolve entirely with successful treatment of the hyperlipidaemia.

Type III hyperlipoproteinaemia is rare in women before the menopause, perhaps because uptake of hepatic remnant particles is enhanced by oestrogen. It is also rare in childhood, but has a definite incidence in men by early adulthood. Type III hyperlipoproteinaemia is generally an autosomal recessive condition with variable penetrance. In all cases there appears to be a mutation or polymorphism of the apoE gene, which impairs the receptor binding of apoE. The most frequent is a polymorphism, called apoE_2, in which cysteine is substituted for arginine at position 158 of the amino acid sequence. At least 90 per cent of patients with type III hyperlipoproteinaemia are homozygous for apoE_2. More often than not, however, apoE_2 homozygosity, which is present in around 1 per cent of the population, does not itself impose such a severe strain on lipoprotein metabolism that hyperlipoproteinaemia develops: its combination with some other disorder, leading to overproduction of VLDL or some additional catabolic defect, is required. This explains the association of type III hyperlipoproteinaemia with diabetes and hypothyroidism. More often, however, the additional stimulus to hyperlipoproteinaemia is obesity or the coinheritance of a polygenic tendency to hypertriglyceridaemia. Rarer mutations of apoE have been described, which behave clinically similarly to apoE_2 homozygosity. More severe is a mutation leading to apoE deficiency, which in homozygotes does not require other factors for the expression of the type III phenotype. Heterozygous apoE deficiency finds little clinical expression, but, interestingly, mutations directly involving the receptor-binding domain of apoE (amino acids 124 to 150) produce the type III phenotype even in heterozygotes (dominant expression), implying that such mutations are a greater handicap to receptor clearance than mutations in which one gene is not producing apoE.

Type III hyperlipoproteinaemia undoubtedly causes accelerated atherosclerosis in the coronary, femoral, and tibial arteries. Intermittent claudication occurs at least as frequently as coronary heart disease and the incidence of the latter is about the same as that in familial hypercholesterolaemia. It is noteworthy that in familial hypercholesterolaemia peripheral arterial disease is uncommon relative to coronary heart disease, indicating that the leg arteries are much more susceptible to the larger lipoprotein particles in type III hyperlipoproteinaemia.

In the presence of typical xanthomas, the diagnosis of type III hyperlipoproteinaemia is not difficult. When these are absent the diagnosis must be made in the laboratory. Type IIb or V hyperlipoproteinaemia can give similar serum lipid levels. Lipoprotein electrophoresis is still available in some hospital laboratories and, when it clearly shows separate pre-beta (VLDL) and beta (LDL) bands, is useful in establishing type IIb rather than III hyperlipoproteinaemia. Frequently, however, the classical broad beta band associated with type III hyperlipoproteinaemia cannot be distinguished from a smear stretching from the origin into the pre-beta and sometimes beta region in the more severe IIb or type V phenotype. However, polyacrylamide isoelectric focusing or genotyping, available in many specialized centres, can identify apoE_2 homozygosity and this, in the presence of hyperlipidaemia, makes type III virtually certain. Rarely, the apoE mutation does not affect the electrical charge of apoE, or affects only one gene so that apoE_2 homozygosity is not found. The only way then to confirm the diagnosis is to send plasma to a centre that can provide ultracentrifugation to identify the cholesterol-rich VLDL (b-VLDL) typical of type III hyperlipoproteinaemia. It is also important in these circumstances to exclude paraproteinaemia, which can produce both hyper- and hypolipoproteinaemia and can mimic typical type III hyperlipoproteinaemia.

Type IIB hyperlipoproteinaemia

The common lipoprotein phenotype associated with a combined increase in serum cholesterol and triglycerides is IIb. In the majority of people with this, in whom it is primary, the cause is probably best regarded as a polygenic tendency exacerbated by acquired nutritional factors, such as obesity. A few patients will have tendon xanthomas, indicating familial hypercholesterolaemia (see above) but the great majority will not. Cardiovascular risk is greater for any given level of cholesterol when the serum triglyceride concentration is also elevated (Fig. 6(b)). Often the HDL is low, which further compounds the risk. In addition patients with hypertriglyceridaemia frequently have increased levels of a cholesterol-depleted small, dense LDL which contributes little to the total serum cholesterol concentration, but which is susceptible to oxidation and to which increasing attention is being paid because it may be highly atherogenic. Some authorities also believe that there is a specific syndrome in which there is a combined increase in serum cholesterol and triglycerides and a greatly increased coronary risk. They term this familial combined hyperlipidaemia. In this, multiple lipoprotein phenotypes occur in different family members: some IIa, some IIb, some IV, or occasionally even V. It is more than probable that what is being observed is the genetic tendency for hypercholesterolaemia and hypertriglyceridaemia running in the same family to combine in some members and not in others, and that when this occurs in a family susceptible to coronary disease, a particularly high premature mortality ensues. However, until the arguments about whether familial combined hyperlipidaemia is a distinct genetic entity are resolved, for practical purposes hypertriglyceridaemia (especially when HDL cholesterol is low) should be considered as an additional factor increasing the risk of hypercholesterolaemia. When these abnormalities are combined with a family history of premature coronary heart disease, there is a greatly increased risk of cardiovascular disease unless the condition is detected and treated.

Primary hyperlipidaemias in which hypertriglyceridaemia predominates

Severe hypertriglyceridaemia (types I and V)

Diagnosis and underlying mechanism

In any circumstance in which the serum triglycerides exceed 11 mmol/litre (1000 mg/dl) chylomicrons in addition to VLDL will be major contributors to the hyperlipidaemia, even when the patient is fasting. This is because in the circulation both chylomicrons and VLDL compete for the same clearance mechanism (lipoprotein lipase). The lipoprotein phenotype is usually type V. This severe hypertriglyceridaemia generally ensues when an increase in hepatic VLDL production, either familial or secondary to, for example, obesity, diabetes, alcohol, or oestrogen administration, is associated with decreased triglyceride clearance, which again may be genetic or acquired, for example hypothyroidism, beta blockade, or diabetes mellitus (diabetes can cause both an overproduction of VLDL and decreased lipoprotein lipase activity). With the clearance mechanism already overloaded with VLDL, the postprandial elevation in serum triglyceride concentrations when chylomicrons enter the circulation may be astronomical and they may spend days rather than hours in the circulation. The plasma takes on the appearance of milk and triglycerides may exceed 100 mmol/litre (9000 mg/dl) (Plate 4). Thus a patient, who might otherwise have a fasting serum triglyceride level of 5 mmol/l, can, with the injudicious use of alcohol or the development of intercurrent diabetes, achieve extraordinarily high serum triglyceride levels. Overall the frequency of severe hypertriglyceridaemia (> 11 mmol/litre (1000 mg/dl)) is probably no more than 1 in 1000 in adults and less in children.

Rarely, severe hypertriglyceridaemia is caused by familial lipoprotein lipase deficiency, a genetic deficiency in lipoprotein lipase activity. This is inherited as an autosomal recessive trait. Usually it is due to mutation in the lipoprotein lipase gene, leading to defective function or production, but occasionally it is due to a genetic deficiency of apoC-II, the activator of lipoprotein lipase. In familial lipoprotein lipase deficiency, severe hypertriglyceridaemia may be encountered in childhood. Occasionally, in children and young adults presenting for the first time, it produces type I hyperlipoproteinaemia, in which only serum chylomicron levels are elevated. It is not known why the VLDL is not also raised, but with advancing age the increase in both VLDL and chylomicrons, which might be expected if lipoprotein lipase is ineffective, becomes the rule.

Physical signs in severe hypertriglyceridaemia

Tuberoeruptive xanthomas are characteristic of extreme hypertriglyceridaemia. These appear as yellow papules on the extensor surfaces of the arms and legs, buttocks, and back. Often there is hepatosplenomegaly. Liver imaging shows the liver to be fatty, and bone marrow biopsy may reveal macrophages engorged with lipid droplets (foam cells). Because the triglyceride-rich lipoprotein may interfere with the determination of transaminases, giving spuriously high values, liver disease, in particular alcoholic liver disease, may be difficult to exclude, other than by the prompt resolution of the syndrome when a low-fat diet is instituted. Other features include lipaemia retinalis (pallor of the optic fundus, with both the retinal veins and arteries appearing white).

Complications of severe hypertriglyceridaemia

Atheroma is not a prominent complication of familial lipoprotein lipase deficiency, but it does complicate severe hypertriglyceridaemia in which there is residual lipoprotein lipase activity. It is difficult to make a precise estimate of the risk from the hyperlipidaemia *per se* because it is so frequently associated with insulin resistance or frank diabetes, which are themselves risk factors for atherosclerosis. If these are included as part of the syndrome, both coronary heart disease and

peripheral arterial disease are common. The explanation for the only modest risk of atheroma in patients lacking lipoprotein lipase is not understood but it may be because the incidence of diabetes is not increased in familial lipoprotein lipase deficiency. Also fibrinogen and factor VII activity are not increased; it is also notable that the conversion of VLDL and chylomicrons to the atherogenic IDL and remnant lipoproteins, respectively, is impaired in the absence of lipoprotein lipase.

Although atheroma may not be directly due to the high levels of triglyceride-rich lipoproteins, other complications are: acute pancreatitis may occur when serum triglyceride levels exceed 20 to 30 mmol/litre (2000–3000 mg/dl) (see above). The presentation of acute pancreatitis is similar to that from other causes (see Chapter 14.18.3.1). However, the diagnosis may not be confirmed by detecting increased serum amylase activity, because falsely low values may be encountered due to interference by triglyceride-rich lipoproteins in the laboratory method. All laboratories should inspect plasma or serum samples for milkiness before reporting normal or only moderately raised serum amylase activity in patients with severe abdominal pain (Plate 4). Clinicians may otherwise wrongly exclude the diagnosis of acute pancreatitis in favour, for example, of perforated peptic ulcer. Some patients do not develop acute pancreatitis, even when serum triglyceride levels exceed 100 mmol/litre (9000 mg/dl). Others, who are more susceptible, experience recurring acute episodes. Generally the pain subsides within a few hours or days of commencing nasogastric aspiration and intravenous fluids with nothing taken by mouth. Occasionally, if such treatment is delayed, pancreatic pseudocysts or abscesses may develop. Recurrent abdominal pain, not typical of pancreatitis, sometimes occurs in patients prone to marked hypertriglyceridaemia. It may mimic irritable bowel syndrome. Severe abdominal pain may also sometimes be the result of splenic infarction.

Pseudohyponatraemia is another consequence of extreme hypertriglyceridaemia, which may lead to serious misdiagnosis if the artefact is unrecognized. Spuriously low serum sodium values are reported, because much of the volume of the serum aliquot on which the sodium measurement is made is occupied by lipoproteins rather than water. When the serum triglycerides exceed 40 to 50 mmol/litre (3500–4500 mg/dl) the concentration of sodium in the aqueous phase (and thus the serum osmolality) may be normal while spurious serum sodium levels of 120 to 130 mmol/litre are being reported. The hazard is that these will be misinterpreted by the clinician and a patient already seriously ill with pancreatitis, or occasionally uncontrolled diabetes, will be made worse by restricting fluid intake or the infusion of hypertonic saline.

Focal neurological syndromes such as loss of vision, hemiparesis, memory loss, and loss of mental concentration may complicate extreme hypertriglyceridaemia, perhaps because of ischaemia due to sluggish microcirculation caused by the high concentrations of chylomicrons in the blood. Uniocular visual loss due to occlusion of the retinal microcirculation may likewise complicate hypertriglyceridaemia and is an indication for rapid institution of lipid-lowering therapy, and possibly antiplatelet agents. Paraesthesiae, especially in the feet, may also be an occasional feature, even in the absence of diabetes. Sicca syndrome and polyarthritis have also been described, but undoubtedly the commonest articular association is gout (see below).

Moderate hypertriglyceridaemia (type IV)

Raised fasting serum triglyceride levels in the range 2.2 to 10.0 mmol/litre (200–900 mg/dl) in the absence of a cholesterol level exceeding 5.0 mmol/litre (200 mg/dl) are occasionally discovered. Diabetes and excess ingestion of alcohol are important causes. Sometimes marked hypertriglyceridaemia is present in a fit, non-obese person with none of these factors. Family studies may then reveal similar increases in relatives, when the condition is called familial as opposed to sporadic hypertriglyceridaemia. Epidemiological studies show a univariate association between plasma triglyceride concentration and the risk of coronary heart disease, but there is little evidence that triglycerides are directly causal. Hypertriglyceridaemia is associated with low levels of HDL and glucose intolerance. When patients with established coronary disease and hypertriglyceridaemia whose serum cholesterol does not exceed 5.0 mmol/litre (200 mg/dl), are encountered they generally have low levels of HDL cholesterol and may have an increased level of cholesterol-depleted, small, dense LDL which is not evident from their cholesterol level. Such patients are likely to benefit from lipid-lowering therapy. They also have a greatly increased risk of developing diabetes mellitus over the next few years.

Hypertriglyceridaemia increases the risk of any associated increase in serum cholesterol (Fig. 6(b)), but present evidence would not favour its treatment in the absence of hypercholesterolaemia as a means of primary prevention of coronary heart disease. Occasionally, triglyceride concentrations of 5 mmol/litre (450 mg/dl) or less must be treated if they occur in patients prone to periodic exacerbations of more severe hypertriglyceridaemia associated with acute pancreatitis. Generally, levels exceeding 10 mmol/litre justify therapy, but for levels between 5 and 10 mmol/litre individual judgement should apply. In diabetes, evidence that serum triglycerides are an independent risk factor for coronary heart disease has been considered by some authorities to justify lipid-lowering therapy at lower levels than in non-diabetics when improvements in diet and glycaemic control have failed to decrease hypertriglyceridaemia.

Secondary hyperlipoproteinaemias

Secondary hyperlipoproteinaemias are those which are caused by another primary disorder (Table 3). When a disease that has hyperlipidaemia as a complication occurs in an individual who has a primary hyperlipoproteinaemia, the two frequently synergize to produce markedhyperlipoproteinaemia. This means that in societies in which poly-genic hyperlipoproteinaemia is prevalent, secondary hyperlipoproteinaemia will have most impact. The best-known example of this is diabetes mellitus, which in Japan is only rarely complicated by coronary heart disease, whereas in the United Kingdom and the United States, coronary heart disease is the most common cause of premature death in diabetics.

Diabetes mellitus

The dominant hyperlipidaemia in diabetes is hypertriglyceridaemia. This is more likely to be associated with hypercholesterolaemia and with decreased HDL cholesterol in type 2 diabetes. Despite this, the risks of coronary heart disease and peripheral arterial disease are increased in both types 1 and 2 diabetes. This may be because in both disorders the hypertriglyceridaemia results not simply in an increase in VLDL, but also from an increase in IDL and a small triglyceride-rich, cholesterol-depleted LDL particle. Since neither of these may contribute greatly to an increase in lipids, the term dyslipoproteinaemia is particularly aptly applied in diabetes. Also, plasma fibrinogen levels, which are increased in both types of diabetes, relate to serum triglyceride levels. Although lipoprotein abnormalities in type 1 diabetes may be less frequent than in type 2, the risk of coronary heart disease in type 1 is more often compounded by the presence of proteinuria. In diabetes uncomplicated by proteinuria, the risk of coronary heart disease is about two to three times (Fig. 5) that of non-diabetic people of a similar age. Proteinuria increases the risk by as much as 40 times. This may stem partly from hypertension and an exacerbation of the dyslipoproteinaemia, both of which may reflect the development of proteinuria. However, the increase in risk is greater than can be explained in this way (see Chapter 11.11) and may result because the proteinuria reflects a generalized increase in the permeability of arterial endothelium, enhancing the entry of macromolecules into the subintima and thus accelerating atherogenesis (see above).

The increased blood glucose in diabetes mellitus results from insulin resistance, insulin deficiency, or both. Insulin resistance may be present in non-diabetic, usually obese, people who are still able to secrete sufficient insulin to maintain control of blood sugar, but in such people there is often hypertriglyceridaemia with low HDL cholesterol and hypercholesterolaemia, hypertension, and increased risk of coronary heart disease. This syndrome is often referred to as the insulin resistance syndrome (syndrome X) or chronic cardiovascular risk syndrome. Clearly it has features in common with familial combined hyperlipidaemia and also with diabetes. Indeed, a proportion of people with syndrome X ultimately develop diabetes, sometimes not until after they have already developed coronary heart disease. This may explain in part why glycaemic control in diabetes seems to have little impact in preventing its atheromatous complications.

Diabetic women, particularly those with type 2 disease, tend to have a distribution of adipose tissue resembling that of obese men, being mostly around the abdomen and waist rather than the more female pattern which involves the buttocks and thighs, but leaves the waist relatively small. The relative protection from coronary heart disease which most women have, even those with familial hypercholesterolaemia, is largely lost by diabetic women, and it has been suggested that this may result from this androgenization. Many women with a similar body habitus, but who have not yet developed diabetes, are insulin resistant, hypertensive, have hyperlipidaemia, and have an associated increased risk of coronary heart disease.

Other secondary hyperlipoproteinaemias

Obesity

Obesity is a potent cause of hyperlipidaemia and has most impact in people with glucose intolerance. In its own right, obesity predominantly causes hypertriglyceridaemia (usually type IV), but, there is no form of primary hyperlipidaemia that it will not exacerbate. It therefore frequently accompanies hypercholesterolaemia as well as hypertriglyceridaemia. The exception appears to be familial hypercholesterolaemia, which is not associated with obesity. Alcoholic beverages, particularly wine and beer, are energy rich and may be a cause of obesity. Alcohol itself also induces hypertriglyceridaemia. Weight loss is generally associated with decreases in serum cholesterol and triglyceride levels. Anorexia nervosa is paradoxical in that it may be associated with quite marked elevations of

serum cholesterol.

Thyroid failure

In hypothyroidism, serum LDL cholesterol and, less frequently, serum triglycerides are raised. Levels of HDL tend to be increased. There is decreased receptor-mediated LDL catabolism and lipoprotein lipase activity may be decreased. Hypothyroidism should always be considered in the diagnosis of hyperlipidaemia, and it is particularly important to exclude it when marked hyperlipidaemia occurs in women and in diabetic patients.

Renal disease

Renal disease is becoming an important cause of secondary hyperlipidaemia in clinical practice, because improvements in long-term renal management are now exposing coronary heart disease as the major cause of premature death in many renal disorders. In nephrotic syndrome the major lipoprotein disorder is a rise in serum LDL cholesterol. In chronic renal failure hypertriglyceridaemia is produced by an increase in both VLDL and in LDL triglycerides. Haemodialysis, chronic ambulatory peritoneal dialysis, and high-energy diets exacerbate the hyperlipidaemia. Following renal transplantation, many of the lipoprotein abnormalities resolve if good renal function is established, but corticosteroid therapy, weight gain, antihypertensive therapy, and perhaps cyclosporin treatment mean that even then hyperlipidaemia persists in about one-quarter of patients. Lipoprotein (a) is markedly elevated in renal disease, even after transplantation.

Drugs

Drugs are a common cause of hyperlipidaemia. b-adrenergic antagonists without intrinsic sympathomimetic activity raise triglycerides and lower HDL cholesterol. Thiazide diuretics tend to increase both cholesterol and triglycerides. These effects may be relatively small in people whose serum lipids are not elevated at the outset, but in patients with hypertriglyceridaemia or with diabetes they may be substantial. Oestrogens tend to raise serum triglycerides, but will often lower LDL cholesterol after the menopause. They also raise serum HDL. Androgens have the opposite effect, decreasing triglycerides, raising LDL cholesterol, and lowering HDL. They may contribute to premature cardiac death in athletes unwise enough to use them in training. Glucocorticoids increase serum LDL cholesterol and triglycerides and often HDL cholesterol. Retinoic acid derivatives used in the management of skin disorders cause hypertriglyceridaemia. Phenytoin and phenobarbitone raise serum HDL cholesterol.

Liver disease

Cholestatic liver diseases, such as primary biliary cirrhosis, produce hypercholesterolaemia. This is not due to an increase in apolipoprotein B-containing LDL, but to an abnormal lipoprotein, designated lipoprotein X (**LpX**), produced largely as the result of reflux of biliary phospholipids into the circulation. Xanthelasmas are common in biliary obstruction and other xanthomas occasionally develop. In the later phase of chronic biliary obstruction, when secondary biliary cirrhosis and hepatocellular disease sets in, hepatic lipid biosynthesis plummets and the hyperlipidaemia of biliary obstruction resolves. Hepatocellular diseases may be associated with moderate hypertriglyceridaemia, probably because of impaired hepatic lipoprotein clearance. Concentrations of HDL are markedly decreased and lecithin:cholesterol acyltransferase activity is low. Some authorities believe that this defect in cholesterol esterification contributes to the complications of liver failure.

Hyperuricaemia

Hyperuricaemia is present in as many as half the men with hypertriglyceridaemia. It may lead to gout, particularly if such patients are receiving diuretic therapy. The association of hypertriglyceridaemia and hyperuricaemia appears to be more common than can be entirely explained by the coincidence of common aetiological factors, such as obesity and high alcohol consumption. Yet they are not causally related, because specifically lowering one does not usually decrease the other. They must therefore have some unknown antecedent in common.

Management of hyperlipoproteinaemia

Clinical trials have established beyond all question of doubt that reduction of serum cholesterol decreases both coronary morbidity and mortality and can prolong survival. The risk of coronary heart disease ascribable to a particular cholesterol level does, however, vary widely in different individuals depending on the presence of other risk factors for coronary heart disease. Thus a serum cholesterol of 6.0 mmol/litre (230 mg/dl) in a 50-year-old woman with an HDL cholesterol level of 1.9 mmol/litre (75 mg/dl) who does not smoke and is neither hypertensive nor diabetic will carry a risk of a coronary event of 1 in 40 over the next 10 years, whereas in a man of similar age the same serum cholesterol associated with an HDL cholesterol value of 0.9 mmol/litre (35 mg/dl) who is hypertensive, smokes and has diabetes the risk will be 1 in 3 over the same time interval. His likelihood of benefit from a given reduction in cholesterol will thus be much greater than hers, although both have the same concentration of serum cholesterol. The coronary risk attaching to the cholesterol level in individual patients could, were it known with reasonable accuracy, thus guide the clinician in deciding how rigorously treatment should be given. Below a certain level of risk, treatment may be more trouble than it is worth for the patient's lifestyle, presence of mind, or pocket. For a state healthcare system too there will also be a level of risk below which the cost-effectiveness of cholesterol lowering may mean that resources should be directed to some more cost-effective clinical practice.

Another consideration, as with any therapeutic intervention, is that there may be side-effects of treatment which should limit it to those patients whose risk of the disease it is intended to prevent (in this case primarily coronary heart disease) is substantially higher than the potential risk of serious side-effects. Dietary management is generally viewed as safe, and meta-analyses of dietary trials show no increase in non-cardiac mortality. Until recently, however, cholesterol-lowering drugs were often viewed with suspicion. Since 1994, however, results from six clinical trials of statin drugs have established that these drugs are safe with adequate medical supervision during the 5 to 6 years of the trials. In that time the risk of coronary heart disease was decreased by one-third, the decrease becoming greater with more prolonged therapy. The lowest average annual coronary risk of participants in these trials was 1 per cent (one event per 100 people per year) and the highest 4.5 per cent. The relative reduction in risk of one-third was similar regardless of the level of risk, so a greater number of coronary events was prevented when the risk was highest. Other cholesterol-lowering drug therapies such as fibrates and bile acid sequestrating agents decrease coronary risk, but their safety and the magnitude of their overall benefit is not as clear as with statins, partly because design and analysis of clinical trials were better in the more recent statin trials. In a recently reported trial of men with established coronary disease and relatively low levels of serum cholesterol and HDL cholesterol, gemfibrozil was found to be both safe and effective. Other fibrate trials are under way.

The essential point to grasp is that the decision to treat hyperlipidaemia is not based simply on any particular cholesterol value, but on an assessment of individual risk of coronary heart disease. It is sensible to select for treatment those patients with a high overall probability of dying prematurely of coronary disease. If the balance of risk suggests that they are not, they will be exposed to any possible ill-effects of such treatment with no likelihood of benefit. The identification of patients with established coronary heart disease, familial hypercholesterolaemia, or with more modest increases in serum cholesterol combined with multiple risk factors, including a bad family history (Fig. 5 and Fig. 6 ((a) and (b)) allows the targeting of cholesterol-lowering management to high-risk individuals, who can benefit most. Charts which can assist in the assessment of coronary risk are to be found in Section 15.16.1.

Dietary management

It is generally agreed that dietary advice should be given to people whose serum cholesterol exceeds a concentration of 5.0 mmol/litre (200 mg/dl). In a country such as the United Kingdom, however, two-thirds of men and women between the ages of 18 and 69 years have cholesterol concentrations exceeding this value. Thus, except in the case of the patients considered to be at high coronary risk, individual dietetic supervision beyond the provision of a diet sheet is not reasonable. It is particularly important to remember that cigarette smoking is a greater cause of ill-health than are minor elevations of serum cholesterol, and advice to stop smoking should be reiterated whenever a medical consultation occurs.

The principal aims of a cholesterol-lowering diet are to reduce obesity by a decrease in dietary energy intake and to decrease saturated fat consumption. Fat is a major source of dietary energy and the reduction in its intake should be the main objective of any weight-reducing diet. In the non-obese, dietary advice should focus on decreasing saturated fat to below 10 per cent of dietary energy intake and substituting it with a mixture of unrefined carbohydrate and monounsaturated and polyunsaturated fats (Table 4). Polyunsaturates in the form of linoleic acid (corn oil, sunflower oil) should not be the only fats to replace saturated fat, because it is not certain that in large amounts they do not have harmful long-term effects. In patients with established coronary disease there is increasing interest in the long-chain omega-3 fatty acids such as those found in fish oil (Table 4) which are more unsaturated and reduce sudden cardiac death, probably by suppressing ventricular arrhythmias. Eating fatty fish twice a week is thus recommended. Increasingly, too, oils rich in monounsaturated oleic acid such as olive oil, present in the diet of Mediterranean people since time immemorial, are being encouraged by nutritionists as substitutes for saturated fat. Rapeseed oil, which is much cheaper, contains

almost as much oleic acid as olive oil. Dietary cholesterol itself, although featuring prominently on food labels, usually has a smaller effect on serum cholesterol concentrations than saturated fat. Decreasing its absorption with foods enriched in plant sterol or stanol esters has a small hypocholesterolaemic effect, as also does mucilaginous fibre in fruit, vegetables, and oats. Avoiding coffee is probably pointless. Some authorities believe that the epidemiological evidence indicating that alcohol is protective against coronary heart disease is strong enough to justify encouraging moderate indulgence (red wine finds particular favour in view of the lower risk of coronary heart disease in southern as opposed to northern Europe). However, alcoholic beverages in excess can lead to obesity, hypertension, atrial fibrillation, and to exacerbation of hypertriglyceridaemia (see above), and a trial of abstinence should be considered in the patient with hyperlipidaemia suspected of overindulgence.

These dietary aims do not need to be modified for the treatment of moderate hypertriglyceridaemia and are also suitable for the management of diabetes. Carbohydrate-restricted diets are no longer in general use for either of these purposes. In patients with severe hypertriglyceridaemia it is necessary to limit the production of chylomicrons and so any fat in the diet must be avoided. Often a 25 to 30 g low-fat diet (in which, if the patient is not obese, carbohydrate is substituted to maintain dietary energy intake) can be employed, but occasionally even lower fat intakes must be achieved. Lipid-lowering drugs are frequently ineffective in patients with severe hypertriglyceridaemia, whereas dietary treatment can be particularly effective. Admission to a specialized centre with experienced dietetic services is often desirable.

Drug therapy of hyperlipidaemia

The indication for drug therapy is not the failure of serum cholesterol concentration to decrease below some arbitrary level despite dietary treatment in all patients. There are people with serum cholesterol concentrations as high as 8 mmol/litre (310 mg/dl) whose risk of coronary heart disease is not sufficiently high to justify the use of lipid-lowering drugs. However, when coronary risk is high there is no scientific basis for choosing different cholesterol (or LDL cholesterol) concentrations as thresholds for intervention or as therapeutic targets. Generally if the patient is in one of the following high-risk categories lipid-lowering therapy should be instituted if the serum cholesterol persists about 5.0 mmol/litre (200 mg/dl) (LDL cholesterol > 3.0 mmol/litre (> 120 mg/dl) and the aim of treatment should be to decrease serum cholesterol to less than 5.0 mmol/litre (200 mg/dl) (LDL cholesterol < 3.0 mmol/litre (< 120 mg/dl) or by 25 per cent (LDL by 30 per cent), whichever is the lowest. Whether dietary management should be instituted at the same time as lipid-lowering drug therapy or before in order to establish whether it alone will suffice is determined by the degree of risk and the degree to which the serum cholesterol is elevated. Dietary management does not typically decrease serum cholesterol by more than 0.5 mmol/litre (20 mg/dl). Certainly in patients with established CHD, statin treatment should be introduced without delay. The high risk categories are discussed in the subsections below.

Patients with established coronary heart disease or other significant atherosclerotic disease

Secondary prevention trials of cholesterol lowering using statin drugs provide strong evidence of prolonged survival due to a decrease in coronary events and strokes. Coronary angiography also provides evidence of regression of atheroma with lipid-lowering therapy. Lipid-lowering drugs are therefore indicated in patients with coronary heart disease (including those who have undergone coronary surgery or angioplasty). It is probably reasonable to extend this policy to patients with peripheral arterial, aortic, or significant carotid atherosclerosis, because there are angiographic studies to demonstrate favourable effects of lipid-lowering therapy on femoral and carotid atheroma and because this type of disease is closely associated with risk of coronary heart disease.

Familial hypercholesterolaemia and type III hyperlipoproteinaemia

The high risk of coronary heart disease and the known metabolic defects in these conditions justifies the use of lipid-lowering drug therapy. Familial hypercholesterolaemia should, if possible, be detected in childhood or early adulthood, and the age at which statin therapy should be commenced has therefore to be considered. Generally in boys a statin should be prescribed by the age of 20 years whereas in many women it can be left until the age of 30 years (discontinuing it temporarily if there is any possibility of conception). Some authorities advocate the earlier use of statins and this should certainly be considered if the family history of coronary disease is particularly adverse.

Patients with type III hyperlipoproteinaemia are generally encountered in adulthood and treatment should be initiated with a fibrate drug in all save the minority who respond to dietary management alone. It should not be assumed that dietary control is adequate if any degree of hypertriglyceridaemia persists, because this generally indicates that significant b-VLDL is still present in the circulation.

Multiple risk factors

The risk of coronary heart disease in some patients with additional adverse factors, whose serum cholesterol remains elevated despite diet, justifies the use of lipid-lowering drugs. Just how high the risk needs to be, and how it can be determined with any degree of exactitude, is a persisting problem for the clinician. Most national and international recommendations for primary prevention of coronary heart disease provide a means of assessing an individual patient's risk (usually based on the equation derived from the Framingham study by Anderson and colleagues) to assist in the clinical decision as to when to introduce lipid-lowering medication and increasingly when to treat mild hypertension. The National Cholesterol Education Program recommends an algorithm and recommends treatment at lower levels of risk than in Europe. The Joint European Guidelines recommend 20 per cent over 10 years as an appropriate threshold of coronary risk for statin therapy. In the Joint British Guidelines the minimum level of care is considered to be treatment when coronary risk is 30 per cent or more over 10 years, but that ideally a 10-year risk of 15 per cent or more should be targeted. A computer program is available from the British Hypertension Society website (www.hyp.ac.uk/bhs/management.htm) and the Family Heart Association website (http://www.familyheart.org/) for the prediction of both coronary and stroke risk. The author's own practice is to target 20 per cent and above. It is always important to seek evidence of existing coronary heart disease, since, if present, this clarifies the decision to start lipid-lowering therapy, and justifies investigation in its own right.

Diabetes mellitus

The relative reduction in coronary risk in patients with diabetes thus far included in statin trials is at least as great as in the non-diabetic participants. Because of the higher coronary risk in diabetes this means that even greater benefit, in terms of new events prevented, accrues from statin treatment than in non-diabetics. Results of statin and fibrate trials specifically conducted in diabetes are awaited. However, current evidence strongly supports the use of statin therapy in diabetic patients with coronary heart disease or any other atherosclerotic complication. What is uncertain is whether in the primary prevention of coronary disease diabetic patients should be stratified according to risk to determine when they receive lipid-lowering drug treatment as in non-diabetics or whether they should be a special category who are all treated in the same way as patients with established coronary heart disease. The latter approach, which has been adopted by the American Diabetic Association, would mean that most patients with serum cholesterol exceeding 5.0 mmol/litre (200 mg/dl) should receive statin therapy. In favour of this approach is the knowledge that coronary risk is substantially higher in diabetics for any given concentration of cholesterol than in non-diabetics, that prediction methods are likely to underestimate risk in non-insulin-dependent diabetes, and that there is no reliable method for predicting risk in insulin-dependent diabetes.

Markedly elevated cholesterol with no other risk factors and no clearly identifiable genetic syndrome

Many people fall into this category. Some will have familial hypercholesterolaemia but have not yet developed tendon xanthomas. Knowledge that a relative has these should weigh heavily in the decision to introduce therapy. The combination of high cholesterol with raised triglycerides and low HDL and an adverse family history also favours the introduction of lipid-lowering drug therapy even in the absence of other risk factors (see above). The risk will be underestimated from coronary risk prediction charts or computer programs when there is an adverse family history or hypertriglyceridaemia. If the risk cannot be read from the charts because the ratio of serum to HDL cholesterol is too high, treatment may in any case be justified.

In women with isolated hypercholesterolaemia who are peri- or postmenopausal, the possibility of prescribing hormone replacement therapy can be considered, particularly if the menopause is surgical or spontaneously premature, or if there are also menopausal symptoms. Hormone replacement therapy often decreases LDL cholesterol and may increase HDL cholesterol. However, at present there is no randomized, placebo-controlled clinical trial evidence that this therapy is beneficial in preventing coronary heart disease. Care should be exercised in patients with hypertension (because of the salt-retaining effects of progestogen), in patients with established coronary heart disease (because of its possible thrombogenic effects), and in patients with hypertriglyceridaemia (which sex steroids exacerbate). In women at high risk of coronary disease the quality of evidence in favour of statin therapy means that reliance should not be placed on hormone replacement therapy as a means of coronary prevention.

Lipid-modifying drugs

No major therapeutic decision, such as the introduction of a particularly restrictive diet or of lipid-modifying drug therapy, should be taken as the result of a single cholesterol determination, because this will be influenced both by biological and by laboratory variation. A laboratory result for cholesterol concentration is generally within ± 10 per cent of the true mean value, but may occasionally fluctuate more widely. Increasingly, portable or 'on-site' cholesterol analysers are being used in an attempt to make cholesterol measurement as immediate for the clinician as that of blood pressure. This has some advantages, but it must be remembered that such tests may be more expensive than those performed in the laboratory, they are generally less accurate unless performed by someone who is trained and regularly uses the instrument, and the calibrations usually differ from those employed in hospital laboratories.

Non-fasting cholesterol concentrations are satisfactory for the management of patients responding to simple dietary measures, but for those in whom drug therapy is under consideration, two fasting determinations of cholesterol, triglycerides, and HDL cholesterol are generally necessary (serum cholesterol and HDL cholesterol concentrations are not affected by meals, but serum triglyceride levels are). Knowledge of the HDL and triglyceride levels is essential at this stage because abnormal values for these would be an additional factor in favour of lipid-lowering drug therapy, and because their concentration may influence the choice of drug. Fasting blood glucose and serum creatinine and transaminases should also be measured, and urine should be tested for protein. Serum thyroxine should be measured if there is any suspicion of hypothyroidism, and some authorities advocate its measurement in all patients whose serum cholesterol exceeds 8 mmol/litre (310 mg/dl) even if hypothyroidism is not clinically evident.

The first-line therapy in all forms of hypercholesterolaemia, except that associated with triglyceride levels exceeding 5 mmol/litre (200 mg/dl), are the statin drugs (3-hydroxy-3-methylglutaryl CoA reductase inhibitors)—atorvastatin, fluvastatin, lovastatin, pravastatin, rosuvastatin, and simvastatin. These agents are often effective, even in marked hypercholesterolaemia, as monotherapy. They also have a triglyceride-lowering effect, which tends to be related to the extent to which they lower cholesterol but which is generally less than with a fibrate drug. Evidence that statins decrease coronary events is provided by three large secondary prevention trials using simvastatin or pravastatin, two primary prevention trials which employed pravastatin or lovastatin, and one trial which combined primary and secondary prevention patients and involved simvastation. Advantage may be taken of the synergism of statins with bile acid sequestrating agents (cholestyramine and colestipol), by prescribing two sachets in the morning with an evening dose of statin, in patients resistant to statins alone. Their use in combination with fibrate drugs requires strict clinical supervision, because there is an increased risk that myositis may ensue. There is a small incidence of this occurring spontaneously in patients on statins, and creatine kinase levels should be monitored. Erythromycin and cyclosporin also increase the risk of myositis, and care must be taken if statins are used after cardiac or renal transplantation. Statins may be particularly valuable in patients with renal disease in whom fibrates are contraindicated and in whom bile acid sequestrating agents may exacerbate hypertriglyceridaemia; these latter agents are particularly poorly tolerated in patients already receiving multiple drug regimes.

Bile acid sequestrating agents can be used in the treatment of hypercholesterolaemia in the absence of hypertriglyceridaemia, which they may exacerbate. A dose (two sachets) is best taken well soaked in fruit juice before breakfast. In larger more frequent doses these agents often cause nausea, heartburn, and constipation. Generally for this reason they have been increasingly relegated to the sidelines since the introduction of statins. In children and women of child-bearing potential, who have heterozygous familial hypercholesterolaemia and in whom drug therapy is justified because of a particularly adverse family history, the author remains reluctant to turn to other agents, although it is often better to wait until it is safe to commence statin treatment (which is better tolerated) than to alienate the patient from the clinic with unpalatable treatment earlier. If they are prescribed, folate and vitamin D supplementation should be considered, particularly in women who may become pregnant.

In patients whose hypercholesterolaemia is combined with more marked hypertriglyceridaemia, the fibrate drugs (bezafibrate, ciprofibrate, fenofibrate, gemfibrozil) are first-line therapy. They are also often highly effective in type III hyperlipoproteinaemia and useful in primary type V hyperlipoproteinaemia and in the dyslipoproteinaemia of diabetes mellitus. Fibrates are less effective in lowering LDL cholesterol than are statins. Most of their cholesterol-lowering effect is due to a decrease in VLDL cholesterol. They do, however, decrease small dense LDL levels. This is not readily evident from routine laboratory tests, because it is unaccompanied by any substantial reduction in cholesterol. In some particularly high-risk patients with combined hyperlipidaemia statin therapy may be added to fibrate therapy in order to satisfactorily lower LDL cholesterol. The fibrate drugs raise HDL cholesterol by more than statins. They must be avoided in patients with disturbed hepatic or renal function. They potentiate anticoagulants. The mode of action of fibrate drugs, which diminish serum triglyceride levels by stimulating lipoprotein lipase and decreasing circulating non-esterified fatty acids (NEFA), probably involves stimulation of the nuclear peroxisome proliferator-activated receptor a.

Nicotinic acid (niacin) can be used to lower serum cholesterol and triglyceride levels. The effective dose is usually associated with unpleasant flushing. This can be minimized if aspirin is taken before the nicotinic acid. There are also many other side-effects, and liver function must be monitored. Nicotinic acid has not found great therapeutic favour outside the United States. Unlike other lipid-lowering drugs, it is effective in lowering serum Lp(a). Acipimox, a niacin analogue, has a similar spectrum of action to the fibrate drugs and causes less flushing. Probucol is a cholesterol-lowering drug, which lowers HDL cholesterol relatively more than LDL. Despite its undoubted antioxidant properties, it requires further clinical evaluation before it can be regarded as beneficial in its overall action and is now of limited availability. Fish oil pharmacological preparations have triglyceride-lowering properties in daily doses of several millilitres, but do not lower LDL cholesterol and may even exacerbate diabetic hyperlipidaemia. Preparations which concentrate the omega-3 long-chain fatty acids, eicosapentaenoic and docosahexaenoic acid (Table 4), may have greater therapeutic potential. Fish oil improves survival after myocardial infarction in doses which have little effect on serum triglycerides and may relate to a decreased likelihood of ventricular arrhythmias.

Non-pharmacological lipid-lowering treatment

In addition to pharmacological agents and diet, extracorporeal removal of LDL is available in many centres for severe hypercholesterolaemia, usually homozygous familial hypercholesterolaemia in which it improves survival. Plasmapheresis or LDL apheresis, using systems that absorb LDL, are the two methods employed. Plasmapheresis and most methods of LDL apheresis also lower serum Lp(a). They must be repeated every 2 to 4 weeks. Occasionally, patients with homozygous familial hypercholesterolaemia have also been treated with liver transplantation to provide an organ with normally functioning LDL receptors. Partial ileal bypass surgery has been used to treat heterozygous familial hypercholesterolaemia (it is ineffective in homozygotes), but with the advent of more effective lipid-lowering drugs this is now very rarely necessary.

Hypolipoproteinaemia

Hypolipoproteinaemia is increasing as a clinical problem, because more cases are being discovered as a result of population screening for high cholesterol. People who have had a low serum cholesterol level all their lives do not seem to be at any disadvantage unless the decrease is profound, as in abetalipoproteinaemia. Indeed, their relative freedom from cardiovascular disease may lead to longevity. When the condition is discovered for the first time it is often difficult, however, to be sure that the low cholesterol is not due to an acquired disease, such as malignancy (for example colonic or prostatic neoplasms, leukaemia, reticulosis, or myeloma) or malabsorption (due, for example, to a short bowel, blind-loop syndrome, coeliac disease, pancreatic exocrine insufficiency, or giardiasis).

Some people with serum cholesterol levels around 1.0 to 3.5 mmol/litre (40 to 140 mg/dl) will have heterozygous familial hypobetalipoproteinaemia, an autosomal dominant condition in which truncated apoB mutations have been described. The condition is benign. However, homozygous hypoapobetalipoproteinaemia and another condition, abetalipoproteinaemia (inherited as an autosomal recessive), which produce more profound hypocholesterolaemia, are associated with retinitis pigmentosa, unusually shaped erythrocytes (acanthocytes), a syndrome resembling Friedreich's ataxia (preventable with administration fat-soluble vitamins), steatorrhoea (which can create diagnostic confusion with other causes of malabsorption leading to secondary hypocholesterolaemia), and fatty liver. Mutation of the *MTP* gene rather than of the apoB gene is associated with apobetalipoproteinaemia.

Analphalipoproteinaemia (Tangier disease) is a very rare autosomal recessive disorder with virtually absent HDL, reduced LDL cholesteryl ester, and cholesteryl ester deposition throughout the body, leading to enlarged orange-yellow tonsils and adenoids, lymph node enlargement, hepatosplenomegaly, bone marrow infiltration (thrombocytopenia), orange-brown spots on the rectal mucosa, neuropathy, and corneal cloudiness. Heterozygotes for this condition are at increased risk of premature coronary artery disease. A less severe form of this disorder (fish-eye disease) has been described. In another disorder, combined deficiency of apoA-I and apoC-III due to a rearrangement of DNA affecting the transcription of both their genes, which are clustered together on chromosome 11, leads to markedly decreased serum HDL levels, accelerated atherosclerosis, and corneal opacities. Some authorities believe that a much more common genetic HDL deficiency is the cause of HDL cholesterol levels in the lower 10 per cent of the frequency distribution. Evidence for this contention is incomplete.

11.7.1 Hereditary haemochromatosis

T. M. Cox

Definition

Haemochromatosis is an hereditary disorder generally caused by inappropriate absorption of iron by the small intestine that leads to iron deposition in the viscera, in endocrine organs, and at other sites. The toxic effects of iron impair the function of these organs and cause structural injury. Haemochromatosis cannot be diagnosed in the absence of excess tissue iron, and there is strong evidence for a cause-and-effect relationship between tissue iron storage and parenchymal injury. Several genetic syndromes associated with iron storage have been identified (Table 1); these may rarely involve specific tissues selectively, such as the lens of the eye or basal ganglia of the brain, or a characteristic range of tissues including the liver, heart, and endocrine system. By common agreement, the term 'hereditary haemochromatosis' refers to a group of inherited iron-storage diseases that affect diverse tissues and cause a multisystem disorder.

Pathological storage of iron

The body contains about 4 g of iron, 3 g of which is complexed with haem to form haemoglobin, myoglobin, and the cytochromes. The non-haem storage compartment, which consists of ferritin and its proteolytic degradation product, haemosiderin, represents up to 0.5 g of elemental iron in adult women and slightly more than 1 g in adult men. Excess storage of body iron (iron overload) is associated with an increase in hepatic iron concentrations and of the surrogate biomarker, serum ferritin. Minimal iron storage occurs when more than 1.5 g of total body iron is present; this is reflected in a hepatic iron concentration of approximately 30 µg atoms/g of tissue with a serum ferritin level of usually less than 250 µg/litre. Moderate iron-storage disease is reflected by a serum ferritin of approximately 500 µg/litre; under these circumstances the hepatic iron concentration rises to 100 µg atoms/g. Severe iron-storage disease (more than 5 g of storage iron) is shown by a hepatic iron concentration over 200 µg atoms/g liver tissue, with a serum ferritin level of at least 750 µg/litre—under these circumstances, tissue injury with impaired function is almost invariably present.

Clinical subtypes of haemochromatosis

Adult haemochromatosis

The familiar form of haemochromatosis is the classical adult type, which typically presents in middle age and is usually expressed in men. The disorder is inherited as a recessive trait and is due to mutations in a gene, *HFE*, that maps to the short arm of chromosome 6 in close apposition to the HLA class I loci of the human major histocompatibility complex (MHC). Expression of iron-storage disease in individuals carrying mutations in the *HFE* gene is very variable and is influenced by several environmental and sexual factors. Mutant alleles of the *HFE* gene that predispose to adult-type haemochromatosis are widespread and frequent in populations of North European origin. There is evidence from haplotype analysis that a single mutation arose on an ancestral chromosome 6 and spread throughout this population, probably as a result of the migration of the Vikings from Scandinavia. The disease occurs throughout the world as a result of intermarriage but is at its highest frequency in France, Germany, Great Britain, Scandinavia, Ireland, Northern Italy, Spain, and Eastern Europe as far as European Russia. Colonization has led to its appearance in all populations of the United States and in Australasia; for this reason hereditary adult-type haemochromatosis also occurs in South America.

Classical adult-type haemochromatosis is a slowly progressive disease affecting the liver, endocrine system, heart, and joints; it is often only diagnosed when irreversible tissue injury has occurred. The condition predisposes to the development of primary carcinomas of the liver. Other, rare, genetic forms of adult haemochromatosis occur in patients homozygous for mutations in the transferrin receptor gene type 2 (*TFR 2*) and in those heterozygous for mutant alleles of the human ferroportin gene.

Juvenile haemochromatosis

Since the identification of adult iron-storage disease by several European physicians during the nineteenth century, a similar disease has been recognized in children and young adults who may develop iron-storage disease of a more severe character, and which is now designated 'juvenile haemochromatosis'. Juvenile haemochromatosis is defined as iron-storage disease occurring before the age of 35 years; it evolves rapidly, typically affects the heart and endocrine system, and causes infantilism and hypogonadism as well as life-threatening cardiac arrhythmias. Juvenile haemochromatosis is inherited as a very rare recessive trait in which there is an increased frequency of consanguinity amongst the parents of affected subjects. Juvenile haemochromatosis resembles the severe iron-storage disease associated with the iron-loading anaemias, such as b-thalassaemia. Juvenile haemochromatosis affects males and females equally—an observation that reflects the overwhelming nature of the iron homeostatic defect: iron overload develops before the modifying effects of menstruation and dietary factors supervene. Recent studies have mapped at least one form of juvenile haemochromatosis to the long arm of chromosome 1. At the time of writing, the nature of the product of this gene is unknown.

Neonatal haemochromatosis

Neonatal haemochromatosis is a newly identified syndrome of uncertain cause, characterized by congenital cirrhosis or fulminant hepatitis associated with the

widespread deposition of iron in hepatic and extrahepatic tissues. Approximately 100 cases of neonatal haemochromatosis have been reported. Neonatal haemochromatosis occurs in the context of maternal disease—including viral infection, as a complication of metabolic disease in the fetus, and sporadically or recurrently, without overt cause, in siblings. In some families, although neonatal haemochromatosis appears to have an hereditary basis, no predictive genetic test is available to inform the outcome of at-risk pregnancies.

Prevalence and epidemiology

Juvenile and neonatal haemochromatosis are rare disorders that occur sporadically, but hereditary adult haemochromatosis is widely disseminated and of global importance. Removal of toxic iron by repeated venesection improves the outcome for adult haemochromatosis. If this treatment is instituted before irreversible tissue injury occurs, venesection may restore health and a normal life expectancy. For these reasons, there has been much discussion about the early recognition of iron-storage disease by the introduction of population-based screening programmes (using genetic testing or phenotypic biochemical screening methods) that can be applied to communities at risk.

In European populations, about 1 in 10 individuals carries one copy of an allele of the *HFE* gene that predisposes to iron-storage disease, and between 1 in 100 and 1 in 400 persons in these populations are homozygotes or compound heterozygotes with biochemical abnormalities of iron storage that may lead to full-blown clinical haemochromatosis. Thus the mutant allele, designated *C282Y* of *HFE*, which is the principal determinant of iron-storage disease, occurs at polymorphic frequency and is one of the most common genetic abnormalities leading to an autosomal recessive disease in populations of North-European origin. In European patients with iron-storage disease due to hereditary haemochromatosis, the frequency of homozygosity for the *C282Y HFE* allele ranges from about 35 per cent in Southern Italy to more than 90 per cent in the British Isles, including Ireland; in Australia, homozygosity for *C282Y* occurs in almost 100 per cent of patients with hereditary haemochromatosis. However, as discussed later, although useful for diagnosis, homozygosity for the *C282Y* mutation of *HFE* is **not** tantamount to a diagnosis of established iron-storage disease nor, therefore, of clinical haemochromatosis.

Clinical expression of haemochromatosis is highly dependent on age and it is very rare for there to be detectable disease in adults below the age of 20 years. As clinical disease is much more common in men than women, it is likely to reflect environmental factors and the modification of disease expression due to blood loss associated with menstruation and the investment in pregnancies, as well as the comparatively reduced dietary complement of iron in women. Other environmental factors, particularly the consumption of alcohol, appear to interact with predisposing genetic factors to induce the clinical expression of iron-storage disease in *C282Y* homozygotes. Most patients with the disease develop symptoms at, or above, the age of 40 years. However, studies of iron metabolism by biochemical measurements or tissue biopsy may reveal early evidence of iron storage in the long presymptomatic phase of this condition. With greater awareness of the diverse clinical manifestations of adult-type hereditary haemochromatosis, detection on the basis of early symptoms, for example arthritis or endocrine disease, may be possible. Thus, although the mutations that predispose to the development of haemochromatosis as a clinical entity are frequent in populations of European ancestry, there is a marked disparity in populations in which *C282Y* homozygosity is prevalent and the frequency with which symptomatic haemochromatosis is diagnosed.

Phenotypic expression of disease

For epidemiological purposes, since there is no internationally agreed case definition of haemochromatosis, caution is needed in interpreting claims that haemochromatosis is the most common inherited disorder affecting European peoples. Phenotypic expression of disease may range from the established clinical syndrome (cutaneous pigmentation, cardiomyopathy, endocrine failure—especially diabetes mellitus and hypogonadism, arthritis, and pigment cirrhosis) to a slight abnormality of blood parameters that reflect iron metabolism—elevated serum transferrin iron saturation and serum ferritin measurements. Such studies that are available to determine the penetrance and expressivity of the haemochromatosis gene have provided widely varying results in different populations: in Australia, where the mean intake of iron in the diet appears to be much greater than in the average European population today, most middle-aged male *C282Y* homozygotes appear to express at least one clinical manifestation of iron-storage disease. Similarly, a study of homozygous relatives (principally siblings) within pedigrees known to have haemochromatosis suggest that about half the men over 40 years of age, and about 1 in 6 of the women over 50 years of age, have at least one haemochromatosis-related clinical disorder. This latter survey, conducted in the United States, suggests that an important proportion of homozygous relatives of patients with established haemochromatosis, especially men, have conditions such as cirrhosis and arthropathy as well as abnormalities of serum liver-related tests that are not detected by spontaneous clinical referral.

Many reports of disease expression in haemochromatosis may, however, be questioned because of the prevalence of co-segregating genes within affected pedigrees, as well as early household environmental factors common to siblings that may predispose to disease expression. Studies in mice support this explanation, since it has been shown that several independent genetic determinants control the extent of iron-loading observed in mouse models of iron-storage disease generated by targeted disruption of the murine homologue of the *HFE* gene. In contrast, surveys conducted in outbred populations, for example in Jersey, show a great disparity between the predicted frequency of homozygosity for *C282Y* and the number of recorded cases with the disease attending local hospitals. These latter studies may reflect the widely suspected inability of clinicians to diagnose haemochromatosis, and an inability to bring together the unitary clinical manifestations of the disease into a unifying diagnostic category. However, widely differing degrees of disease penetrance almost certainly account for the apparent shortfall of diagnosed cases in populations at risk.

At present, no clear data in large unbiased population surveys are available to assess disease penetrance and the modifying effects of lifestyle factors (including alcohol, nutrition, diet) as well as pregnancy and menstruation that are likely to influence the effects and rate of iron storage in human *C282Y* homozygotes. Mortality figures show that death is rarely attributed to hereditary haemochromatosis in populations at risk. This fact contrasts starkly with the well-established known complications of the fully penetrant clinical syndrome, in which early death results from cirrhosis of the liver, hepatocellular carcinoma, endocrine failure or cardiac complications.

A contemporary study that examined the frequency of the most common symptoms of haemochromatosis in *C282Y* homozygotes, *C282Y/H63D* compound heterozygotes, and persons wild-type at these loci has been reported from California. In more than 41 000 individuals attending a health appraisal clinic, no evidence of an increased frequency of symptoms was identified in those genetically predisposed to iron-storage disease. The only significant clinical history identified in the at-risk group was that of 'hepatitis' or prior 'liver complaints'; only one of the 152 identified *C282Y* homozygotes had signs and symptoms of adult haemochromatosis. This provocative report, indicating a very low clinical penetrance (less than 1 per cent) of the haemochromatosis genotype in an unusual group of adults over the age of 26 years, raises important questions about the introduction of mass population screening for this potentially treatable iron-storage disease by genetic or even biochemical methods. However, the high prevalence of impotence, joint symptoms, chronic fatigue, and other complaints such as cardiac arrhythmias in the study group as a whole, raises disturbing questions about the valid application of this report to other populations. It is perhaps not surprising that in a group where, on average, more than 40 per cent complained of a general limitation of their health and/or joint symptoms, and in which more than 35 per cent of the male participants scored positively on symptom enquiry about impotence, a significant contribution from predisposing haemochromatosis alleles could not be identified. Nonetheless, this large study raises key questions about the utility of screening for adult haemochromatosis as a genetic disease. Before screening for haemochromatosis is introduced, there is clearly a need for other population surveys to be carried out in which the morbidity and mortality of individuals with the wild-type genotype as well as those harbouring disease alleles are investigated.

Pathophysiology and pathogenesis

Young patients with haemochromatosis absorb an increased amount of dietary iron in their upper intestine compared with normal control subjects. In established iron-storage disease, iron absorption continues at a rate that is inappropriate for the level of iron stores as reflected by serum ferritin and tissue iron determinations.

In the absence of an effective excretory pathway, the increased absorption of iron by the intestine leads to a progressive accumulation of the metal in the parenchymal cells of the liver, heart, endocrine glands, and specialized B-type synoviocytes. Excess iron accumulates in the pancreas where it is found in both acinar and endocrine cells of the islet, although there is a particular predisposition in the early phases of iron loading to the islet beta-cell. Iron also accumulates to toxic levels in the gonadotrophs of the anterior hypophysis, leading to hypogonadotrophic hypogonadism. Iron may accumulate in the adrenal gland, where it is concentrated particularly in those cells that secrete aldosterone, in the zona glomerulosa. Iron accumulates in the cardiac myocytes and conducting tissue of the heart, in the chief cells of the parathyroid, and in parenchymal cells throughout the body. The consequences of toxic iron storage include diabetes mellitus, cirrhosis of the liver, cardiomyopathy with or without conduction defects, hypogonadism, arthritis with chondrocalcinosis, adrenocortical deficiency, and, rarely, hypoparathyroidism. Evidence for the intrinsic toxicity of iron in haemochromatosis is provided by the regression of the pathological changes following measures taken to reduce iron, for example the use of iron chelators and removal of body iron by venesection. Venesection stimulates the mobilization and removal of iron from the storage compartment by increasing the demand for red cell production in the bone marrow.

Mechanism of iron toxicity

High concentrations of iron salts are toxic to cultured cells. The administration of iron chelates to experimental animals has induced diabetes with iron loading in the liver and pancreas as well as the generation of (renal) carcinomas. Injections of iron salts induce local sarcomas in experimental animals, with evidence of species susceptibility. In humans, sarcomas or carcinomas have arisen, albeit rarely, at sites of therapeutic injections of iron, and it is possible that the complications of silicosis and asbestos exposure result from the complement of iron associated with these particulates. A wealth of indirect but corroborative evidence indicates that the primary effect of excess free iron is to promote the formation of oxygen free radicals, which mediate the damage to cells and tissues that is observed in iron-storage disease. In established haemochromatosis, the iron-binding capacity of plasma transferrin may be exceeded so that a proportion of the iron present in the blood remains reactive as a low-molecular-weight species only loosely attached to plasma proteins. Non-transferrin iron in human plasma stimulates the peroxidation of unsaturated lipids and can form reactive complexes that react with DNA—thus suggesting a mechanism for genome toxicity and carcinogenesis related to iron overload. Iron is highly electroreactive, and coupling of the Fenton and Harber–Weiss reactions leads to the formation of hydroxyl radicals as a result of the catalytic interactions between superoxide and ferric ions. Tissues with significant iron storage show peroxidative injury in membrane lipid fractions.

The lysosomal compartment appears to be particularly susceptible to iron-mediated damage, since iron in the form of ferritin and its degradation product, haemosiderin, accumulates within lysosomes to form the particulate ferrugineous granules known as 'siderosomes'. In haemochromatosis, there is an increased activity of lysosomal enzymes with biochemical evidence of increased lysosomal fragility indicating disruption of the integrity of the lysosomal membrane by iron; these changes revert to normal when the tissue iron is removed by venesection or by the use of specific iron chelators. It seems likely that the electrochemical reactivity of iron and its particular propensity to accelerate the formation of oxygen free radicals mediate its injurious effects on cell membranes, as well as the nuclear genome leading to cancerous change. However, despite great advances in the understanding of free-radical chemistry, the cause-and-effect relationship between iron storage and tissue injury is difficult to prove unequivocally. Nonetheless, much experimental evidence points to the development of iron-mediated peroxidative injury of cellular membranes including the lysosome, as well as iron-mediated genotoxicity. Whatever their physiochemical basis might be, common mechanisms of iron toxicity clearly exist, since the pathological and clinical manifestations of all iron-storage syndromes, including secondary haemochromatosis associated with blood transfusion and the iron-loading anaemias, are almost identical.

Pathology of iron storage

Heavy deposits of iron in the tissues are associated with fibrosis and cell loss. Simple inspection reveals an overt rust-like discoloration of the liver, spleen, pancreas, heart, and lymph nodes. The liver is usually enlarged; haemosiderin is found in all cell types with the formation of fibrous septa and hyperplastic nodules. These nodules, which may be the forerunners of adenomas and hepatocellular carcinomas, contain little stainable iron—unlike the adjacent parenchyma.

The dominant site of iron deposition during the early phases is within hepatocytes but soon iron loading may be observed in all cell types, including the lining cells of biliary canaliculi, Kupffer cells, and stellate cells (Fig. 1 and Fig. 2 and Plate 1 and Plate 2).

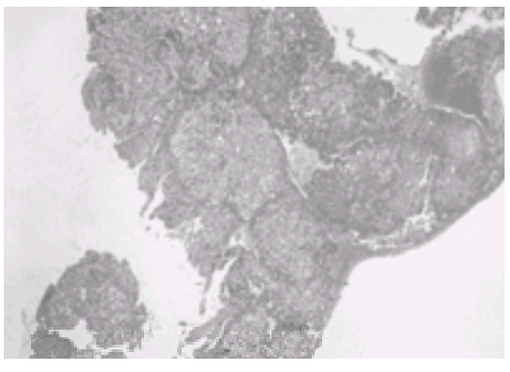

Fig. 1 Low-power, needle-biopsy appearance of liver specimen stained with haematoxylin and eosin from a 67-year-old man with adult haemochromatosis due to homozygosity for the *C282Y* mutation. Note the large hyperplastic nodules and fibrosis. (See also Plate 1.)

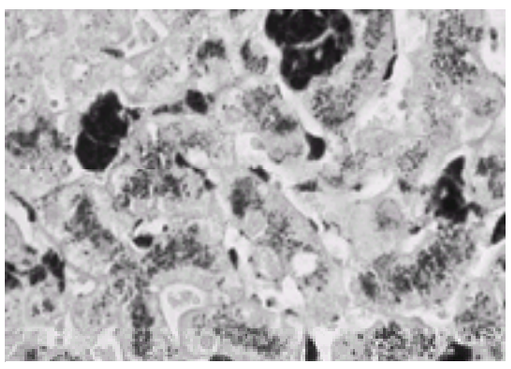

Fig. 2 High-power micrograph of the liver biopsy specimen shown in Fig. 1 stained with Perls' reagent. Note extensive deposits of ferric iron in all cell types including Kupffer cells, cells lining small biliary radicles, and in a punctate distribution within parenchymal hepatocytes. Liver cells are hyperplastic. (See also Plate 2.)

Similarly, in the pancreas there is fibrosis and iron deposition in the acini, ducts, and islets of Langerhans. Staining with Perls' reagent reveals arked haemosiderin deposition in the exocrine and endocrine glands, including many cell types in the testes. Haemosiderin is also markedly increased in the chief cells of the parathyroid, the adenohypophysis, the zona glomerulosa of the adrenal, and the thyroid.

In the joints, there is loss of the intra-articular space with chondrocalcinosis and deposits of haemosiderin in the synovium; electron microscopy shows selective deposits of ferritin and haemosiderin within type B synoviocytes. Radiological examination of the joints shows collapse of articular surfaces, subchondral cyst formation, and prominent formation of periarticular osteophytes. In the heart, pericardial constriction with fibrosis may occasionally be observed, but the principal abnormality is seen in the myocardium with degeneration and vacuolation of cardiac myocytes and intermyocyte fibrosis that involves conducting tissue in the septa. Surviving myocytes show eosinophilic degeneration and evidence of hypertrophy. Microscopical examination shows that in established cases of haemochromatosis, all tissues (except the choroid plexus) are affected by the iron-storage process. In the past, it was considered that transfusional and other types of secondary iron-storage disease predominantly affected the cells of the mononuclear macrophage system, such as the Kupffer cells of the liver, rather than the parenchymal cells. Iron deposits in the macrophage system may be less damaging than in other cell types, but it is difficult at present to relate evidence of iron-mediated injury to its cellular distribution. Progressive tissue injury follows the long-term cumulative toxicity of iron storage and its consequential effects on organ structure and cellular function. A striking, but unexplained, feature of iron-storage disease in the liver and other tissues is the absence of overt necrosis; careful study of the cellular effects of iron storage on apoptotic mechanisms in diseased tissues is clearly warranted.

Quantitative aspects of iron-storage disease

Chemical determination of tissue iron content yields useful information about the severity of iron loading in haemochromatosis, and may also provide a means to judge local responses to iron-depletion therapy, such as venesection. In normal individuals, the total concentrations of liver iron do not exceed 0.15 per cent by dry weight, but in established haemochromatosis the value is usually 1 per cent or more; in severely affected patients with untreated hereditary haemochromatosis or secondary haemochromatosis the amount of iron may exceed 5 per cent of the dry weight of tissue. The overall burden of body iron in patients with

haemochromatosis is usually in excess of 5 g in hereditary disease, a figure that rises with age. Estimates indicate that the total burden in patients with advanced haemochromatosis can be as much as 40 to 60 g—most of this accumulating in the liver—the pancreas and other organs such as the lymph, thyroid, pituitary, and salivary glands typically show an increase of more than 10 times the normal iron content.

Nature of the metabolic defect

In established haemochromatosis, where the burden of iron may increase body iron stores by at least tenfold, measurements usually show that iron absorption is within the normal range. Studies in young patients with rapidly progressive disease show a markedly increased absorption of iron, and all the evidence points to an increase in iron absorption to 2 to 3 mg daily throughout the lifetime of patients with haemochromatosis. After depletion therapy, the rate of recovery of iron stores is greatly enhanced for many years in patients with haemochromatosis, reflecting a persistent homeostatic abnormality in the retention of dietary iron. The daily absorption of between 2 and 4 mg of iron over a period of 30 to 40 years accounts for the degree of iron loading that occurs at presentation in patients with haemochromatosis, and compares with the normal absorption of 0.8 to 1.0 mg in men and in women, up to 2 mg daily. In effect, the abnormal absorption of iron represents a disturbed regulation of the final common pathway for the acquisition of iron from the environment by the small intestinal mucosa.

Iron absorption in hereditary haemochromatosis

A recent report, describing the transplantation of intestine and liver from an *HFE C282Y* homozygote into a recipient without haemochromatosis, has provided evidence that the small intestine is the principal site of expression of the hereditary defect in adult haemochromatosis. The transplantation was associated with early iron overloading in the recipient, together with raised serum transferrin iron saturations—a phenomenon not observed in recipients of hepatic allografts obtained from donors later found to be homozygous for the haemochromatosis gene. Studies *in vitro* and *in vivo* have suggested that there is a qualitative abnormality of the uptake and transfer of iron from the intestinal lumen in patients with hereditary haemochromatosis, although, until recently, the nature of this abnormality was unclear.

Latterly, genetic studies of mutant strains of mice with abnormalities of iron metabolism have shed light on the iron-absorption mechanism. The identification of a single gene encoding the divalent metal transporter protein, DMT 1, which is expressed in the upper small intestine and cells of the erythron, provides a molecular understanding of the iron deficiency—and the microcytic anaemia that occurs in the *mk/mk* mouse strain. A single point mutation in the *DMT1* gene interferes with the uptake of ferrous iron, since it disrupts the cognate transmembrane carrier protein mainly expressed in the mucosa of the proximal small intestine at the site of iron absorption and in the erythroid precursor cells. Since *in vitro* studies of the expressed protein DMT 1 show that it serves only as a carrier of divalent cations, and that interference with this pathway is sufficient to induce iron deficiency in a mammalian species, ferrous iron uptake is probably the main pathway by which inorganic iron is acquired by the intestine. Human *DMT1* maps to the long arm of chromosome 12 and encodes a 12 membrane-spanning protein that is expressed in the apical membrane of the upper intestine and in the apical membrane of differentiated human CaCo-2 cells of small intestinal phenotype. DMT 1 is also expressed in developing erythroid cells in which it is responsible for the intracellular delivery of iron derived from transferrin for haemoglobin synthesis.

The discovery of DMT 1 immediately indicated a possible role for this important protein in human haemochromatosis. Overexpression of *DMT1* mRNA has been identified in the intestinal mucosa of patients homozygous for the *C282Y* mutation with hereditary haemochromatosis, as well as in mice with iron-storage disease due to targeted disruption of the *HFE* gene. At the same time, studies in experimental animals have identified a cytochrome-containing ferrireductase that is also localized to the intestinal brush-border membrane; this reductase has been cloned from murine intestine and its human homologue has been identified. Expression of mucosal ferrireductase is specific to the apical microvillous membrane of mammalian intestinal mucosa and appears to be induced in response to nutritional iron deficiency. Mucosal ferrireductase reduces ferric irons derived from the diet in the lumen for delivery to the DMT 1 carrier protein, the final divalent pathway for inorganic iron uptake by intestinal mucosa. The mRNA species encoding murine *DMT1* exist in two isoforms, one of which contains an iron-response element (**IRE**) 3' region—which would allow for the post-transcriptional regulation of protein expression controlled by intracellular iron status. A similar translational control of transferrin receptor expression has been described with the 3' IRE in the mRNA encoding the human transferrin receptor. Since the IRE-containing isoform of DMT 1 is preferentially expressed in the duodenum, it seems likely that changes in intracellular iron status regulate the expression of this carrier protein in iron deficiency and haemochromatosis. Studies in *HFE* knockout mice indicate that the functional expression of the DMT1 protein is enhanced in the murine model of haemochromatosis, leading to increased iron uptake across the brush-border membrane of iron presented in the ferrous form; the action of non-rate-limiting ferrireductases at the brush-border membrane functionally coupled to DMT 1 activity appears to explain the enhanced isotopic uptake of ferrous iron in this model of haemochromatosis.

At present, our molecular understanding of transepithelial iron uptake in haemochromatosis and in health is somewhat rudimentary. A novel gene termed ' *ferroportin*', encoding a multitransmembrane domain protein, has been identified. The cognate protein may function as an exporter of iron across the brush-border membrane at the basal surface of the intestine as well as in placental syncytotrophoblasts. Ferrroportin appears also to be responsible for the export of iron retrieved by erythrophagocytosis by macrophages. After initial uptake, the enhanced transfer of iron across the mucosal epithelium in haemochromatosis and iron deficiency is mediated by, as yet, unknown iron-binding proteins. Delivery of the iron to the systemic circulation is mediated by the regulated downstream coexpression of the membrane protein, ferroportin. It seems likely that, in hereditary haemochromatosis and physiological iron deficiency, post-transcriptional control of carrier proteins responsible for the uptake and transfer of iron occurs in the absorptive epithelium on the tips of the intestinal villi. Thus homeostatic mechanisms in the proximal intestine operate to bring about the co-ordinated transfer of iron presented in the intestinal lumen specifically to meet body requirements. Proteins including hephaestin encoded on the X- chromosome, which is mutated in the sex-linked anaemic mouse *sla*, also mediates the transfer of iron across the intestinal mucosa.

The signal for regulating the absorptive activity of the ferrous ion transport pathway is not known. However, it seems likely that interactions between the wild-type HFE protein and transferrin receptors, including the newly described transferrin receptor 2 isoform that may be expressed in intestinal crypts, in some way instruct the developing epithelial cells within the intestinal crypt about body iron requirements. Although functional interactions of HFE molecules with the identified components of the absorptive pathway have yet to be clarified, the HFE protein probably influences iron status in intestinal stem cells within the crypt. By these means, the expression of key transport proteins such as DMT 1 and ferroportin may be imprinted, thus influencing their subsequent functional activity during ascent up the villus. At present, however, much more experimental work will be required to further our understanding of the signalling pathways by which the body iron status regulates the avidity of the proximal small intestine for nutritional iron presented within the lumen.

A variable but often substantial, component of dietary iron is present in the organic form as haem; a full molecular understanding of the uptake and transfer pathways for the absorption of iron complexes to the porphyrias is also needed. Whole-body studies show that the absorption of the radiolabelled iron moiety of haemoglobin is enhanced in patients with adult-type haemochromatosis. Early studies in dogs have shown that, in the presence of proteolytic digestion products of globin, the haem complex is taken up intact by mucosal epithelial cells; free iron is then released by the action of intracellular haem oxygenases. The contribution of haemoglobin, myoglobin, and cytochromes to the iron overload in patients with haemochromatosis has not been quantified but iron complexed to haem may well represent an important component of the total burden of body iron in symptomatic haemochromatosis.

Genetics and molecular biology of haemochromatosis

The principal determinant of adult haemochromatosis has long been known to be tightly linked to the human MHC loci on the short arm of chromosome 6. In 1996, mutations in the HLA class I-linked haemochromatosis gene, *HFE*, were shown to predispose to the adult form of the disease. The most common mutation in the non-classical MHC class I HFE protein affects a key cysteine residue, which contributes to the formation of the conserved a-3 helix that interacts co-translationally with the b_{2}-microglobulin protein. This association is required for the cell-surface expression of all class I MHC molecules. Most patients with haemochromatosis are thus homozygous for a cysteine-to-tyrosine mutation at codon 282 (*C282Y*) of the nascent HFE protein; an increased frequency of this mutation, in association with the more common *H63D* missense mutation, also occurs in adult haemochromatosis (Fig. 3). A minor variant, affecting the same region in the a-1 helix, *S65C*, is also occasionally associated with the *C282Y* allele in compound heterozygotes with adult iron-storage disease.

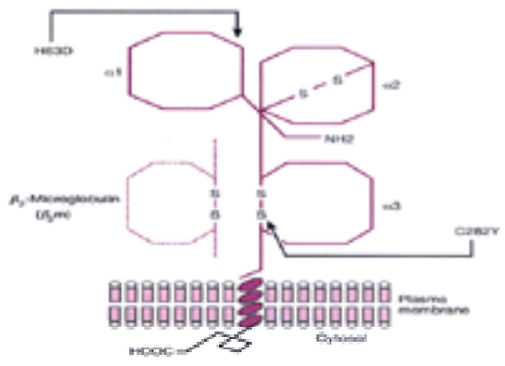

Fig. 3 Diagram of non-classical MHC class I-like HFE molecule shown in juxtaposition with the b $_2$-microglobulin. The location of the two frequent amino-acid substitutions (*C282Y* and H63D) that predispose to the development of adult haemochromatosis is indicated by the arrows.

These missense mutations in HFE occur at a much lower frequency in control populations without iron overload. Apart from reducing cell-surface expression of the mutant C282Y polypeptide, and thus the abundance of this protein within a population of cytoplasmic vesicles, a functional explanation for the qualitative abnormality of iron metabolism that characterizes haemochromatosis is not available. Recent unsubstantiated experiments have indicated the coexpression of HFE with transferrin receptor isoforms within a vesicular intracellular compartment. Structural studies have provided a molecular basis for this interaction based on the expression of truncated soluble HFE and transferrin receptor protein *in vitro*, combined with elegant structural studies using X-ray diffraction. Latterly, a novel isoform of the transferrin receptor, transferrin receptor type 2, has been identified in intestinal crypt cells where it may colocalize with the HFE protein within intracellular vesicles. Since rare cases of adult haemochromatosis have been reported with nonsense and inactivating (null) mutations in the *TfR2* (transferrin receptor 2) gene, it seems likely that the HFE protein participates in the regulation of iron delivery to cells through the transferrin ligand. HFE may affect the delivery of transferrin-bound iron by way of the transferrin receptor, or, also plausibly, by the transferrin isoform *TfR2* in intestinal crypt cells, thereby influencing their subsequent absorptive behaviour.

Mutations in *HFE* can be easily detected by the use of restriction enzymes and analysis of amplified *HFE* gene sequences obtained from genomic DNA. Point mutations in rare cases of non-HFE-associated haemochromatosis have been identified in the *ferroportin* and in the *TfR2* genes. Patients harbouring inactivating mutations in the gene encoding the iron-transfer ligand, serum transferrin, are also reported in association with severe iron-storage disease. This finding, together with the iron-storage disease associated with enhanced iron absorption in hypotransferrinaemic mice (*hpx*), implicates this transferrin-receptor subtype in the physiological regulation of iron homeostasis.

Clinical features

Adult haemochromatosis.

The clinical features of adult haemochromatosis include skin pigmentation. The pigment may be manifest as a generalized slate-grey coloration, due principally to melanin, or localized bronzed pigmentation particularly of the lower limbs, associated with iron deposits in adnexal dermal structures as well as melanin. Histological examination of the skin reveals increased melanocyte activity in conjunction with iron deposits, particularly in cutaneous sweat and apocrine glands. Increased skin pigmentation is a common but not invariable manifestation of haemochromatosis. It increases as the disease progresses and may be a late manifestation of the condition; absence of pigmentation should never, as a consequence, be regarded as a contraindication to the diagnosis of iron-storage disease.

Iron-storage disease invariably affects the liver. The liver is usually enlarged and may be cirrhotic, but portal hypertension and splenomegaly are rare endstage features of haemochromatosis. The enlarged liver, even in the absence of cirrhosis, may contain single or multifocal hepatocellular carcinomas. Hypogonadism is often present; it is typically preceded by a long history of fatigue, sexual asthenia, and impotence, as well as premature menopause and loss of libido in women. In men, there is gynaecomastia, circumoral vertical skin wrinkling, and loss of body hair; the genitalia show premature atrophy.

Many patients with haemochromatosis suffer from arthritis at an early phase in the illness and this may indeed be the sole manifestation of the condition for many years. The arthritis typically affects the second and third metacarpophalangeal joints of the hands and feet (Fig. 4 and Plate 3). These joints show painful swelling without obvious inflammatory changes. Distal interphalangeal joint disease is also recorded and is usually considered to be typical of osteoarthritis. Many joints, including the wrist, elbow, shoulder, and knee, may be affected and the changes in these joints are typically associated with chondrocalcinosis that is detected radiologically. The affected joints show loss of joint space, subchondral cysts, and, especially in the digits, prominent osteophyte formation (Fig. 5). Recent studies show that premature and disabling arthritis in the hip and other large joints is a characteristic feature of haemochromatosis.

Fig. 4 Arthropathy in a man with adult haemochromatosis forced to stop manual work because of painful arthritis especially in the second and third metacarpophalangeal joints; note increased skin pigmentation. (See also Plate 3.)

Fig. 5 Radiograph of hands in a 51-year-old woman with haemochromatotic arthropathy of the hands for many years. Note loss of joint space especially in metacarpophalangeal joints with subchondral cyst formation and osteophyte growth. Chondrocalcinosis is present in the ulnar fibro-cartilage at the wrist.

The symptoms of haemochromatosis are notoriously non-specific and slow in their progression. Fatigue is often reported and may be a manifestation of

hypogonadism and the onset of diabetes mellitus. Atrial fibrillation may be an early manifestation of cardiomyopathy. Later, paroxysmal arrhythmias and cardiac failure supervene, leading to shortness of breath and fatigue. Occasional patients with haemochromatosis present with isolated features, such as abnormal liver-related tests detected during routine examination for health insurance, or with arthralgia and signs of arthropathy in association with either diabetes, impaired libido, or sexual failure. Cardiomyopathy with heart failure or isolated arrhythmias is an unusual lone presentation of the disease.

The differential diagnosis of haemochromatosis is very wide, but the presence of diabetes with abnormal liver function or hepatomegaly, or an association with endocrine failure or arthropathy, should prompt consideration of iron-storage disease. Likewise, the presence of seronegative polyarthropathy with pigmentation, hepatomegaly, or any of the associated endocrinological changes should initiate immediate testing for evidence of iron-storage disease.

In young patients with hypogonadism or cardiomyopathy, iron-storage disease should be considered; juvenile haemochromatosis is often neglected by endocrinologists investigating young patients for infantilism or hypogonadotrophic hypogonadism. The condition may be responsible for cases of undiagnosed seronegative polyarthropathy. Iron-storage disease should be considered in any patient with signs and symptoms of chronic liver disease, including those with sustained mild elevation of serum transaminase activities, particularly since the liver is affected early in the course of the iron overload.

In fully established cases, skin pigmentation which may either be of a grey colour as a result of increased melanin, or, especially on the shins, a yellow-brown 'bronze' colour. Pigmentation in association with diabetes with or without arthropathy and hepatomegaly almost always signifies established iron-storage disease.

Diagnosis

It is critically important to make a diagnosis of haemochromatosis at the earliest opportunity. There is strong evidence that if treatment to remove iron before established structural injury occurs, then tissue function and symptoms improve. Several surveys indicate that removal of iron from patients diagnosed in the precirrhotic phase of adult haemochromatosis is associated with a normal or near-normal life expectancy.

Laboratory investigations

In adult haemochromatosis, the diagnosis can be usually established by demonstrating abnormalities of iron metabolism (fasting serum transferrin saturation with iron greater than 60 per cent), together with a measurement of serum ferritin concentration that provides evidence of increased iron stores. In most, but not all, untreated patients with pathological iron-storage disease due to haemochromatosis, the serum concentration of ferritin is elevated. Molecular analysis of the *HFE* gene for homozygosity for the common (*C282Y*) predisposing allele to the development of adult haemochromatosis may be very useful in patients of European ancestry. There is an increased frequency of compound heterozygotes for the *C282Y/H63D* or, more rarely, *C282Y/S65C* genotypes in patients with evidence of iron-storage disease.

Not all patients with adult haemochromatosis have mutations in the *HFE* gene; moreover, genetic tests are not at present available for the diagnosis of juvenile haemochromatosis or of neonatal haemochromatosis. In some patients with adult iron-storage disease, mutations have been identified in a newly identified gene that encodes a variant of the transferrin receptor—transferrin receptor type 2 (*TfR2*). Homozygosity for mutations in *TfR2* are found in some Southern European patients with adult haemochromatosis. Adult haemochromatosis due to mutations in the *HFE* gene is now known as HFE 1; juvenile haemochromatosis due to lesions in an, as yet, uncharacterized locus on chromosome 1q are now designated HFE 2, and mutations in the type 2 transferrin receptor gene cause HFE 3—another adult variant of hereditary haemochromatosis. As indicated above, HFE 2 (juvenile haemochromatosis) is a much more severe disease than either HFE 1 or HFE 3—although hypogonadism can be a presenting symptom in both HFE 1 and HFE 3 (see Table 1). A rare form of adult haemochromatosis, principally transmitted as a dominant trait, appears to be associated with point mutations in the newly described *ferroportin* gene (see above). It is believed that ferroportin is involved in the transport of iron from the intestinal epithelial cells to the body as well as to the liver. This type of haemochromatosis, now designated HFE 4, appears, if anything, to be slightly milder than haemochromatosis in the homozygous recessive forms of HFE 1, 2, and 3. HFE 4 responds poorly to iron-depletion therapy by venesection; histological examination reveals prominent iron storage within Kupffer cells.

Given the genetic variants that are now recognized as causes of haemochromatosis, it is clear that if any doubt exists as to the diagnosis, or molecular analysis of the *HFE* gene fails to identify known pathogenic mutations, then tissue diagnosis is indicated. This is usually carried out by liver biopsy with histochemical determination, and preferably chemical quantification, of tissue iron content. Although a liver biopsy is associated with small but definable risks, it does offer a key opportunity for the evaluation of liver structure and of the injury consequent upon iron deposition. The finding of cirrhotic change carries with it a poor prognosis; cirrhotic change is also a major predictor of the occurrence of hepatocellular carcinoma, which occurs rarely in non-cirrhotic subjects with iron-storage disease (Fig. 6 and Plate 4).

Fig. 6 Adult haemochromatosis. Section of liver lobe after surgical resection to remove a primary hepatocellular carcinoma arising in an iron-loaded but, unusually, non-cirrhotic liver in this disorder. The patient, aged 62 years, had been partially treated by venesection but recently noticed increasing lethargy: a raised serum a-fetoprotein concentration led to the diagnosis; moderate histochemical evidence of iron storage was found in the non-malignant tissue excised at surgery. (See also Plate 4.)

Serum iron-saturation determinations, and particularly serum ferritin concentrations, may signify conditions other than iron-storage disease. Serum ferritin is elevated in inflammatory states, certain malignancies such as Hodgkin's disease and in any condition associated with significant necrosis of parenchymal liver cells. Under these circumstances liver biopsy is recommended, since it is most likely to provide a definitive diagnosis of iron-storage disease. Sometimes, however, liver biopsy is not possible—either because the patient will not consent to it, or because of the presence of ascites and a bleeding disorder (especially thrombocytopenia). Under these circumstances, magnetic resonance imaging (**MRI**) may provide additional information but it is an insensitive test for the presence of iron-storage disease. If a liver biopsy is not possible and MRI of the liver does not reveal increased ferromagnetic signals indicative of iron storage, there are two further options: measurement of urinary iron excretion after parenteral administration of desferrioxamine, and, where the patient will tolerate it, quantitative phlebotomy. Injection of 500 mg of desferrioxamine intramuscularly in a patient with iron overload will usually induce the daily excretion of more than 2 mg of iron as the ferrioxamine complex in the urine. Ferrioxamine excretion may be increased in patients with haemolytic anaemia but when elevated is generally indicative of iron-storage disease. Weekly phlebotomy of 500 ml will remove approximately 225 mg of iron, and thus provides a means of estimating the amount of iron removed from the storage compartment when undertaken to induce a mild hypochromic anaemia of approximately 10.5 to 11.0 g of haemoglobin/dl or a serum ferritin concentration of less than 30 µg/l. Iron overload exists when the estimated iron removed by this method exceeds 1.5 g; unfortunately quantitative phlebotomy is cumbersome and may not be possible in patients with severe liver disease associated with hypoalbuminaemia.

Diagnosis in family members

The diagnosis of haemochromatosis, whether it be of adult or juvenile form, in an individual has immediate implications for first-degree relatives. All forms of haemochromatosis have a strong hereditary basis; and even some forms of neonatal haemochromatosis may, in some families, be inherited as an autosomal recessive trait. A dominant transmission pattern has been established in the case of HFE 4.

Although the penetrance and expressivity of homozygosity for the various alleles that predispose to haemochromatosis is not yet established, the risks of the disease in first-degree family members is sufficiently high to warrant systematic study. Clearly, the implications for asymptomatic or undiagnosed relatives of the propositus

are potentially very large. Hence, considerable care and sensitivity are needed in the means of informing them about the condition through the identified index case. In large families there may be formidable difficulties, so that the help of genetic counselling services as well as formal assistance from physicians practised in medical genetics may be needed. There can be little doubt, however, that at-risk relatives should be offered the opportunity for further diagnostic and clinical evaluation in relation to iron-storage disease. The condition is readily susceptible to iron-depletion therapy in its early stages; moreover, there may be additional considerations for patients who will wish to make reproductive choices and who will need to be reassured that appropriate testing can be carried out on their future offspring.

In HFE haemochromatosis, molecular analysis of the *HFE* gene (and, formerly, the tightly linked class I HLA class typing) may assist in assessing the risk of disease, particularly in asymptomatic siblings. Phenotypic screening, however, is useful at the level of clinical evaluation for evidence of liver disease, hypogonadism, arthritis, pigmentation, and diabetes. Determining the biochemical phenotype first involves assay of the serum parameters of disordered iron metabolism. Since the serum parameters may be abnormal before iron-mediated tissue injury has occurred, tissue biopsy should be offered to patients with serum ferritin concentrations in excess of 500 µg/l who are at risk from the liver disease.

In first-degree relatives, in whom HLA typing or molecular analysis of the *HFE* or *TfR2* genes indicates a genetic predisposition to the disease, periodic re-evaluation is needed by clinical and biochemical testing at intervals of not more than 5 years. In members of families affected by haemochromatosis due to mutations in the *HFE* or *TfR2* gene who were not found to carry the predisposing mutations and whose ferritin and iron parameters are normal, liver biopsy is not mandatory and the risk of the development of significant iron-storage disease in less than 5 or 10 years is extremely low. In patients with no known pregenetic disposition and normal tissue-biopsy findings, further follow-up screening is not indicated.

From the foregoing it can be seen that there is an urgent need to identify the gene responsible for juvenile haemochromatosis, accompanied by a complete genotype/phenotype evaluation for other forms of haemochromatosis. Unfortunately, no genetic locus has yet been identified for neonatal haemochromatosis, although this is a subject of continuing research. In at-risk pregnancies, neonatal haemochromatosis may be occasionally recognized by MRI during the third trimester, which may show increased iron signals in the fetal liver. After birth, biopsy of the oral mucosa on the gums or inner lip may reveal histological evidence of iron storage in minor salivary glands of affected infants.

Environmental cofactors and disease expression

Many patients with adult haemochromatosis give a history of excessive current or prior alcohol consumption. In the past, physicians have been tempted to attribute evidence of excess tissue iron in these individuals solely to the consumption of alcohol. In practice, however, it appears that those individuals who have biopsy-proven evidence of hepatic iron storage usually prove to carry two predisposing alleles of the *HFE* gene and therefore have true haemochromatosis. Although no clear predictors for the expression of disease in first-degree relatives at risk are available, disease expression is reduced in women of reproductive age; most practising clinicians consider that age and alcohol consumption are the main identifiable environmental factors that contribute to disease expression in predisposed homozygotes. Other comorbid factors, including heritable factors, that may influence the expression of *HFE* mutations in homozygous subjects, include the presence of adult coeliac disease. There are few data that define the relationship between haemochromatosis and coeliac disease but subclinical coeliac disease may ameliorate the long-standing effects of iron loading in *C282Y* homozygotes. Co-segregation of haemochromatosis and coeliac disease has not hitherto been reported.

Treatment

Since it is the toxicity of iron that is responsible for the manifestations of all forms of haemochromatosis, treatment is directed to the removal of iron at the earliest possible stage.

Venesection

In adult and juvenile haemochromatosis the preferred method of treatment is iron depletion by means of phlebotomy. This is best instituted by the removal of approximately 500 ml of venous blood each week by needle puncture of peripheral veins in the antecubital fossa. In young patients it may be possible to increase the frequency of venesection to twice per week after several once-weekly procedures. In elderly patients and those with hypoalbuminaemia as well as end-organ failure and heart disease, the frequency of venesection should be commuted to within the rate tolerated. Coincidental inflammatory disease may impede the erythropoietin-mediated drive to haemopoiesis, and, particularly in the early phases of treatment, mild haemorrhagic anaemia may ensure. Thus adjustments need to be made according to the early responses to venesection therapy, and regular monitoring of the haemoglobin concentration or haematocrit is advisable.

Difficulties may arise in delivering this deceptively simple treatment as a result of poor organization of health service provision and of the availability of suitable healthcare personnel to carry out the venesection procedure. Venesection should not be carried out by naïve or incompetent medical and nursing staff. Every practical effort should be made to ensure that the procedure is convenient for the patient—who is often a young or middle-aged person in full-time employment and who may find regular access to the treatment centre problematic. In cold weather, or in patients with poor circulation or inconspicuous superficial venous access, the use of local anaesthetic creams (such as EMLA cream™) or even local diffusable preparations of glyceryl trinitrate, applied 30 to 60 min before the venesection procedure may greatly improve venous access. Likewise, the simple technique of immersing the arm in warm water to improve peripheral blood flow may be critical for establishing confidence in treating staff. Since patients with haemochromatosis usually harbour a large burden of iron requiring repeated phlebotomy over a period of several years, every effort should be made to preserve the integrity of their peripheral veins. In the author's view, the use of a local anaesthetic is usually unwarranted since it involves further tissue invasion in the region of the antecubital fossa with needles; moreover, repeated injections of the irritant fluid often leads to sclerosis around the venous access site.

Duration of venesection therapy

One 500-ml unit of peripheral blood contains approximately 225 mg of elemental iron. Thus most patients with established haemochromatosis will require weekly phlebotomy for a period of 2 to 3 years. The objective of this treatment is to restore serum ferritin concentrations to within the low normal range and, if possible, to induce a mild iron-deficiency anaemia of approximately 11.5 g haemoglobin/dl. Having thus achieved a satisfactory depletion of body iron stores, interval maintenance phlebotomy, carried out according to ferritin measurements, four to six times per year is usually sufficient to maintain normal iron stores with a serum ferritin concentration less than 100 µg/l. Some authorities suggest that serum ferritin values below 30 µg/l should ideally be achieved. In patients with juvenile haemochromatosis, who have a higher than normal intestinal iron absorption, more frequent phlebotomy may be needed to maintain a healthy iron balance.

Iron chelation therapy

Alternative methods of iron removal are needed for patients with severe clinical manifestations of haemochromatosis, such as life-threatening cardiac arrhythmias and those with severe liver disease and hypoalbuminaemia, who are incapable of withstanding frequent phlebotomy. The preferred alternative involves chelation therapy with the parenteral agent, desferrioxamine. As indicated in Chapter 22.4.4, the subcutaneous administration of desferrioxamine brings about the removal of a maximum of 20 to 25 mg of iron daily and is thus generally less efficient than vigorous weekly phlebotomy. However, desferrioxamine may gain access to cellular pools of iron that are important in the pathogenesis of tissue injury in established iron-storage disease, and therefore may offer particular benefit in patients critically ill with arrhythmias due to haemochromatotic cardiomyopathy. Although the nature of this so-called 'chelatable iron pool' is unknown, there is strong circumstantial evidence that its depletion by means of intravenous desferrioxamine treatment may reverse the life-threatening consequences of terminal iron-storage disease in patients with haemochromatosis. Moreover, the removal of 140 mg of chelatable iron per week represents about two-thirds of the amount that can be removed by weekly phlebotomy. A biological advantage may also be gained by therapeutic access to a reactive low-molecular weight chelatable fraction responsible for the injurious effects of cellular iron overload.

Parenteral desferrioxamine may be given intravenously for life-threatening cardiac disease, as described in Chapter 22.4.4, or, in the non-emergent situation, by subcutaneous infusion using portable infusion pumps for 12 to 14 h five or six times per week. It must be stressed, however, that chelation therapy is not the preferred option for the treatment of established haemochromatosis and should be restricted to those patients unable to tolerate phlebotomy as a result of anaemia or hypoalbuminaemia, or in whom life-threatening cardiomyopathy or liver disease is present.

General measures

Attention should be given in patients with haemochromatosis to the diagnosis and treatment of end-organ failure. This particularly applies to the management of diabetes mellitus by diet and insulin where necessary, as well as hormone-replacement therapy for hypogonadism. (See Chapter 12.8.2.) In men, intramuscular depôt

injections of testosterone enantate (250 mg every 2–3 weeks) are recommended to improve libido and inhibit the development of premature osteoporosis; similarly, conventional sex hormone-replacement therapy should be used in women with premature gonadal failure as a result of haemochromatosis. Cardiac failure in patients with haemochromatosis due to cardiomyopathy and hepatic failure consequential upon pigmentary cirrhosis should be treated by standard methods; organ transplantation may be used successfully but correction of systemic iron overload should be undertaken as soon as practicable to restore normal function in all organ systems. Rarely, end-organ hormone deficiencies result from thyroid infiltration and parathyroid and adrenocortical disease. These deficiencies should be vigorously sought for in the clinical evaluation of the patient at presentation. The appearance of lethargy, faintness due to postural hypotension, or symptomatic hypocalcaemia demands immediate investigation and institution of appropriate replacement therapy.

Prognosis

The main causes of death in untreated patients with haemochromatosis are hepatocellular failure, primary carcinoma of the liver (including hepatocellular carcinoma), and, rarely, cholangiocarcinomas. Cardiac failure due to haemochromatotic cardiomyopathy and untreated diabetes also contribute to death. Although not categorically proven, evidence from retrospective surveys suggest that life expectancy is improved by removing iron from patients with haemochromatosis of whatever cause and the subsequent maintenance of normal iron homeostasis. Most patients experience an improvement in well being on iron-depletion therapy and, during its early phases, there is evidence that hypogonadotrophic hypogonadism may improve with this therapy. Similarly, the manifestations of cardiomyopathy with intractable cardiac failure or tachyarrhythmias can improve after the removal of iron.

The cirrhosis of haemochromatosis appears not to be reversible, although the earlier precirrhotic manifestations of hepatic disease improve greatly on the removal of iron with an apparent restoration of normal life-expectancy. In all patients there is at least a twofold increase in the survival rate at 5 years from the point of diagnosis with the introduction of phlebotomy. In patients studied during the 1950s and 1960s, the 5-year survival rate improved from 18 per cent to more than 65 per cent in all haemochromatosis subjects treated.

In patients diagnosed with haemochromatosis but without cirrhosis, iron-depletion therapy is associated with a near-normal or normal life expectancy compared with a sex- and age-matched control cohort derived from the same population. It is notable, however, that the indolent nature of this storage disorder and the long-term survival of patients who are affected by it has so far rendered long-term controlled studies of the effects of phlebotomy on eventual outcome almost impossible to achieve. However, a wealth of evidence, based on the understanding of the pathogenesis and documented responses to iron depletion in individual patient cohorts, indicates that early removal of iron is highly desirable: indeed it may be decisive in determining a good outcome from all forms of human iron-storage disease—including all subtypes of hereditary haemochromatosis so far established.

Hepatocellular carcinoma occurs mostly in patients with iron-storage disease who have established cirrhosis (which is irreversible). Although hepatocellular carcinoma and cholangiocarcinoma have been reported in non-cirrhotic patients with haemochromatosis, these are rare phenomena. Moreover, since all the evidence suggests that patients with haemochromatosis are more likely to have diabetes mellitus and other manifestations of the disease, every encouragement should be given to the prompt diagnosis of the condition and early institution of iron-depletion therapy.

Increasingly, it has been recognized that the arthropathy of haemochromatosis can be disabling whether or not it is associated simply with joint pain (arthralgia) or progressive and non-inflammatory joint destruction. The disease is associated with a loss of cartilage and, in many large joints, chondrocalcinosis. Although the response of the arthropathy to iron-depletion therapy is controversial, the weight of observation indicates that, once established, the arthropathy of haemochromatosis progresses independently of body iron status and of iron-depletion treatment. It seems intrinsically likely that effective removal of excess body iron stores before the development of joint symptoms will prevent their onset and progression. However, at present only cross-sectional data are available to support this contention.

In summary, observations in adult haemochromatosis suggest that once the disease is established in association with cirrhosis or diabetes mellitus, it diminishes life expectancy. The prognosis for cardiomyopathy in juvenile haemochromatosis is very poor but it may be improved by early diagnosis and the early institution of vigorous iron-depletion therapy. In several cases, the outcome has been improved by allogeneic cardiac transplantation. In adult patients with established pigment cirrhosis, hepatic transplantation has been undertaken and, provided the other systemic manifestations of haemochromatosis have been adequately treated, the procedure is associated with a good overall prognosis.

Prevention and control

The importance of early recognition and the institution of iron-depletion therapy in all forms of haemochromatosis cannot be overemphasized. Molecular analysis of the *HFE* gene or HLA class I haplotype screening, together with biochemical characterization using serum transferrin iron saturation estimations and serum ferritin concentrations, has the power greatly to assist in the detection of presymptomatic first-degree relatives of patients with haemochromatosis.

In relation to whole populations in which mutations in the *HFE* gene are frequent, the health implications based on mass screening remain contentious. Superficially, adult hereditary haemochromatosis due to mutations in the *HFE* gene appears to be an ideal condition for DNA-based mass-population screening. The condition is attributable to a single gene, and a single mutation of diagnostic significance is prevalent (gene frequency 5–10 per cent). Disease-related mutations in *HFE* (especially *C282Y*) are easily tested for by means of polymerase chain reaction-based techniques. At the same time, HFE-mediated haemochromatosis has a long incubation period without symptoms—and all the evidence suggests that the institution of treatment for presymptomatic disease is cheap, simple, and effective.

On the other hand, however, genetic identification of at-risk individuals is associated with problems of stigmatization, increased anxiety, and potential life-insurance weighting—all of which are familiar aspects in well-rehearsed debates about genetic testing in the general population. These aspects must be considered, together with the age-related penetrance of the homozygous state for *HFE C282Y* variants and, as yet, unknown combined genetic and environmental influences on disease expression. Uncertainty as to the significance of these factors has held back the introduction of mass-population screening by DNA-based methods. In light of the present state of knowledge, it is clear that homozygosity for the *C282Y* allele of *HFE* cannot be considered to be tantamount to a diagnosis of hereditary haemochromatosis.

More information is needed from outbred populations, rather than from homozygotes identified as a result of screening family members of index cases having full-blown clinical disease. Family studies provide a false measure of disease expressivity, presumably as a result of shared environments and of the co-segregation of potential disease-modifying genes within defined pedigrees. Finally, it must be emphasized that difficulties also occur for the evaluation of the burden of haemochromatosis in the population at large: although there are definitions of iron-storage disease that reflect the abnormal biochemical genotype, the manifestations of the clinical disease are variable and protean. Moreover, as pointed out earlier, no internationally agreed case definition of haemochromatosis exists, which creates additional difficulties for the introduction of public health measures and appropriate policy review of nationwide screening procedures.

Future directions

Although startling progress has been made in the discovery of many components that serve to regulate iron homeostasis in humans, more information is needed before a full molecular understanding of the mechanisms of iron homeostasis can be achieved. The genes responsible for severe juvenile neonatal and variant forms of adult haemochromatosis are yet to be characterized. At the same time, the functional interactions of the HFE molecule with the two transferrin receptor isoforms requires more study. An even more challenging task will be the identification of the environmental cofactors that determine the expression of iron-storage disease in genetically predisposed individuals; alcohol is a long-standing candidate but the mechanism by which it leads to increased delivery of toxic iron to the tissues is, at present, completely unknown.

Newly identified iron-storage diseases

By general agreement, the term 'haemochromatosis' is used to describe systemic syndromes of pathological iron storage that affects many tissue and disturbs the function of diverse organ systems. Conversely, several distinct clinical syndromes of local iron toxicity have been identified, especially in the eye and brain. Although these syndromes are individually rare, they are important because they are potentially accessible to measures that reduce cellular free iron (for example, metal chelation (see above)), and because they demonstrate the central importance of metabolic iron in selected tissues. A fuller understanding of these disorders and the cognate cell metabolic pathways they affect, may well shed light on ill-understood aspects of tissue iron physiology. Additional information is available by reference to the online Mendelian Inheritance in Man (OMIM) website at www.ncbi.nlm.nih.gov/omim.

Hereditary hyperferritinaemia cataract syndrome (OMIM 600886)

The sole clinical manifestation of this condition is of congenital bilateral ferrugineous nuclear cataracts due to the disposition of excess ferritin light-chain polypeptide in the ocular lenses. The serum ferritin concentrations are moderately elevated but no evidence of systemic iron storage is found. The disorder is caused by mutations in the non-coding 5' IRE of the ferritin L-chain gene that leads to unregulated translational overexpression of ferritin light chains. These polypeptides accumulate in the lenses and disturb their tissue organization and refractile properties. The hyperferritinaemia cataract syndrome is, as expected for an overexpression disease, inherited as a dominant trait; measurement of serum ferritin concentrations may identify at-risk family members. The gene encoding ferritin light-chain polypeptide maps to chromosome 19q3.3-qter.

Adult-onset basal ganglia disease (OMIM 606159)

A single pedigree has been identified with a dominantly inherited disorder showing features of late-onset extrapyramidal dysfunction resembling parkinsonism or Huntington's disease. Imaging and autopsy studies revealed cavitation of the basal ganglia with deposition of iron and ferritin protein in adjacent tissue, especially in the putamen and the globus pallidus; the macroscopic appearances showed widespread reddish discoloration of affected tissues. This disorder was mapped to chromosome 19q13.3 and a single mutation, a point insertion of a single adenine at nucleotide 461, was identified in exon 4 of the ferritin L-chain gene. The mutation is predicted to disrupt the carboxyterminal sequence of the ferritin light-chain molecule and disturb the iron-binding core of the hetero- or homomeric protein. Serum ferritin concentrations were found to be abnormally low in affected heterozygotes. Although this disorder has so far only been identified in a single large pedigree, it further illustrates the importance of ferritin in tissue iron metabolism and, especially, in selective regions of the brain. This disorder has been termed a 'neuroferritinopathy' and may be the first of several diseases affecting cellular iron pathways in iron-rich brain tissue.

Acaeruloplasminaemia with iron deposition (haemosiderosis) in basal ganglia (OMIM 277900)

This disorder is associated with mild systemic iron deposition and deficiency of the plasma copper-binding protein, caeruloplasmin. Caeruloplasmin has long been known to possess ferroxidase activity, and that it enhances the mobilization and delivery of iron to and from macrophages and hepatocytes: caeruloplasmin promotes iron loading of intact ferritin micelles. Acaeruloplasminaemia, due to mutations in the gene encoding caeruloplasmin on chromosome 3q21–24, is an autosomal recessive trait. The deficiency is associated with diabetes mellitus, dementia, and extrapyramidal features including parkinsonism, with choreoathetosis as well as cerebellar ataxia. MRI shows altered signals in the basal ganglia, and retinal degeneration may be apparent by fundoscopy. Excess systemic iron is demonstrable by examination of liver tissue and the serum ferritin concentration is moderately elevated; however, low serum iron transferrin saturations with hypochromic microcytic anaemia, reminiscent of copper deficiency, are usually present.

Infusions of plasma or purified caeruloplasmin may correct the systemic abnormalities of iron metabolism, but probably do not influence the dementia or the other neurological deficits—at least once these are established. The role of caeruloplasmin replacement or indeed parenteral chelation therapy with desferrioxamine or trientine, especially in the early evolution of the neurological syndrome, has not yet been established. The interplay between copper and iron metabolism is well illustrated by this severely disabling illness. Acaeruloplasminaemia illustrates the particular sensitivity of the basal ganglia to disturbances of iron metabolism. In this context, it is notable that caeruloplasmin expression is abundant in glia in the brain microvasculature juxtaposed to the pigment-containing dopaminergic neurones of the substantia nigra and inner layer of the retina.

Hallervorden–Spatz disease: pantothenate kinase-associated neurodegeneration—OMIM 234200

This disease has been familiar to neurologists and neuropathologists since its original description by two now discredited German neuroscientists of the Nazi period. The clinical features indicate basal ganglia disease and dementia with retinal degeneration leading to optic atrophy. The disorder often presents with equinovarus deformity in children and adolescents; extrapyramidal rigidity preceded by choreoathetosis usually follows rapidly. Dementia, optic atrophy, and generalized seizures occur in the latter stages, and death usually ensues by the age of 30 years. Although late-onset forms of the disease are known, a striking feature is the presence of iron pigment in the basal ganglia and substantia nigra, now easily recognized by MRI. The heredofamilial nature of this syndrome has been known since its first description. Hallervorden–Spatz disease is now known to be an autosomal recessive trait due to mutations in the pantothenate kinase 2 (**PANK2**) gene that maps to chromosome 20p13.

Pantothenate kinase-2 is abundant in the retina and target regions of the brain; it regulates the formation of coenzyme A. Deficiency of PANK-2 would deplete sensitive neural tissues with a high metabolic rate of coenzyme A; the defect may also lead to a consequential accumulation of cysteine, which normally condenses with the enzyme product, phosphopantothenate. In the presence of high concentrations of free iron, excess cysteine may accelerate the formation of cytotoxic oxygen free radicals. For some years, cysteine accumulation has been independently observed in the iron-rich nigrostriatal regions of the brain affected by this disorder. Identification of *PANK2* mutations offers the hope of improved diagnosis of this neurodegenerative disorder, and, more importantly, the prospect of specific therapy using supplementation to enhance local coenzyme A activity and phosphopantothenate concentrations in affected neural tissue.

Further practical information

Many patients' associations and societies exist to serve the needs of patients in their respective countries: International Association of Haemochromatosis Societies.

In the United Kingdom, useful information can be obtained from: The Haemochromatosis Society, Hollybush House, Hadley Green Road, Barnet, EN5 5PR. Fax: 44 (0) 208 449 1363; Email: info@ghsoc.org; Website: http://www.ghsoc.org/

11.7.2 Wilson's disease, Menke's disease: inherited disorders of copper metabolism

C. A. Seymour

Copper

Copper is ubiquitous and is present in relative excess in most diets. It is a prosthetic element of many metalloenzymes, playing a vital role in mitochondrial energy generation, melanin formation, and cross-linking of collagen and elastin. Since the liver efficiently maintains copper homeotstasis by regulating excretion of copper into the bile, acquired copper deficiency is rare. Excretion of copper is dependent on its incorporation into caeruloplasmin (the major copper-binding protein in plasma, normally 20–40 mg/dl); and defects in this homeostatic mechanism lead to toxic accumulation (Fig. 1).

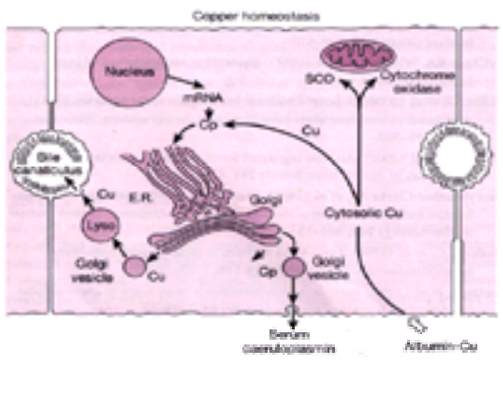

Fig. 1 Hepatic caeruloplasmin isoforms—copper transport in the liver.

Copper homeostasis

Total body copper is in the range of 50 to 150 mg, of which some 8 per cent is found in the liver. Relatively high concentrations are also found in the brain, kidney, heart, and bone. Neonatal and fetal liver tissue tolerate much higher quantities than does the adult liver, where copper is stored within lysosomes in association with metallothionein.

Copper (2–5 mg daily) absorbed from the diet is transported loosely bound to albumin. This accounts for about 10 per cent of circulating copper. Net uptake of copper (around 40–60 per cent) reflects its differential binding to low molecular weight ligands present in saliva, gastric and duodenal juice, and high molecular weight ligands present in bile. The regulatory mechanisms involved in intestinal copper transport are still unknown, although binding occurs to two cytosolic proteins, one similar to superoxide dismutase and metallothionein. Metallothionein and active transport of copper–amino acid complexes are involved in absorption but maintenance of copper homeostasis depends uniquely on its excretion in bile (1.5–1.7 mg/day); only about 0.7 µg/day is normally excreted in the urine. Any interruption in the secretion of bile leads to accumulation of copper in the liver.

Copper overload or toxicity

Copper toxicity occurs naturally in animals: the Bedlington terrier, Domenican toad (*Bufo marinus*), the mute swan (*Cygnus olor*), Long-Evans cinnamon rat, and in experimental animals given copper or in acquired copper toxicity in sheep. The Long-Evans cinnamon rat, an inbred mutant strain with autosomal recessive inheritance, most closely mimics Wilson's disease. In all these models, copper accumulates in the liver and not in the nervous system—as it does in man.

Chronic copper toxicity in man occurs in two major forms:

1. A primary (inherited) form, where copper accumulates in and damages the liver initially, and later the nervous system and other tissues, giving rise to hepatolenticular degeneration or Wilson's disease.
2. A secondary (acquired) form, where copper accumulates in similar amounts to Wilson's disease as a consequence of cholestasis, due either to biliary atresia or Indian childhood cirrhosis (congenital) or primary biliary cirrhosis (acquired). In chronic active hepatitis, lesser amounts of accumulated copper exacerbate pre-existing hepatocyte injury.

Wilson's disease

In 1912, Samuel Kinnier-Wilson, described a neurological condition with severe motor (movement) and mental disturbance due to a disorder of the basal ganglia; this was associated with cirrhosis of the liver. Perceptively, Wilson developed the hypothesis that abnormalities in the liver might be caused by 'a morbid agent' (toxin) generated within a cirrhotic liver.

Definition

Wilson's disease or hepatolenticular degeneration is an autosomal, recessively inherited disorder arising from an abnormal gene located on chromosome 13. Pathognomonic features of the disease are inadequate biliary excretion of copper (less than 1.5 mg/day), reduction in plasma caeruloplasmin (less than 200 mg/l), the major copper-carrying protein in plasma, with reduction in incorporation of copper, and consequent hepatic accumulation of copper (more than 25 µg/g dry weight). The genetic defect results in copper accumulation, initially within hepatocytes, with damage leading to cirrhosis, portal hypertension, and then as the liver is bypassed, to increased copper in the circulation which deposits in the central nervous system, cornea, kidneys, and other organs. Undiagnosed or untreated, the disorder has a fatal outcome within a few years of the onset of symptoms. Removal of copper (e.g. by chelation therapy) prevents progression of the disease, and may reverse some neurological and the corneal abnormalities. Regression of the neurological signs has also occurred after liver transplantation.

Incidence

The Wilson's disease gene is distributed world-wide and is present in all racial groups. Although generally considered a rare inborn error of metabolism, it has a prevalence of 1 in 30 000 live births, with an incidence of 15 to 30 per million live births, although this may be a low estimate as some patients are still undiagnosed when they die. Carrier frequency is about 1 per cent. There is no HLA association. A higher incidence has been noted in Jews of Eastern Europe, inhabitants of Southern Italy, Arabs, Japanese, Chinese, and Indians, and populations with high consanguinity, where the frequency may increase to 60 per million births. Because there is a high mortality associated with failure to diagnose the disease, point prevalence rates are lower than frequency at birth.

Genetics and molecular biology

Extended family studies confirmed an autosomal recessive mode of inheritance. Genetic studies of an Israeli-Arab kindred mapped the Wilson's disease gene to chromosome 13 by demonstrating a linkage between the Wilson's disease locus and the red cell enzyme, esterase D. Multipoint linkage techniques using highly variable markers in many families further localized the gene to 13q14–q21. By 1993, a candidate gene for Wilson's disease was identified by several groups, using different positional cloning strategies. The Wilson's disease gene is expressed predominantly in liver (in the transGolgi network), kidney, and placenta and less in brain, heart, lung, and pancreas. It shows functional homology with the Menkes' disease gene. Both genes are predicted to encode copper-transporting membrane p-type ATPases, with characteristic motifs and homology with the heavy-metal transporting ATPases found in bacteria and yeast. Sequence analysis of cDNA predicts that the Wilson's disease protein (ATP7B) has specific metal-binding domains, an ATP-binding domain, a cation channel, and a phosphorylation region which is involved in energy transduction from ATP hydrolysis to copper (cation) transport. Table 1 compares Wilson's with Menkes' disease.

About 70 mutations have been identified in patients with Wilson's disease. Gene deletions, nonsense and splice site mutations, likely to represent null alleles, are associated with a more severe form of the disease. A common mutation in European populations arises from substitution of histidine for glutamine (H1069Q) in the highly conserved ATP-binding region. This is associated with hepatic and neurological disease, and onset at around 20 years. Many other mutations have been reported in various ethnic groups, but none has yet clearly identified particular phenotypes. Detailed genetic and epidemiological studies have suggested that allelic heterogeneity may not be the sole cause of clinical variability of the disease; different ages of onset and disease course have been found in family members with identical mutant alleles. In the United Kingdom, a total of 37 different mutations, including H1069Q, have been reported in 52 British patients, which included 10 patients of mixed ethnic groups; 70 per cent of the mutations corresponded to those described in other Europeans. Thirty per cent of the mutations are not detectable by single mutation tests.

Clinical features (Table 1)

Wilson's disease may present in childhood, adolescence, or early adulthood. Symptoms and signs may be clinically undetectable under 5 years of age, and few present after the age of 35 years, although diagnosis over 55 years has been reported. In 90 per cent of patients, the disease presents with juvenile hepatic disease or with neurological/psychiatric manifestations. In large studies of Wilson's disease patients, initial manifestations were hepatic (40 per cent); neurological (30 per cent); psychiatric (10 per cent); haematological (12 per cent); and renal (1 per cent). 25 per cent of patients have two or more organs involved (usually liver and brain) at the initial assessment.

Clinical presentations

Haemolytic

During the early period (neonatal to under 5 years of age), copper may accumulate in the liver without clinical signs and excess copper in red cells may present as acute haemolysis or as chronic haemolytic anaemia.

Hepatic

Hepatic presentation of Wilson's disease usually occurs at 8 to 12 years. Acute hepatitis, chronic hepatitis/cirrhosis, and fulminant hepatic failure are the three principal patterns of liver disease. Before puberty, symptoms and signs of hepatic dysfunction are common and may mimic acute hepatitis. A diagnosis of Wilson's disease should be considered if these features coincide with abdominal pain and haemolysis, or in children with hepatomegaly, increased serum transaminases, and a fatty liver.

Five to thirty per cent of patients with Wilson's disease present with chronic liver damage which progresses to cirrhosis. In the early stages, patients are vaguely unwell but later develop more specific features of liver dysfunction such as nausea, easy bruising/bleeding, fluid retention, and jaundice. Portal hypertension develops with progressive hepatic insufficiency, splenomegaly, gastro-oesophageal varices, and ascites. In adolescents and older patients, splenomegaly should always raise the diagnosis of portal hypertension and liver disease. A minority of patients present with fulminant hepatitis, encephalopathy, and coagulopathy. Hepatocellular carcinoma is rare in the cirrhosis of Wilson's disease, unlike haemochromatosis.

Neurological

Neurological presentation usually occurs in older patients, between ages 14 and 40 years and are of two general patterns, movement disorders or rigid dystonia. Symptoms may be acute or chronic in onset and rapidly progressive. In all patients there is some degree of liver damage or cirrhosis.

A common presentation in adolescence is with the insidious onset of dysarthria, deteriorating physical performance at school, with clumsiness in using a knife and fork or chopsticks, deterioration in handwriting, and in physical performance at sport. Early physical signs include flexion–extension tremor of the hands, becoming a parkinsonian 'bat's wing' or intention type; abnormal movements become more obvious, with grimacing and choreiform movements. Orolaryngeal dysphagia and sialorrhoea are associated with hypokinesia. Later features include spasticity, rigidity of limbs and neck muscles, and convulsions, which may occur as a presenting sign or on commencement of treatment. Involuntary movement disorders respond to treatment, unlike the spastic-tonic features which mimic Parkinson's disease. Cognitive and sensory functions are usually preserved until a late stage.

Psychiatric

About 60 per cent of patients with neurological features also show evidence of behavioural or psychiatric disorders caused by excess cerebral copper. Adolescents may present with a fall off in intellectual ability at school and/or with truancy. About 20 per cent of patients present with early psychiatric symptoms. Presentations vary from depression, phobias, and compulsive disorders to aggressive and antisocial behaviour. In older patients, anxiety states, intellectual deterioration, and memory loss are more common. These are important to recognize since otherwise the patient may be placed solely in mental health care rather than in the joint care of a neurologist, psychiatrist, and physician who will offer specific therapy.

Ophthalmic

Kayser–Fleischer rings (Fig. 2 and Plate 1) are almost pathognomonic of Wilson's disease. They are due to the deposition of copper in the limbus of the cornea and

appear brown in a grey-blue iris, or grey in a brown eye; they are best seen by slit lamp examination. Similar appearances have been noticed in cryptogenic cirrhosis and with prolonged cholestasis. Rarely, the posterior membrane of the lens is involved, producing the appearance of a sunflower cataract.

Fig. 2 Kayser–Fleischer ring in Wilson's disease. (See also Plate 1.)

Renal

Renal tubular acidosis due to damage by copper in the proximal and/or distal tubules is not uncommon. Aminoaciduria and nephrolithiasis may also occur. Osteomalacia and vitamin D-resistant rickets may result from tubular loss of phosphate.

Joints

Skeletal abnormalities, particularly early osteoarthritis of the spine (Scheuermann's disease), polyarthritis, hypermobile joints, and chondromalacia patellae are recognized features. In the very disabled patient with neurological disease, hypokinesia may lead to flexion contractures.

Dermatological

Rarely, the skin may be hyperpigmented, appearing slightly grey with a bluish appearance of the lunulae of the nails. Long-standing copper excess may increase skin elasticity.

Cardiac/skeletal muscle

Cardiac abnormalities occur rarely, with cardiac hypertrophy associated with interstitial fibrosis, small vessel sclerosis and perivascular myocarditis, and rarely cardiomyopathy, which may lead to congestive cardiac failure. Copper-induced rhabdomyolysis has also been described.

Endocrine disturbances

Endocrine disturbances occur as a result of liver dysfunction (for example, gynaecomastia in men). Women with cirrhosis and copper toxicity have an increased frequency of abortion, stillbirth, premature delivery, and menstrual disturbance. Once chelation therapy has reduced the copper overload, successful pregnancies occur and chelating agents do not appear to harm the fetus or cause fetal copper deficiency. Copper may also injure other endocrine organs (e.g. causing hypoparathyroidism).

Pathology

In Wilson's disease the liver is almost invariably damaged and the histological changes vary with the amount of copper accumulated. The neonatal liver tolerates concentrations of copper that are six to eight times greater than those which injure the adult liver. The evolution of hepatocyte changes after the neonatal period is uncertain. There may be few changes in the liver lobular structure in the asymptomatic patient. Early changes evident on the liver biopsy are pericellular fatty droplet infiltration of the cytoplasm, 'glycogen' degeneration of the nuclei, and copper distributed diffusely in the cytoplasm. Other pathological changes are summarized in Table 2.

Diagnosis

General investigations

Most patients with Wilson's disease have Kayser–Fleischer rings (Fig. 2) and low plasma caeruloplasmin concentrations. Haematological investigations, such as a full blood count and haptoglobin, detect anaemia and haemolysis; mean corpuscular volume, prothrombin time, and clotting studies detect malfunction of the liver. Biochemical investigations will provide additional information. These include increased serum transaminases (altered liver cell turnover) and reduced albumin and urea (disturbed hepatocellular function). Measurement of autoantibody titres (e.g. antimitochondrial antibody) are important to exclude primary biliary cirrhosis.

Specific investigations

These are necessary to confirm the diagnosis of suspected Wilson's disease, and to monitor the efficacy and side-effects of treatment.

Serum caeruloplasmin

This can be measured enzymatically (copper oxidase), by radial immunodiffusion, or by reverse passive haemagglutination. The activity and concentration of this glycoprotein is reduced or absent (less than 200 mg/l) in 95 per cent of patients with Wilson's disease. Some patients have caeruloplasmin levels in the lower range of the normal distribution which overlap with obligate heterozygotes and normal subjects (Fig. 3). Hypocaeruloplasminaemia and acaeruloplasminaemia do not always indicate Wilson's disease. The normal neonatal liver mimics the Wilson's disease patient, with low or absent plasma caeruloplasmin and high hepatic copper concentration; synthesis and secretion of caeruloplasmin to the plasma start during the first 3 to 6 months of life and hepatic copper concentrations decrease within the first 2 years of life.

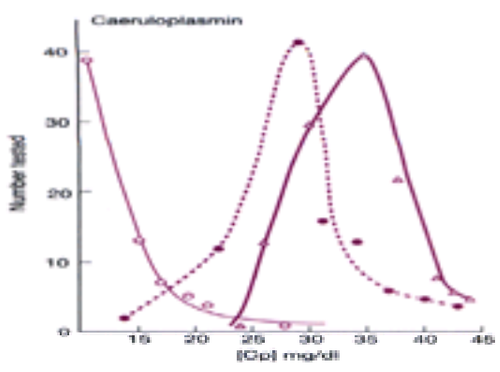

Fig. 3 Serum caeruloplasmin concentrations in controls, heterozygotes, and Wilson's disease.

Caeruloplasmin will also be reduced in protein malnourished states, reduced protein synthesis due to liver disease, protein loss due to the nephrotic syndrome, or a protein-losing enteropathy. Conversely hypercaeruloplasminaemia occurs as an acute phase protein reactant in acute inflammation, infection, pregnancy, and after oestrogen administration. This may increase previously low plasma caeruloplasmin concentrations to within the normal range.

Serum copper

Total serum copper will be reduced or low in Wilson's disease. However, non-caeruloplasmin-bound copper concentrations (loosely bound to albumin or amino acids; normally 50–100 µg/l) will be increased (more than 200 µg/l) in the untreated patient.

Urine copper

Urine excretion of copper is always increased in untreated Wilson's disease (more than 70–100 µg/24 h; normally less than 40 µg/24 h). Increased urinary copper may also occur in other liver diseases such as chronic active hepatitis and primary biliary cirrhosis. However, an increased urine copper in association with a low caeruloplasmin indicates Wilson's disease; the presymptomatic patient may still have a normal urinary copper excretion. Measurement of urine copper excretion is also important in monitoring the effects of chelating therapy where, early in treatment, urine levels may rise to 2000 µg/24 h and fall to less than 100 µg/24 h as the copper overload is reduced. Special care is needed when collecting urine samples to avoid contamination, and copper-free containers are required for the collection.

Provocation of urine copper excretion by giving penicillamine (500 mg orally) may be helpful in patients where the basal urinary copper is equivocal, and to assess the response of the Wilson's disease patient to treatment with chelating agents.

Liver copper concentration

Normal hepatic copper concentrations (15–55 µg/g dry weight of liver) can be measured by spectrophotometric assay, by atomic absorption spectrophotometry, or by neutron activation analysis. Liver biopsy allows measurement of liver copper concentration as well as histological assessment. In children or in the presence of significant liver disease (for example associated with coagulopathy), a transjugular liver biopsy may need to be considered.

In untreated Wilson's disease patients, the hepatic copper concentration is greater than 250 µg/g dry weight, and in heterozygotes, the concentration range is between 55 and 250 µg/g dry weight. Increased hepatic copper concentrations also occur in secondary copper overload conditions such as Indian childhood cirrhosis, primary biliary cirrhosis, sclerosing cholangitis, and chronic active hepatitis. These can be readily distinguished from Wilson's disease on clinical, biochemical, and histological grounds. Normal hepatic copper concentration excludes Wilson's disease in an untreated patient.

Radiocopper studies

Incorporation of orally administered radiocopper (^{64}Cu, ^{67}Cu, or ^{65}Cu) into caeruloplasmin at 1, 2, 3, and 48 h distinguishes clearly between normal patients and those with Wilson's disease, where little or no radiocopper is incorporated into the newly-synthesized caeruloplasmin.

Radiological imaging

Computer-assisted tomography and magnetic resonance imaging of the liver do not help in the specific diagnosis of Wilson's disease, although these imaging techniques will also detect non-specific associations of Wilson's disease such as splenomegaly and abnormalities in hepatic parenchyma. Central nervous system imaging with computer-assisted tomography or MRI demonstrate generalized cerebral atrophy and abnormalities in the basal ganglia.

Screening of family members

It is important that all first-degree relatives are screened for Wilson's disease once the diagnosis has been confirmed in the index patient. This is an essential part of the management of any patient with Wilson's disease. Screening of children should be after 3 years of age. It should include a history, clinical examination, slit-lamp examination of the eyes, liver enzyme and function tests, and serum caeruloplasmin concentration. If the results are suggestive of Wilson's disease, liver biopsy and a quantitative measurement of hepatic copper should follow (or radiocopper studies where liver biopsy is contraindicated).

Molecular tests

The diagnosis of Wilson's disease should be made on the basis of the clinical presentation, biochemical tests, and confirmed by DNA testing in patients with a high index of suspicion of the disease. Analysis of DNA from whole blood may be carried out to detect the common mutation H1069Q or, in Oriental populations, mutation H714Q. Most patients are compound heterozygotes carrying two mutations for the Wilson's disease gene. If the common mutations are not present, each of 21 exons in the gene must be screened by single strand conformational polymorphism (SSCP) or complete sequencing. Currently, this can only be undertaken in genetic units interested in Wilson's disease, and is not available for screening the general population. As methods for mutation detection improve, screening for this disease may become more practical.

Western blotting of caeruloplasmin isoforms obtained from whole blood or dried blood spots may be another, more simple, way of screening for Wilson's disease in the neonate and children over the age of 2 years.

Pathogenesis of the liver lesion

Copper, in free ionic form, is toxic to hepatocytes in man and in animals. Although the retained copper accumulates in lysosomes, there is no evidence that copper-filled lysosomes are more fragile, as is the case in haemochromatosis. Increased numbers of hepatic lysosomes and mitochondria have been described in untreated Wilson's disease, and lysosomes participate in excretion of copper into bile. Copper-containing mitochondria are more fragile, and it is likely that copper-induced hepatocyte damage results from impaired oxidative phosphorylation due to mitochondrial damage.

Several hypotheses have been advanced to explain the primary defect of failure in biliary excretion of copper. A link has been postulated between this gene defect and reduced plasma caeruloplasmin (Fig. 1). The liver in Wilson's disease does produce caeruloplasmin even when it is undetectable in plasma. Thus defects in this glycoprotein are likely to reflect abnormalities of processing or secretion. Evidence of reduced amounts of hepatic mRNA for caeruloplasmin has not yet been linked to the underlying metabolic defect. Two major molecular forms of caeruloplasmin are changed in Wilson's disease. The 132 kDa (plasma form) is reduced and the 125 kDa (biliary form) is absent, giving further support for a post-translational abnormality. It also suggests that caeruloplasmin may play more than a bystander role in the underlying metabolic defect. It is well established that reabsorption of biliary copper from the intestine in Wilson's disease is not increased. Characterization of the Wilson's disease gene suggests that the abnormality may be caused by an alteration in a specific membrane copper transporter (ATP7B) which may fail to bind copper and caeruloplasmin.

Management

The management of Wilson's disease involves the general care of any patient with liver disease and anaemia, and investigation of the family and siblings of the propositus, as well as specific therapy.

Diet

Strict dietary restriction of copper is not practical, but Wilson's disease patients should know which foods are high in copper. These include chocolate, liver, nuts, mushrooms, legumes, and shellfish. In addition, many Chinese dishes are high in copper and Oriental Wilson's disease patients and vegetarians will need special dietary advice. However, reducing copper in the diet is only an adjunct to the main pharmacological therapy.

Specific therapy

Walsh (1956) was the first to show how effective D-penicillamine was in removing copper from patients with Wilson's disease. The optimum time for treatment is in the early stages, and all patients with Wilson's disease should be treated, even if asymptomatic. Treatment is lifelong, unless the patient undergoes liver transplantation. The aim of treating a patient with Wilson's disease is to reduce toxic copper levels in the body tissues. This can be achieved by increasing the urinary excretion of copper. A negative copper balance should be monitored carefully since, with an increase in urine and faecal copper excretion which exceeds copper intake, increased urinary copper may reflect increased plasma non-caeruloplasmin copper (copper in its most damaging form). The effect of any therapy should be regularly monitored by clinical and radiological assessment, and by biochemical monitoring of abnormal liver enzymes and liver function. The agents commonly used in treatment of Wilson's disease, together with mechanisms of action and side-effects, are summarized in Table 3 and Fig. 4. (See also Plate 2).

Fig. 4 Penicillamine dermatopathy—elastosis perfringens serpiginosa. (See also Plate 2.)

Prognosis

Early diagnosis and chelation therapy is the only way to ensure a good outcome in Wilson's disease. Most symptomatic patients improve and have an almost complete resolution of their symptoms. The prognosis is best in the asymptomatic individuals who are detected early, often by meticulous screening of families of index cases. A poor prognosis is more likely in patients with severe liver damage, acute fulminant hepatic failure, acute neurological disease, and dystonia. In addition, in the presence of cirrhosis, even when copper-depleted, the risk of variceal bleeding and intercurrent infections remains.

Non-compliant patients who discontinue treatment may relapse rapidly and die; they are refractory to reversal of copper overload on restarting chelation therapy. In these patients, only liver transplantation would improve their prognosis.

Copper deficiency

Copper deficiency disorders in man are rare, occur in two forms, and have different clinical features:

1. Genetic: Menkes' disease ('steely' or 'kinky' hair syndrome) due to an X-linked recessive defect of intestinal absorption leading to defective synthesis of important copper-containing enzymes, and typical clinical features with damage to the brain and arteries. The occipital horn syndrome is a milder form of Menkes' disease.
2. Acquired: this may occur in malnourished children, adults with severe malabsorption syndromes, in patients taking regular total parenteral nutrition, or in patients regularly taking chelating agents (penicillamine) as treatment for rheumatoid arthritis. The diagnosis rests on low serum copper measurements, hypochromic microcytic anaemia, and evidence of bone demineralization.

Menkes' disease

Menkes first described the disease in 1962, noting the X-linked recessive inheritance in a family of English–Irish descent. Subsequently, a number of case reports defined the clinical features of this disorder, and pattern of inheritance. Danks (1972) described the defect in intestinal absorption of copper which caused serum copper deficiency and which explained the diverse clinical features.

In 1982, the gene for Menkes' disease was isolated by three different groups. The gene maps to human Xq13 and encodes a p-type copper transporting ATPase (ATP7A). In 1983, Peltonen described abnormalities of copper and collagen metabolism in cultured fibroblasts as a feature of Menkes' disease; an increased rate of copper incorporation and accumulation of metallothionein was shown. The occipital horn syndrome, with survival to adult life, was described in 1983. renatal diagnosis for Menkes' disease was commenced in 1974 by measuring ^{64}Cu accumulation in cultured amniotic cells. Treatment of Menkes' disease with copper histidine commenced in 1989, with some improvement in the neurological symptoms and survival (Table 1).

Definition

Menkes' disease is a multisystem, lethal disorder of intracellular copper metabolism. It presents with the symptoms of neurodegeneration and connective tissue manifestations in skin, hair, and bone. A pathognomonic feature is the sparse, coarse, depigmented hair termed 'kinky' or 'steely' hair syndrome (Fig. 5 and Plate 3). A defect in intestinal copper absorption is associated with defective synthesis of copper enzymes and tissue copper accumulation, and this explains the changes in hair, characteristic facies, skin, and other changes. Importantly, fibroblasts in this disease contain five times the copper of normal cells. The untreated condition results in death, usually under 2 years of age. A milder form of the disease, a possible allelic mutation, is the occipital horn syndrome.

Fig. 5 Appearance in Menkes' disease. (See also Plate 3.)

Incidence

The population frequency has been suggested by Danks to be around 1 in 40 000 per live births in Australia, but, as with Wilson's disease, this may be higher because some patients may remain undiagnosed even at death. More recent estimates suggest an incidence of 1 in about 300 000 live births in European countries, with an estimated mutation rate around 1.96×10^{-6} based on isolated Menkes' disease cases born during 1976 to 1987.

Clinical features

The first symptoms occur between 6 weeks and 6 months of age; major signs are poor growth, mental retardation, and hair abnormality. The disorder can present as a premature birth, and episodes of hypothermia may occur within the first few days or weeks of life. Some babies develop normally until 3 months of age, but many are ill from birth. The disease is progressive, culminating in death by the age of 3 years.

Classical characteristics are an abnormal facial appearance (Fig. 5) with flaccid skin, typical of cutis laxa, defective grey pigmentation of the skin, and lightly pigmented hair. Typically, the hair shaft is twisted to give pili torti, which is termed 'steely' or 'kinky' hair syndrome. Abnormalities of major arteries occur, giving thickened, tortuous vessels due to abnormal elastin fibres. Vascular complications, particularly subdural haematoma, can occur. Abnormalities in bone include Wormian bones in the skull and osteoporosis with widened metaphyses, which may fracture. Child abuse may be wrongly considered in these patients.

Progressive focal cerebral and cerebellar degeneration are also typical of the disorder, with associated convulsions and mental retardation. In the milder case of Menkes' disease, the occipital horn syndrome, ataxia and the complications of bladder or urinary diverticulae, hernias, and skin or joint laxity are prominent.

Genetics

Pedigree studies have confirmed Menkes as an X-linked recessive disease. The gene has now been mapped to Xq13.3 (Table 1).

Pathogenesis

Defective intestinal copper absorption leading to a copper deficiency and defective activity of copper-containing enzymes explain the clinical features of connective tissue and arterial abnormalities: tyrosinase (depigmentation and skin pallor); lysyl oxidase (abnormalities in arterial intima due to lack of formation of cross-links in elastin and collagen); monoamine oxidase ('kinky' hair); cytochrome c oxidase (hypothermia); and ascorbate oxidase (skeletal demineralization). The diagnostic hair abnormality probably arises from defective formation of disulphide bonds in keratin, another copper-dependent process. In Menkes' disease, most tissues including intestinal mucosa, kidney, placenta, and testis, with the exception of the liver, have an increased copper concentration. ^{64}Cu studies have demonstrated defective cellular efflux of copper.

Pathology

Major changes are in the arteries and central nervous system. In arteries, degenerative changes lead to aneurysmal dilatation, rupture or stenosis, and areas of intimal proliferation and thrombosis. In the larger arteries, fragmentation of the internal elastic lamina occurs, probably secondary to defective elastin formation. In the later stages of the disease, brain infarcts and haemorrhage occur.

Neuronal destruction and gliosis are found in the cerebral cortex. In the cerebellum, Purkinje cells are destroyed. Myelin is also defective. Changes in skeletal muscle, the iris, and retina have also been noted.

Diagnosis

Although hair changes may not be evident in the first few months of life, the initial diagnosis is based on the principal clinical features of Menkes' disease.

Biochemical tests

Reduced concentrations of serum copper and caeruloplasmin with reduction in gut mucosal and hepatic copper in association with the clinical features are diagnostic. Liver histology is normal but reduced concentrations of liver cuproenzymes, such as cytochrome oxidase and superoxide dismutase, are found in infants over 3 months of age. Accumulation of ^{64}Cu in cultured skin fibroblasts after a 20-h pulse and impaired efflux after a 24-h pulse confirms the diagnosis. Laboratories need to be skilled in radiocopper assays.

Molecular tests

Following identification of the Menkes' disease gene (*MNK*), fluorescence *in situ* hybridization, Southern blot hybridization, or PCR-based mutation analysis may detect various mutations. Chromosomal aberrations can be investigated by standard chromosome banding techniques and confirmed by *in situ* hybridization.

Prenatal diagnosis in the first trimester by measuring the copper content of chorionic villi using neutron activation analysis is unreliable. Contamination of samples gave false-positive results, as did intracellular copper analysis of cultured amniotic fluid cells. DNA analysis can now be carried out, but mutations must first be identified in the family and the mother's carrier status should be known. However, mutation analysis is a difficult undertaking because of the large size of *MNK*. Carrier detection may be possible by ^{64}Cu uptake in cultured fibroblasts, but, because of random activation of the X chromosome, may also be unreliable.

Management

Only administration of copper as copper histidinate has been shown to be successful in correcting skin, hair, and pigmentation abnormalities. The neurological damage appears to be irreversible unless treatment is started very early, as it is likely that copper damage to neurones is well established *in utero*. Thus, treatment should be commenced as early as possible before irreversible neuronal damage occurs. Late diagnosis treatment may prolong survival in patients up to 10 or 20 years but without significant improvement in the clinical features. Treatment with monoamine oxidase inhibitors, with the aim of correcting defective catecholamine synthesis due to deficiency of monoamine oxidase, has not been successful. What is now required is the means to deliver amounts of copper in an appropriate form, sufficient to replace tissue deficiency, but avoiding copper toxicity.

Prognosis

Prognosis varies with the mutations and clinical severity of the disease. Untreated, patients are unlikely to survive beyond 2 to 3 years of age. Use of copper histidine, particularly when commenced early, has prolonged survival to 20 years, with improvement in most of the clinical features except those due to neurological damage. In the occipital horn syndrome survival is longer.

11.8Lysosomal storage diseases

T. M. Cox

Definition

Lysosomal storage diseases represent the consequences of disordered lysosomal digestive function. The lysosome is an intracellular organelle that serves to degrade biological macromolecules derived either endogenously, from metabolism or cell structures, or from the breakdown of exogenous material incorporated by endocytosis.

Since lysosomes are found in most cells, disruption of their function leading to the storage of undegraded macromolecules usually affects many tissues. More than 40 lysosomal disorders are now recognized; they represent single or multiple defects in the organellar complement of specific acid hydrolases, their activator proteins, membrane proteins, or the intrinsic carrier proteins that transport the substrates or products of lysosomal digestion.

Lysosomal diseases, though often considered to be very rare, occur with a surprisingly high birth frequency. About one in 5000 live-born infants have a lysosomal storage disorder; many of these are disabling conditions: Gaucher's disease and Fabry's disease—which are glycosphingolipidoses—are possibly the most frequent. The recent addition of Batten's disease and other ceroid neuronal lipofuscinoses to this burgeoning family of disorders emphasizes the importance of the lysosomal diseases in biology and in medicine: they represent a large and disproportionate burden of illness in the population and for clinical services.

Biological importance of lysosomes

Since their discovery nearly 50 years ago by the medically qualified biologist Christian de Duve, lysosomes and their associated endosomal structures have been at the focus of an impressive body of research into molecular cell biology. De Duve recognized that, with their ready access to extracellular fluid, lysosomes could be used to deliver therapeutic proteins and other agents to the heart of the cell—a prophecy well rewarded with the development of targeted enzyme-replacement therapy for several lysosomal diseases today. The success of these treatments is predicated on detailed knowledge about the delivery of nascent lysosomal proteins to the organelle during its biogenesis, the definition of inherited defects in lysosomal function—and of the development of recombinant DNA technology for the manufacture and the post-translational modification of human proteins for therapeutic use. Greater understanding of lysosomal storage diseases has emanated from research into the metabolism of particular cellular macromolecules that accumulate in lysosomal storage diseases, and into the ebb-and-flow of substrates and products as they pass through lysosomal compartments.

Structure and function of lysosomes

Lysosomes are strikingly diverse in shape and size, but all belong to a single class of ubiquitous organelles containing numerous acid hydrolases (around 40 of which are known) with optimum activity in the pH range, 5 to 6. The matrix space of these organelles is surrounded by a single unit membrane containing transport proteins that facilitate the export of digestion products. Specialized carrier components use energy derived from ATP to maintain the optimal intraorganellar acid pH for enzymatic hydrolysis. The integrity of the lysosome membrane is maintained by highly glycosylated membrane proteins that offer protection from the activated luminal proteases with which they are in contact. Histochemical stains can identify pathological lysosomes in tissue preparations; together with electron microscopy, these methods can be used to detect abnormal lysosomes engorged with storage material in diseased tissues.

Delivery of macromolecules for lysosomal digestion

The lysosome is an intracellular digestive system but acquires complex macromolecules for breakdown by three main pathways: (1) receptor-mediated endocytosis; (2) engulfment and fusion; (3) autophagy. Receptor-mediated endocytosis occurs by means of clathrin-coated pits, a process in which molecules are delivered after internalization to a peripheral, and later to a perinuclear endosomal compartment, 'the endolysosome'. The endolysosome undergoes maturation to form a lysosome after the loss of certain membrane components and further acidification. Some molecules acquired by receptor-mediated endocytosis (for example, low-density lipoproteins) are specifically retrieved and ultimately returned to the cell surface having delivered their cargo of cholesterol within the lysosome. Other molecules that are not retrieved are ultimately degraded by fusion with mature lysosomes and enzymatic hydrolysis (for example, the epidermal growth factor (**EGF**) receptor system).

Lysosomes are also involved in a specialized process for the degradation of exogenous particulates and proteins, including microbes and effete cells such as erythrocytes and neutrophils. Although this engulfment and fusion process involving phagolysosomes is distributed throughout nature, it is particularly active in macrophages and dendritic cells that exhibit active phagocytosis. A specialized phagolysosome variant occurs in osteoclasts that are derived from myeloid cells of mononuclear phagocyte origin. The osteoclastic resorptive vacuole serves as a large exteriorized lysosomal compartment which is independently acidified for the process of bone resorption. In macrophages, cell-surface components that occur on bacteria and yeast, as well as exogenous cells, are recognized and bound by specific receptors on the plasma membrane. The phagocytes engulf foreign material to form large vesicles in which acidification and proteolysis, as well as the secretion of degradative molecules (including reactive oxygen and nitrogen species), is initiated. The phagolysosome fuses with lysosomes and further acidification occurs, so that the acid hydrolases are activated to bring about the breakdown of the ingested material.

Autophagy occurs within cells. It appears that, in a constant process of membrane fusion and flow, organelles (including the endoplasmic reticulum, mitochondria, peroxisomes, and other lysosomes) fuse with lysosomes, by which they are engulfed before breakdown. This process retrieves the basic building blocks of cellular components and proceeds hand-in-hand with *de novo* synthesis and the renewal of intracellular compartments throughout the life of all cells. When lysosomal function is impeded, the breakdown of endogenous organelle-derived macromolecules is impaired; this, together with a failure to breakdown exogenous macromolecules, results in the pathological storage of partially degraded and undegraded material.

Enzyme-replacement therapy for lysosomal storage diseases

Early experiments using fibroblasts obtained from patients suffering from mucopolysaccharidoses such as Hurler's disease and Hunter's syndrome, showed that the rate of degradation—rather than the rates of synthesis or secretion of radiolabelled glycosaminoglycans that accumulate in these diseases—is severely disrupted. In experiments in which fibroblasts obtained from genetically distinct storage disorders were co-cultured, the progressive accumulation of glycosaminoglycan that occurs

when the fibroblasts are cultured separately, was prevented. Biosynthetic labelling experiments showed that degradation of the previously accumulating substrates was restored to normal in these co-culture experiments.

An investigation of this phenomenon by Elizabeth Neufeld and colleagues later showed that each of the fibroblast cultures elaborated and delivered a specific corrective factor to the medium, which ultimately proved to be a high molecular weight form of the specific hydrolases that were lacking in each of the pathological fibroblasts. These corrective factors, when taken up from the medium, restore the normal intracellular degradation of glycosaminoglycans. This secretion–recapture process was shown to be mediated by an unusual carbohydrate component, the so-called 'recognition marker', mannose-6-phosphate. This sugar is found as a terminal moiety derived by post-translational modification and during the secretion of lysosomal enzymes. Neufeld's findings led to the identification of specific receptor pathways for the biosynthesis and uptake of nascent lysosomal proteins by the organelle during the course of organellar formation—and have subtended a great deal of productive biological research. From the therapeutic aspect, however, the experiments immediately raised the possibility of functional complementation of lysosomal storage disorders by supplying particular molecular isoforms of the enzymes that are deficient in the individual storage disorders.

Characterization of lysosomal recognition markers occurred at a time when other cell-surface glycoprotein recognition systems were being identified: for example, the asialoglycoprotein receptor which was implicated by Ashwell and colleagues in the uptake of plasma proteins by parenchymal liver cells *in vivo*. Thus the concept of enzyme replacement for lysosomal storage disorders was established but it was many years before an effective treatment based on glycoprotein targeting was brought into clinical practice. Indeed, the successful use of enzyme replacement was dependent on an understanding of glycoprotein chemistry, receptor-mediated endocytosis, and the molecular cell biology of lysosomal biogenesis—all subjects that themselves depended on a detailed molecular understanding of human lysosomal storage diseases. Identification of the secretion–recapture process in the lysosomal diseases provided the key theoretical underpinning to empirical complementation studies that preceded successful enzyme-replacement therapy. Cellular complementation, by providing a source of wild-type enzyme delivered from allogeneic bone marrow transplantation, has also had spectacular successes in several lysosomal disorders.

Alternative treatments for the glycolipid disorders

For many years it has been recognized that the accumulation of storage material within lysosomes is the precipitating factor for the development of tissue injury and the inflammatory response that accompanies the lysosomal storage disorders. Although it is principally a failure of degradation or export from the lysosome that leads to the excess storage, the concept of depleting the supply of macromolecular substrate to prevent the accumulation of storage material has been developed experimentally and brought to human clinical trials.

Of particular interest has been the discovery that certain iminosugars related to deoxynojirimycin selectively inhibit the glucosyltransferase step as the first committed reaction in the biosynthesis of glycosphingolipids. Experimental studies in cultured cells with pathological storage of glycolipids in lysosomes showed regression of the intralysosomal material after exposure to low concentrations of these natural product derivatives. Later studies demonstrated the reduced storage and delayed symptom onset in experimental animal models of debilitating human glycosphingolipidoses such as Tay–Sachs disease and Sandhoff disease (see Chapter 24.6.1). *N*-butyldeoxynojirimycin, a particular analogue of these iminosugars, has previously been used in clinical trials in an attempt to inhibit the replication of human immunodeficiency virus (**HIV**), as a result of its related inhibitory activity towards a-glucosidases; in these trials, such drugs appear to be relatively non-toxic in large doses. With these data in mind, studies were undertaken to investigate the concept of substrate depletion as a treatment for established glycosphingolipidoses. Evidence of disease regression was obtained in an open-labelled trial of *N*-butyldeoxynojirimycin in patients with Gaucher's disease, as shown by the reduction in visceral enlargement, enzymatic markers of Gaucher's disease activity (plasma chitotriosidase activity), and a slow improvement in haematological parameters. In Gaucher's disease, it was anticipated that the beneficial effects of substrate depletion would be indirect, since they would result from the decrease in the delivery to the macrophage system of glycolipid substrates on the membrane of blood cells. In any event, since the iminosugars are small molecules that penetrate the blood–brain barrier, the possibility of their use (either as a monotherapy or as a synergistic treatment with enzyme therapy) for neuronopathic Gaucher's disease has been raised, as well as for the treatment of the otherwise intractable glycosphingolipidoses that cause severe neurological disease. No effective treatment is currently available for Tay–Sachs disease, Sandhoff disease, and GM1 gangliosidosis, and the juvenile and late-onset variants are thus potential targets for substrate depletion with the iminosugars.

Substrate-depletion therapy depends upon the presence of residual enzymatic activity in the lysosomes. Disturbances of the dynamic equilibrium in the supply and handling of macromolecular lysosomal substrates occur, but most, if not all, patients with glycosphingolipid disorders express residual enzymatic function. At present, clinical trials are underway not only in Gaucher's disease but in patients suffering from severe neuronopathic glycolipidoses such as late-onset GM2 gangliosidosis as well as Niemann–Pick-disease type C. This latter disorder is itself associated with a secondary accumulation of toxic glycolipids within neuronal lysosomes (see below).

The iminosugars appear to be relatively well tolerated apart from causing diarrhoea, probably as a result of impaired biosynthesis of intestinal disaccharidases as a subsidiary effect on oligosaccharide processing. Indeed, experience shows that they appear to be well-tolerated once appropriate dietary restrictions are introduced. However, several cases of peripheral neuropathy have been reported in long-term studies of patients with Gaucher's disease. The sugars are absorbed after oral ingestion and offer the hope of a therapy to arrest the progression of several severe neurological sphingolipidoses that are otherwise beyond therapeutic correction. At present, the outcome of the clinical trials based on promising animal experiments with the iminosugars and other inhibitors of glycolipid biosynthesis derivatives is urgently awaited but few better general strategic options than substrate deletion appear to be available for exploration in patients who might otherwise be without hope.

Pharmaceutical development

Lysosomal storage diseases have been a focus for several prominent therapeutic discoveries. The cooperation of informed patient groups, applied medical research funded by government organizations, and the commercial interest of medium-sized pharmaceutical companies has been promoted by recently introduced Orphan Drug legislation. This legislation has facilitated the early exclusive licensing of products for rare diseases—and has greatly enhanced corporate pharmaceutical investment.

At present, at least six recombinant human enzyme preparations are in clinical use or late stages of development. Indeed, several companies continue to express interest in this area with gene therapy, recombinant proteins, and small-molecule products in active competitive development. There can be little doubt that industry has drawn encouragement from the commercial success of recombinant human products such as erythropoietin, human insulin, and interferon-b and -g. These are top-selling agents that have brought handsome rewards for their parent companies, whose manufacturing patents have several times been vigorously defended. At the time of writing, Genzyme Therapeutics, the United States-based company first involved in the development of targeted enzyme-replacement therapy for Gaucher's disease, is providing treatment to about 3000 patients worldwide. The company reports an annual operating profit of more than $500000000. As described here, many of the 40 or so known human lysosomal disorders are disabling and distressing conditions that cause pain and disability in infants, children and adults of all ages, and for which, until recently, no definitive treatments have been available. The unpredicted magnification of interest that has accompanied successful medical research into this area over a period of less than 50 years has been a model of utility and progress; it continues to provide for many patients the hope that, at last, definitive relief may be forthcoming.

Pathology

Although lysosomal defects occur in all tissues, the principal focus of each disease is observed in those tissues where turnover of the parent macromolecule with impaired degradation is greatest. For example, in Gaucher's disease, the turnover of parent glycolipids appears to be greatest in the mononuclear phagocytes. Here the accumulation of glycolipids derived from the breakdown of membranes present in the formed blood elements occurs; with mild or moderate impairment of the responsible enzyme, glucocerebrosidase, the pathology is restricted to the macrophage-containing tissues of the liver, spleen, bone marrow, and, occasionally, the lung. When inherited defects further impair the activity of glucocerebrosidase, additional pathology is seen in the nervous system where the accumulating glycolipid is derived from the turnover of endogenous neural sphingolipids.

Microscopic pathology shows storage within dilated vesicular spaces, which represent diseased lysosomes. Sphingolipids, being hydrophobic molecules, tend o accumulate in whorls known as 'membranous cytoplasmic bodies' where they assume a lamellar structure within lysosomal spaces. Paracrystalline and crystalline material in distended lysosomes may also be seen under electron microscopy, for example in the accumulation of the charged glycolipid sulphatide that occurs in metachromatic leucodystrophy (arylsulphatase A deficiency). With more water-soluble substrates, granular material accumulates within the vesicular spaces. These spaces represent distended and often fused lysosomes, filled for example with undegraded glycogen macromolecular complexes in acid maltase deficiency (Pompe's disease, glycogen storage disease type II, see Chapter 11.3.1). Pompe's disease was the first lysosomal storage disease to be identified. Its recognition by

Henri-Gery Hers (a colleague of de Duve) led to the concept of 'autophagy' and of the rapid turnover of normal macromolecular components of the cell—including glycogen—by the lysosomal compartment. Pompe's disease has also been the subject of intensive clinical research and early successes have been reported in trials of enzyme-replacement therapy (see the Further reading list).

Although the amount of storage material that accumulates within lysosomes in the lysosomal diseases is several hundred- or thousand-fold greater than normal, the absolute amount of material may amount to only a few grams or so. The quantity of storage material, however, bears no relationship to its pathophysiological effects. In some instances, the presence of a few grams of, for example, the sphingolipid sphingomyelin in Niemann–Pick disease, is associated with massive visceral enlargement with accompanying inflammatory ischaemic and other destructive changes due to the presence of storage cells. Similarly, marked pathological injury occurs: in the viscera and bone marrow spaces of patients with Gaucher's disease; in the heart and skeletal muscles of patients with a-glucosidase deficiency, due to modest glycogen accumulation in the sarcoplasm of striated and cardiac myocytes; and, in the form of neuronophagia, in the brain of patients with Tay–Sachs disease and GM_1 gangliosidosis. Microscopic examination of diseased tissues may also reveal pathognomic storage cells, for example the modified macrophage-derived microglia ('globoid cells') in Krabbe's disease, the striking pathological macrophages of Gaucher's disease, and the foam cells of Niemann–Pick disease types A, B, and C.

Pathogenesis

At present, there is only rudimentary knowledge about the pathological link between lysosomal storage, tissue injury, and the diverse clinical manifestations that accompany lysosomal storage diseases. In the case of the sphingolipidoses, sphingolipids participate in cell-recognition events and receptor biology; sphingolipid metabolic intermediates (lysosphingolipids) also function as signalling molecules in apoptotic and proliferative responses. However, the precise relationship between the storage material and the development of overt clinical disease is not fully understood. In one striking instance (Krabbe's disease due to b-galactosidase deficiency), however, it has been found that the unusual globoid cell can be induced *in vitro* by the pathological lysosphingolipid, psychosine, that accumulates in the diseased tissues. Psychosine and related glycolipids are thus implicated in the final pathological pathway that leads to the disease phenotype. Psychosine itself interacts with a G-protein-coupled receptor on human monocytic-lineage cells. This finding may have profound implications for other lysosomal disorders associated with cell loss and apoptotic as well as inflammatory fibrotic responses. Several indirect studies have indicated the release of inflammatory cytokines in at least one lysosomal storage disease (Gaucher's disease), which may explain the metabolic and plasma protein abnormalities associated with a sustained inflammatory response that characterizes the clinical syndrome.

In a scientific era in which the combined study of gene and protein expression offers a powerful means to understand complex functional networks that lead to tissue pathology, the lysosomal storage diseases represent a promising field for exploration using large-scale, high-throughput methods to investigate altered cell metabolism and signalling responses. An early potential application of this work has been the use of authentic experimental models of some of the more severe storage diseases generated by gene knockout technology; these models facilitate research on otherwise inaccessible tissues such as the brain during the development of the storage phenotype. Gene-expression profiling experiments conducted during periods of neuronal cell death have shown upregulation of genes related to the inflammatory process in the nervous system of mice that serve as a model of GM_2 gangliosidosis. The activation of local microglia is shown by the signature of upregulated macrophage expression markers and lymphocyte chemoattractants, as well as genes encoding antigen-presenting MHC class II molecules. Since this particular GM_2 gangliosidosis is partially ameliorated by bone marrow transplantation that supplies a population of genetically competent immune cells (and which is accompanied by the use of powerful immunosuppressant agents), it seems probable that the altered immunity accompanying bone marrow transplantation may itself modify the clinical expression of lysosomal storage diseases affecting the brain. This may occur without directly affecting the storage material.

Biochemical classification of the lysosomal storage diseases Table 1)

Lysosomal diseases result from inherited defects in lysosomal hydrolases and the mechanisms for delivering them to the organelle; lysosomal enzyme activators and cofactors; lysosomal membrane proteins; and carrier systems for the transport of the substrates and products of lysosomal digestion between the organelle and the cytoplasm. Most of the enzymatic defects are restricted to the activity of a single hydrolase but defects of activators and cofactors, as well as proteins involved in the processing of nascent lysosomal enzymes for organellar delivery, can lead to generalized defects of lysosome function.

As the clinical manifestations for the 40 or more diseases associated with disturbed lysosomal function are very diverse, the reader is referred to specialized literature including the paediatric literature for further information (see Further reading). Broadly, the lysosomal diseases may be associated with: slowly progressive, connective-tissue disease with skeletal abnormalities; neurological symptoms that include deafness and progressive mental deterioration; and visceral syndromes affecting the spleen, liver, lung, kidney, and heart. Ocular disease occurs particularly in the mucopolysaccharidoses and in the neurosphingolipidoses: this may cause corneal opacities or severe retinal changes, including a macular cherry-red spot. Neurological symptoms may have their onset from early infancy to adulthood, beyond even 60 years. In the past, patients with Tay–Sachs disease and other late-onset gangliosidoses were misdiagnosed as having demyelinating disease, Parkinson's disease, or even hereditary ataxia.

Diagnostic features

All lysosomal diseases disturb the catabolism of complex molecules in several tissues. Thus the symptoms are usually permanent and progressive; they show no relationship to food intake and are generally independent of intercurrent illness. Those disorders that affect metabolically active organs, such as the liver and kidney, often cause functional impairment, including the manifestations of liver failure, portal hypertension, and, in the case of the kidney, rickets, metabolic acidosis, and the effects of the renal Fanconi syndrome.

The occurrence of coarse facies, joint stiffness, vacuolation in circulating lymphocytes or neutrophils, with or without associated bone changes and hepatosplenomegaly, suggests the presence of one of the mucopolysaccharidoses or glycosphingolipidoses. Disorders associated with progressive neurological and mental deterioration with visceral and skeletal changes or other somatic disturbances strongly suggest the presence of a glycoproteinosis, such as mannosidosis or fucosidosis, or one of the mucopolysaccharidoses (**MPS**) including Hurler's, Hunter's, or Sanfilippo's disease (MPS I–III, respectively). Skin signs are unusual in lysosomal diseases, but the presence of small angiokeratomas, particularly in the region of the buttocks and genitals, strongly suggests the diagnosis of the sphingolipidosis, Fabry disease (see below), or fucosidosis or the rare condition, Schindler's disease (acetylgalactosaminidase deficiency).

Prominent bone necrotic lesions in association with the early onset of visceral disease, with or without supranuclear ophthalmoplegias, suggest either Niemann–Pick disease type A and C or neuronopathic Gaucher's disease (type III). Ataxia is a feature of GM_1 and GM_2 gangliosidoses, and a flaccid paraparesis in young children might suggest metachromatic leucodystrophy; widespread white-matter disease in association with a frontal dementia is a characteristic presentation of juvenile and adult forms of metachromatic leucodystrophy. Early-onset leucodystrophy is often caused by metachromatic leucodystrophy and Krabbe disease is a rare but important diagnostic entity in this group since the disease may be arrested by allogeneic marrow transplantation in the first 2 months of life. Lysosomal diseases with prominent neurological manifestations are often associated with progressive mental deterioration, with or without the onset of spasticity, myoclonic seizures, and optic atrophy. Extrapyramidal signs including parkinsonism, athetoid movements, and dystonia are frequent in this group of disorders.

Lysosomal diseases are a prominent cause of progressive neurological and mental deterioration in patients whose disease starts during adolescence up to mature adult life, and should always be considered in the diagnostic examination. Corneal opacities suggest cystinosis, I-cell disease, mucopolysaccharidoses, mannosidosis, Fabry disease, and galactosialidosis, as well as one form of Gaucher's disease with neuronopathic features (the D409H type IIIc variant). Specific syndromes are described below.

Diagnostic pathology

As described earlier, the pathological manifestations of the lysosomal diseases are diverse. They may range from enlargement of viscera with infiltration by abnormal macrophages containing storage material (foam cells of Niemann–Pick disease or Gaucher's cells) to bone infarction, neuronophagia, vacuolation of renal tubular cells, and diverse tissue infiltrates. Inclusion bodies may be observed in metachromatic-stained cells of the urine deposit or in circulating neutrophils and lymphocytes (Maroteaux–Lamy disease); staining with a periodic acid–Schiff reagent may reveal diastase-resistant glycolipid storage in the kidney and other organs in Fabry disease and other glycosphingolipidoses. The presence of metachromatic storage material in nervous tissue, including peripheral nerves, is characteristic of the sphingolipidosis, metachromatic leucodystrophy (Fig. 1 and Plate 1).

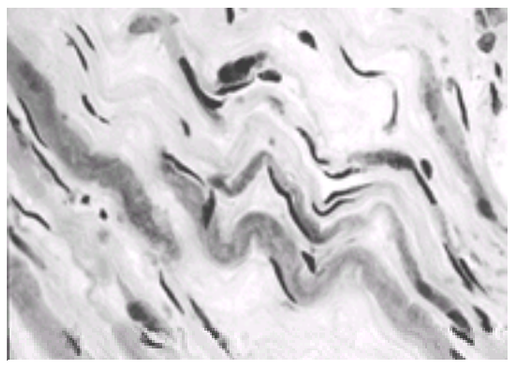

Fig. 1 Sural nerve biopsy stained with toluidine blue from the patient shown in Fig. 2 with metachromatic leucodystrophy. Note the brown-staining granular material within Schwann cells and perineurial macrophages typical of this disorder due to the deposition of the glycolipid sulphatide. (By courtesy of Dr. J. Xuereb, Addenbrooke's Hospital). (See also Plate 1.)

Ultrastructural examination is often diagnostic for lysosomal diseases: membrane-bound vesicles containing storage material that may show a crystalline or concentric appearance, or, in the case of glycogen in Pompe's disease, a granular appearance. The presence of concentric arrays of material strongly suggest a sphingolipidosis. Amorphous material accumulates within the lysosomal vacuoles in the mucopolysaccharidoses and glycoproteinoses. The secondary effects of lysosomal hypertrophy include increased staining for tartrate-resistant acid phosphatase and other lysosomal markers, including intrinsic lysosomal membrane proteins, for example LAMP-1.

Radiology

Ultrasonography, magnetic resonance imaging (**MR**I), and computed tomography (**CT**) may reveal visceral enlargement and infiltration, for example Niemann–Pick disease, mucopolysaccharidoses, Gaucher's disease. Skeletal radiographs may reveal bone expansion in vertebrae and in the phalangeal and long bones, sometimes associated with infarction and collapse, particularly in Niemann–Pick disease type B and Gaucher's disease. Echocardiography may reveal thickening and calcification of the cardiac valves (particularly of the aortic ring), infiltration of cardiac muscle causing ventricular hypertrophy in Pompe's disease, Fabry's disease, and, especially, in mucopolysaccharidoses I, IV, and VI.

Neuroradiology is of value—particularly in patients with mucopolysaccharidoses, and in Morquio's syndrome as well as MPS syndromes I, II, and VI where instability of the atlantoaxial joint may cause fatal subluxation in relation to increased soft tissue surrounding the dens. MRI of the cervical spine in MPS is critical in judging the need for joint stabilization by posterior fusion. Similarly, investigations of the lower spine may determine the cause of progressive spinal deformity due to lumbar kyphosis, and assist in the evaluation of the need for surgical intervention. MRI of the brain is invaluable in the assessment of dementing illnesses: cortical and/or white-matter disease may be delineated. Magnetic resonance imaging is often critical for diagnosing the striking white-matter changes that occur in patients with metachromatic leucodystrophy (Fig. 2).

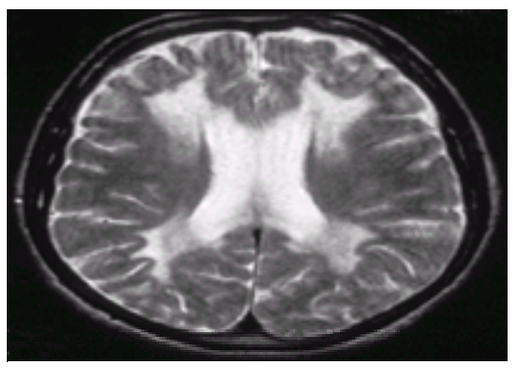

Fig. 2 Magnetic resonance imaging of the brain of a young woman with adult-onset metachromatic leucodystrophy. Notice the high signal intensity especially in the frontal white matter and periventricular regions. This patient presented with bizarre behaviour due to a frontal-type dementia; there are no neurological signs or symptoms. Short-term memory loss and lack of planning and higher executive functions are prominent features of her illness.

Diagnosis of lysosomal diseases

It is critical to establish a definitive diagnosis of a suspected lysosomal disease, even in critically ill patients, for two reasons: these disorders are inherited either as X-linked or as autosomal recessive traits, and the diagnosis may have important consequences for reproductive choice in other family members and for clarifying unexplained symptoms in at-risk relatives. Increasingly, enzyme-replacement therapy, bone marrow transplantation, or even substrate-reduction therapies may be available for their definitive treatment. Furthermore, several disorders respond well to palliative measures including renal transplantation and hepatic transplantation. Finally, a great deal of expertise is available from specialist groups with experience of treating these conditions.

Charitable associations now exist in many countries for members to share their experiences and provide advice and counselling. Above all, invaluable information about available medical services for specific conditions can be obtained through patient organizations. The Worldwide Web provides a useful entry into this, often untapped, resource where key information of importance to both patients and their doctors—and other relevant healthcare personnel—can be obtained.

The key to making the diagnosis of a lysosomal disease is enthusiastic and curious suspicion. In most circumstances, once suspected, the diagnosis can be made with relative ease by referral to a specialized regional reference laboratory for the diagnosis of metabolic disorders; senior laboratory staff will usually advise about the handling of appropriate tissue material for diagnostic studies. In the first instance, simple histochemical stains of existing biopsy material and examination of urine metabolites, including lipids and oligosaccharides, may narrow down the diagnosis. More commonly, specific enzymatic assays are used—generally carried out on leucocytes isolated from fresh heparinized blood samples, or on fibroblasts cultured from small skin biopsies.

Molecular analysis of genes encoding lysosomal enzymes may often support the enzymatic diagnosis, and may, on occasion, provide rough guidance as to the expected phenotype of the disease. DNA-based studies are of particular value for future prenatal diagnosis in a particular pedigree, and for the diagnosis of carrier status in at-risk females for heterozygosity in the X-linked diseases such as Hunter's and Fabry's disease. Lately, there has been a strong and justified trend in favour of specific enzymatic and genetic diagnoses, rather than for diagnoses based on the examination of biopsy material by light microscopy with or without the additional use of special histochemical stains. However, electron microscopy of biopsy material may be of particular value in recognizing the type of disorder but it is rarely essential for a specific diagnosis. Hitherto, histochemical and histopathological methods have led to diagnostic inaccuracies, but it must be admitted that many cases of lysosomal disease, particularly as they affect adults, have come to light as a result in the past of bone marrow examinations, liver biopsies, and other procedures carried out in an attempt to arrive at a diagnosis in an otherwise puzzling condition.

Fabry's disease, Niemann–Pick disease type B and C, as well as Gaucher's disease, have often been diagnosed as a result in young or adult patients who have presented with particular symptoms. General physicians, haematologists, nephrologists, neurologists, gastroenterologists and hepatologists, dermatologists, and even orthopaedic surgeons may be the first to evaluate the patient—all of whom identify the condition by following diagnostic pathways appropriate to their specialty. In any event, the diagnosis of lysosomal storage diseases is rarely difficult, provided the expertise of a trusted laboratory service is available for performing biochemical assays, diagnostic DNA studies, and wide-ranging histopathological examination. The value of good communications between laboratory staff and clinical

investigators to whom these patients are referred cannot be overestimated.

Specific lysosomal diseases

Gaucher's disease

This disorder may occur at any age and is the most frequent of the lysosomal storage diseases. The condition is usually due to a catalytic deficiency of glucocerebrosidase, although rare cases of deficiency of its cognate sphingolipid activator protein (**SAP-C**) may cause a severe disease intermediate between Gaucher's disease and metachromatic leucodystrophy. Numerous mutations responsible for the enzymatic deficiency have been identified in the human glucocerebrosidase gene and the reader is referred to the specialist literature for those genotype/phenotype correlations that broadly apply to this protean disorder.

Rarely, infants are born with an almost complete lack of glucocerebrosidase activity: they die within a few days of birth or are stillborn due to skeletal deformities and/or dehydration as a result of loss of skin integrity (collodion babies). Infantile Gaucher's disease is a rare condition that is associated with death in the first 2 years of life: there is neuronopathic disease with bulbar palsy, opisthotonus, and minor visceral enlargement. This disease is invariably fatal and does not respond to either systemic or intrathecal enzyme-replacement therapy. While neurological disease may occur in children, adolescents, and young adults with Gaucher's disease, it is less severe than in the infantile variant. This clinical variant is associated with supranuclear gaze palsies, myoclonus, ataxia, and, occasionally, seizures. The neurological condition usually deteriorates slowly but is exacerbated if splenectomy is performed for the accompanying splenomegaly and associated pancytopenia.

Where possible, and with vigorous enzyme therapy, splenectomy is best avoided—a partial splenectomy may be carried out to ameliorate pressure effects and life-threatening thrombocytopenia. Subacute neuronopathic disease is not always fatal and often improves with combined bone marrow transplantation and enzyme-replacement therapy (see below). Affected children may show striking visceromegaly, with the associated gaze palsies often playing a small part in the clinical presentation. Although juvenile ('neuronopathic') Gaucher's disease (type III) occurs sporadically in all populations, there is a small isolate in Northern Sweden where all individuals are homozygous for a single point mutation in the glucocerebrosidase gene (*L444P*) that has arisen by descent from a common ancestor.

The most frequent form of Gaucher's disease is the so-called 'adult non-neuronopathic form' (type I). This disease is found in all populations, but is over-represented in Jews of Ashkenazi origin. Although the condition does not affect the nervous system, visceral and skeletal manifestations are prominent. The pathognomic abnormality is the presence of large storage cells, which are activated macrophages (Gaucher's cells), typically found in the splenic sinusoids. The Gaucher's cells (Fig. 3, Fig. 4, and Plate 2) replace the Kupffer cells of the liver, alveolar macrophages of the lung and in the bone marrow.

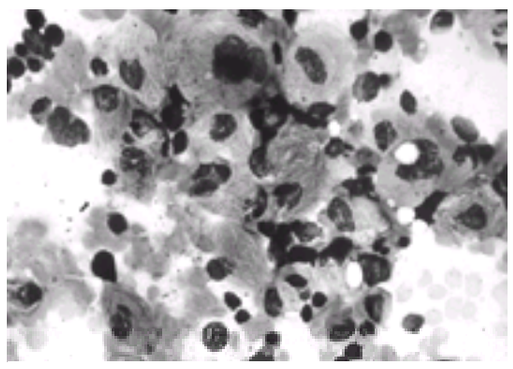

Fig. 3 Light micrograph of a Leishmann-stained bone marrow biopsy obtained from a 23-year-old man with type 1 Gaucher's disease. Note that the large, pale-blue staining Gaucher's cells with striated cytoplasm replace the Kupffer cells of the liver, alveolar macrophages of the lung and of the bone marrow. (See also Plate 2.)

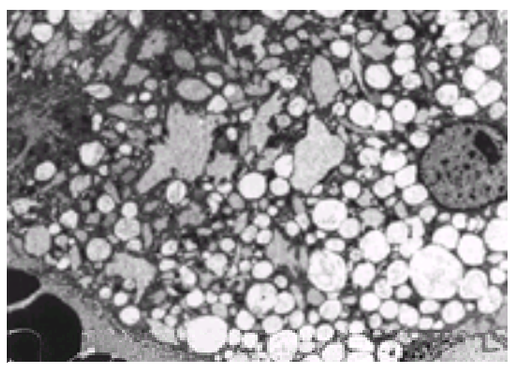

Fig. 4 Electron micrograph showing the cytoplasm of a Gaucher's cell in the spleen of a 56-year-old man removed because of life-threatening thrombocytopenia and pain due to a recent splenic infarct. Note the vesicular spaces filled with fibrillary glycolipid storage material.

Characteristically, Gaucher's disease presents with pancytopenia, with bleeding due to thrombocytopenia and splenic enlargement. Acutely painful episodes also occur in the bones, particularly during growth; these episodes are followed by avascular necrosis of the bone with consequential effects on the integrity of large joints, including the hip, knee, and shoulder (Fig. 5). In the era before enzyme-replacement therapy, splenectomy was often carried out during childhood to relieve the pressure effects of the enlarged organ and to ameliorate the effects of accompanying cytopenias. Although there appears to be an association between splenectomy and the development of severe bone disease, it is unclear as to whether this is directly due to the effects of the splenectomy or the consequential manifestations of disease severity. For this reason, splenectomy is avoided where at all possible. Splenectomy in Gaucher's disease carries a greatly enhanced risk of overwhelming infection; this includes infection with protozoa, such as babesia and malaria, as well as capsulated bacteria, for example the pneumococcus, *Haemophilus influenzae*, and *Neisseria meningitidis*.

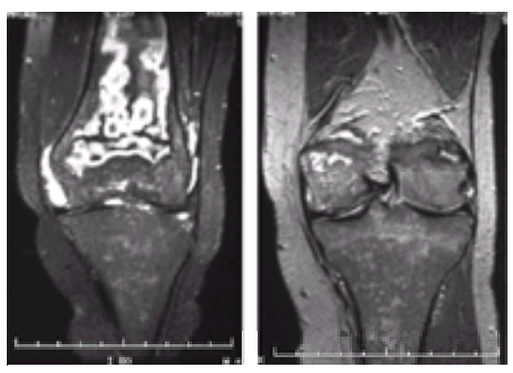

Fig. 5 T_1 (left)- and T_2 (right)-weighted magnetic resonance images obtained from the lower femur and upper tibia of a 30-year-old woman with non-neuronopathic Gaucher's disease experiencing pain due to acute avascular necrosis of bone. Note the geographical areas of increased signal intensity on the T_2-weighted image due to increased tissue water representing oedema surrounding the necrotic tissue. (By courtesy of Professor D. Lomas, Addenbrooke's Hospital.)

Painful episodes may occur in patients with Gaucher's disease either due to infarction of the liver and spleen or to the so-called 'bone crises'. These latter episodes represent acute bone necrosis due to infarction. The increased frequency of infarction events is an important aspect of Gaucher's disease that, as yet, has not been explained. Bone necrosis remains an aspect of the condition that often persists despite enzyme therapy and presents a significant challenge for clinical research.

Gaucher's disease is a truly multisystem disorder, which is accompanied by many ill-understood plasma and metabolic abnormalities. These include a polyclonal immunoglobulin response that may progress to monoclonal gammopathy, amyloidosis, or even frank myeloma. Low-density lipoprotein (LDL) and high-density lipoprotein (**HDL**) cholesterol fractions are abnormal in the plasma. Some lysosomal enzymes are elevated, including tartrate-resistant acid phosphatase, hexosaminidase, and a human chitinase, chitotriosidase. This latter enzyme has proved to be very useful for monitoring Gaucher's disease activity in response to treatment, and may reflect the severity of the disease. The enzyme is elevated sometimes several hundred-fold above normal in untreated Gaucher's disease.

Gaucher's disease may rarely be associated with pulmonary infiltrates, including reticulonodular opacities, restrictive lung defects, and various abnormalities of the pulmonary circulation causing pulmonary hypertension. The hepatopulmonary syndrome, accompanied by platypnoea and associated with severe scarring liver disease or cirrhosis and portal venous hypertension, has also been reported in severely affected adults. The osseous manifestations of Gaucher's disease are very diverse and include the presence of expanded bone lesions (Fig. 6) with surrounding cortical thinning related to Gaucher's cell infiltrates within the bone marrow ('Gauchomas'). Diffuse osteoporosis accompanied by pathological fractures may also compound the skeletal manifestations of Gaucher's disease. Kyphoscoliotic deformity due to crush fractures and vertebral avascular necrosis are common in untreated adults, particularly in postmenopausal women.

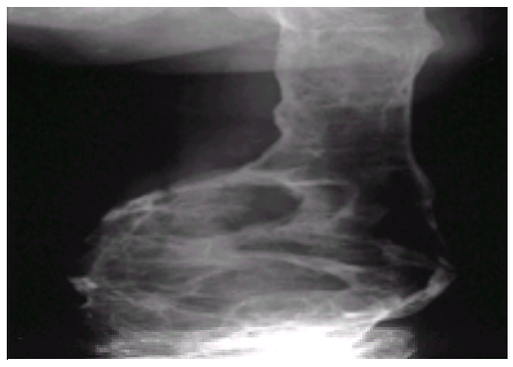

Fig. 6 Expanded lytic lesion at the distal end of the femur in a 44-year-old woman with severe Gaucher's disease complicated by osteoporosis, avascular necrosis, and, as shown, expansile lytic lesions in long bones leading to local infiltration of the marrow space by Gaucher's tissue.

In its untreated state, Gaucher's disease is a miserable condition leading to progressive skeletal deformity, pancytopenia, and visceral enlargement with failing organ function punctuated by painful visceral bone crises. The mean age of death in a single large series reported from Pittsburgh, Pennsylvania, was 60 years during the pretreatment era but this does not take into account the poor quality of life of most affected individuals. Some homozygotes for 'mild' missense mutations in the glucocerebrosidase gene (especially the widespread mutation, *N370S*) may escape detection and remain asymptomatic throughout a long adult life. Detailed investigation reveals only a mild thrombocytopenia and trivial splenomegaly in some cases. However, monoclonal gammopathy is frequently present after the age of 45 years. It is uncertain as to what extent the presence of such mutations in the population at large (homozygosity for *N370S* occurs in about 1 in 960 Ashkenazi Jews) contributes to the development of B-cell lymphoproliferative disorders, such as B-cell lymphoma and myeloma, in this at-risk group.

The diagnosis of Gaucher's disease is based on white-cell acid b-glucosidase activity, which may be accompanied by the elevation of one or more related marker enzymes such as chitotriosidase or tartrate-resistant acid phosphatase in the serum. Spleen tissue, liver biopsy material, or bone marrow aspirates may show the characteristic oligonucleate storage cells demonstrating striated cytoplasm on Leishmann staining (see Fig. 3), but which appear as pink sheets in tissue sections stained with haematoxylin and eosin. Molecular analysis of the glucocerebrosidase gene may identify widespread mutant glucocerebrosidase alleles that cause this disease and may assist in the diagnosis and investigation of family members at risk for this recessive disorder.

Treatment

Until recently, the treatment for Gaucher's disease was palliative. Bone marrow transplantation has been undertaken in a few infants and children with rapidly progressive disease, including those with the subacute neuronopathic form type III. When successful, this may correct most of the systemic manifestations of the condition and restore growth. It may arrest further neurological deterioration. However, bone marrow transplantation is no longer in routine use because of the accompanying severe risk resulting from the procedures and constraints in the supply of donors, especially MHC-matched, first-degree relatives.

Enzyme-replacement therapy was introduced during the early 1990s in the form of a natural product extracted from the human placenta, alglucerase, 'Ceredase'. A recombinant glycoform, imiglucerase, 'Cerezyme', is now available that, like alglucerase, is modified to reveal terminal mannose residues. The recombinant protein is supplied as a lyophilized powder which is reconstituted for intravenous infusion; the preparation is given at variable frequencies, from three times a week to once every 2 weeks, and infused over approximately 60 min. Modification of the sugar residues on this protein facilitates targeting to macrophage-containing organs, in which it complements the enzyme deficiency in the pathological storage cells. After a few weeks of enzyme administration, most patients show an improvement in the blood parameters of disease activity and a reduction of the chronic inflammatory response that accompanies Gaucher's disease: the platelet count rises; and there is a correction of the hypersplenic picture, with a reduction in hepatosplenomegaly and an improvement in the asthenia that complicates Gaucher's disease. Quality-of-life measures also show clear improvement.

Controversy remains as to the appropriate dose of imiglucerase; however, most authorities agree that the administration of the enzyme should be a lifelong therapy. There are two schools of thought as to whether enzyme therapy should be administered at a high dose to start with and then reduced as evidence of disease regression becomes clear, or whether a stepwise increase in this expensive agent can be undertaken in patients with long-standing disease until evidence of disease regression can be established. Disease activity is assessed by objective parameters, including visceral enlargement, and by determination of surrogate biomarkers such as chitotriosidase and blood counts. At present, there is no agreed protocol for therapy in adults with Gaucher's disease; but in patients with the subacute neuronopathic form of the condition, international guidelines suggest that a dose of at least 120 units of enzyme per kilogram bodyweight per month is necessary to secure disease regression.

Although it would not be expected that enzyme-replacement therapy would improve the neuronopathic aspects of Gaucher's disease, there is emerging evidence that clinical improvement may be induced by enzyme-replacement therapy given at this high dosage. Enzyme-replacement therapy for Gaucher's disease is very expensive and the doses recommended range from below 5 to at least 60 IU/kg per month. Thus for an adult, this may cost as much as £200 000 per year, so placing enormous demands on healthcare provision in the long-term. In response to these pressures, there have been initiatives to develop alternative methods to treat the condition—including the use of an oral agent that inhibits the formation of the substrate delivered to macrophages. When taken for several months, the trial agent, *N*-butyldeoxynojirimycin reduces glycolipid storage and clinical as well as laboratory parameters of Gaucher's disease activity.

Enzyme-replacement therapy, although very expensive, is a successful treatment for Gaucher's disease, and, since most patients do express the protein antigen endogenously, hypersensitivity and immune reactions are very rare. Apart from the inconvenience of periodic intravenous infusions, treatment is well tolerated and many patients in Europe and the United Kingdom choose to take their treatment as self-administered infusions at home. In relation to treatment with iminosugars, short-duration unwanted effects (including diarrhoea due to inhibition of intestinal disaccharidases) are frequent, although they usually respond well to dietary adjustments. However, at the time of writing it is unclear as to whether or not *N*-butyldeoxynojirimycin will be licensed as an Orphan drug, although clearly there is an international demand for a more readily available treatment for Gaucher's disease. The occurrence of peripheral neuropathy after long-term administration in a few patients with non-neuronopathic Gaucher's disease may indicate a neurotoxicity, and restrict the indications for use of *N*-butyl deoxynojirimycin. Substrate-reduction therapy may, however, have wider applications in the treatment of certain sphingolipidoses, including late-onset Tay–Sachs disease, GM1 gangliosidosis, and Niemann–Pick disease type C, which affect the brain and for which no other therapy is currently available. Moreover, since the iminosugars may penetrate the brain and are orally active, they may also be of value as an adjunctive therapy in type III Gaucher's disease. Several agents of this class have been found to be effective in

animal models of glycosphingolipidoses and successors to *N*-butyl deoxynojirimycin are actively undergoing preclinical study.

Treatment for Gaucher's disease should include appropriate immunization and antimicrobial prophylaxis in patients who have undergone splenectomy. The widespread osseous manifestations, including osteoporosis, may respond to therapy with bisphosphonate drugs, including pamidronate. Patients may require joint-replacement surgery to ameliorate the effects of bone infarction crises and, in rare instances, liver transplantation for endstage liver disease. Bone marrow transplantation probably does not have a role today, except in rare circumstances. Evidence of metabolic bone disease complicating the disorder should be always sought and osteoporosis should be treated promptly with hormone-replacement therapy, with the additional consideration of oral active or parenteral bisphosphonates. Where present, a deficiency of 25-hydroxyvitamin D should probably be treated with appropriate supplements. Because of the increased risk of infection due to intrinsic chemotactic and phagocytic defects as well as splenectomy, patients with Gaucher's disease undergoing surgery or with systemic infection should be promptly treated—preferably with parenteral antimicrobial agents.

Niemann–Pick disease

Niemann–Pick disease A and B are, respectively, neuronopathic and non-neuronopathic variants of acid sphingomyelinase deficiency, a sphingolipid disorder leading to the accumulation of sphingomyelin. Niemann–Pick disease resembles many of the manifestations of Gaucher's disease with a characteristic secondary storage cell which is also a macrophage. The Niemann–Pick cell has a foamy appearance rather than the characteristic striated cytoplasm of the Gaucher's cell. In Niemann–Pick disease, there is prominent infiltration of the lungs as well as the marrow cavity. At present, no specific treatments are available, apart from the prompt treatment of pulmonary infection and the management of the consequences of skeletal infiltrates and episodes of avascular necrosis. Some patients, including those previously misdiagnosed as having Gaucher's disease, may have undergone splenectomy to relieve pressure symptoms or the haematological effects of hypersplenism.

Niemann–Pick disease type A is associated with disabling neuronopathic features and dementia. At the present time no specific therapy for it exists. Niemann–Pick disease type B may occur in adults who have only trivial splenomegaly and minor pulmonary infiltrates that are only exacerbated at times of intercurrent pneumonic infection; they are at risk from osseous disease related to marrow infiltration, as with Gaucher's disease. Since this disease is primarily a disorder of macrophages, it should be susceptible to enzymatic complementation using the mannose receptor. At the time of writing, clinical research to develop macrophage-targeted, recombinant, human acid sphingomyelinase is well advanced. Unfortunately, no iminosugar derivatives are available for substrate-reduction therapy for the neuronopathic manifestations of Niemann–Pick disease type A, since the biosynthesis of sphingomyelin is not regulated by the uridine diphosphate-glucosylceramide synthase reaction.

Niemann–Pick disease type C (**NPC**) may present with jaundice in infants or children, but the initial hepatitic illness usually resolves. Later evidence of neuronopathic disease occurs, with ataxia, seizures, supranuclear palsy, and progressive diffuse cortical injury. NPC is not due to a primary defect of acid sphingomyelinase but to mutations in two distinct lysosomal membrane proteins. These are responsible for the NPC-1 and NPC-2 subtypes of disease. Although the function of the NPC-1 and NPC-2 proteins is not fully understood, they are implicated in the intracellular transport of cholesterol and cholesterol esters to and from the lysosomal compartment. NPC is also associated with the appearance of foam cells in the macrophages; the Kupffer cells of the liver may be enlarged and a cholesterol trafficking defect is apparent in most cells. Thus the defect, though not manifest in the skin, may be detected in skin and fibroblasts after culture and exposure to low-density lipoprotein-cholesterol: in NPC, cholesterol is taken up and accumulates in intracellular droplets that stain positively with the fluorescent dye filipin. Within the brain, NPC causes neuronophagia and the accumulation of gangliosides and other complex sphingolipid storage products that may induce neuronal injury. Clinical trials are under way with the use of the iminosugar *N*-butyldeoxynojirimycin. These trials follow on from the successful arrest of the disease in mice homozygous for a spontaneous mutation in the *NPC-1* gene that provide a convincing model of the human disease. The outcome of further investigations of these mice and of the trial of this therapy in patients with NPC is urgently awaited. Niemann–Pick disease type C is an intractable condition associated with progressive neurological disease in childhood and early adult life. Biological deterioration progresses inexorably and death usually occurs in the third or fourth decade. The use of statins and other agents that interfere with cholesterol metabolism has not been effective in arresting the course of this cruel illness.

Anderson–Fabry disease (usually shortened to Fabry's disease)

This disease is an X-linked disorder, unlike many of the lysosomal diseases, apart from Hunter's disease (MPS II). An unusual feature of Fabry's disease, is the presence of clinical signs and symptoms in the majority of heterozygous female carriers of the condition. Although these manifestations are usually less severe and of later onset than in affected hemizygous males, florid and life-shortening clinical disease has often been observed (and ignored) in affected women. Deficiency of a-galactosidase causes the accumulation of ceramidetrihexoside (otherwise known as globotriaosylceramide), which principally derives from the breakdown of lipids present in senescent red cells. Affected male hemizygotes have small, raised, red vascular skin lesions (angiokeratomas) particularly around the buttocks and genital region. These lesions are often detected in limited areas of affected heterozygous females and reflect X-chromosome inactivation patterns in the skin. With increasing age, impaired capillary circulation and progressive tubular, interstitial, and glomerular disease in the kidney leads to proteinuria and renal failure. Many patients require renal support, including haemodialysis, peritoneal dialysis, or kidney transplantation. Patients with Fabry's disease have disturbing gastrointestinal symptoms, characterized by diarrhoea shortly after eating and often abdominal pain associated with febrile attacks that are otherwise unexplained.

The most characteristic symptoms of the disease are the onset in early childhood of lancinating pain with background burning sensations in the extremities that are worse with exercise and with extremes of temperature. These attacks can be very disabling and represent neuropathic pain, which is notoriously difficult to control. The acroparasthesias are frequently attributed to Raynaud's phenomenon but this relationship is unclear, although many of the symptoms of Fabry's disease can be explained by neuropathy affecting autonomic nervous tone. Most men with established disease notice a striking absence of peripheral sweating, and impotence is very common. The abdominal symptoms may also result from autonomic neuropathy. High-tone loss of hearing is also a frequent feature of Fabry's disease, which appears to reflect a selective loss of functioning cochlear neurones. Cardiac hypertrophy occurs, especially of the left ventricle, with conduction defects leading to a shortened PR interval and a prolonged QRS complex—later accompanied by tachyarrhythmias and complete heart block. Left ventricular hypertrophy may or may not be associated with hypertension and cardiac embolic disease; disease of capillaries and medium-sized vessels in the brain associated with unusual microvascular changes, particularly in the posterior cerebral circulation, also causes stroke.

Stroke and renal failure are the most common causes of death in patients with Fabry's disease; in men, death occurs at a median age of 48 to 49 years, with a greatly reduced quality of life during the antecedent symptomatic period. Life expectancy in affected heterozygous women is also shortened. Sometimes the lancinating acroparasthesias are sufficient to cause severe depression and even suicide. Disease expression in many carrier females, who may develop renal failure, is accompanied by angiokeratomas restricted to certain dermatomes on careful examination and asymptomatic corneal opacification with whorl-like cataracts on slit-lamp examination.

Diagnosis is made by demonstrating the abnormal glycolipid in urine or plasma, as well as by assay of a-galactosidase in tears, plasma, white cells, or other tissue material. Molecular analysis of the a-galactosidase gene on the long arm of the X chromosome is worthwhile because it allows the unambiguous detection of female heterozygotes and may thus be useful during the reproductive period, particularly for antenatal diagnosis. Despite the presence of active disease, ceramide trihexoside concentrations and a-galactosidase assays are often within normal limits in affected female heterozygotes.

Hitherto, the treatment for Fabry's disease has been palliative, involving the use of anticonvulsants (including gabapentin) for the acroparasthesiae and neuropathic pain. Gastrointestinal symptoms sometimes respond to antimotility agents or to pancreatic enzyme supplements but these agents have not been subjected to control trials. Renal failure is managed by dialysis or by renal transplantation; occasionally, cardiac transplantation has been required for cardiomyopathy; pacemakers and antiarrhythmic drugs may also be needed. There is a rare cardiac variant in this disease, which appears to be predominantly manifested by restrictive cardiomyopathy in elderly patients who have a small amount of residual a-galactosidase activity in their tissues. In one remarkable instance, therapy with galactose infusions appears to have ameliorated this condition by stabilizing the nascent mutant enzyme, thereby enhancing residual a-galactosidase activity with slow clearance of cardiac glycolipid storage.

Recently, enzyme replacement using recombinant human a-galactosidase has been developed as a more definitive treatment. To date, two preparations—which may differ slightly in their post-translational glycosylation status for delivery to endothelial, epithelial, and other cells that represent the pathological focus of this disease—have been licensed: agalsidase-a (Replagal) and agalsidase-b (Fabrazyme). Administration of these preparations to male hemizygotes has improved lipid accumulation in the plasma and in renal biopsy samples from male hemizygotes with this disease. Agalsidase-a has also been shown in double-blind, crossover, placebo-controlled trials to improve clinical endpoints of the disease, including neuropathic pain, stabilization of renal function, and ventricular mass as well as conduction defects that represent infiltrative cardiomyopathy. Further clinical observations continue to be made but it is now clear that enzyme therapy is likely to be a safe and effective long-term treatment for Fabry's disease. Unlike Gaucher's disease, targeting to the affected cells and tissues in Fabry's disease probably results from uptake by the common lysosomal recognition marker, mannose-6 phosphate, as the principal ligand for protein delivery to this organelle.

The glycoproteinoses

These disorders fall into a group of lysosomal diseases associated with impaired degradation of glycoproteins. The most frequent of these disorders include fucosidosis and mannosidosis, which are inherited as autosomal recessive traits. Glycoproteinoses show some of the manifestations of the sphingolipidoses and the mucopolysaccharidoses: they are almost invariably associated with neurological disease and variable systemic manifestations. An unusual clinical feature of these conditions, which are associated with visceral enlargement (particularly hepatomegaly) and mental retardation occurring in childhood, is the appearance of angiokeratomas that are otherwise characteristic of Fabry's disease.

In a few patients, bone marrow transplantation has improved some of the systemic manifestations of mannosidosis and fucosidosis. However, trials of enzyme-replacement therapy have yet to be published beyond the study of experimental models, such as those that occur spontaneously in cattle, dogs, and other large animals. Diagnosis of the glycoproteinoses is usually prompted by the finding of increased excretion of oligosaccharides in the urine and by clinical suspicion of the diagnosis in patients with a multisystem disease that may have an obvious hereditary component. Definitive diagnosis is dependent on enzymatic studies in leucocytes or cultured skin fibroblasts. As with other lysosomal diseases, prenatal diagnosis using cultured amniocytes and chorionic villus cells may be offered by specialized laboratories.

Mucopolysaccharidoses (MPS)

These disorders are caused by a deficiency of lysosomal hydrolases that catalyse the cleavage of complex glycosaminoglycans—macromolecular components of connective tissues including joints, bones, heart, and the major arteries. Clinical manifestations of each of these disorders reflect an individual enzymatic deficiency and the resulting accumulation of mucopolysaccharide derivatives, of which dermatan, keratan, and chondroitin sulphate as well as heparan sulphate are the principal components. In general, the accumulation of the complex substrates that are normally linked to proteins to form proteoglycans is associated with visceral enlargement, as well as bony abnormalities, joint stiffness, corneal clouding, and short stature; the accumulation of heparan sulphate may particularly be associated with the development of brain disease, including thickening of the leptomeninges. Thus hydrocephalus is an often-neglected factor in cerebral impairment that may also be attributed to lysosomal storage affecting neurones of the brain and peripheral ganglia—as well as the retina.

Clinical features and pathology

Typically, these disorders are associated with coarse facial features, bone shortening, and skeletal abnormalities, as well as disturbances of dentition, the gums, and auditory canal. Abnormalities of the tracheobronchial cartilages and upper airways may be associated with respiratory infections. In the heart, the coronary arteries and valves may be infiltrated by glycosaminoglycans, leading to nodular thickening of aortic and mitral valves with clinical evidence of valvular disease malfunction. In some cases, accumulation of glycosaminoglycan occurs in the coronary arteries, which may be occluded. Similar changes may occur in peripheral arteries—particularly those supplying the viscera. In the eye, the basal layers of the cornea show swelling, cytoplasmic vacuolization, and storage granules leading to opacification.

Excess urinary excretion of glycosaminoglycan products, including dermatan sulphate and heparan sulphate, characteristically occur in the mucopolysaccharidoses. This abnormality should immediately prompt further investigations by enzymatic and genetic studies in blood leucocytes and/or fibroblasts obtained from cultured skin-biopsy samples. The inheritance pattern of the mucopolysaccharidoses is typical of autosomal recessive traits—with the exception of Hunter's disease (MPS II, which is due to iduronate sulphatase deficiency) that maps to the X chromosome and, unlike Fabry's disease, is expressed predominantly in boys and men. Female heterozygotes for Hunter's disease only very rarely show evidence of neurological impairment or connective tissue abnormalities.

Treatment of the mucopolysaccharidoses

Palliative treatment is a very important aspect of the management of these diseases, and should include the provision of multidisciplinary support for children and young adults with the accompanying developmental disabilities. Sustained provision for the long-term management of the condition in affected families is desirable.

Surgical procedures

Corneal transplantation may be required to improve vision where retinal degeneration is not dominant. Carpel tunnel syndrome with compression neuropathy of the median nerve is very common in the mucopolysaccharidoses and, when indicated, surgical treatment is often beneficial. Particular care is required in patients with mucopolysaccharidoses such as Hurler's syndrome when surgical procedures under general anaesthetic are required for relief of hydrocephalus, myringotomy, hernia repair, relief of airways obstruction due to laryngeal disease, and corrective spinal or joint surgery. Infiltration of the soft tissues of the upper and lower airways, as well as the heart and cervical spine (which may include subluxation of the atlanto-occipital joint) is associated with high perioperative mortality. Complications thus arise with the administration of a general anaesthetic beyond that of difficulties with endotracheal intubation. In particular, a tracheostomy may be required to avoid life-threatening complications of intubation. An extensive preoperative examination should be conducted when an anaesthetic is required for any procedure, particularly to assess the stability of the atlantoaxial joint, the airway, and the presence of coronary artery disease (that may predispose to perioperative myocardial infarction).

Specific treatment

Bone marrow transplantation using HLA-identical sibling and HLA-matched non-sibling donors has been extensively investigated in the mucopolysaccharidoses. Long-term clinical trials have confirmed the beneficial effects of successful transplantation with reversal of hepatosplenomegaly and obstructive airways disease. In some cases there is improved longevity, with a possible reduction also in the incidence of secondary hydrocephalus. However, at present, transplantation does not cure the condition and is unable to reverse established brain injury and most of the crippling skeletal manifestations of the mucopolysaccharidoses. If it is to be considered, bone marrow transplantation should thus be carried out early in the course of these diseases.

Enzyme-replacement therapy has long been under investigation in MPS I (Hurler's syndrome, Hurler–Scheie syndrome, and Scheie's syndrome), which was one of the first of such disorders to be subjected to intensive laboratory study. Recent studies with recombinant human a- L-iduronidase, given by weekly infusion intravenously, after 1 year clearly show a reduction in lysosomal storage: liver volume decreased; there was an improved rate of growth as well as improvement in the range of joint movements at sites characteristic of connective tissue infiltration in this condition. With a reduction in the storage material in the upper airways, there was also an improvement in episodes of hypoventilation during sleep. After a few weeks of enzyme treatment, urinary glycosaminoglycans abnormalities were corrected. Although a few patients developed serum antibodies, only transient immune reactions, including urticaria, occurred during the infusions. It appears that in patients with this disease, the first to be shown by experiments with fibroblasts *in vitro* to be corrected by enzymatic complementation, treatment with a recombinant human product reduces lysosomal storage and ameliorates several of the important clinical manifestations. Enzyme-replacement therapy is currently under clinical evaluation for patients suffering from MPS II (Hunter's syndrome with iduronate sulphatase deficiency) and MPS VI (Maroteaux–Lamy due to arylsulphatase B deficiency). Favourable responses to enzyme-replacement therapy have also been reported in animal models of related disorders, including the cone head mouse that represents a faithful model of MPS VII (Sly disease), due to deficiency of acid b-glucuronidase.

Although enzyme therapy is in an early clinical phase of application in the mucopolysaccharidoses, there has been a remarkable response from the pharmaceutical industry for the therapeutic development of enzyme-replacement therapy for lysosomal diseases. With the present state of knowledge, bone marrow transplantation seems to be ineffective for many patients with MPS; if it is to be restricted to use before the development of mental decline, the risks associated with the procedure and the need for matched donors to provide competent marrow cells limit its acceptability. Questions still arise of how clinical benefits and an improved quality of life can be best assessed. However, encouraging results showing an improved quality of life, mobility, nutrition, and educational achievements have already been documented in several MPS disorders in response to enzyme therapy—even where pre-existing developmental effects and mental retardation are established. The combined effects of marrow transplantation and enzyme replacement have yet to be systematically evaluated in clinical trials for evidence of therapeutic synergy. At the time of writing, the whole field of the lysosomal diseases such as MPS is attracting much attention as a promising area of clinical and pharmaceutical research. The earlier definition of Orphan diseases 'as those in which treatments offer little or no financial incentive for commercial development' has been abandoned: Orphan diseases are now conveniently defined 'as those which individually affect less than 1 per cent of the population'.

Recently characterized lysosomal diseases

The characterization of lysosomal defects in several ill-understood disorders with diverse clinical manifestations continues to reveal much about the role of the lysosome in cellular functions of significance in medicine and molecular physiology. Several recently studied lysosomal diseases in this category are briefly described here.

Neuronal ceroid lipofuscinoses

The neuronal ceroid lipofuscinoses (**CLN**) represent the most common group of progressive brain diseases that affect children and young adults. Childhood forms of these disorders are inherited as recessive traits and result in a progressive dementia combined with epilepsy, blindness, and an early death. The most familiar form of these diseases was previously known as Batten's disease. Pathological studies of affected patients show the characteristic accumulation of an autofluorescent storage material within neuronal lysosomes and lysosomes in other cells. The storage of this material occurs preferentially in the nervous system and is associated with progressive neuronal death leading to a marked atrophy of the brain; cerebral atrophy is particularly obvious in the early-onset forms of the neuronal lipofuscinoses. Although this complex of neurodegenerative conditions associated with lipofuscin pigments has long been recognized, the diseases were previously thought to represent disorders of other organelles. Mitochondria were implicated because degraded fragments of mitochondrial cytochrome C polypeptide were found to be one of the prominent storage molecules in neuronal tissue from patients with Batten's disease. Latterly, advances in molecular genetics have allowed the identification of defective genes and their protein products in several distinct clinical phenotypes of the neuronal ceroid lipofuscinoses.

Typical clinical forms of the neuronal ceroid lipofuscinoses include late infantile and juvenile neurodegenerative disorders; at least eight genetic loci, which encode proteins implicated in different aspects of lysosomal metabolism, have been assigned to distinct CLN phenotypes. Neuronal ceroid lipofuscinosis type I (CLN 1) is due to mutations in a gene encoding palmitoyl: protein thioesterase 1. CLN 2 is due to defects in the gene encoding tripeptidyl-peptidase, and CLN 8 is due to defects in the gene encoding human cathepsin D. To date, two lysosomal proteins of membrane location, CLN 4 and CLN 5, have also been identified. No specific therapy for Batten's disease yet exists, but the discovery of the basis of the condition and the genes involved allows for prenatal and postnatal diagnosis in affected pedigrees by molecular analysis of the implicated cognate genes. In most instances, neuronal ceroid lipofuscinoses represents defects in elements of intralysosomal protein catabolism, indicating that the turnover of the cognate proteins is very high in cortical neurones. Very recent *in vitro* studies have suggested that the use of the thiol agent, cysteamine, which is used with benefit in patients with cystinosis, may activate residual palmitoyl-protein phytoesterase activity in patients with ceroid lipofuscinosis type 1.

The realization that the neuronal ceroid lipofuscinoses in fact represent intrinsic disorders of lysosomal protein metabolism is very recent. The discovery clearly has important consequences for understanding the pathology of this family of diseases and for developing better diagnostic tools (especially for prenatal application) as well as new treatments.

Papillon–Lefèvre syndrome

This is an unusual syndrome resulting in periodontal disease with tooth loss and palmoplantar keratosis. Papillon–Lefèvre syndrome is associated with a selective deficiency of cathepsin C activity within the specific granules of neutrophilic polymorphonuclear leucocytes. It appears that the enzyme deficiency leads to the failure of bacterial clearance in the gums, thereby causing destructive periodontitis and tooth loss. The corresponding role of cathepsin C within the dermal epithelium is not known, but a failure of cathepsin C activity reproducibly leads to epithelial abnormalities and thickening of the skin, particularly on the soles of the feet. Papillon–Lefèvre syndrome is inherited as an autosomal recessive trait and several mutations have been identified within the gene encoding the cathepsin C polypeptide. Some patients with disabling skin manifestations have obtained benefit with the use of retinoids. These agents are, however, unlikely to improve early-onset destructive periodontal disease.

The importance of the Papillon–Lefèvre syndrome rests not only on the identification of lysosomal cathepsin C as an important component of immune defences against bacteria that specifically invade the privileged periodontal site, but also on the involvement of this enzyme in the normal turnover of keratinized skin. The molecular characterization of this disorder illustrates the protean manifestations of lysosomal defects and of the ubiquitous importance of lysosomes in the destruction and recycling of exogenous microbial, as well as endogenous cellular components.

Defects of organellar assembly: Chediak–Higashi (CHS) and Hermansky–Pudlak (HPS) syndromes

These rare disorders are inherited as autosomal recessive traits. Both cause oculocutaneous albinism in association with abnormal platelet granules and melanosomes in the skin and eyes. CHS predisposes to microbial infection and there are giant lysosomal granules in peripheral blood granulocytes; ceroid storage occurs in the nervous system and lungs. Although very rare, HPS occurs at a high frequency in the Swiss Alps and the Puerto-Rican population where it is the most common single gene defect. HPS causes a mild bleeding diathesis and platelet dense bodies are absent. Granulomatous colitis occurs and pulmonary changes lead to interstitial lung fibrosis; unexplained cardiomyopathy has been reported.

The Hermansky–Pudlak syndrome is caused by mutations in the adaptin, b-3A gene which is associated with altered trafficking of lysosomal proteins in melanosomes, lysosomes, and platelet-dense granules leading to storage pool deficiency. The gene maps to chromosome 10q. Chediak–Higashi syndrome has a clinical phenotype with a complex set of immune defects affecting natural killer cells and neutrophic leucocytes. Recurrent cutaneous and systemic pyogenic infections occur with defective neutrophil and monocyte migration; natural killer-cell cytotoxicity is absent. Neutrophils, melanocytes, neurones, muscle cells, and Schwann cells show giant inclusion bodies. Neurodegeneration is a prominent feature of the disease in young adults, but death often results from a rapidly progressive lymphoproliferative disorder. CHS is caused by mutations in the lysosomal trafficking regulator gene located on chromosome 1q44.

There are clear similarities between HPS and CHS, and further functional studies of their respective cognate proteins should reveal important information about the synthesis and assembly of lysosomes and related organelles.

Defects of lysosomal membrane function

In 1981 two cases of cardiomyopathy in male infants with skeletal myopathy and mental retardation were reported by Danon and colleagues. The skeletal pathology sugguested type II glycogenosis but no deficiency of acid maltase activity was present. Defects in LAMP–2, a major lysosomal membrane protein, have subsequently been identified in Danon's disease due to mutations in the gene encoding LAMP–2, located on the X-chromosome. The disease is responsible for rare forms of cardiomyopathy in adults and may also occur in heterozygous females.

Pycnodysostosis

Pycnodystostosis is a unique disorder of the skeleton caused by an inherited deficiency of another lysosomal-type acid hydrolase, cathepsin K. Cathepsin K is expressed prominently in osteoclasts, in which it is the most abundant secreted protein.

The clinical features of pycnodysostosis includes skull deformity, bone fragility with short stature, and mild osteopetrosis. Delayed fusion of the membrane bones of the skull leads to persistence of the anterior fontanelle; modelling deformities occur with micrognathia, as well as disordered eruption of the primary and secondary teeth. The dwarfed artist, Henri Toulouse-Lautrec—the product of a highly consanguineous marriage—exhibited many features of pycnodysostosis and was disabled by multiple pathological fractures that typically complicate the dense osteopetrotic bones.

A characteristic radiological feature of this disorder is the presence of short, resorbed terminal phalanges with shortened fingers; acro-osteolysis also occurs at the acromial end of the clavicle. Histological examination of affected bone reveals abnormal osteoclasts containing undigested type I collagen fragments within vacuolar spaces. Linkage studies mapped pycnodystostosis to the long arm of chromosome 1 in the same region on 1q21 as cathepsin K: multiple mutations in the cathepsin K gene have now been shown to segregate with the disease in affected pedigrees.

Thus cathepsin K, a cysteine-proteinase expressed in the lysosomes of the pathological macrophages in Gaucher's disease, is particularly abundant in the secretory products of the subosteoclastic resorptive vacuole and is critical for bone modelling and development. Defective digestion of the principal collagen in bone leads to a diffuse skeletal phenotype with clear applications for furthering our knowledge of bone physiology: at least one pharmaceutical company is currently exploring this system as a therapeutic target in osteoporosis.

Further reading

A key reference source for these and other inherited disorders is Victor McKusick's *Mendelian inheritance in man*, published by The Johns Hopkins University Press, Baltimore, MD. This catalogue of human autosomal, X-linked, and mitochondrial phenotypes contains invaluable information that is continually updated in the online version (OMIM) available through the worldwide web at: http://www.ncbi.nlm.nih.gov/htbit-post/omim

Detailed descriptions of all aspects of individual disorders are provided in the acclaimed reference book: *The metabolic and molecular bases of inherited disease*, 8th edition (2001), edited by CR Scriver, AL Beaudet, WS Sly, and D Valle, and published by McGraw-Hill, New York. The lysosomal diseases are principally described in Part 16, pp 3371–894 in the third volume of this large, four-volume work.

11.9 Peroxisomal diseases

Ronald J. A. Wanders and Ruud B. H. Schutgens

Introduction

The peroxisomal disorders are relative newcomers to the field of inherited diseases in humans. The reason for this is that peroxisomes were the last true subcellular organelles to be discovered and were long thought to play only a minor role in cellular metabolism. Two key observations in patients suffering from a rare disease, the cerebrohepatorenal syndrome of Zellweger, changed this view completely.

A major hallmark in studies of Zellweger syndrome was the finding by Goldfischer and colleagues in 1973 that peroxisomes were completely absent in the hepatocytes and renal tubule cells of Zellweger patients. In 1982 the accumulation of certain saturated very long-chain fatty acids, notably hexacosanoic (cerotic) acid (C26:0), was reported in plasma from Zellweger patients whereas other fatty acids like palmitate, oleate, and linoleate were normal. At the same time our group reported that plasmalogens, a specific type of phospholipid, were deficient in tissues and erythrocytes from Zellweger patients. Subsequent studies soon resolved that these abnormalities were a direct consequence of the absence of peroxisomes in these patients.

Since then much has happened and it is now clear that Zellweger syndrome is the prototype of an expanding group of genetic diseases all caused by an impairment in one or more peroxisomal functions.

To provide the necessary background we will briefly describe the main functions of peroxisomes in humans as well as their biogenesis.

Functions of peroxisomes

Peroxisomes play an essential role in a range of cellular activities, which mainly have to do with lipid metabolism (see Table 1). The following functions are essential and are directly linked to certain peroxisomal disorders.

b-Oxidation of fatty acids and fatty acid derivatives

Just like mitochondria, peroxisomes are capable of oxidizing fatty acids by both a- and b-oxidation. The mechanism whereby fatty acids are b-oxidized in peroxisomes is the same as in mitochondria, involving four sequential steps of oxidation, hydration, dehydrogenation, and thiolytic cleavage.

It is well established now that there are major differences between the mitochondrial and peroxisomal b-oxidation systems, each catalysing the oxidation of a distinct set of substrates. Indeed, mitochondria take care of the oxidation of the vast majority of dietary fatty acids including oleate, palmitate, and linoleate whereas peroxisomes catalyse the b-oxidation of a range of fatty acids which are not so important for energy purposes but which do require breakdown.

These include (see Fig. 1):

1. Very long-chain fatty acids: fatty acids like tetracosanoic (lignoceric) acid (C24:0) and hexacosanoic (cerotic) acid (C26:0) cannot be b-oxidized by mitochondria but are good substrates for peroxisomal b-oxidation. Peroxisomes are not capable of fully degrading C26:0 and C24:0 to acetyl coenzyme A (**CoA**) units. Instead only a few cycles occur in peroxisomes after which the chain-shortened acyl CoA units move to the mitochondria for further oxidation.
2. Pristanic acid (2,6,10,14-tetramethylpentadecanoic acid): this branched-chain fatty acid is in part derived directly from dietary sources but is also formed from phytanic acid by a process called a-oxidation (see later). Pristanic acid undergoes three cycles of b-oxidation in the peroxisome to produce 4,8-dimethylnonanoyl-CoA which is then transported to the mitochondrion for full oxidation to CO_2 and H_2O (Fig. 1).
3. Di- and trihydroxycholestanoic acid: the CoA esters of di- and trihydroxycholestanoic acid undergo one cycle of b-oxidation in the peroxisome, giving rise to the CoA esters of chenodeoxycholic acid and cholic acid respectively, which are then converted into the corresponding taurine or glycine conjugates (tauro/glycochenodeoxycholate and tauro/glycocholate respectively). This is followed by transport into bile. This implies that peroxisomes play an indispensable role in bile acid formation.

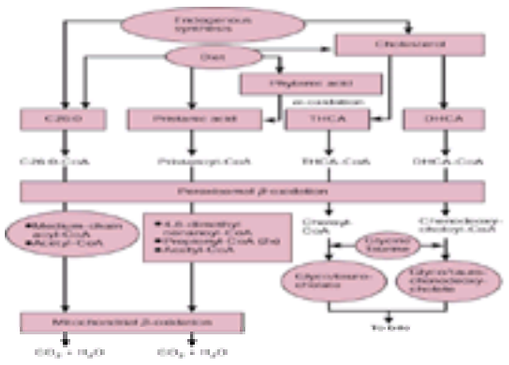

Fig. 1 Involvement of peroxisomes and mitochondria in the b-oxidation of hexacosanoic acid (C26:0), pristanic acid, and di- and trihydroxycholestanoic acid. See text for details.

It is now clear that peroxisomes contain multiple enzymes involved in b-oxidation. These include (see Fig. 2):

1. Two acyl-CoA oxidases: both these oxidases (acyl-CoA oxidase 1 and 2) react with a variety of straight-chain acyl-CoAs whereas only acyl-CoA oxidase 2 is reactive with branched-chain acyl-CoAs. This implies that acyl-CoA oxidase 2 is involved in the oxidation of pristanoyl CoA as well as dihydroxycholestanoic acid CoA and trihydroxycholestanoic acid CoA whereas acyl-CoA oxidase 1 is not. Acyl-CoA oxidase 1 is probably the major enzyme involved in C26:0 b-oxidation.
2. Two bifunctional proteins with both enoyl-CoA hydratase and 3-hydroxyacyl-CoA dehydrogenase activity: a major difference between the two proteins is that the first bifunctional protein forms and dehydrogenates L-3-hydroxyacyl-CoA in contrast to the second enzyme, which forms and dehydrogenates D-3-hydroxyacyl-CoA. Hence the names L-bifunctional protein and D-bifunctional protein.
3. Two peroxisomal thiolases: recent studies have led to the identification of a new thiolase called SCP_x or peroxisomal thiolase 2 which is the main if not exclusive enzyme involved in b-oxidation of pristanic acid as well as dihydroxycholestanoic acid and trihydroxycholestanoic acid, whereas the original thiolase (peroxisomal thiolase 1) is the main enzyme in C26:0 b-oxidation (see Fig. 2).

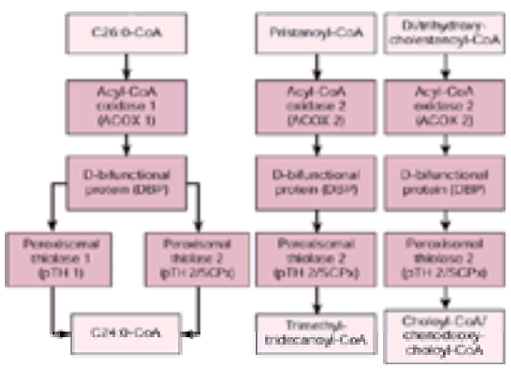

Fig. 2 Enzymology of the peroxisomal fatty acid b-oxidation machinery. See text for details.

Ether-phospholipid biosynthesis

A second major function of peroxisomes concerns their role in the synthesis of ether-phospholipids. Indeed, the two enzyme activities responsible for the introduction of the characteristic ether linkage in ether-linked phospholipids (i.e. dihydroxyacetonephosphate acyltransferase (**DHAPAT**) and alkyldihydroxyacetonephosphate synthase (**alkyl-DHAP synthase**)), are both localized in peroxisomes. The next enzyme, acyl/alkyl-DHAP:NAD(P) oxidoreductase, is localized in both peroxisomes and the endoplasmic reticulum so that the product of the alkyl-DHAP synthase reaction, (i.e. alkyl-DHAP), is converted into alkylglycerol-3-phosphate in the peroxisome or endoplasmic reticulum (Fig. 3). All subsequent reactions involved in ether-phospholipid synthesis take place in the endoplasmic reticulum.

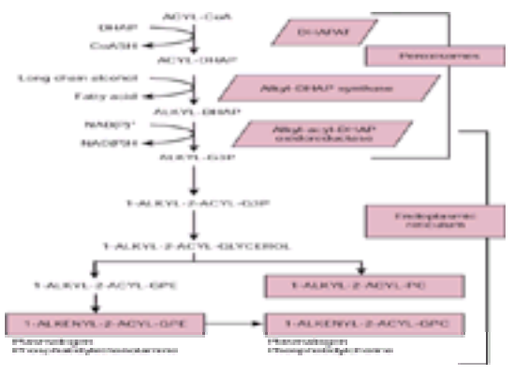

Fig. 3 Enzymology of ether–phospholipid biosynthesis. See text for details.

The functional role of plasmalogens has remained enigmatic until now. However, the identification of an isolated deficiency of either DHAPAT or alkyl-DHAP synthase in patients with severe clinical abnormalities comparable to rhizomelic chondrodysplasia punctata clearly shows that ether-phospholipids are of central importance in humans.

Phytanic acid a-oxidation

The pathway of phytanic acid a-oxidation has long remained an enigma but has recently been resolved. Phytanic acid first undergoes activation to phytanoyl-CoA after which a hydroxylation reaction takes place to generate 2-hydroxyphytanoyl-CoA as catalysed by the enzyme phytanoyl-CoA hydroxylase, which is deficient in Refsum disease (discussed later). Subsequently 2-hydroxyphytanoyl-CoA undergoes cleavage to produce formyl-CoA and pristanal, which is then dehydrogenated to pristanic acid. Activation of pristanic acid produces pristanoyl CoA, which can be degraded via b-oxidation in the peroxisome.

L-pipecolic acid oxidation

L-lysine is normally degraded by the saccharopine pathway involving the sequential action of L-lysine:2-oxoglutarate reductase and saccharopine dehydrogenase. However, L-lysine may also be degraded via the L-pipecolic acid pathway, which may especially be important in the brain. In the L-pipecolic acid pathway, L-pipecolic acid is produced from L-lysine via two enzymatic steps. L-pipecolic acid is then oxidized by L-pipecolate oxidase, a peroxisomal enzyme, at least in humans.

The function of the L-pipecolic acid pathway remains incompletely understood.

Biosynthesis of polyunsaturated fatty acids such as docosahexaenoic acid

In tissues and erythrocytes from patients with Zellweger syndrome there is a profound deficiency of docosahexaenoic acid (C22:6w3) suggesting the involvement of peroxisomes in the formation of docosahexaenoic acid. Subsequent studies have not only established the role of peroxisomes in docosahexaenoic acid formation but have also revealed that the last step involved in formation of docosahexaenoic acid, the desaturation of clupanodonic acid (C22:5w3) to docosahexaenoic acid, is not catalysed by a presumed ‡4-desaturase but involves a three-step pathway. In this pathway C22:5w3 is first elongated to C24:5w3, followed by ‡6-desaturation to C24:6w3. The latter compound is then chain-shortened to C22:6w3 (docosahexaenoic acid) via b-oxidation in peroxisomes.

This latter finding explains the deficiency of docosahexaenoic acid in patients with Zellweger syndrome.

Biogenesis of peroxisomes

In recent years much has been learned about peroxisome biogenesis, and many of the genes involved in peroxisome biogenesis, called *PEX* genes, are known. Although there is still discussion about the possible involvement of the endoplasmic reticulum, the model proposed by Lazarow and Fujiki is still generally accepted. The principal features of this model are:

1. Peroxisomal membrane and matrix proteins are synthesized on free polyribosomes.
2. The newly synthesized proteins are post-translationally imported from the cytosol into pre-existing peroxisomes.
3. Import of new polypeptides expands the peroxisomal compartment, making them grow until they reach a critical size which results either in division of peroxisomes into two daughter peroxisomes or in budding from the peroxisomal reticulum followed by subsequent growth.

The fact that proteins destined for peroxisomes are synthesized on free polyribosomes implies that these proteins must have specific signals which direct them to peroxisomes.

Studies, notably by Subramani and colleagues, have shown the existence of two such peroxisome targeting signals (**PTS**). Most of the peroxisomal matrix proteins are equipped with a PTS1 signal which involves a C-terminal tripeptide of the sequence serine–lysine–leucine or a conserved variant thereof. The second peroxisome targeting signal (PTS2) has been found in far fewer peroxisomal proteins and involves a stretch of nine amino acids of which amino acids numbers one, two, eight, and nine are essential with the following consensus: (arginine/lysine)–(leucine/valine/isoleucine)–XXXXX–(histidine/glutamine)–(leucine/alanine) in which X may be any amino acid. In mammals, the PTS2 signal has only been identified in peroxisomal thiolase 1, alkyl-DHAP synthase, and phytanoyl-CoA hydroxylase. Peroxisomal membrane proteins lack either a PTS1 a PTS2 signal which implies that there must be separate signals directing membrane proteins to peroxisomes.

The identification of the PTS1 and PTS2 targeting signals was soon followed by discovery of a growing number of so-called *PEX* genes required for peroxisome biogenesis. Most of these genes were first identified in the yeast *Saccharomyces cerevisiae*. Making use of databases of expressed sequence the human counterparts of these yeast genes have been identified in recent years, notably by Gould and colleagues. Most of these *PEX* genes code for peroxisomal membrane proteins with the exception of PEX5p and PEX7p. These two proteins are predominantly cytosolic and recognize the PTS1 and PTS2 signals respectively on peroxisomal proteins in the cytosol. In humans at least, the two loaded receptors functionally interact to form a complex which subsequently docks at the peroxisomal membrane. The proteins PEX13p and PEX14p play a central role in this docking process.

The following step involves dissociation of the complex followed by transport of the PTS1 and PTS2 proteins across the membrane and recycling of the receptors back to the cytosol for another round (Fig. 4). In this process multiple PEX proteins are involved, all of which essential since disruption of each single *PEX* gene is associated with a full block in peroxisome biogenesis.

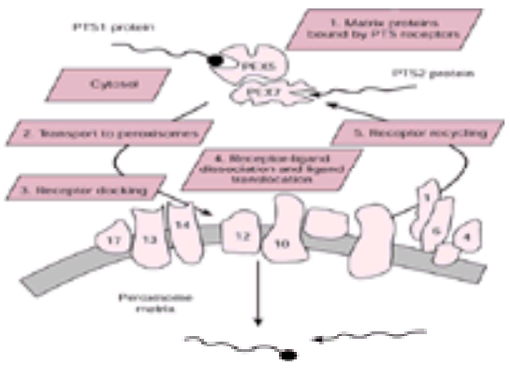

Fig. 4 Overview of the steps involved in peroxisome biogenesis including: (1) binding of ligands in the cytosol by PEX5p and PEX7p, the PTS1 and PTS2 receptors; (2) transport to and docking of PEX5p–ligand and PEX7p–ligand complexes with the peroxisomal membrane; (3) translocation of ligands into the peroxisome; and (4) recycling of the receptors back to the cytoplasm.

Figure 4 shows a current model for peroxisome biogenesis in humans. Our increasing knowledge about the human genes involved in peroxisome biogenesis has been of tremendous importance for studies on the genetic basis of Zellweger syndrome and the other disorders of peroxisome biogenesis. Indeed, at present, 11 of the 12 *PEX* genes which underlie the 12 complementation groups which have been identified so far are now known.

The peroxisomal disorders

Table 2 lists the peroxisomal disorders identified so far. Throughout the years several classifications have been proposed for the different peroxisomal disorders. The first proposed classifying the peroxisomal disorders into three groups reflecting the extent of peroxisomal dysfunction with a generalized (group A), multiple (group B), and single (group C) loss of peroxisomal function. A second classification divided the peroxisomal disorders into two groups with the disorders of peroxisome biogenesis in group 1 and the peroxisomal disorders in which a single peroxisomal function has been lost in group 2.

Below we will describe the characteristics of the individual peroxisomal disorders followed by the laboratory diagnosis of these disorders making use of a new classification based on the concept of diagnostic groups.

Cerebrohepatorenal (Zellweger) syndrome

The clinical presentation of Zellweger syndrome is dominated by craniofacial dysmorphia and profound neurological abnormalities. The craniofacial dysmorphia includes a high forehead, flat occiput, wide open sutures, large fontanelle, hypoplastic orbital ridges, epicanthus, high arched palate, external ear deformities, micrognathia, and redundant skin folds of the neck. Neurological abnormalities include severe hypo/areflexia, poor sucking, epileptic seizures, severe neonatal hypotonia, nystagmus, and sensorineural hearing loss. Furthermore, there is profound psychomotor retardation. There are also ocular abnormalities including cataracts, glaucoma, corneal clouding, Brushfield spots, pigmentary retinopathy, and optic nerve dysplasia. Because of the hypotonia and mongoloid appearance, Zellweger patients are sometimes wrongly suspected of suffering from Down's syndrome.

Pathological studies in Zellweger patients have shown a great number of abnormalities in various organs including the brain. Macroscopic abnormalities include deviant sulci and gyri with almost vertical parietal clefts and pachymicrogyria. The most striking and intriguing neuropathological abnormality is the impaired neuronal migration which leads to characteristic and unique cytoarchitectural abnormalities involving the cerebral hemispheres, the cerebellum, and the inferior olivary

complex.

Patients with Zellweger syndrome usually die early in life with an average lifespan of a few months.

Neonatal adrenoleucodystrophy

The first case of neonatal adrenoleucodystrophy was described in 1978 in a boy with hypotonia, convulsions, absent grasp reflexes, slight Moro response, and little spontaneous movement at birth. Characteristic signs of adrenoleucodystrophy were found in this patient which included demyelination of the central nervous system white matter, atrophy of the adrenal cortex, ballooned adrenocortical cells, and the presence of lamellar inclusions of electrondense leaflets separated by a clear space. However, there were also a number of additional central nervous abnormalities not described for X-linked adrenoleucodystrophy and it was noted that this new type of leucodystrophy resembled Zellweger syndrome in several respects, suggesting a common aetiology. This was soon found to be true when multiple peroxisomal abnormalities resulting from a defect in peroxisome biogenesis were described in patients with neonatal adrenoleucodystrophy.

Infantile Refsum disease

Infantile phytanic acid storage disease was first described in 1982 in three unrelated patients showing hepatomegaly, mental retardation, (minor) facial dysmorphia, retinopathy, neurosensory deafness, osteopenia, growth retardation, and elevated plasma phytanic acid levels. Because phytanic acid was known to accumulate in Refsum disease, the name infantile Refsum disease was coined. Since this initial report many additional patients have been described.

As with neonatal adrenoleucodystrophy it was soon realized that there were certain similarities between infantile Refsum disease and Zellweger syndrome, and we now know that infantile Refsum disease is also a disorder of peroxisome biogenesis which explains the multiple peroxisomal abnormalities observed in patients with infantile Refsum disease.

Hyperpipecolic acidaemia

Several cases have been reported in the literature of hyperpipecolic acidaemia. It is now clear that not all of these patients are true cases of isolated hyperpipecolic acidaemia. This implies that hyperpipecolic acidaemia has become obsolete in the classification of peroxisomal disorders. On the other hand, recent reports document the existence of apparently true cases of hyperpipecolic acidaemia although the underlying defect remains to be established.

Biochemistry of Zellweger syndrome, neonatal adrenoleucodystrophy, and infantile Refsum disease

In Zellweger syndrome, neonatal adrenoleucodystrophy, and infantile Refsum disease peroxisome biogenesis is defective resulting in the virtual absence of morphologically distinguishable peroxisomes in all the patient's cells. This has been demonstrated most convincingly in liver biopsy specimens from patients, notably by Roels and colleagues. The deficiency of peroxisomes can also be demonstrated in cultured fibroblasts from patients using immunofluorescence microscopy.

The absence of peroxisomes in patients with Zellweger syndrome, neonatal adrenoleucodystrophy, and infantile Refsum disease explains the multiplicity of biochemical abnormalities observed in these patients which are summarized in Table 3.

Molecular basis of the peroxisome deficiency disorders

The genetic basis of the different disorders of peroxisome biogenesis has been elucidated. Earlier studies had already shown that the genetic basis of Zellweger syndrome, neonatal adrenoleucodystrophy, and infantile Refsum disease is very heterogeneous. This was concluded from complementation studies, which involved fusion of fibroblasts of two different patients with the same abnormality such as a defect in peroxisome biogenesis so that hybrid cells (heterokaryons) are generated containing nuclei from each patient's fibroblasts. If the defective genes in the two patients' cell lines were different, one would expect restoration of peroxisome formation, whereas in the case when the mutant genes are identical, no complementation would occur. This is most easily done using catalase immunofluorescence. Large-scale complementation studies have now shown that there are at least 12 different complementation groups representing 12 different *PEX* genes. Interestingly, there is strong over-representation of one particular group, occurring in 60 to 70 per cent of all patients with a disorder of peroxisome biogenesis. The gene defective in this group is the *PEX1* gene which codes for a protein (PEX1p) belonging to the family of ATPases associated with diverse cellular activities which obviously plays an indispensable role in peroxisome biogenesis, although its precise mode of action is unknown. Eleven of the 12 genes which underlie the different complementation groups have now been identified. We have applied complementation analysis on a systematic basis to more than 200 patients with disorders of peroxisome biogenesis: most patients belong to the PEX1 group (63 per cent), followed by PEX6 (10 per cent), and PEX12 (5.4 per cent).

The identification of the mutant *PEX* genes is important for carrier detection and prenatal diagnosis in families at risk. On the other hand current prenatal diagnostic procedures which involve analyses at the enzyme (activity measurements) and protein (immunoblotting) level are very reliable.

Rhizomelic chondrodysplasia punctata type 1

Chondrodysplasia punctata represents a genetically heterogeneous group of bone dysplasias with stippling of the epiphyses as a common feature. The rhizomelic form is characterized by the presence of stippled foci of calcification within the hyaline cartilage with coronal clefts in the vertebral bodies associated with dwarfing, cataracts, multiple malformations due to contractures, and mental retardation in virtually all patients. Ichthyosis is frequent. Inheritance is autosomal recessive. Rhizomelic chondrodysplasia punctata must be distinguished from the milder autosomal dominant form of chondrodysplasia punctata (Conradi–Hunermann syndrome) with longer survival, absence of severe limb shortening, and usually intact intellect.

Apart from the classic presentation of rhizomelic chondrodysplasia punctata, a number of patients have now been described in the literature with a much milder presentation lacking the characteristic stigmata of rhizomelic chondrodysplasia punctata. Indeed, one such patient is still alive now at 16 years of age, has no rhizomelia, and only mild mental retardation. As we will describe below, there is not only clinical variability within rhizomelic chondrodysplasia punctata but also genetic diversity with two additional genetic types of rhizomelic chondrodysplasia punctata named types 2 and 3.

Biochemistry of rhizomelic chondrodysplasia punctata type 1 and molecular basis

Rhizomelic chondrodysplasia punctata is a true peroxisomal disorder, with the original description being of deficiency of plasmalogens in tissues and erythrocytes from patients and elevated phytanic acid levels in plasma. Subsequent studies have led to the remarkable finding of four distinct peroxisomal enzyme deficiencies at the level of:

1. dihydroxyacetonephosphate acyltransferase (DHAPAT)
2. alkyldihydroxyacetonephosphate synthase (alkyl-DHAP synthase)
3. phytanoyl-CoA hydroxylase, and
4. 41 kDa peroxisomal thiolase.

The underlying basis for this peculiar observation came when it was discovered that alkyl-DHAP synthase, phytanoyl-CoA hydroxylase, and peroxisomal thiolase all turned out to be PTS2 proteins, suggesting that the defect in rhizomelic chondrodysplasia punctata had to be in the PTS2 receptor. The gene coding for the PTS2 receptor was identified in 1997 and mutations were found in patients with rhizomelic chondrodysplasia punctata, thus establishing its molecular basis. Although many different mutations have been identified there is one frequent mutation, the Leu292Stop mutation, which occurs in more than 50 per cent of the mutant alleles.

Rhizomelic chondrodysplasia punctata type 2 (DHAPAT deficiency)

In 1992 the first patient was described with classic rhizomelic chondrodysplasia punctata but lacking the characteristic set of four peroxisomal abnormalities. Instead an isolated deficiency of only a single enzyme (DHAPAT) was found (Table 4). This enzyme catalyses the first committed step in plasmalogen synthesis and its deficiency is associated with the inability to synthesize plasmalogens.

At present several cases of rhizomelic chondrodysplasia punctata type 2 have been described. Most cases had a severe clinical presentation resembling classic rhizomelic chondrodysplasia punctata type 1. As could be expected, there is also clinical heterogeneity within rhizomelic chondrodysplasia punctata type 2. In all patients identified so far, the deficiency of DHAPAT is the single abnormality due to mutations in the structural gene coding for DHAPAT.

Rhizomelic chondrodysplasia punctata type 3 (alkyl-DHAP synthase deficiency)

The first case of rhizomelic chondrodysplasia punctata type 3 in a patient showing all the clinical stigmata of classic rhizomelic chondrodysplasia punctata was identified in 1994. In this patient plasmalogen biosynthesis was found to be blocked due to the deficient activity of the second enzyme involved in plasmalogen biosynthesis, i.e. alkyl-DHAP synthase. The least affected of those patients so far identified is alive at 7½ years with mild to moderate rhizomelia, generalized flexion contractures, inability to sit, roll, or crawl, cataract, continued seizures, and profound developmental delay. The deficient activity of alkyl-DHAP synthase in these patients has been found to result from different mutations in the structural gene coding for alkyl-DHAP synthase.

X-linked adrenoleucodystrophy

There is considerable clinical heterogeneity within X-linked adrenoleucodystrophy with at least six phenotypic variants. The classification of the different phenotypes of X-linked adrenoleucodystrophy is somewhat arbitrary and is based upon the age of onset and the organs principally affected. It should be noted that there are also patients not easily assignable to either phenotype, emphasizing the variable clinical expression of X-linked adrenoleucodystrophy. The two most frequently observed phenotypes, accounting for approximately 80 per cent of all cases, are childhood adrenoleucodystrophy and adrenomyeloneuropathy.

Childhood cerebral adrenoleucodystrophy

Childhood cerebral adrenoleucodystrophy is characterized by rapidly progressive cerebral demyelination. The onset is between 3 and 10 years of age. Frequent early neurological symptoms are behavioural disturbances, a decline in school performance, deterioration of vision, and impaired auditory discrimination. The course is relentlessly progressive, and seizures, spastic tetraplegia, and dementia develop within months. Most patients die within 2 to 3 years of the onset of neurological symptoms. Some patients survive longer, albeit in a persistent vegetative state.

In most patients with childhood cerebral adrenoleucodystrophy, cerebral magnetic resonance imaging typically reveals extensive demyelination in the occipital periventricular white matter, with sparing of the U fibres. Much less frequently, the frontal lobes are affected first. The early symptoms of childhood cerebral adrenoleucodystrophy are frequently attributed to an attention deficit disorder or hyperactivity. Before the advent of reliable diagnostic tests and magnetic resonance imaging, metachromatic leucodystrophy, ceroid lipofuscinosis, globoid cell leucodystrophy (Krabbe disease), and subacute sclerosing panencephalitis were sometimes diagnosed instead of childhood cerebral adrenoleucodystrophy.

Adrenomyeloneuropathy

Adrenomyeloneuropathy is the most frequent phenotype of X-linked adrenoleucodystrophy. The onset of neurological symptoms in this phenotype usually occurs in the third and fourth decade. Neurological deficits are primarily due to myelopathy and to a lesser extent to neuropathy. Patients gradually develop a spastic paraparesis, often in combination with a disturbed vibration sense in the legs and sphincter dysfunction. Approximately 50 per cent of men with adrenomyeloneuropathy show mild to moderate cerebral involvement on magnetic resonance imaging, and in some the abnormalities of white matter may resemble the demyelination seen in childhood cerebral adrenoleucodystrophy; the spinal cord is frequently atrophic. Nerve conduction studies and electromyography are compatible with a predominantly axonal, sensorimotor polyneuropathy. Life expectancy is probably normal, unless patients develop cerebral demyelination, or when adrenocortical insufficiency is not recognized and remains untreated. Many patients with adrenomyeloneuropathy were initially diagnosed with neurological diseases such as chronic progressive multiple sclerosis and hereditary spastic paraparesis.

Biochemistry and molecular basis of X-linked adrenoleucodystrophy

The biochemical hallmark of X-linked adrenoleucodystrophy is the accumulation of very long-chain fatty acids in plasma, fibroblasts, and other cell types. Analysis of plasma very long-chain fatty acids has turned out to be an extremely powerful diagnostic method with only a few if any false negatives, at least when analysed in experienced laboratories.

The accumulation of very long-chain fatty acids, notably C26:0, is due to their impaired oxidation in peroxisomes. It was initially thought that this was due to the deficient activity of a peroxisomal enzyme catalysing the activation of very long-chain fatty acids to their CoA esters which is the first obligatory step in fatty acid b-oxidation. The *X-ALD* gene was identified using a positional cloning strategy. Remarkably the deduced ALD protein did not appear to be an acyl-CoA synthetase but instead turned out to belong to the family of ABC proteins which also includes the CFTR protein involved in cystic fibrosis and the MDR protein involved in multidrug resistance. The ALD protein is a so-called halftransporter with six transmembrane spanning elements, and probably functions as a transporter of very long-chain fatty acid CoA esters across the peroxisomal membrane either as homo- or heterodimers localized in the peroxisomal membrane. The identification of the *X-ALD* gene has allowed molecular studies in X-linked adrenoleucodystrophy patients, which have shown diverse often unique mutations.

Acyl CoA oxidase deficiency (pseudoneonatal adrenoleucodystrophy)

In 1988 Poll-The and colleagues described patients with neonatal onset hypotonia together with delayed motor development, sensory deafness, and retinopathy with extinguished electroretinograms. There was no craniofacial dysmorphia in any of the patients. Psychomotor development was severely delayed, and after the first 2 years of life a progressive neurological regression set in. Computed tomography with contrast enhancement revealed bilateral enhancing lesions and a generally hypodense cerebral white matter which led to the diagnosis of neonatal adrenoleucodystrophy. The finding of elevated levels of very long-chain fatty acids in the plasma of these patients supported this conclusion. In contrast to the findings in other patients with neonatal adrenoleucodystrophy, however, these patients had peroxisomes normally present, albeit of enlarged size, and biochemical abnormalities were restricted to the accumulation of very long-chain fatty acids. The defect in these patients was at the level of acyl-CoA oxidase, the first obligatory enzyme involved in the peroxisomal b-oxidation of very long-chain fatty acids (see Fig. 2).

All patients identified so far have severe neurological abnormalities, mild to absent craniofacial dysmorphia, and failure to thrive. In patients with acyl-CoA oxidase deficiency, plasma abnormalities are restricted to the accumulation of very long-chain fatty acids which follows logically from the role of acyl-CoA oxidase in very long-chain fatty acid b-oxidation (see Fig. 2). A large deletion in the acyl-CoA oxidase gene in the two original patients has been reported.

D-Bifunctional protein deficiency

Bifunctional protein deficiency was first described in 1989 in a patient with severe hypotonia and seizures of neonatal onset. An electroencephalogram revealed multifocal spikes. No developmental progress was observed. There was no dysmorphia and no hepatomegaly. Fontanelles were open with open metopic sutures. Visual evoked responses and brainstem auditory evoked responses were grossly abnormal. A brain biopsy at 6 weeks revealed polymicrogyria. The patient died at 5 months of age after a clinical course marked by absent developmental progress and seizures refractory to treatment. Neuropathological studies revealed a polymicrogyric neocortex and focal areas of cortical heterotopia.

Laboratory analysis revealed elevated very long-chain fatty acids but liver morphology revealed the normal presence of peroxisomes. Subsequent immunoblot experiments revealed the absence of one of the peroxisomal b-oxidation enzyme proteins, i.e. bifunctional protein.

Many additional patients with bifunctional protein deficiency have since been described. Identification of such cases usually starts in a patient with a Zellweger-like phenotype in which subsequent laboratory studies reveal an isolated defect in peroxisomal b-oxidation with no abnormalities in other peroxisomal functions like plasmalogen biosyntheses and the normal presence of peroxisomes, although they are usually enlarged in both liver and in fibroblasts. Such data clearly point to a disorder of peroxisomal b-oxidation. Complementation studies have led to the identification of four groups with group 1 representing acyl-CoA oxidase deficiency, group 2 bifunctional protein deficiency, and groups 3 and 4 involving unknown defects.

Most patients turned out to belong to group 2. Remarkably, molecular studies in fibroblasts from patients belonging to group 2 failed to identify any mutations in the

gene for L-bifunctional protein. This puzzling situation was resolved when a new bifunctional protein called D-bifunctional protein or multifunctional enzyme 2 was discovered which turned out to be the enzyme deficient in group 2. Molecular studies clearly identified mutations in the gene for D-bifunctional protein, thus resolving the true molecular basis of bifunctional protein deficiency. Recent studies have shown that there are three subgroups within the bifunctional protein deficiency group, which finds its basis in the fact that bifunctional protein is a single protein with two catalytic activities.

The clinical presentation of patients affected by D-bifunctional protein deficiency is usually very severe and resembles that of Zellweger syndrome in many respects. Indeed, in a recent series neonatal hypotonia (94 per cent), dysmorphic features (80 per cent), neonatal seizures (92 per cent), hepatomegaly (43 per cent), developmental delay (100 per cent), poor feeding (86 per cent), and a disordered neuronal migration (88 per cent) were found.

Biochemistry of D-bifunctional protein deficiency

In patients suffering from D-bifunctional protein deficiency there is accumulation of very long-chain fatty acids, pristanic acid, and di- and trihydroxycholestanoic acid which follows logically from the scheme of Fig. 2. This is true for most cases, but in one form of D-bifunctional protein deficiency (type B) in which the enoyl-CoA hydratase component of D-bifunctional protein is functionally inactive there is no accumulation of bile acid intermediates although the underlying basis is unclear.

Peroxisomal thiolase-1 deficiency (pseudo-Zellweger syndrome)

In 1986 a girl from consanguineous parents showing marked facial dysmorphia, muscle weakness, and hypotonia at birth was described. The patient showed no psychomotor development during her 11-month life. At autopsy the patient had renal cysts, atrophic adrenals with striated cells, minimal liver fibrosis, hypomyelination in the cerebral white matter, foci of neuronal heterotopia, and a sudanophilic leucodystophy. Taken together, these clinical findings suggested that the patient was affected by Zellweger syndrome. Morphological analysis of the liver, however, revealed abundant peroxisomes. The subsequent finding that very long-chain fatty acids in plasma were clearly elevated did suggest a peroxisomal defect possibly restricted to the peroxisomal b-oxidation system. Further proof came when elevated levels of di- and trihydroxycholestanoic acid were found in a duodenal aspirate. Immunoblot studies revealed that both the 44 kDa precursor form of peroxisomal thiolase-1 as well as the mature 41 kDa form were completely missing, indicating peroxisomal thiolase deficiency. No additional patients have been described in the literature.

Peroxisomal 2-methylacyl-CoA racemase deficiency associated with a late onset motor neuropathy: a newly identified peroxisomal disorder

A new defect in the peroxisomal fatty acid b-oxidation pathway in a number of patients suffering from an adult onset sensory motor neuropathy has been described. Sensory motor neuropathy is associated with inherited disorders including Charcot–Marie–Tooth disease, X-linked adrenoleucodystrophy/adrenomyeloneuropathy, and Refsum disease. In the latter two, the neuropathy is thought to result from the accumulation of very long-chain fatty acids and phytanic acid respectively. The plasma of two patients with adult onset sensory motor neuropathy and additional signs suggesting Refsum disease (patient 1) and X-linked adrenoleucodystrophy (patient 2) had a similar profile: normal very long-chain fatty acids, marginally elevated phytanic acid, and definitely increased levels of the 2-methyl branched-chain fatty acids pristanic acid and di- and trihydroxycholestanoic acid. This suggested a specific defect in the peroxisomal b-oxidation of branched-chain fatty acids and not in the a-oxidation system, the first enzyme step of which is defective in Refsum disease. Studies in fibroblasts revealed normal values for all parameters measured except for pristanic acid b-oxidation, which was reduced to 20 to 30 per cent of control. The activities of the enzymes directly involved in the b-oxidation of branched-chain fatty acids, which includes branched-chain acyl-CoA oxidase, D-bifunctional protein, and peroxisomal thiolase 2 (pTH2/SCPx), were all normal.

Attention was focused on 2-methylacyl-CoA racemase. As described before, this enzyme is not directly involved in the b-oxidation process itself but is important in the b-oxidation of both pristanic acid and di- and trihydroxycholestanoic acid (Fig. 2) since the enzyme catalyses the interconversion of (2*R*) and (2*S*) stereoisomers of 2-methyl branched-chain fatty acyl-CoA esters. Measurement of racemase activity in fibroblasts using (25 *S*)-2,5,5-trihydroxycholestanoyl-CoA as substrate revealed a complete deficiency of the enzyme.

The finding of defined abnormalities in patients with late onset motor neuropathy resulting from a defect in the peroxisomal oxidation of 2-methyl branched-chain fatty acids at the level of 2-methylacyl-CoA racemase may have implications for the diagnosis of adult onset neuropathies of unknown aetiology.

Hyperoxaluria type 1 (alanine glyoxylate aminotransferase deficiency)

See Chapter 11.10 for further discussion.

Refsum disease

Refsum disease was first delineated as a distinct disease entity on a clinical basis by Sigvald Refsum in the 1940s under the name heredopathia atactica polyneuritiformis. Cardinal manifestations of the disease include retinitis pigmentosa, cerebellar ataxia, chronic polyneuropathy, and an elevated protein level in the cerebrospinal fluid with a normal cell count. Less constant features include sensorineural hearing loss, anosmia, ichthyosis, skeletal malformations, and cardiac abnormalities. The clinical picture of Refsum disease is often that of a slowly developing, progressive peripheral neuropathy manifested by severe motor weakness and muscular wasting, especially of the lower extremities.

Patients in whom Refsum disease is destined to develop appear to be perfectly normal as infants and do not show any obvious defects in growth and development. Onset has occasionally been detected in early childhood but not until the fifth decade in others. Most patients have clear-cut manifestations before the age of 20.

Biochemistry of Refsum disease

Studies in the early 1960s led to the identification of phytanic acid in tissues and plasma samples of Refsum patients. The enzyme defect in Refsum disease was identified at the level of phytanoyl-CoA hydroxylase.

Molecular basis of Refsum disease

The identification of the phytanoyl-CoA hydroxylase complementary DNA and gene structure has allowed molecular studies which show a variety of often unique mutations.

Glutaric aciduria type 3

In 1991 Bennett and colleagues described a patient who was investigated at 11 months of age because of failure to thrive and postprandial vomiting. Two abnormalities were found. First, she was shown to be homozygous for b-thalassemia and second, significant glutaric aciduria was found. Studies in fibroblasts revealed normal glutaryl-CoA dehydrogenase activity whereas glutaryl-CoA oxidase activity was not detectable. This study has not been followed up at the enzyme protein and/or DNA level. No additional cases have been identified so far.

Mevalonate kinase deficiency (see Chapter 11.12.3)

Mevalonate kinase deficiency is the only disorder involving the peroxisomal part of isoprenoid biosynthesis. Interestingly, apart from the classical form of mevalonate kinase deficiency which is associated with severe abnormalities early in life including profound developmental delay, facial dysmorphia, cataract, hepatosplenomegaly, lymphadenopathy, and early death, mevalonate kinase deficiency has also been observed in hyperimmunoglobulinaemia D and periodic fever syndrome. This syndrome is an autosomal recessive disorder characterized by recurrent episodes of fever associated with lymphadenopathy, arthralgia, gastrointestinal dismay, and skin rash. In patients with hyperimmunoglobulinaemia D/periodic fever syndrome mevalonate kinase was found to be strongly reduced (1.2 to 3.4 per cent of normal) but not fully deficient as in classical mevalonate kinase deficiency.

Acatalasaemia

Acatalasaemia is a rare disease which has mainly been described in Japan and Switzerland. In Japan, acatalasemia is associated with ulcerating, often gangrenous,

oral lesions whereas these abnormalities were not seen in Swiss patients.

Laboratory diagnosis of peroxisomal disorders: postnatal diagnosis

Although discussed in this chapter as a single group, the peroxisomal disorders comprise a heterogeneous group of disorders with a large spectrum of clinical signs and symptoms. Furthermore, different biochemical abnormalities are found in the various peroxisomal disorders reflecting the peroxisomal pathway(s) primarily affected. This immediately explains why there is not a single laboratory method allowing diagnosis of all peroxisomal disorders.

Earlier we introduced the concept of diagnostic groups in order to develop logical guidelines for the laboratory diagnosis of the various peroxisomal disorders. These diagnostic groups are:

I. The disorders of peroxisome biogenesis plus the disorders of peroxisomal b-oxidation with the exception of X-linked adrenoleucodystrophy which forms a distinct diagnostic group (group III). This group includes Zellweger syndrome, neonatal adrenoleucodystrophy, infantile Refsum disease, acyl-CoA oxidase deficiency, D-bifunctional protein deficiency, and peroxisomal thiolase deficiency.
II. Rhizomelic chondrodysplasia punctata complex.This includes: rhizomelic chondrodysplasia types 1, 2, and 3.
III. X-linked adrenoleucodystrophy complex.This includes all forms of X-linked adrenoleucodystrophy.
IV. The remaining peroxisomal disorders.This includes: racemase deficiency, hyperoxaluria type 1, Refsum disease, glutaryl-CoA oxidase deficiency, mevalonate kinase deficiency, and acatalasaemia.

Laboratory diagnosis of the disorders of diagnostic group I

As described earlier, the clinical presentation of the disorders of peroxisomal b-oxidation resembles that of the disorders of peroxisome biogenesis in many respects. This is immediately clear if is realized that the first cases of acyl-CoA oxidase deficiency were described under the name pseudoneonatal adrenoleucodystrophy and peroxisomal thiolase deficiency as pseudo-Zellweger syndrome. The similarity between the disorders of peroxisome biogenesis and peroxisomal b-oxidation is also clear in the case of D-bifunctional protein deficiency: patients with this defect show severe neurological abnormalities including hypotonia, seizures, and psychomotor retardation as well as craniofacial dysmorphia as discussed before.

The biochemical abnormalities of the different disorders belonging to diagnostic group I are listed in Table 3. Inspection of these data shows that very long-chain fatty acids are abnormal in all these disorders making very long-chain fatty acid analysis a reliable first-line diagnostic test to verify whether a patient with the clinical signs and symptoms of a disorder of peroxisome biogenesis or peroxisomal b-oxidation is truely affected by such a peroxisomal disorder. If abnormal, additional tests have to be performed to discriminate between either a disorder of peroxisome biogenesis or peroxisomal b-oxidation. This includes analyses in erythrocytes (plasmalogens) and plasma (bile acid intermediates, pristanic acid, and phytanic acid).

If plasmalogen levels are deficient, the diagnosis 'disorder of peroxisome biogenesis' is established. This should be followed by detailed studies in fibroblasts, to establish whether the defect is truely expressed in fibroblasts and to establish the gene defective in this patient. If plasmalogen levels are normal this usually, but not invariably, points to a disorder of peroxisomal b-oxidation thus emphasizing the value of examining fibroblasts.

Laboratory diagnosis of the disorders of diagnostic group II

Since the clinical characteristics of rhizomelic chondrodysplasia punctata type 1 (PTS2 receptor deficiency), type 2 (DHAPAT deficiency), and type 3 (alkyl-DHAP synthase deficiency) are very similar, it makes sense to include these three forms of chondrodysplasia punctata in a single diagnostic group.

The biochemical characteristics of these disorders are listed in Table 4. The fact that erythrocyte plasmalogens are deficient in all three types indicates that analysis of erythrocyte plasmalogens is a reliable initial laboratory test to establish whether one is dealing with rhizomelic chondrodysplasia punctata type 1, 2, or 3. Erythrocyte plasmalogens have always been found to be deficient, even in more mildly affected cases. This implies that if erythrocyte plasmalogens have been found to be normal, rhizomelic chondrodysplasia punctata type 1, 2, or 3 is excluded whereas the finding of deficient plasmalogen levels is diagnostic for all types of rhizomelic chondrodysplasia punctata. Detailed studies of fibroblasts are required to discriminate between types 1, 2, and 3.

Laboratory diagnosis of X-linked adrenoleucodystrophy complex (diagnostic group III)

As described above, there is great heterogeneity within X-linked adrenoleucodystrophy with childhood cerebral adrenoleucodystrophy and adrenomyeloneuropathy as the most frequent phenotypes. Studies in hundreds of patients have shown that analysis of plasma very long-chain fatty acids is a reliable initial test to verify whether a certain patient is affected by X-linked adrenoleucodystrophy. If abnormal, we usually proceed by doing a full study in fibroblasts followed by molecular analyses in blood cells of fibroblasts.

Fibroblast studies are not obligatory and it may be advisable to perform direct molecular studies in blood cells of the patient as soon as plasma very long-chain fatty acids have been found to be abnormal. Heterozygote detection is not so straightforward as for hemizygotes. Indeed, plasma very long-chain fatty acids levels have been found to be normal in about 15 per cent of obligate heterozygotes making such analysis unreliable for the detection of heterozygotes. For this reason we advocate molecular studies and omit very long-chain fatty acids analysis in families in which the molecular defect has been established. In case the family history is negative, we usually start by doing plasma very long-chain fatty acid analysis followed by detailed studies in fibroblasts including measurements of C26:0 b-oxidation activity, very long-chain fatty acid analysis, and analysis of the ALD protein by means of immunofluorescence microscopy. The latter method may be especially rewarding since it is a general feature of X-linked adrenoleucodystrophy that in many instances the product of the mutant *X-ALD* allele produces an unstable protein so that in cells from heterozygotes a mosaic pattern is observed with positive and negative cells upon immunofluorescence.

Laboratory diagnosis of the disorders of group IV

The disorders of group IV share no similarities and all require separate laboratory tests for diagnosis as described below.

Peroxisomal 2-methylacyl-CoA racemase deficiency

Patients with a deficiency of 2-methylacyl-CoA racemase are unable to degrade pristanic acid and the bile acid intermediates di- and trihydroxycholestanoic acid. For this reason pristanic acid and di- and trihydroxycholestanoic acid are elevated in patients whereas very long-chain fatty acids are normal. Although experience is limited, it is probably safe to say that postnatal diagnosis of such patients may either be based on analysis of pristanic acid by gas chromatography or mass spectrometry or bile acid intermediates preferably by tandem mass spectrometry. Definitive diagnosis of racemase deficiency requires detailed studies in fibroblasts including measurement of racemase activity making use of specifically synthesized substrates.

Primary hyperoxaluria type 1

In patients with hyperoxaluria type 1 alanine glyoxylate aminotransferase is deficient which leads to a block in glyoxylate detoxification. Glyoxylate may either be oxidized to oxalate or reduced to glycolate which explains why in most patients with primary hyperoxaluria type 1 there is increased urinary excretion of all three acids. Definitive diagnosis of primary hyperoxaluria type 1 requires a liver biopsy for assessment of alanine glyoxylate aminotransferase activity.

Refsum disease

In Refsum disease phytanoyl-CoA hydroxylase is deficient, leading to the impaired degradation of phytanic acid. Since phytanic acid is solely derived from exogenous sources, plasma phytanic acid levels may vary widely. Definitive diagnosis requires measurement of phytanoyl-CoA hydroxylase in fibroblasts followed by molecular analysis at the complementary DNA or preferably the genomic level.

Glutaryl-CoA oxidase deficiency (glutaric aciduria type 3).

Only a single patient with this defect has been described in the literature. In this patient there was increased urinary excretion of glutaric acid not due to glutaric aciduria type 1 (glutaryl-CoA dehydrogenase deficiency) or glutaric aciduria type 2 (electron transfer flavoprotein (ETF)/ETF dehydrogenase deficiency). Glutaryl CoA oxidase was deficient.

Mevalonate kinase deficiency

In the classic form of mevalonate kinase deficiency, urinary mevalonic acid is extremely high in all patients studied making urinary analysis of mevalonic acid a reliable method for identification. If abnormal, mevalonate kinase activity should be measured in various types of blood cell (except erythrocytes) and/or in fibroblasts followed by molecular studies.

In hyperimmunoglobulinaemia D/periodic fever syndrome mevalonate kinase is also deficient, although to a lesser extent compared with the classic type of mevalonate kinase deficiency. Importantly, urinary mevalonic acid may be completely normal in these patients, which implies that diagnosis should be based on direct enzyme analysis in white blood cells, platelets, and/or fibroblasts.

Acatalasaemia

The diagnosis of acatalasaemia is not discussed here.

Laboratory diagnosis of peroxisomal disorders: prenatal diagnosis

In recent years reliable methods for the prenatal diagnosis of virtually all peroxisomal disorders have become available, in most cases employing cultured chorionic villus samples. For this specialized area, the reader is referred to the literature listed below.

11.10 Disorders of oxalate metabolism

Richard W. E. Watts and C. J. Danpure

Introduction—oxalate, hyperoxaluria, oxalosis

The oxalate anion is metabolically inert in humans and its overall metabolism can be represented by a single-compartment model in which the oxalate metabolic pool is a little larger than the extracellular fluid volume and contains approximately 10 to 30 µmol of oxalate. The system is normally in equilibrium but expansion of the oxalate metabolic pool occurs in renal failure and when there is either overproduction or overabsorption of oxalate. Tissue deposition of calcium oxalate (oxalosis) only occurs when renal failure is combined with one of these other factors. The normal plasma oxalate concentration is 1 to 3 µmol/l and shows a circadian rhythm, being lowest in the morning and highest in the evening with superimposed postprandial rises. The urinary excretion of oxalate does not normally exceed 450 µmol/24 h in adults. The results in children are similar if they are adjusted to a standard body surface area (1.73 m^2), and adult levels are reached by about 14 years of age. The urinary excretion of oxalate also increases during the waking hours and shows seasonal variations related to dietary oxalate and calcium intakes; vitamin D supply also affects calcium absorption. The oxalate in the plasma and tissues is of dietary and biosynthetic origin. The following foods and beverages have particularly high oxalate contents: beets, beetroot, celery, chocolate, cocoa, nuts, rhubarb, strawberries, spinach, and tea. They provide about 0.8 to 1.7 mmol per day, of which, only about 5 per cent is absorbed depending upon the proportion that is in soluble form and the calcium content of the diet. Some dietary oxalate is degraded by gut commensal bacteria, for example *Oxalatobacter formigenes*. The main biosynthetic source of oxalate in humans is glycine; oxalate accounts for only about 1 per cent of the total glycine metabolic turnover, via the glyoxylate anion and the C_1–C_2 fragment of ascorbate.

Glycolate, hydroxyproline, serine and the sidechains of the aromatic amino acids have been shown to be minor metabolic precursors of oxalate in experimental animals. Negligible amounts of oxalate appear to be derived from carbohydrate and polyols (for example xylitol) under normal dietary conditions. The claim that the artificial sweetening agent diethylene glycol is converted to oxalate in humans has not been confirmed. The absorption of oxalate from the small intestine involves both an active carrier mediated transport system with oxalate–chloride exchange as well as passive diffusion.

The kidney handles the oxalate ion by 100 per cent filtration at the glomerulus, tubular secretion involving active tubular transport into the lumen, and passive backdiffusion into the peritubular capillaries. The ratio (oxalate clearance)/(glomerular filtration rate) is normally about 1.2, indicating net tubular secretion. Apart from acute oxalic acid poisoning, diseases attributable to oxalate present when calcium oxalate stones form in the urinary tract and when this salt crystallizes in either the renal parenchyma (calcium oxalate nephrocalcinosis) or in other tissues (oxalosis). The disorders of oxalate metabolism are due to either overproduction or excessive absorption of oxalate, although hyperoxaluria could, at least theoretically, arise from a renal tubular abnormality causing increased net renal tubular secretion of oxalate. Impaired renal function causes oxalate retention, and there is a linear relationship between the plasma oxalate and creatinine concentrations. However, the plasma oxalate concentration does not exceed the critical value (48.5 µmol/l) at which the solubility product of calcium oxalate in plasma is exceeded and oxalosis develops before endstage renal failure supervenes, unless there is also either oxalate overproduction, as in primary hyperoxalurias I and II, or oxalate hyperabsorption. Conversely, increased oxalate biosynthesis and hyperabsorption do not cause oxalosis unless recurrent oxalate urolithiasis and nephrocalcinosis have impaired renal function. The risk of oxalosis developing, as judged by rapidly rising plasma oxalate concentration and expansion of the oxalate metabolic pool, is greatly increased when the glomerular filtration rate decreases to about 25 ml/min/1.73 m^2. Hyperoxaluria is the hallmark of the disorders of oxalate metabolism and Table 1 lists its causes.

Primary hyperoxaluria type I

Epidemiology

The estimated prevalence of primary hyperoxaluria type I is about 10.5 per million inhabitants with an incidence of about 1 in 120 000 live births in European countries. The prevalence and incidence are greater in countries with a higher consanguinity rate.

Biochemistry and molecular biology

Primary hyperoxaluria type I is an autosomal recessive disorder of glyoxylate metabolism caused by deficiency of the liver-specific peroxisomal pyridoxal phosphate-dependent enzyme alanine:glyoxylate aminotransferase (EC 2.6.1.44). In some cases the deficient alanine:glyoxylate aminotransferase activity can be augmented by administration of pyridoxine. Alanine:glyoxylate aminotransferase normally catalyses the conversion of the intermediary metabolite glyoxylate to glycine, but its absence in primary hyperoxaluria type I allows glyoxylate to be oxidized to oxalate and reduced to glycolate instead (Fig. 1). The elevated synthesis of oxalate and glycolate leads to the hyperoxaluria and hyperglycolic aciduria characteristic of primary hyperoxaluria type I. In some families, a pseudodominant pattern of inheritance is apparent due to the segregation of three, rather than two, mutant alleles. Primary hyperoxaluria type I is phenotypically heterogeneous at both the enzymic and clinical levels. Three major enzymic categories are recognized, characterized by:

1. The absence of both alanine:glyoxylate aminotransferase catalytic activity and alanine:glyoxylate aminotransferase immunoreactive protein (ENZ–/CRM–).
2. The absence of alanine:glyoxylate aminotransferase catalytic activity but the presence of alanine:glyoxylate aminotransferase immunoreactive protein (ENZ–/CRM+).
3. The presence of both alanine:glyoxylate aminotransferase catalytic activity and alanine:glyoxylate aminotransferase immunoreactive protein (ENZ+/CRM+).

Many patients in the last category can have alanine:glyoxylate aminotransferase activities similar to those found in asymptomatic heterozygotes (Fig. 2). In most of these patients disease is caused by an unparalleled protein trafficking defect in which alanine:glyoxylate aminotransferase is mistargeted to the mitochondria, where it is unable to fulfil its metabolic function (i.e. glyoxylate transamination) properly.

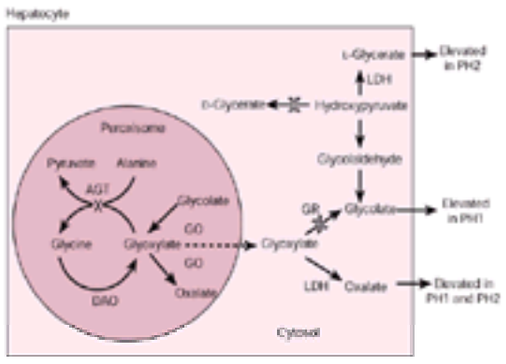

Fig. 1 Main pathways of glyoxylate metabolism in human liver cells. The black 'X' indicates the location of the defect in primary hyperoxaluria type I and the white 'X' indicates the same in primary hyperoxaluria type II: AGT, alanine:glyoxylate aminotransferase; GO, glycolate oxidase; DAO, D-amino acid oxidase; GR, glyoxylate reductase; LDH, lactate dehydrogenase. The peroxisomal membrane could be permeable to most or all of the metabolites shown. However, only the peroxisomal efflux of glyoxylate (dotted line) is shown to highlight the relationship between alanine:glyoxylate aminotransferase deficiency and the hyperoxaluria and hyperglycolic aciduria characteristic of primary hyperoxaluria type I.

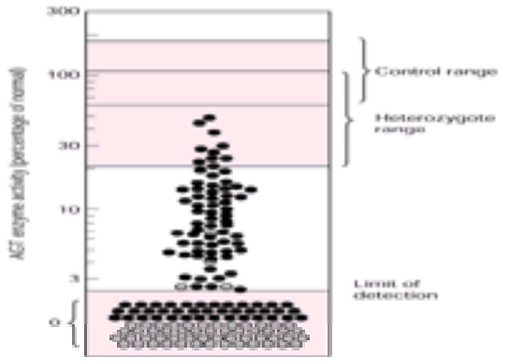

Fig. 2 Hepatic alanine:glyoxylate aminotransferase heterogeneity in patients with primary hyperoxaluria type I. Alanine:glyoxylate aminotransferase activity, expressed as a percentage of the mean normal control value, is shown for 162 patients with primary hyperoxaluria type I. Black circles, CRM+; grey circles, CRM–. Almost all patients with significant alanine:glyoxylate aminotransferase activity express the peroxisome-to-mitochondrion mistargeting phenotype.

Alanine:glyoxylate aminotransferase is encoded by the *AGXT* gene located on chromosome 2q37.3, where it spans about 10 kbases and consists of 11 exons and 10 introns. Numerous polymorphisms and mutations have been identified at the *AGXT* locus; more details can be found in the review by Danpure (2001) listed in Further reading. The most common mutation found in primary hyperoxaluria type I, with an allelic frequency of 30 per cent, leads to a substitution of arginine for glycine at residue 170 and, in combination with a proline®leucine polymorphism at residue 11, is responsible for the peroxisome-to-mitochondrion mistargeting of alanine:glyoxylate aminotransferase.

Pathology

In the early stages, the pathological findings are confined to the kidney, which shows a variable degree of hydrocalycosis and hydronephrosis with multiple calculi. Nephrocalcinosis forms later, causing severe renal fibrosis and shrinkage, and the kidney feels tough and gritty when incised. Changes due to renal hypertension and recurrent pyelonephritis are often present, and the renal tubules may be blocked by aggregates of calcium oxalate crystals, particularly if the terminal illness has been associated with a hypotensive oliguric episode. The characteristic rosette-like calcium oxalate monohydrate crystals are highly birefringent and easily recognized under a polarizing microscope. Their full extent will only be observed if either unfixed tissues are examined or if non-aqueous fixatives are used, but they are usually sufficiently insoluble for some to remain and be apparent after routine fixation in formal saline. They are found most extensively in the myocardium, the tunica media of muscular arteries and arterioles, the rete testes, and at sites of rapid bone turnover. Careful examination reveals a few crystals associated with the arterial supply of all organs and tissues. Similar deposits have been found intra-axonally in peripheral nerves.

Clinical aspects

Patients usually present with recurrent urolithiasis in childhood, and if untreated die from renal failure before they are 20 years old. The terminal phase of rapidly progressing oliguric renal failure usually lasts, at most, only a few months and is associated with dense calcium oxalate nephrocalcinosis and with the development of systemic oxalosis. Ischaemic lesions occur on the extremities, particularly in the pulps of the fingers and toes, and are attributable to the extensive crystallization of calcium oxalate in the walls of small muscular arteries and arterioles. Progressive peripheral neuropathy and mononeuritis multiplex are associated with calcium oxalate deposition within axons and in the walls of the vasa nervorum. These vascular and neurological manifestations, as well as a wider range of oxalotic features, occur particularly in patients in whom the terminal renal failure has been treated by standard haemodialysis, by peritoneal dialysis, or by an unsuccessful renal transplantation. Additional manifestations include livedo reticularis, subcutaneous calcinosis which may ulcerate, retinal changes (white flecks, exudates, infarcts, yellow crystalline deposits, especially along the courses of the ophthalmic arteries, black 'geographic' lesions at the macula), dilated cardiomyopathy, cardiac conduction defects, synovitis, a painful osteodystrophy with dense osteosclerosis and skeletal deformation, stress fractures (especially in the vertebrae), and the changes of coincidental secondary and tertiary hyperparathyroidism.

Hyperoxaluria may present during the first months of life with seizures, advanced renal failure, and dense nephrocalcinosis but few if any calculi (the infantile type). Another small group (the adult type) follows a benign course, presenting in adult life and surviving into the fourth and fifth decade with only occasional stone formation. This latter type shows less elevation of urinary oxalate excretion than is usual in the group (juvenile type) which follows the typical clinical pattern. However, the amount of oxalate excreted and the age at which renal failure develops are not very closely correlated.

Although the usual clinical pattern is one of recurrent stones, with or without nephrocalcinosis leading inexorably to renal failure, a few patients present with severe uraemia and may give no history of urolithiasis. A few present with symptoms arising from oxalosis involving principally the heart, arteries, bones, and peripheral nerves. Considering this clinical grouping in relation to the patient's age, pyridoxine responsiveness, and the plasma and urine oxalate concentrations gives a clinical guide to prognosis.

Although the 'metabolic lesion' of primary hyperoxaluria type I is located in the peroxisome, it does not share any of the features of the other peroxisomal diseases. Similarly, patients in whom alanine:glyoxylate aminotransferase has been misrouted into mitochondria do not show evidence of mitochondrial disease (impaired fatty acid oxidation and disorders of function of the respiratory chain).

Diagnosis

Primary hyperoxaluria type I should be considered in any child with urinary stones or nephrocalcinosis and in adults with recurrent calcium oxalate stones for which no alternative explanation has been found, especially if the clinical history extends back into childhood. The presence of calcium oxalate crystals in the urinary centrifuged deposit is not a specific diagnostic sign; the 24-h urinary oxalate excretion must be measured chemically and related to the creatinine excretion. The urinary oxalate excretion can be misleadingly low in patients in advanced renal failure. About 75 per cent of patients have an associated hyperglycolic aciduria. The definitive diagnosis is made by assaying alanine:glyoxylate aminotransferase activity on a percutaneous needle biopsy of the liver, which can also be examined by immunoelectron microscopy to establish whether the enzyme protein is present and its intracellular location. It is now possible to combine this with an assay for hydroxypyruvate/glyoxylate reductase, which is essential for the diagnosis of primary hyperoxaluria type II, on the same biopsy tissue. Figure 2 shows the results of

enzyme assays on patients, compared with the ranges obtained from carriers and other normals. The plasma oxalate concentration is determined when the patient is first evaluated and subsequently as a guide to prognosis and management. A progressively increasing plasma oxalate concentration indicates an increasing risk of oxalosis developing. A plasma oxalate value that is high relative to the corresponding creatinine is a valuable pointer to either oxalate overproduction or overabsorption. Early oxalosis is usually clinically silent. Some procedures that may be used to detect and evaluate it are listed in Table 2.

Prenatal diagnosis

Until a few years ago, prenatal diagnosis of primary hyperoxaluria type I was only possible by measuring alanine:glyoxylate aminotransferase activity in fetal liver biopsies in the second trimester. However, it is now possible to carry out the procedure in the first trimester by DNA (either mutation or polymorphism) analysis of material obtained from chorionic villi.

Treatment

Fluid and diet

Like all patients suffering from urinary stone disease those with primary hyperoxaluria type I should drink sufficient fluid to maintain a measured urine volume of 3 litres every 24 h with proportionately less in children. The diet should be low in oxalate and have minimum intakes of vitamins C and D, although this may need modification in children to meet the needs of growth and development.

Pyridoxine

The effect of pharmacological doses (150 to 1000 mg/day) of pyridoxine (pyridoxal phosphate is the prosthetic group in alanine:glyoxylate aminotransferase) on urinary oxalate excretion should be assessed over three 1-week periods, pretreatment, during treatment, and post-treatment, with assays of urinary oxalate and creatinine (a check for completeness of urine collection) on each 24-h urine collection. Smaller doses are occasionally effective. If the urinary oxalate decreases appreciably, pyridoxine should be continued indefinitely. A favourable response can probably be anticipated in between about 10 and 30 per cent of cases. The risks of pyridoxine-induced neuropathy have to be considered. Patients presenting in endstage renal disease may be given pyridoxine blindly.

Crystallization inhibitors

Citrates, either as sodium citrate (0.1–0.15 g/kg body weight/day) or equivalent doses of either sodium–potassium citrate (urolyte U Madaus®) or effervescent anhydrous sodium acid phosphate (phosphate Sandoz®) reduce the degree of urine calcium oxalate saturation. Neutral orthophosphates (equivalent to 2 g of elemental phosphorus per day) increase the excretion of pyrophosphate ions which inhibit heterogeneous calcium oxalate crystal nucleation, seeded growth, and aggregation. It also reduces calcium absorption. Magnesium supplements (for example 200 mg of magnesium oxide per day) also inhibit crystal growth and aggregation. The doses used should be sufficient to produce a material increase in either the urinary excretion of phosphate or magnesium. Phosphate and magnesium should be avoided if there is renal insufficiency. They may also produce diarrhoea.

Associated abnormalities

Coincidental urinary tract infections, hypercalciuria, and any urinary acidification defect should be treated vigorously on their merits. Excessive alkalization of the urine should be avoided because it may predispose to urinary tract infections and to the superimposition of phosphatic stones.

Treatment of urinary stones

Obstructive uropathy requires an immediate percutaneous nephrostomy to relieve the obstruction. Nephroscopic lithotomy, endoscopic lithotripsy with ultrasonic, electrohydraulic, and laser techniques, as well as extracorporeal shockwave lithotripsy, which produce relatively little damage to functioning kidney tissue, can be used to deal with asymptomatic stones. The kidneys should be kept as free from stones as possible and open lithotomy for large calculi should now rarely be needed. Stone debris may require either external drainage via a nephrostomy or internal drainage via a stent. However, stents and other foreign bodies in the urinary tract rapidly become encrusted with calcium oxalate deposits. Close follow-up is essential with regular radiological and/or ultrasonographic assessment. Patients who have previously passed stones often do so with little pain and unsuspected collections of stones may be found in the lower ureter on a routine abdominal radiograph. Acute hypotensive episodes are particularly dangerous causing intrarenal precipitation of calcium oxalate with acute and irreversible loss of renal function.

Transplantation

The oxalate ion has low dialysance and low filterability in the clinical context, and none of the currently available methods of replacing renal function can keep up indefinitely with the rate of oxalate overproduction once renal failure has occurred. Thus, almost all pyridoxine-resistant patients ultimately require orthotopic liver transplantation to correct the metabolic and genetic lesion together with a simultaneous renal transplant if they are approaching endstage renal disease. A small group of patients with relatively large amounts of residual catalytic enzyme activity may be suitable for an isolated renal graft. A renal transplant while the glomerular filtration rate is in the 15 to 20 ml/min/1.73 m^2 range may also be used to 'buy time' during which liver transplantation can be organized. The patient should be either haemodialysed or haemofiltered as vigorously as possible before, during, and after any grafting procedure in order to deplete the oxalate metabolic pool, minimize oxalosis, and reduce the risk to the grafted kidney.

Ideally, planning for liver and/or renal transplantation should begin when the glomerular filtration rate falls below 25 ml/min/1.73 m^2 (or 20 per cent of the mean predicted normal value) to minimize oxalosis and reduce the risk of oxalate deposits in the grafted kidney.

After a successful liver transplant the hyperglycolic aciduria returns to normal immediately. The plasma oxalate value normalizes over the course of a few weeks or months, and the urinary oxalate excretion returns to normal over the course of one or more years depending on the size of the oxalate deposits that are gradually mobilized from the tissues.

The plasma oxalate concentration should be followed sequentially before and after operation in these patients. Preoperatively, it is a guide to the extent to which the superimposition of oxalate retention on oxalate overproduction is occurring and hence to the rate at which the risk of oxalosis is increasing. Values approaching 35 µmol/l indicate that measures to reduce it are very urgently needed. Postoperatively, it is an indication of the risk of calcium oxalate damage to the grafted kidney.

Pre-emptive liver transplantation before renal failure has decreased to 25 ml/min/1.73 m^2 is an option if the disease is diagnosed early and is following an aggressive course. Partial orthotopic hepatic transplantation using tissue from a live related histocompatible donor has been proposed, but it is uncertain whether this would produce a clinically useful degree of metabolic correction. Heteroptic auxiliary liver transplantation is theoretically unsound. Although primary hyperoxaluria type I presents certain advantages as a candidate for gene therapy using retrovirus- or adenovirus-based constructs there has, as yet, been no definitive work in this area.

Primary hyperoxaluria type II

Primary hyperoxaluria type II is significantly rarer than primary hyperoxaluria type I and, as such, has been much less studied. Primary hyperoxaluria type II is caused by a deficiency of the widely-distributed enzyme glyoxylate reductase (EC 1.1.1.26/79, also known as hydroxypyruvate reductase and D-glycerate dehydrogenase, EC 1.1.1.29). Glyoxylate reductase catalyses a number of reactions, including the reduction of glyoxylate to glycolate and the reduction of hydroxypyruvate to D-glycerate (Fig. 1). Its absence in primary hyperoxaluria type II, however, allows glyoxylate to be oxidized to oxalate and hydroxypyruvate to be reduced to L-glycerate. The resulting increased synthesis of oxalate and L-glycerate, which leads to hyperoxaluria and hyper L-glyceric aciduria, is characteristic of primary hyperoxaluria type II.

Glyoxylate reductase is encoded by the *GRHPR* gene, which contains nine exons and eight introns, and spans about 9 kbases in the pericentromeric region of chromosome 9. A series of mutations in the *GRHPR* gene has been found in patients with primary hyperoxaluria type II. One case without hyper L-glyceric aciduria has been identified on the basis of immunoelectrophoresis.The clinical features, complications, and pathological findings are similar to those of primary hyperoxaluria type I. There have been no reports of possible biochemical and genetic heterogeniety of this disease. Enzyme replacement by organ transplantation has not been attempted in the type II disease, although if the liver proved to contain most of the complement of glyoxylate reductase activity, liver transplantation might be

beneficial. The expression of the enzyme in leucocytes suggests that bone marrow transplantation from a fully histocompatible sibling might also be a therapeutic option.

Primary hyperoxaluria type III

Patients with primary hyperoxaluria type III, which has been attributed to oxalate hyperabsorption, do not have an associated hyperglycolic or L-glyceric aciduria and have, therefore, to be distinguished from the approximately 25 per cent of patients with primary hyperoxaluria type I with isolated hyperoxaluria. The diagnosis of primary hyperoxaluria type III rests on: firm evidence of normal intestinal anatomy, histology, and absorptive function; the demonstration of excessive oxalate absorption (this may be difficult to establish by the available ^{14}C-labelled oxalate absorption and/or oxalate loading tests); normal hepatic alanine:glyoxylate aminotransferase and glyoxylate reductase levels. The urinary oxalate excretion (usually 1–2 mmol/24 h) is similar to that in some patients with the other types of primary hyperoxaluria, and type III patients are at risk of urinary stones, renal failure, and oxalosis. The metabolic lesion has not been identified but it might involve an oxalate–chloride exchanger in the small intestine. It has been reported that thiazides reduce urinary oxalate excretion in primary hyperoxaluria type III. As in secondary hyperoxaluria due to diffuse small intestinal disease, treatment is by a low-oxalate diet with oxalate binding agents such a cholestyramine and calcium ions (given as calcium carbonate). A marine hydrocolloid preparation (ox-absorb®) has recently been developed as an intestinal oxalate binding therapeutic agent. Patients with primary hyperoxaluria type III may not be a homogeneous group and some may represent an as yet unidentified disorder of either glyoxylate or glycolate metabolism. Others may be due to deficient colonization of the gut by *Oxalatobacter formigenes*. Disorders of renal tubular function are also a theoretical possibility.

Enteric hyperoxaluria

Enteric hyperoxaluria is an uncommon but potentially serious complication of the diseases listed under this heading in Table 1. It can cause extensive urolithiasis with nephrocalcinosis and renal failure. Expansion of the oxalate pool has been demonstrated and there is the same potential for oxalosis developing as in the primary hyperoxalurias. Treatment depends upon reducing dietary oxalate intake, the use of oxalate binding agents, and correcting the steatorrhoea or abnormal gut flora in the case of cystic fibrosis.

11.11 Disturbances of acid–base homeostasis

R. D. Cohen and H. F. Woods

In resting humans arterial blood, pH (pH_a) is normally maintained between 7.36 and 7.42, by control of the arterial partial pressure of CO_2 ($PaCO_2$) and plasma bicarbonate, between the limits 4.7 to 5.8 kPa and 24 to 30 mmol/l, respectively. Intracellular pH is also controlled, but varies substantially between organs within the range 6.3 to 7.4, depending on prevailing physiological or pathological circumstances. Some intracellular organelles are particularly acid, notably lysosomes. There is a substantial daily burden of hydrogen ions (protons) derived principally from metabolism (Table 1), and disordered neutralization or elimination of this burden shifts pH in the acid direction. Inappropriate loss of protons or proton-generating substrates, or excessive input of alkali, shifts pH in the alkaline direction.

Extra- and intracellular buffers, notably haemoglobin, other proteins, bicarbonate, and phosphate, play a transient role in countering acute pH changes but normally the acid burdens listed in Table 1 are ultimately eliminated quantitatively or neutralized. These burdens have been grouped into three classes according to their mode of disposal. Carbon dioxide derived from cellular respiration is much the largest potential generator of protons, the burden in the resting subject being an order of magnitude greater than that resulting from lactic and other organic acid production as well as from urea synthesis. Protons derived from the metabolism of sulphur- and phosphorus-containing compounds constitute the smallest source and represent a burden that is about one-hundredth of that derived from carbon dioxide. Disposal of carbon dioxide is dependent on adequate respiratory function. The metabolism of sulphur-containing amino acids in the diet eventually results in the production of so-called fixed acids, namely sulphuric acid and phosphoric acid, which may originate from many sources. Neither of these acids is volatile and they are thus excreted by the kidney.

The organic acids listed in Table 1 have pK values much below that of blood pH. They are therefore present in the blood as acid anions, rather than as the undissociated acids. The equivalent amount of hydrogen ions, generated at the site of production of these acids, titrate with local tissue and blood bicarbonate and other buffers. The organic acid anions (lactate, 3-hydroxybutyrate, acetoacetate, and fatty acids) are non-volatile but, unlike the fixed acids, may be eliminated by metabolism. Figure 1 shows an example of the important principle that when these organic acid anions are metabolized to electroneutral products (e.g. glucose, or carbon dioxide and water) protons are consumed and the bicarbonate consumed at their site of production is regenerated. Protons from organic acids can also be eliminated in the urine, but normally this is a much slower process than the metabolic route. Particularly in the case of the ketone bodies, for which the renal threshold is relatively low, substantial amounts can be lost in the urine when their plasma concentration is elevated. Although in maximally acidified urine (pH 4.5) about half of the urinary ketone bodies are in the form of the undissociated acid, the remaining free anion moiety represents loss of potential alkali, since it eludes metabolism to bicarbonate.

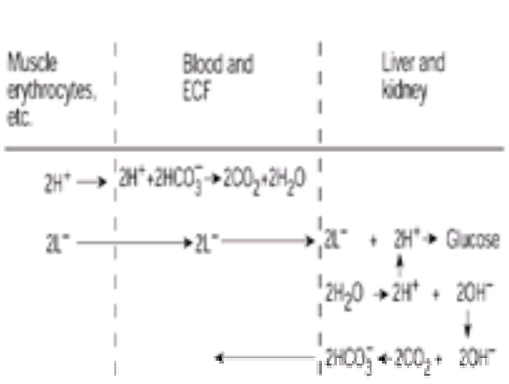

Fig. 1 A scheme, using lactate (L^-) conversion to glucose as an example, showing how conversion of the anion of an organic acid of low pK to an electroneutral substance consumes H^+ and regenerates HCO_3^-.

Despite the large quantitative differences in the burden due to the three classes of acid shown in Fig. 1, their correct elimination is, in a sense, equally important, for no class is able substantially to be disposed of by a route normally used to eliminate another class. Normally, the rates of production and elimination of each class of acid are matched in a long-term steady state. The homeostasis of arterial blood pH thus provided is given quantitative expression in the Henderson–Hasselbalch equation:

$$pH_a = 6.1 + \log_{10} \{[HCO_3^-]_a/(0.225 \times PaCO_2)\}$$

The constancy of arterial plasma bicarbonate concentration ($[HCO_3^-]_a$) is maintained by the removal of class I and II acids and by proton generation during ureagenesis (see below) and that of $PaCO_2$ by the lungs, thereby fixing pH_a within a narrow range.

The roles of the kidneys and liver in acid–base homeostasis

The interplay of these organs in acid–base homeostasis has been a matter of controversy. The authors' view is that the contribution of the kidneys is not entirely what it has appeared to be, and that the role of the liver requires emphasis. Classical descriptions are based on the kidneys as the principal controllers of $[HCO_3^-]$. Yet, as may be seen in Table 1, the liver is responsible for the major part of lactate disposal and consequent bicarbonate regeneration as well as the generation of ketoacids, with the opposite acid–base consequence. There is, however evidence that both these hepatic functions are normally controlled in an attempt to preserve acid–base homeostasis. Thus at normal concentrations of blood lactate, deviations in the acid direction enhance hepatic lactate disposal. As will be seen in the case of lactate, the homeostasis may be lost at higher concentrations of lactate. Ketogenesis is itself suppressed by increasing acidosis.

Urea production is another important feature of hepatic metabolism. The production of each molecule of urea (ultimately from ammonium and carbon dioxide) is accompanied by the generation of two protons. Ureagenesis is therefore a potential acidifying mechanism. Most of the protons produced in ureagenesis are neutralized by the bicarbonate generated during the oxidation of the carbon skeleton of amino acids, but normally there is a slight excess of protons produced, which have to be eliminated by the kidneys. Urea synthesis and accompanying proton production are negatively regulated by acidosis, which constitute another acid–base regulatory system intrinsic to the liver.

The renal tubules secrete protons and those not involved in the process of bicarbonate reabsorption are buffered by urinary phosphate. Under normal conditions, about 30 mmol/day of protons are excreted in this way. Classically, urinary ammonia (NH_3) is regarded as another buffer for hydrogen ions, which are therefore

removed as ammonium (NH_4^+); normally the excretion of hydrogen ions in the supposed NH_4^+ buffer amounts to about 70 mmol/day, but may increase to 500 mmol/day under severe acidifying stress in maximally acidified urine. It is, however, not possible to reconcile this view with the physicochemical fact that the ammonia/ammonium equilibrium is almost entirely in the form of ammonium at the time of generation from glutamine, and is therefore not available for buffering further protons. A more plausible explanation of the role of the kidneys is that the increase in ammonium excretion during acidosis serves to divert nitrogen from hepatic urea synthesis and consequent proton production, thus countering the acidosis.

These considerations provide a background to the interpretation of many acid–base syndromes described below.

Acid–base disorders

Definitions

The terminology of acid–base disturbances has always been confused. The terms acidaemia and alkalaemia simply indicate that pH_a is lower or higher than the normal range. Here we use the term acidosis to encompass both the situation where pH_a is low, and also that in which, although pH_a is normal, it would have been lowered if compensatory mechanisms had not occurred; an equivalent definition applies to alkalosis. When the primary disturbance is related to abnormal carbon dioxide elimination, the disturbance is referred to as 'respiratory'. All other primary disturbances, that is those related to disturbances of class II or III acid production or removal, are referred to as 'metabolic' or 'non-respiratory'. The term 'primary' is used to distinguish these processes from those which are compensatory in nature. Thus primary metabolic acidosis, lowering $[HCO_3^-]_a$, is compensated for by hyperventilation, which decreases $PaCO_2$; respiratory acidosis, driven by elevation of $PaCO_2$, is compensated for by metabolic events which result in an elevation of $[HCO_3^-]_a$.

The diagnosis of acid–base disturbances

Since the clinical manifestations of acid–base disturbances, described later, are frequently non-specific and may not be apparent until the disturbance is quite severe, laboratory investigation is indispensable. Measurement of pH_a, $PaCO_2$, and $[HCO_3^-]_a$ on arterial blood is the primary investigation. Estimation of plasma urea, creatinine, sodium, potassium, and chloride, and, when appropriate, lactate, ketoacids, and salicylate provides further important information.

Measurement of pH_a and $PaCO_2$—acid–base diagram

Blood gas analysers measure pH and PCO_2 and calculate plasma bicarbonate from the Henderson–Hasselbalch equation. Interpretation of results is best achieved by the use of an acid–base diagram which has pH_a and $PaCO_2$ as its axes. Diagrams which use $[HCO_3^-]_a$ on one of the axes are less suitable, since $[HCO_3^-]_a$ is calculated from pH_a and $PaCO_2$ and is not only subject to compounding errors in those measurements, but is affected by some poorly understood variations in pK_a in the Henderson–Hasselbalch equation in blood from severely ill patients.

The acid–base diagram in Fig. 2 has bands drawn in to show the ranges of data expected in uncomplicated acid–base disorders. It not only aids the diagnosis of acid–base disorders, but in addition the course of an individual patients disturbance and its response to treatment can be followed by serial plotting of data. The shaded square represents the approximate limits of pH_a and $PaCO_2$ in normal individuals. Thus a patient with uncomplicated metabolic acidosis will have values lying in the band marked 'metabolic' in the region above and to the left of the normal zone; the 'metabolic' band is the envelope of measurements of pH_a and $PaCO_2$ in patients with uncomplicated metabolic acidosis and alkalosis. The metabolic band is rather restricted on the alkalotic side, below and to the right of the normal zone. This is because compensation by hypoventilation for metabolic alkalosis is often poor; hypoxia may limit the degree of hypoventilation and metabolic alkaloses may be associated with intracellular acidosis, which could stimulate the respiratory centre. Marked hypocapnia is, however, occasionally seen in metabolic alkalosis.

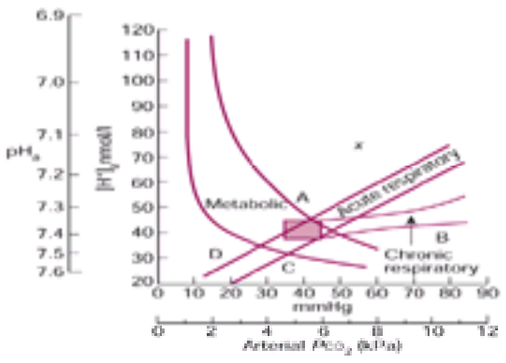

Fig. 2 A practical acid–base diagram. For explanation see text.

The band marked 'acute respiratory' is the 95 per cent confidence range of values obtained in normal individuals voluntarily hyperventilating or breathing air carbon dioxide mixtures for short periods. After a few days of carbon dioxide retention, an increase in plasma bicarbonate produces substantial or complete compensation for the respiratory acidosis; the band in chronic respiratory acidosis is therefore different from the acute response, the presence of the extra bicarbonate decreasing the fall in pH_a expected for a given rise in $PaCO_2$.

pH_a and $PaCO_2$ measurements in some patients will not fall within any of the defined bands in Fig. 2. Such patients have a mixture of acid–base disorders. Thus a patient whose pH_a and $PaCO_2$ are represented by the point '×' has mixed respiratory and metabolic acidosis, for example a patient with uraemic acidosis and an exacerbation of chronic bronchitis with respiratory failure. pH_a and $PaCO_2$ values lying in sectors A and C result from a combination of two primary acid–base conditions; in sectors B and D one of the two disturbances might be compensatory for the other.

Acid–base analytical equipment usually also provides at least two additional derived acid–base variables—the standard bicarbonate and base excess or deficit. The standard bicarbonate represents what the plasma bicarbonate would be if the blood had the normal $PaCO_2$ of 5.33 kPa (40 mmHg) rather than its actual value. Standard bicarbonate was introduced in an attempt to provide a measurement which was independent of respiratory disturbance and thus indicative of the underlying pure metabolic disturbance. Base deficit represents the amount of alkali in mmol needed to restore the pH of 1 litre of the patient's blood *in vitro* to normal (pH 7.4) at a PCO_2 of 5.33 kPa, and might at first sight be considered a quantitative measure of metabolic acidosis. Unfortunately the titration curve of blood *in vitro* is different from when it is circulating *in vivo*, since in the latter situation the interstitial and intracellular fluids also interact in the titration and may gain or lose bicarbonate from it; in addition, their buffering capacity differs from that of blood. These considerations detract from the usefulness of base excess/deficit as a guide either to diagnosis or therapy.

Further difficulties arise from ambiguities in the interpretation of base excess/deficit. Thus a patient with chronic respiratory acidosis will have a high standard bicarbonate and a base excess due to compensatory increase of plasma bicarbonate. It could be said, therefore, that this patient has simultaneously a respiratory acidosis and a metabolic alkalosis, as a base excess indicates the latter. This way of regarding the situation seems to us confusing and is incompatible with the definitions of acidosis and alkalosis we have given, which are intended to indicate the direction of the primary disturbance.

Use of the anion gap

In measurements of plasma electrolytes, the sum of the cations ($Na^+ + K^+$) normally exceeds that of the anions ($Cl^- + HCO_3^-$) by about 14 mmol/l (reference range 10–18 mmol/l). This difference is known as the anion gap and in health is attributable largely to the net negative charge on plasma proteins, but also to phosphate, sulphate, and several organic acids. Calculation of the anion gap is of great value in the differential diagnosis of metabolic acidosis, but the regrettably increasingly

common practice of omitting chloride estimation from sets of plasma electrolytes frequently deprives the clinician of this important diagnostic tool.

Metabolic acidoses may be divided broadly into those with high and those with normal anion gap. Metabolic acidoses with high anion gap are due to the ingestion or endogenous generation of acids, usually organic, whose anions are not measured in routine sets of plasma electrolytes. Plasma bicarbonate is titrated by these acids and therefore decreases; the anion gap is thus widened by the presence of these unmeasured anions. The most frequent organic acids concerned are lactic and ketoacids. In uraemic acidosis, the anion gap seldom exceeds 28 mmol/l. but considerably higher values may be found in severe lactic acidosis and ketoacidosis. It should be noted that there are causes of raised anion gap other than metabolic acidosis, for example therapy with sodium salts of relatively strong acids (e.g. lactate, acetate) and high-dose sodium carbenicillin treatment.

Metabolic acidoses with normal anion gap are due to the direct loss of bicarbonate from the body, either through the gut or fistulae, through the kidney, or, rarely, to the ingestion or infusion of acid or acidifying substances. When bicarbonate is lost, more chloride is retained by the renal tubules; thus low plasma bicarbonate is accompanied by hyperchloraemia and the anion gap remains unchanged.

Causes of acid–base disturbance

Table 2 classifies those conditions associated with high anion gap metabolic acidosis by the principal organic acid involved. Often a mixture of acids is involved but where possible the predominant acid has been shown in italics. Normal anion gap metabolic acidoses are shown in Table 3, classified according to whether they are due to gut or renal bicarbonate loss, or to ingestion or infusion of acidifying agents. Metabolic alkalosis (Table 4) is due either to ingestion or infusion of excessive alkali in circumstances when it cannot be excreted (e.g. poor renal function), or to the secretion of urine which is inappropriate both in its acidity and in its ammonium content. Most of the causes of the latter occurrence are related to the complex events in potassium and chloride deficiency and are dealt with later, as is the pathogenesis of the metabolic alkalosis of acute hepatic failure. Table 5 classifies respiratory acidosis according to the level of the problem, namely, the lungs and airways, the neuromuscular and mechanical aspects of respiration, and the central nervous system. Except in the case of deliberate or inadvertent external hyperventilation, respiratory alkalosis is always due to some form of stimulus to the respiratory centre, as classified in Table 6.

The effects of acid–base disturbances

These are widespread and we limit ourselves here to a brief description of those with known clinical consequences.

Respiratory effects

Both metabolic acidosis and acute respiratory acidosis induced by breathing high $P\mathrm{CO}_2$ gas mixtures result in hyperventilation. Deep sighing respiration (Kussmaul breathing) is a familiar sign of metabolic acidosis. pH control of ventilation is determined by the pH perceived by the carotid and aortic body chemoreceptors and by receptors in the medulla, which appear to monitor the pH of brain extracellular fluid. In the steady state, brain extracellular fluid pH is closely similar to that of cerebrospinal fluid. Sudden development of metabolic acidosis, resulting in low pH_a and arterial bicarbonate, induces hyperventilation by stimulating the carotid body and aortic chemoreceptors and $P\mathrm{aCO}_2$ is thus lowered. However, the first effect on brain extracellular fluid pH is to raise it. This is because brain extracellular fluid $P\mathrm{CO}_2$ is lowered since carbon dioxide is rapidly equilibrated across the blood–brain barrier. However, it takes many hours for the brain extracellular fluid bicarbonate to fall in response to the lowering of plasma bicarbonate, because movement of bicarbonate across the barrier is much slower than that of carbon dioxide. The temporary alkalinization of brain extracellular fluid somewhat offsets the extra ventilatory drive from the carotid and aortic chemoreceptors, so the hyperventilatory compensatory response takes some hours to reach its maximum. Though clinical circumstances usually prevent the observation of this sequence of events, the opposite, namely persistence of hyperventilation after restoration of normal pH during therapy of metabolic acidosis is commonly seen, and may last for over 24 h.

In chronic respiratory failure, with high $P\mathrm{aCO}_2$, direct depression of the respiratory centre occurs; the respiratory response to increments of $P\mathrm{aCO}_2$ is progressively lost and ventilation becomes increasingly dependent on hypoxic drive. Alkalosis also may depress respiration and increases the difficulties of weaning artificially ventilated patients from the respirator.

Cardiovascular effects

Acidosis decreases cardiac contractility (negative inotropism) and alkalosis has smaller but opposite effects. Acidosis and alkalosis both predispose to cardiac arrythmias. The negative inotropic effects are particularly related to changes in myocardial intracellular pH and are experimentally found to be rather greater in acute respiratory than in acute metabolic acidosis. In the rat, progressive metabolic acidosis reduces cardiac output as a result of bradycardia and negative inotropy; there is consequent hypotension and decreased renal and hepatic blood flow. This sequence of events may provide a model for the circulatory collapse which often occurs in patients after some hours of metabolic acidosis not originally attributable to shock. Mild to moderate metabolic acidosis has not often been associated with negative inotropic effects in the intact animal; this appears to be due to the protective effects of catecholamine release, which is increased in acidosis. In more severe acidosis, this protection breaks down. Patients receiving b-blockers may be more susceptible to the negative inotropic effects of acidosis.

Cerebral arterioles are very sensitive to the pH of brain extracellular fluid; they dilate when this falls and constrict when the pH rises. The cerebrovascular resistance is thus subject to the same type of phased responses to acid–base disturbances as described above for ventilation. Dilatation is also the response of most systemic arterioles to acidosis, although this response may be modified by catecholamine effects. The peripheral veins, however, constrict in acidosis, resulting in a shift of blood from the peripheral capacitance vessels to the central circulation. This effect has been shown to have important clinical consequences during treatment (see below).

Effects on intermediary carbohydrate metabolism

In all tissues in which observations have been made, glycolysis is inhibited by acidosis and stimulated by alkalosis, due to the effects of intracellular pH on phosphofructokinase, a rate-limiting enzyme of glycolysis. Respiratory alkalosis might therefore be expected to raise blood lactate but this effect is usually small, probably due to removal of lactate by the liver. However, in the presence of severe liver disease, gross elevation of blood lactate may be seen in association with respiratory alkalosis, and the increased production of lactate may partially compensate for the alkalosis.

Animal studies have shown that hepatic gluconeogenesis from lactate is inhibited by acidosis due to an effect on the metabolic step between pyruvate and oxaloacetate. This phenomenon may override the stimulatory effect on hepatic lactate disposal described earlier and may be responsible for perpetuating and worsening lactic acidosis.

Effects on nitrogen balance

Chronic acidosis produces negative nitrogen balance, mainly due to accelerated proteolysis in skeletal muscle. This effect is mediated through increased expression of the genes coding for ubiquitin and proteasome subunits.

Effects on blood oxygen uptake and delivery to the tissues

One of the factors determining blood uptake of oxygen during passage through the lungs, and subsequent delivery of oxygen to the tissues, is the position of the blood oxygen dissociation curve with respect to the abscissa ($P\mathrm{O}_2$). Right shifts of this curve improve unloading of oxygen in the tissues, but under some circumstances may impair oxygen uptake in the lungs. Left shifts have the opposite effect. The position of the curve is determined by three haemoglobin ligands, namely hydrogen ions, carbon dioxide, and 2,3-bisphosphoglycerate (2,3-BPG). Increases in all of these shift the curve to the right. Changes in intraerythrocytic pH and $P\mathrm{CO}_2$ are often rapid, but those of 2,3-BPG are much slower. In chronic acidosis, the synthesis of 2,3-BPG is inhibited and marked reductions in the erythrocyte content of this metabolite may occur, with opposite effects in alkalosis. These changes are, however, slow in comparison with the immediate effects of changes in pH and $P\mathrm{CO}_2$ (the Bohr effect).

The effect of these differences in time scale on oxygen delivery gives rise to a characteristic sequence of events during the development and treatment of acute metabolic acidosis. Initially, the acute acidosis causes a right shift of the curve, and thus improved oxygen release to the tissues. After several hours, erythrocyte

2,3-BPG falls, thus restoring the position of the curve towards normal. If the patient is now rapidly treated with alkali, the Bohr effect results in rapid shift to a position to the left of normal, because of the low level of 2,3-BPG. The resulting sudden deterioration of oxygen release may have adverse clinical effects unless the consequences of left shift are ameliorated by other factors, such as an increase in tissue blood flow. It may be many hours or days before erythrocyte 2,3-BPG concentrations are restored to normal.

Effects on the nervous system

Severe acidosis is frequently associated with impairment of consciousness, varying from mild drowsiness to coma. This effect is not closely related to systemic pH, and the mechanism is poorly understood. The effects on the respiratory and cardiovascular centres have been discussed above. The excitability of neural and muscular tissues is increased by alkalosis and diminished by acidosis. Tetany is a common feature of respiratory alkalosis, and may also be seen when chronic metabolic acidosis is corrected in patients with hypocalcaemia, a sequence of events which may occur in chronic renal failure. Epileptic attacks in susceptible individuals may be precipitated by alkalosis and suppressed by acidosis.

Effects on potassium homeostasis

Acute acidosis results in a shift of potassium out of the intracellular compartment into the extracellular fluid. Hyperkalaemia is thus often seen in the acidosis of renal failure, untreated diabetic ketoacidosis, and in acute respiratory failure; its mechanism is not entirely clear, factors other than extracellular pH being implicated. Alkali therapy in such patients causes a shift of potassium back into cells. As substantial amounts of potassium may be lost in the urine during the period of hyperkalaemia, overall depletion of body potassium occurs; thus alkali therapy may result in a rapid fall of plasma potassium to dangerous levels. This is a well-known hazard in the treatment of diabetic ketoacidosis and is even more dangerous in types 1 and 2 renal tubular acidosis in which plasma potassium is frequently low in the presence of acidosis (see also under Treatment below).

Chronic metabolic alkalosis is also frequently accompanied by potassium depletion, which results from distal tubular potassium secretion uninhibited by competition with hydrogen ions for secretion.

Effects on the kidney

The kidney is a major organ of acid–base regulation and many of its responses are therefore geared to acid–base homeostasis. Proton secretion is a principal function of tubular cells and in the proximal tubule is a crucial part of the mechanism for the apparent reabsorption of the large quantities of bicarbonate filtered at the glomerulus. In the cortical and medullary collecting tubules, where the main acidification of the urine takes place, the intercalated cell is equipped with the H^+-ATPase, residing in the apical (luminal) membrane, and the band 3 general anion exchanger, in the basolateral membrane. Under acid conditions H^+ and bicarbonate are generated by carbonic anhydrase within these intercalated cells. The protons are secreted into the lumen, where they titrate the phosphate buffer, or convert any bicarbonate present into carbon dioxide and water; the bicarbonate is transported by the anion exchanger in the opposite direction into the blood stream. There is now evidence of considerable plasticity of function of these cells so that in alkaline conditions the polarity of transporter expression is reversed, with the H^+-ATPase now predominating in the basolateral membrane and the anion exchanger in the luminal membrane, secreting bicarbonate into the urine. The maximum urinary pH thereby achieved is about 8.0.

As indicated earlier, there is a large increase in renal ammonium production and excretion in the urine in acidosis. The ammonium ions are derived from glutamine by the action of glutaminase in the proximal tubule; they are mainly secreted by pH-dependent non-ionic diffusion into the collecting tubule lumen, where the blood-lumen pH gradient is the greatest in acidosis. Chronic acidosis results in an increased expression of glutaminase and phosphoenolpyruvate carboxykinase. The latter enzyme is rate-limiting for gluconeogenesis, and an increase in renal gluconeogenesis is thought to play a crucial role in the high rate of ammonium production. A reinterpretation of the role of increased ammonium excretion in acidosis has been discussed above.

Effects on the distribution of metabolites and drugs

Many weak acids and bases are distributed between body compartments by the simple physicochemical process of pH-dependent non-ionic diffusion, which is based on movement of the non-dissociated hydrophobic moiety across the lipid membranes separating compartments, quite independently of any transporter. The pH differences between the compartments will determine the relative concentrations in the two spaces at equilibrium. Weak acids accumulate in the more alkaline compartment and weak alkalis in the more acid compartment. Examples of physiological metabolites distributed by this mechanism include ammonia/ammonium (weak base) and urobilinogen (weak acid). The distribution of ammonium and other amines present in advanced liver disease between blood and cerebrospinal fluid is partly determined in this way. Examples of drugs exhibiting this behaviour are salicylates and phenobarbitone (weak acids); use of their pH-dependent distribution is made in the treatment of poisoning with these drugs by forced alkaline diuresis.

Effects on bone

Bone acts as a buffer in chronic metabolic acidosis. Leaching out of bone calcium carbonate and exchange of extracellular phosphate for carbonate within the apatite crytal result in the neutralization of protons. The first of these mechanisms causes a negative calcium balance in chronic metabolic acidosis and in chronic uraemic acidotic subjects it has been shown that calcium balance can be restored by treatment with sodium bicarbonate. Although chronic metabolic acidosis in rats results in osteoporosis, renal tubular acidosis and the acidosis associated with ureterosigmoidostomy may lead to osteomalacia, which can be corrected by alkali therapy alone.

Effects on leucocytes

Severe acidosis is often associated with marked leucocytosis, unrelated to the presence of infection. Blood leucocyte counts of up to 60 000/mm^3 have been recorded in lactic acidosis and high values are also common in diabetic ketoacidosis. This phenomenon may be partly a specific reaction to acidosis and not merely a general manifestation of stress or dehydration.

Major acid–base syndromes

Lactic acidosis

In normal resting individuals, venous blood lactate concentration is in the range 0.6 to 1.0 mmol/l. In extreme exercise this may rise to 20 mmol/l or more. Lactate is the end-product of anaerobic glycolysis. Its production by many tissues, even at rest, is accompanied by equal amounts of hydrogen ions, since its pK is low (3.8) and the undissociated acid is therefore present only in minute amounts. These protons react with blood and tissue bicarbonate to form carbon dioxide and water, but the lost bicarbonate is quantitatively restored when the lactate is converted to glucose (see Fig. 1), mainly in the liver, or oxidized in many tissues to carbon dioxide and water. When lactate is produced at a rate which exceeds the disposal rate, the regeneration of bicarbonate is incomplete and acidosis results. The pathological mechanisms leading to lactic acidosis are therefore excess production, defective disposal, or, commonly, a mixture of both. As the acidosis develops, hepatic disposal of lactate by gluconeogenesis may become further inhibited (see above), leading to a vicious circle which provides a model for the often fulminating course of lactic acidosis.

Clinically, lactic acidosis falls into two main categories. In type A lactic acidosis, much the more common, there is clinical evidence of shock, poor tissue perfusion, or hypoxia. Though increased peripheral glycolysis is an important contributor, associated poor hepatic and renal perfusion limit the lactate disposal mechanisms. Indeed in circulatory failure, the liver and kidneys may produce lactate rather than dispose of it. In type B lactic acidosis, there is no evidence at the outset of circulatory insufficiency or hypoxia, though after many hours of increasing acidosis these may supervene. The original diagnosis and cause of acidosis may be obscured if the patient does not present until this late stage. Type A lactic acidosis is a frequent manifestation of haemorraghic, septic, cardiogenic, or traumatic shock and there is a direct relationship between the concentration of blood lactate and poor prognosis. The causes of type B lactic acidosis (Table 2) are varied and some of the mechanisms will be described below.

The initial clinical presentation in type B lactic acidosis is fairly uniform and consists of hyperventilation or dyspnoea, drowsiness or coma, vomiting, and abdominal pain, in approximately that order of frequency. The condition usually develops over a few hours, but may be more chronic, for example in the mitochondrial myopathies. Although by definition there is initially no clinical evidence of poor tissue perfusion or hypoxia, patients with severe type B lactic acidosis commonly

become shocked after a few hours.

The diagnosis of lactic acidosis is based on the clinical circumstances, including the presence of a known aetiological factor, the presence of a high anion gap acidosis, and the measurement of blood lactate, for which automated apparatus is now widely available.

Biguanide-induced lactic acidosis

This class of oral hypoglycaemic agent has widespread metabolic effects, including inhibition of gluconeogenesis and the monocarboxylate transporter responsible for movement of lactate ions across cell membranes, and stimulation of glycolysis. The lactic acidosis is of the type B variety though, as indicated above, circulatory insufficiency may eventually supervene. The principal culprits were phenformin and buformin and the mortality was about 50 per cent; these biguanides are no longer used. Metformin is, however, widely used; the incidence of lactic acidosis with metformin is less than one-tenth of that with phenformin. Since metformin is almost entirely excreted in the urine, lactic acidosis may be largely avoided by care not to prescribe this drug in patients with even mild degrees of renal insufficiency, or conditions such as uncontrolled heart failure which might be expected to diminish renal function. Attempts have been made to show that the risk of lactic acidosis in diabetics taking metformin is no greater than in diabetics not receiving the drug. There have, however, been serious criticisms of those studies, and since the use of metformin is likely to increase because of its value in the prevention of diabetic microvascular complications, we strongly advise that the above precautions for its use continue to be followed.

Postictal lactic acidosis

The severe muscular contractions during convulsions may produce severe lactic acidosis in the same way as vigorous exercise. The finding of lactic acidosis in these circumstances occasionally gives rise to confusion but may be distinguished from other causes of lactic acidosis by the rapid decline of blood lactate after the cessation of convulsions, with a half-life of approximately 20 min.

Lactic acidosis in liver disease

Though impaired disposal of an administered lactate load is readily demonstrable in chronic liver disease, clinical lactic acidosis is uncommon. However, in the later stages of fulminant hepatic necrosis it may be an important part of the clinical picture. Acid–base disturbances in the earlier stages are discussed below.

Lactic acidosis in severe falciparum malaria

Lactic acidosis is a common feature of severe malaria due to *P. falciparum*, particularly in children, where it is the strongest predictor of poor prognosis. Although shock may be a factor, the lactic acidosis is frequently of the type B variety, and is attributable to many factors, including production of lactate by the parasite itself, occlusion of the microcirculation by parasites, the direct effects of high circulating levels of certain cytokines, notably tumour necrosis factor, inhibition of gluconeogenesis from lactate because of decrease in hepatic blood flow, and overproduction of lactate during the convulsions which are a common feature of cerebral malaria. Hypoglycaemia in severe malaria may be linked with lactic acidosis; it may be a manifestation of decreased gluconeogenesis or of insulin release due to quinine therapy. Acidosis appears to increase the attachment of infected erythrocytes to capillary walls, perhaps thus worsening the capillary blockage seen in the cerebral circulation and other sites. It may also inhibit the uptake of antimalarial drugs into erythrocytes.

Lactic acidosis associated with treatment with nucleoside reverse transcriptase inhibitors

There have been reports of lactic acidosis, which may be severe, associated with AIDS therapy with nucleoside reverse transcriptase inhibitors. Two mechanisms have been described—riboflavine deficiency and a mitochondrial disorder, with myopathy associated with the characteristic ragged red fibres seen in inherited mitochondrial myopathies. In the former type, the lactic acidosis rapidly responds to the administration of riboflavine.

Ethanol and methanol-induced lactic acidosis

Ingestion of ethanol after a period of fasting is a well-known cause of hypoglycaemia, which may be severe. The phenomenon is due to inhibition of gluconeogenesis, which is the sole source of endogenous glucose output when glycogen stores have been depleted. The defect in gluconeogenesis may result in moderate lactic acidosis, because ethanol diverts some of the NAD^+ needed for the oxidation of lactate to pyruvate, the first step in lactate disposal, for its own oxidation, catalysed by alcohol dehydrogenase. With withdrawal of ethanol, administration of glucose, and refeeding, the condition is normally self-limiting.

In methanol poisoning, the main contributor to the acidosis is formic acid, but lactic acidosis also plays a part, due to inhibition of gluconeogenesis by similar mechanisms to those in ethanol-induced lactic acidosis.

Salicylate and ethylene glycol poisoning

See Chapter 8.1.

D(–) lactic acidosis

In all the lactic acidoses described above, the stereoisomer involved is L(+)lactate, the end product of mammalian glycolysis. However, a few cases have been described in which the acidosis has been due to D(–)lactate. There is a very minor pathway of D(–)lactate production in mammalian tissues, but in D(–)lactic acidosis the D(–)lactate arises as a product of glycolysis in bacteria in the gut, and all cases have been associated with short gut or jejunal–ileal bypass syndromes or the therapeutic ingestion of large quantities of *Lactobacillus acidophilus*. The lactic acidosis may be severe and is often associated with disturbances of consciousness; it is presumably due to absorption of large quantities of D(–)lactate from the gut, since it may be treated by appropriate oral antibiotics. In healthy individuals, infused D(–)lactate is cleared at approximately 70 per cent of the rate for L(+)lactate, but by the non-specific 2-hydroxybutyrate dehydrogenase rather than L(+)lactate dehydrogenase. The main problem in diagnosing D(–)lactate acidosis is that D(–)lactate is not detectable by the routine blood lactate assay which employs the enzyme L(+)lactate dehydrogenase. If the condition is suspected because of unexplained high anion gap metabolic acidosis in a patient with a predisposing condition, then D(–) lactate should be assayed either by gas chromatography or using a bacterial D(–)lactate dehydrogenase.

Diabetic ketoacidosis

The pathogenesis and clinical features of diabetic ketoacidosis are described elsewhere (Chapter 12.11). Only the acid–base disturbance will be discussed here. Though the acidosis is conventionally regarded as being due mainly to overproduction of ketoacids by the liver, recent evidence has suggested that the hydrogen ions are wholly or partly derived from other tissues, though the liver is, of course, the source of ketoacid anions. Hepatic gluconeogenesis, a major source of the hyperglycaemia of diabetic ketoacidosis, proceeds at increased rates, in spite of potential inhibition by systemic acidosis. This is because, unlike in acidoses of other origins, hepatic intracellular pH does not fall in diabetic ketoacidosis.

Diabetic ketoacidosis has usually been regarded as a typical high anion gap metabolic acidosis in which extracellular bicarbonate has simply been titrated by the ketoacids. If this were the case, the fall in plasma bicarbonate should roughly equal the rise in anion gap and the plasma concentration of ketoacids. However, Adrogué and colleagues have shown that, whilst in some cases this is true, the situation is frequently more complex. Patients who present in ketoacidosis with relatively well-preserved renal function tend to have a rise in anion gap which is much less than the fall in bicarbonate. This is due to the loss of large quantities of ketoacid anions in the urine, with concomitant tubular reabsorption of chloride to maintain electroneutrality. Hyperchloraemia develops, which, together with the urinary loss of ketoacids, results in a relatively small elevation of anion gap compared with the bicarbonate deficit. In contrast, patients who have relatively poor renal function on presentation, for example because of dehydration, have much smaller urinary losses of ketoacids and present with a more classical high anion gap metabolic acidosis.

The total blood ketone body concentration in the well-controlled diabetic is about 0.1 mmol/l. In diabetic ketoacidosis, the concentration is often above 10 mmol/l and can rise as high as 30 mmol/l. Some of the most severe acidoses seen in clinical practice occur in diabetic ketoacidosis, some with pH_a values as low as 6.8. Urinary pH reaches its minimum possible value (4.5–5.3). At the lower of these values, about half the urinary ketoacids are undissociated and some hydrogen ions are lost in

this way. Severe depletion of erythrocyte 2,3-BPG occurs, leading to left shift of the oxygen dissociation curve, especially during treatment, and with potentially adverse consequences (see below).

In 5 to 10 per cent of patients with diabetic ketoacidosis, there is an accompanying element of lactic acidosis, with blood lactate greater than 5 mmol/l. Lactic acidosis occurs particularly when the patient is shocked, but there are rare instances of lactic acidosis supervening when treatment of the initial ketoacidosis is well advanced. There are also occasional ketotic diabetics in whom the blood lactate is low. This effect is readily reproducible in experimental animals and is thought to be related to increased hepatic disposal of lactate and suppression of peripheral glycolysis by the acidosis.

The acidosis of renal failure

Metabolic acidosis of varying degree is a classical feature of acute and chronic renal failure. It has been traditionally attributed to failure of the kidneys to excrete protons derived from 'fixed acids'—the class III acids of Table 1. In chronic renal failure the remaining functional nephrons are usually able to lower the urinary pH to the normal minimum. However, failure of proximal tubular bicarbonate reabsorption may occasionally occur and leads to a bicarbonate leak, as in type 2 renal tubular acidosis (see Chapter 20.8); in this case urinary pH does not fall to its minimum until the filtered load of bicarbonate has been substantially reduced by the fall in plasma bicarbonate. In some conditions, for example chronic pyelonephritis and chronic obstructive uropathy, the renal medulla is particularly affected, and acidification of the urine may be impaired. Nevertheless, the usually normal acidification in chronic renal failure means that the phosphate buffers in the tubular lumen are titrated by protons to the same extent as is possible in normal kidneys. However, the excretion of ammonium ions is lower than normal in chronic renal failure because of the loss of glutaminase-containing proximal tubules and reduced renal blood flow decreases the supply of glutamine. The conventional explanation of the acidosis of renal failure has been that the diminished supply of ammonia from the glutaminase reaction lowers the ability of the luminal contents to buffer secreted protons, with the result that the minimum urinary pH is attained with less protons in the ammonia/ammonium buffer system, and thus disposing of fewer protons in the urine.

However, as indicated above, the ammonia/ammonium buffer system is already virtually entirely in the protonated form (i.e. ammonium) at the time of its generation in the glutaminase reaction, so there is no capacity remaining for this system to act as a urinary buffer, either in health or in renal failure. An alternative explanation is therefore required for the acidosis of renal failure. Atkinson and Camien have suggested that the nitrogen which would in health be excreted as ammonium ions in the urine is, in chronic renal failure, effectively diverted to the liver, where it is converted to urea with accompanying generation of protons (see above); the acidosis of renal failure is therefore due to relative overproduction of urea, rather than to failure of excretion of protons in the urine as ammonium ions.

The anion gap in uraemic acidosis seldom exceeds 28 to 30 mmol/l. The elevation is due to the accumulation of a relatively small quantities of several acid anions, including phosphate, sulphate, citrate, and other less well characterized contributions. When there is an element of proximal bicarbonate wastage, the anion gap may not be grossly raised; chloride may be reabsorbed instead of bicarbonate, leading to moderate hyperchloraemia.

The renal tubular acidoses, which are tubular disorders not, in the first instance, accompanied by glomerular failure, are discussed in Chapter 20.8.

Metabolic alkaloses associated with potassium and chloride deficiency

The most common cause of metabolic alkalosis is that associated with the use of potassium-losing diuretics; pyloric stenosis and Bartter's syndrome provide further examples of a complex aetiology. Chloride deficiency, indicated by low plasma chloride, may be due to a direct action of the diuretics, to loss from the gastrointestinal tract, as in pyloric stenosis, or to potassium deficiency itself, which has been shown experimentally to impair renal retention of chloride. Normally, most renal sodium reabsorption takes place in the proximal tubule, and it has to be accompanied by a readily reabsorbable anion to maintain electroneutrality. The most readily reabsorbable anion is chloride, and if the filtered load of chloride is low, due to hypochloraemia, some of the sodium which normally would have been reabsorbed proximally, passes to the distal segment of the nephron. Here sodium is reabsorbed by exchange with cations, principally potassium and protons, rather than accompanied by an anion. Since priority over acid–base regulation is accorded to the demands of extracellular volume control, the sodium reabsorption thus dictated causes further loss of potassium and protons into the urine, when the homeostatic response would have been to retain these latter ions. This accounts for the observation that the urine in these circumstances is acid when it should be alkaline ('paradoxical aciduria') and contains substantial quantities of potassium. Potassium loss in the urine is the principal cause of potassium depletion in pyloric stenosis, not loss in the vomit. The hypokalaemia is exacerbated by the fact that extracellular fluid volume is depleted in both diuretic therapy and in pyloric stenosis, leading to activation of the renin/angiotensin/aldosterone system, with further potassium loss. These considerations have important implications for therapy (see below).

An important cause of hypokalaemic hypochloraemic alkalosis, which is often marked, is deliberate overuse by patients of diuretics, notably frusemide, for reasons which may be related to psychological disturbances of the body image. Many of these patients are secretive about their use of diuretics; measurement of plasma frusemide is one way of diagnosing this dangerous condition.

Acid–base disturbances in fulminant hepatic failure

The most frequent acid–base disturbance in the earlier stages of fulminant hepatic failure is respiratory alkalosis, presumably due to the effects of ammonium and other amines on the respiratory centre. Metabolic alkalosis is also frequent, probably due to the failure of ureagenesis and its accompanying proton generation, but in some cases could be contributed to by potassium deficiency. Whatever the mechanism of the alkalosis, blood lactate concentration is frequently elevated, even in the absence of circulatory insufficiency. This phenomenon has been attributed to stimulation of peripheral glycolysis by alkalosis and to impairment of hepatic lactate disposal. Lactic acidosis may be a major feature in the later stages when the circulation is compromised, but is also occasionally seen in the very early stages. This early lactic acidosis is observed in paracetamol poisoning, a common cause of fulminant hepatic failure; it is associated with hypoglycaemia and may be largely related to a direct effect of paracetamol metabolites on hepatic gluconeogenesis from lactate; however, mild hypotension and dehydration also occurs.

Principles of treatment of acid–base disorders

The mainstay of treatment of acid–base disorders is to eliminate the cause of the disorder, the acid–base control mechanisms then restoring the normal situation in due course. However, it may be necessary to make a direct attempt to restore or partly restore normal acid–base status.

The treatment of respiratory acidosis is discussed in Chapter 17.11.

Acute metabolic acidosis

Major controversies still exist as to the advantages of treatment, especially with sodium bicarbonate. Randomized, controlled trials have not resolved these issues completely, largely because of the great variation of the physiological state of patients on presentation and the difficulty in establishing adequate sized, matching groups for trial purposes. Here we attempt to distinguish between conditions in which there is general consensus as to the best therapeutic approach and those in which there is less agreement. This is not an ideal approach, but is unavoidable at present.

The potential advantages of treating severe acidosis directly are improvement in cardiac performance, reduced risk of cardiac arrhythmia, redistribution of the blood volume away from the central circulation, correction of hyperkalaemia, and restoration of hepatic lactate disposal. Disadvantages lie in adverse effects on the oxygen dissociation curve, circulatory overload, especially if isotonic solutions have to be used, alkaline 'overshoot' when the acidosis is due to organic acids such as lactic acid and ketone bodies, and, allegedly, if bicarbonate is used, paradoxical intracellular acidification.

Paradoxical intracellular acidification is a concept arising from the observation that when sodium bicarbonate is infused, a significant rise in P_aCO_2 is observed, due to the titration of bicarbonate by hydrogen ions. Since there is an expectation that carbon dioxide will diffuse into cells much more rapidly than bicarbonate is translocated, it would be expected that intracellular pH would fall at the same time as pH_a rises; since many of the adverse effects of acidosis are directly related to effects on intracellular pH, this would be undesirable. A related observation is that in circulatory insufficiency, $P_{\bar{v}}CO_2$ in mixed venous blood may be much greater than in arterial blood, where it is often normal. On occasion, bicarbonate therapy may exaggerate this difference and it has been inferred that bicarbonate must be acidifying the intracellular compartment by the mechanisms outlined above. However, considerations of the mechanisms responsible for the mixed venous hypercapnia suggest that only if arterial P_aCO_2 is raised after passage of the blood through the lungs is bicarbonate therapy likely to cause intracellular acidification. Whether P_aCO_2 is indeed elevated by intravenous bicarbonate therapy is dependent on numerous factors, including cardiac output, ventilation, the pulmonary dead

space to total volume ratio, and, in particular, the rate of administration of bicarbonate.

Paradoxical intracellular acidification can indeed be demonstrated in closed systems such as platelets in which the carbon dioxide is not removed, and has been the reason for the development of alternative therapies such as an equimolar mixture of sodium bicarbonate and carbonate, for which the rise in P_aCO_2 during administration is substantially attenuated. However, it is difficult to demonstrate such an effect *in vivo*, when carbon dioxide is removed by the lungs, and in experimental animals either no change or actual elevation in intracellular pH in heart, liver, and skeletal muscle may be observed during bicarbonate administration, despite elevation of mixed venous PCO_2. In any case, if doubts remain concerning this issue, the problem may be avoided by the simple expedient of administering bicarbonate slowly. Hindman has made useful calculations of the rates of bicarbonate administration which avoid rises in P_aCO_2 under a range of circumstances.

The situations in which sodium bicarbonate therapy is generally agreed to be advantageous are as follows:

1. Metabolic acidosis in severe renal failure—in acute renal failure, sodium bicarbonate treatment may correct hyperkalaemia by shifting potassium into the intracellular compartment. It may also relieve distressing hyperventilation and make time for definitive renal support therapy to be introduced. If the patient is already fluid overloaded, the bicarbonate may be administered as a hypertonic solution (e.g. 8.4 per cent; 1 mmol/ml). If the patient is dehydrated then the isotonic solution (1.4 per cent; 0.163 mmol/ml) may be given. During haemofiltration for acute renal failure in the presence of lactic acidosis, there is little doubt that the use of bicarbonate rather than lactate-containing replacement fluid is preferable, because of failure of metabolism of lactate to bicarbonate in this situation (see below). In chronically uraemic patients, the use of oral bicarbonate to treat the acidosis may improve well-being, nitrogen balance, and the osteomalacic component of renal osteodystrophy.
2. In the acidosis of severe diarrhoea it has been shown, in the specific instance of cholera, where circulatory insufficiency and loss of alkali are prominent factors, that treatment with bicarbonate is superior to that with sodium chloride solutions. These patients have severe peripheral venoconstriction, displacing their blood volume towards the lungs. The administration of saline solutions may thus induce pulmonary oedema before the volume deficit has been replaced. Sodium bicarbonate appears to relieve the peripheral venoconstriction and full replacement is therefore less hazardous.
3. In renal tubular acidosis, both chronically and in exacerbations—this subject is discussed elsewhere (Chapter 20.8) but it is necessary to re-emphasize here that in types 1 and 2 renal tubular acidosis, where hypokalaemia is a prominent feature, it is mandatory to deal with the hypokalaemia either before or at least simultaneously with the acidosis. Treatment of the acidosis first will result in a further fall in plasma potassium, by driving potassium into the cells, with potentially fatal consequences.

It is in the treatment of lactic acidosis, particularly type A, and in diabetic ketoacidosis that the uncertainty of the value of bicarbonate therapy principally lies. In animal models of lactic acidosis, treatment with bicarbonate has been shown to produce less favourable or no better haemodynamic and metabolic results than with sodium chloride. Interestingly, in an acute model of haemorraghic shock there was little difference between bicarbonate and saline therapies; in these experiments, there had been no time for erythrocyte 2,3-BPG to fall. In contrast, in a model of diabetic ketoacidosis, developing over 48 h, in which 2,3-BPG was now virtually undetectable, treatment with bicarbonate produced a fall in blood pressure and evidence of tissue hypoxia, despite intracellular alkalinization. This suggests that acute acidoses of more than a few hour's duration may become increasingly susceptible to the adverse effects of bicarbonate. In a prospective, randomized trial of bicarbonate compared with saline in critically ill patients with lactic acidosis due to shock, there was no advantage of one therapy over the other, but this trial was not exempt from the general difficulties in mounting such trials.

The following practical guidance is therefore empirical, and largely based on current practice rather than formal trials:

1. Lactic acidosis—of paramount importance in type A lactic acidosis is the correction of hypovolaemic, cardiogenic, and other factors which are the primary cause of the condition. Such correction will promote aerobic metabolism and promote intracellular metabolism of lactate with consequent regeneration of bicarbonate (Fig. 1). Whether administration of exogenous bicarbonate can hasten this process or confer other benefit is uncertain. In short-duration lactic acidosis, there may be less concern about effects on oxygen dissociation related to 2,3-BPG levels, but it should be remembered that unless therapy directed at the primary cause has improved the circulation, alkalinization itself may produce an unfavourable effect on oxygen release from haemoglobin. Nevertheless, the possibility of bicarbonate helping in some circumstances cannot be ruled out. If it is given, this should be relatively slowly, as the isotonic solution, unless there is a circulatory overload problem, and only in amounts sufficient to raise pH_a to a relatively 'safe' level. In the special case of the acidosis of cardiac arrest, the previous priority given to bicarbonate administration has disappeared, because of lack of evidence of efficacy and the risk of alkaline overshoot when the high levels of lactate are metabolized on restoration of cardiac output. Hypertonic sodium bicarbonate is only now recommended as a secondary treatment after prolonged arrest. In type B lactic acidosis due to biguanides, it has been conventional to use bicarbonate therapy at least to bring pH_a to 7.2 to 7.4 over several hours and survival has been linked to the achievement of that goal. However, an alternative interpretation of the data is that those patients in whom acid–base status was restored to normal would have achieved this without the aid of bicarbonate, or with the use of saline instead. Other therapies for type B lactic acidoses of different causes are discussed below.
2. Diabetic ketoacidosis—it is generally accepted that provided pH_a is not below 7.0, bicarbonate treatment is not indicated. Rehydration and insulin therapy result in improved renal function, a fall in ketone body production and an increase in ketone body metabolism, all of which contribute to correction of the acidosis. When pH_a is below 7.0 many give just sufficient bicarbonate (isotonic) to bring pH_a just above 7.0, with careful attention to changes in plasma potassium. There is, however, no evidence that this regimen is better than rehydration (with saline), insulin and potassium replacement alone, and there are data showing that such therapy delays fall in ketone body levels and lactate (if raised). The delayed fall in lactate is consistent with tissue hypoxia related to low erythrocyte 2,3-BPG as discussed above. It is therefore common practice not to give bicarbonate even at low pH_a levels. If bicarbonate is given, then it must be isotonic (1.4 per cent,163 mmol/l); to give hypertonic bicarbonate would merely exacerbate the already present hyperosmolality. The amount required seldom exceeds 0.5 to 1 litre.

The amount of alkali therapy, if given, should be determined by an iterative process of administration of a relatively small amount (e.g. 80 mmol), followed by reassessment of the clinical state, pH_a and P_aCO_2, with the aid of serial plots on the acid–base diagram in Fig. 2 before repeating the cycle.

Alkalinizing agents other than bicarbonate have been considered. Sodium lactate has the disadvantage that it has to be metabolized to neutral products plus bicarbonate before it has an alkalinizing effect (Fig. 1) and if lactate metabolism is impaired, as in shock and hypoxia in particular, it has no effect. Lactate is not a buffer in its own right at pH values encountered in health or disease. The mixture of bicarbonate and carbonate referred to above ('Carbicarb') has not been shown to have clinical advantages and is less effective than saline in animal models of diabetic ketoacidosis. THAM (trishydroxyaminomethane buffer) has the theoretical advantage of producing intracellular as well as extracellular alkalinization, but is seldom used because of unwanted effects. Sodium dichloroacetate increases lactate disposal via oxidation by activation of pyruvate dehyrogenase, and markedly lowers blood lactate in critically ill patients with lactic acidosis. However, in a multicentre trial it did not improve survival over that in a saline control group, possibly because of the severity of the associated pathologies and the diverse clinical state of the patients. However, it is of proven value in the treatment of some congenital lactic acidoses. Thiamine produces dramatic resolution of the severe lactic acidosis sometimes seen in beri-beri. Riboflavine has produced similar results in nucleoside reverse transcriptase inhibitor-associated lactic acidosis.

Treatment of metabolic alkalosis

The first imperative is to identify the primary cause and if possible eliminate it. Where potassium-losing diuretics are responsible, they can be replaced by potassium-sparing preparations. In the most common form of chronic metabolic alkalosis, namely that associated with potassium and chloride deficiency, the primary therapies are potassium and chloride replacement. It has been shown that the potassium deficiency and alkalosis cannot be fully corrected unless there is also replenishment of chloride. Potassium supplements, whether oral or intravenous, should therefore be in the form of potassium chloride or contain other sources of chloride. It is also necessary to deal with any element of extracellular fluid volume contraction to switch off the drive to the renin–aldosterone system. It is seldom necessary to resort to administration of acid.

11.12.1 The acute phase response and c-reactive protein

M. B. Pepys

The acute phase response

Trauma, tissue necrosis, infection, inflammation, and malignant neoplasia induce a complex series of non-specific, systemic, physiological and metabolic responses including fever, leucocytosis, catabolism of muscle proteins, and the greatly increased *de novo* synthesis and secretion of a number of plasma proteins. The synthesis of albumin, transthyretin, and high and low density lipoproteins is correspondingly decreased, and the altered plasma protein concentration profile is called the acute phase response (Table 1). Most acute phase proteins are synthesized by hepatocytes, in which transcription is controlled by cytokines including, interleukin 1 (IL-1), interleukin 6 (IL-6), and tumour necrosis factor (TNFa). The circulating concentrations of complement proteins and clotting factors increase by up to 50 to 100 per cent whereas some of the proteinase inhibitors and a_1-acid glycoprotein can increase three to five fold. C-reactive protein (CRP) and serum amyloid A protein (SAA) are unique in that their concentrations can change by more than one-thousand fold. The response persists in individuals with chronic infections, chronic inflammation, or invasive or metastatic neoplasms, and is sustained, unless there is complete hepatocellular failure, until death. All endothermic animals mount a similar response, suggesting that it may have survival value, and increased availability of proteinase inhibitors, complement, clotting, and transport proteins presumably enhances host resistance, minimizes tissue injury, and promotes regeneration and repair. However, some acute phase proteins may be harmful. For example sustained, increased production of SAA can lead to the deposition of AA-type, reactive systemic amyloid, a serious and usually fatal condition that complicates chronic infective and inflammatory diseases. CRP, through its capacity to activate complement, can exacerbate ischaemic, and possibly also other forms, of tissue damage.

C-reactive protein

CRP was the first protein to be discovered which behaves as an acute phase reactant, and was named for its calcium-dependent interaction with the somatic C-polysaccharide of pneumococci, in which CRP recognizes phosphocholine residues. CRP also binds to other substances which contain phosphocholine, including phospholipids, some plasma lipoproteins, and the plasma membranes of damaged or apoptotic but not intact cells. In addition, CRP binds specifically to small nuclear ribonucleoprotein particles when these are exposed in dead or damaged cells.

Ligand-bound CRP activates the classical complement pathway via Cl, and can trigger the inflammatory, opsonizing, and complex-solubilizing activities of the complement system. A significant biological function of CRP may thus be to recognize and 'scavenge' cellular debris, promoting its safe clearance and helping to maintain tolerance to potential autoantigens. CRP may also protect against infection with pneumococci and *Haemophilus influenzae*, organisms that can express phosphocholine, and may thus contribute to innate immunity. On the other hand, CRP can also have tissue-damaging effects. Complement activation by CRP exacerbates ischaemic injury, the proinflammatory actions of CRP and its binding to phospholipids and lipoproteins may be proatherogenic, and the capacity of CRP to stimulate tissue factor production by macrophages may be prothrombotic. In contrast, CRP can suppress polymorph migration and infiltration *in vivo* and this may be anti-inflammatory.

The CRP molecule consists of five identical, non-glycosylated, non-covalently-associated polypeptide subunits, each of mass 23 027 Da, and containing 206 amino acid residues. The subunits have a flattened b-jellyroll fold with a single intrachain disulphide bond, and are arranged in an annular configuration with cyclic pentameric symmetry. There is a single calcium-dependent ligand binding site on the medial aspect of each subunit, all located on the same planar face of the molecule. A distinct but closely related plasma protein, serum amyloid P component (SAP), which is not an acute phase protein in man, has a very similar molecular structure with the same fold, characteristic of the 'lectin fold' superfamily. CRP and SAP belong to the pentraxin family that has been highly conserved in evolution and no structural polymorphism of CRP has been observed nor has any case of CRP deficiency been described.

Serum concentration of CRP

CRP is a trace protein in overtly normal, healthy individuals, the median value being 0.8 mg/l, with an interquartile range of 0.3 to 1.7 mg/l. Ninety per cent of apparently healthy subjects have levels of less than 3 mg/l and 99 per cent less than 10 mg/l. Serial studies of normal subjects and of monozygotic and dizygotic twins show that each individual's baseline CRP value is rather constant and is substantially genetically determined. Occasional higher values of CRP seen in ostensibly healthy people almost certainly reflect intercurrent subclinical pathology, and it is clear both that values greater than 3 mg/l are not normal and that, if they persist, they may have considerable clinical significance. In large surveys of the unscreened general population, there is a trend towards higher values with increasing age, with the median value rising to about 2 mg/l, and this probably reflects the higher incidence of pathological processes, such as atherosclerosis, osteoarthritis, and other diseases. Serum CRP concentrations are lower in healthy newborns but reach adult values within a few days.

Serum CRP concentration rises rapidly in the acute phase response and can exceed 300 mg/l by 48 h after a severe stimulus such as myocardial infarction, acute systemic bacterial infection, major trauma, or surgery. With uncomplicated resolution of injury or effective treatment of infection the circulating CRP concentration generally falls equally rapidly.

The speed of change and incremental range of CRP concentration are exceptional among all the acute phase proteins, apart from serum amyloid A protein which behaves in a similar fashion. The half-life of CRP in the circulation is 19 h and is constant in all conditions regardless of the presence of an acute phase response or its cause. In contrast to other acute phase proteins, such as clotting factors, complement proteins, transport proteins, and proteinase inhibitors, CRP does not undergo significant local sequestration or consumption, fragmentation, or complex formation. This means that, unlike most of the other acute phase reactants, the single major determinant of the circulating concentration of CRP is its rate of synthesis. Since this in turn is dependent on the intensity of the acute phase stimulus, the serum CRP level usually closely reflects the extent and activity of disease. These properties underlie the value in clinical practice of precise measurement of the serum CRP concentration. Drug or other treatments do not affect CRP production unless they also affect the disease process which is responsible for induction of CRP synthesis. The only exception is combined cyclosporin and steroid treatment given after renal transplantation. This suppresses the CRP response to renal allograft rejection, though not that provoked by infection. The only physical condition which seriously interferes with the capacity to interpret CRP levels is serious hepatocellular impairment, since CRP is made exclusively in the liver.

Clinical measurement of serum CRP concentration

Conditions associated with major elevation of serum CRP concentration

Most tissue-damaging processes, infections, inflammatory diseases of unknown aetiology, and malignant neoplasms are associated with a major acute phase response of CRP. CRP production is thus a non-specific response to disease and it can never, on its own, be used as a diagnostic test. However, if the CRP result is interpreted in the light of full clinical information about the patient it can provide exceptionally useful information for clinical management. Thus in nearly all the conditions listed in Table 2 the CRP level reflects quite precisely the extent and activity of disease. With deterioration the CRP value rises, whilst with spontaneous or

therapeutically induced remission the CRP level falls, and it thereby supplies an objective index of progress which is rarely available in any other way.

Infection

Most forms of systemic microbial infection are associated with high levels of serum CRP and, although the peak values attained in different patients cover a wide range, serial assays in individual subjects usually show an excellent correlation between the serum CRP concentration and the severity of disease and its response to treatment. Acute, systemic, Gram-positive and Gram-negative bacterial infections are among the most potent stimuli for CRP production. Systemic fungal infections occurring in immunodeficient hosts are also associated with high CRP values, whereas the levels in chronic bacterial infections such as tuberculosis and leprosy are usually rather lower, though nevertheless still markedly raised. Uncomplicated viral infections, particularly meningitis, may induce only a very modest response or none at all. Clinical rhinovirus infection (common cold) or influenza are associated with minor CRP elevation in a proportion of individuals, though this may reflect secondary bacterial infection. However, systemic cytomegalovirus or *Herpes simplex* infection of immunosuppressed patients does cause a major CRP response. Little is known about the CRP response to metazoan parasitic infestation in otherwise healthy subjects but malaria, especially *P. falciparum* infection, is associated with high CRP values as are *Pneumocystis* and *Toxoplasma* infections in immunodeficient patients.

Minor or localized, low-grade infection may not stimulate CRP production appreciably but the major CRP response in acute, serious bacterial infection is almost invariable and is present at all ages from premature neonates to the elderly. It also occurs in patients who are immunosuppressed or immunocomprised whether by a primary disease such as leukaemia, lymphoma or other malignancy, or AIDS, or by treatment with cytotoxic drugs, corticosteroids, or irradiation. This is of particular importance in the very young, in the old, in compromised hosts, and in any other patient in whom the usual clinical signs and symptoms of infection, including fever and neutrophil leucocytosis, may be masked or lacking (Fig. 1 and Fig. 2). Furthermore, at the onset of bacterial infection, especially in patients who are otherwise well following elective surgery or myocardial infarction, the CRP response frequently precedes clinical symptoms, including fever, by up to 24 to 48 h.

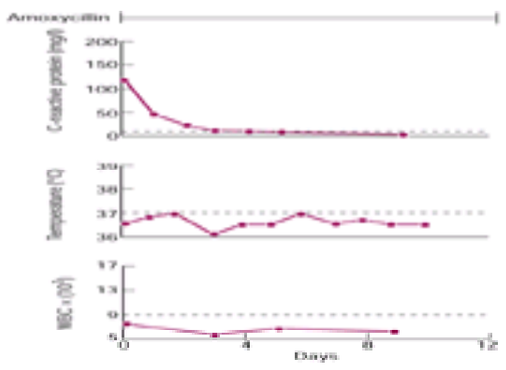

Fig. 1 A 69-year-old diabetic man was admitted with a 3-day history of confusion, cough, and incontinence of urine. There was clinical and radiological evidence of a left-sided pneumonia and although both the temperature and white cell count remained normal, the serum C-reactive protein was high (119 mg/l), confirming the suspicion of infection. Following treatment with amoxicillin, 250 mg thrice daily, the C-reactive protein level fell rapidly, in a characteristic exponential manner, and he made a speedy recovery with return of continence and improved mental state.

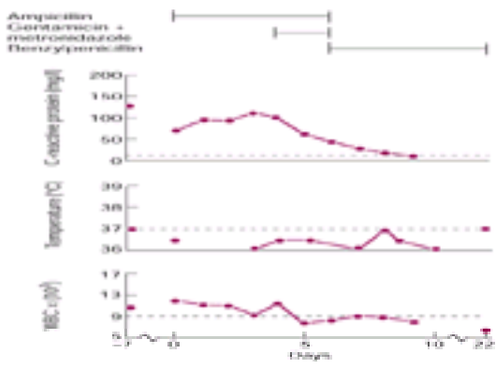

Fig. 2 An 86-year-old woman had been refusing food and drink for 6 weeks. She was dehydrated but rehydration in hospital failed to improve her mental state. She was paranoid and refused nursing and medical care. Paraphrenia was diagnosed and deterioration continued. A C-reactive protein of 130 mg/l and a white cell count of 13.5 × 10^9/l were then found. Chest radiograph, normal on admission, now showed a cavitating lesion from which 150 ml of pus was aspirated. Intravenous ampicillin reduced neither the C-reactive protein nor white cell count prompting a change of therapy to gentamicin and metronidazole. *Strep. equinus* was finally identified in the pus and treatment was changed to benzylpenicillin alone. The C-reactive protein then fell exponentially but rather slowly. The patient's clinical and mental state gradually improved and she was eventually discharged.

Once infection is diagnosed or suspected and antimicrobial treatment has been commenced, frequent monitoring of the serum CRP concentration provides an objective means of assessing the response which is often not available. Effective therapy is associated with a rapid, exponential fall in CRP level, with a half-time of about 24 h, and occurrence of this pattern is an encouraging prognostic sign (Fig. 2). Normalization of the CRP usually corresponds to clinical cure of the infection and may thus be used to determine the necessary duration of antimicrobial therapy. On the other hand, especially in neutropenic or immunodeficient patients, persistent elevation of CRP at the end of a course of antibiotics often presages relapse or recurrence of infection.

When bacterial infection is complicated by abscess formation or for any other reason is less readily eradicated by antimicrobial drugs, the serum CRP concentration may remain elevated or may fall linearly rather than exponentially during treatment. Such a pattern should raise questions regarding dosage of the drugs, sensitivity of the organism, and/or stimulate a diagnostic search both for localized pus and for other underlying, non-infective pathology such as malignancy. Indeed, in the absence of one of the chronic idiopathic inflammatory conditions which are known to be associated with high CRP levels (see below), the persistence of a raised serum CRP concentration is usually a grave prognostic sign, indicating the presence of either uncontrolled infection and/or other serious pathology likely to cause death. However, with alteration in antimicrobial drug regimen or the evacuation of pus or elimination of other pathology, the rapid fall in CRP which may then be observed is a most encouraging objective sign of clinical improvement.

These considerations apply at all ages and regardless of intercurrent pathology, with the exception of severe hepatocellular impairment. In view of the very small amount of serum required for the assay and the speed and precision of automated CRP immunoassays it is apparent that routine monitoring of serum CRP makes a valuable contribution to the recognition and management of infectious diseases. Situations in which these applications have been well documented are listed in Table 3.

Meningitis is of particular interest in view of its potential severity and the importance of rapid diagnosis and appropriate treatment. Bacterial meningitis is associated with much higher serum CRP levels at presentation than cases of aseptic or proven viral meningitis. The latter frequently have CRP concentrations within the normal range or which are only very slightly raised, unless they develop secondary bacterial infective complications, whilst patients with tuberculous have intermediate values. Appropriate therapy for either bacterial or tuberculous meningitis causes the CRP level to fall and this can be used to monitor objectively the response to treatment.

Baseline CRP values are much lower at birth and for the first few days than in older children or adults. Also, neonatal infections progress much more rapidly and can have a fatal outcome before the CRP response has produced concentrations detectable in routine assays. It is therefore essential to use high sensitivity methods capable of detecting and precisely measuring CRP in the range 0.05 to 5.0 mg/l, otherwise the critical initial acute phase response to infection will be missed.

Inflammatory disease

Most of the chronic inflammatory diseases of unknown aetiology (Table 2), with some notable exceptions described below, are associated with high CRP values when they are active. Serial measurements of CRP in individuals with any of these diseases generally reflect the extent and activity of their condition as determined by clinical examination and other laboratory tests. Rheumatoid arthritis is the most common and important disease in this group and the correlation between CRP values in individual patients and the extent and activity of arthritis is very well established. Importantly, there are appreciable differences between the CRP levels attained in different subjects with apparently similar severity of arthritis, but in each case the CRP value always reflects current disease activity. Furthermore, CRP values precisely predict future progression of bone erosion and joint damage. Left unchecked, high CRP levels are inevitably followed by progressive erosive disease, whilst treatments that lower CRP retard or arrest this process.

In some of the inflammatory disorders, for example systemic vasculitis or Crohn's disease (Fig. 3), unlike rheumatoid arthritis, the pathology is relatively inaccessible to direct examination and serum CRP measurement provides the best available, objective index of disease activity. Furthermore, the presence or absence of a CRP response can distinguish between symptoms or organ dysfunction which are due to currently active inflammation or which are the consequence of fibrosis and scarring from previous episodes. This can be very important when treatments include steroids and other powerful and potentially hazardous immunosuppressive, anti-inflammatory, and cytotoxic drugs. It permits precise titration of dosages and may help to avoid excessive or unnecessary use.

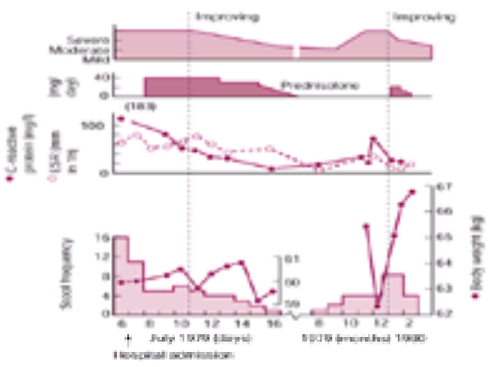

Fig. 3 A 26-year-old man with pancolonic Crohn's disease. He was admitted with severe exacerbation; temperature 38°C; pulse, 110 beats/min; 16 stools per day; haematocrit, 41.5 per cent, leucocytes 13.8 × 10^9/l. Rectal mucosa severely inflamed with histiocytic granulomata on biopsy. Rapid improvement occurred with oral and rectal prednisolone, ampicillin, and metronidazole, with complete clinical and histological remission on day 11. Relapse 5 months later responded promptly to a short course of oral and rectal prednisolone. C-reactive protein and ESR were both high during the initial exacerbation. The rapid response to treatment was paralleled by a prompt fall in C-reactive protein, whereas the ESR responded more slowly. Despite clinical remission and a normal ESR, the C-reactive protein remained slightly elevated, suggesting persistent low-grade inflammatory activity, and it rose further during a subsequent relapse when the ESR did not change. (Reproduced from Fagan A *et al*. (1982). Serum levels of C-reactive protein in Crohn's disease and ulcerative colitis. *European Journal of Clinical Investigation* **12**, 351–9, with permission.)

Induction of clinical remission and control of the underlying disease process is associated with prompt normalization of the CRP. However, CRP also becomes abnormal with intercurrent infection, a common complication of some of these disorders and their treatments, and this serves to focus diagnostic attention often before the infection has become too severe or even before it is clinically evident. Monitoring the CRP response to antimicrobial therapy can then help to confirm the diagnosis and the efficacy of therapy. Persistent elevation of the CRP after eradication of infection may indicate relapse of the underlying inflammatory disease, requiring additional anti-inflammatory treatment.

Necrosis

Myocardial infarction is invariably associated with a major CRP response, as is elective embolization leading to necrosis of tumours in the liver and elsewhere. The peak level of CRP occurs about 50 h after the onset of pain in myocardial infarction and correlates in magnitude, though not in timing, with the peak serum level of cardiac isoenzymes such as creatine kinase MB. In patients who recover uneventfully, the CRP falls rapidly towards normal in the usual exponential fashion. However, complications such as persistent cardiac dysfunction, further infarction, aneurysm formation, intercurrent infection, thromboembolism, or postinfarction syndrome are associated with either persistently raised CRP levels or secondary elevation after the initial decrease. Myocardial rupture is seen only in patients with high peak CRP values, greater than 200 mg/l, and the peak CRP concentration after acute myocardial infarction is inversely correlated with overall outcome, including survival, in the short, medium, and long term.

Stable angina and invasive investigation, such as coronary arteriography, do not stimulate CRP production, whereas some other causes of chest pain, such as pulmonary embolism, pleurisy, or pericarditis, are usually associated with raised CRP levels. Routine assays of CRP after infarction or in patients with chest pain may thus assist in diagnosis and in the recognition and management of complications, including iatrogenic infection associated with invasive cardiovascular monitoring. The role of high-sensitivity measurements of CRP in prediction of coronary heart disease is discussed below.

Serum CRP levels closely reflect the severity and progress of acute pancreatitis, providing a better guide to intra-abdominal events than other markers such as leucocyte counts, erythrocyte sedimentation rate (ESR), temperature, and the plasma concentrations of antiproteinase. A CRP concentration greater than 100 mg/1 at the end of the first week of illness is associated with a more prolonged subsequent course and a higher risk of the development of a pancreatic collection. Serial CRP measurements can therefore guide the use of appropriate imaging techniques and help to confirm resolution before discharge from hospital.

Trauma

The CRP concentration always rises after significant trauma, surgery, or burns, peaking after about 2 days and then falling towards normal with recovery and healing. Infections or other tissue-damaging complications alter this 'normal' pattern of CRP response and the failure of the CRP to continue falling or the appearance of a second peak may precede clinical evidence of intercurrent infection by 1 to 2 days.

Malignancy

Most malignant tumours, especially when they are extensive and metastatic, induce an acute phase response. This is particularly so with those neoplasms which cause systemic symptoms such as fever and weight loss, for example Hodgkin's disease (stage B), and renal carcinoma, but raised CRP levels are seen with many others. In some studies, notably of prostatic carcinoma and bladder carcinoma, the CRP level at presentation has been found to correlate with the overall tumour load and also with the prognosis, being higher for a given mass of tumour in those patients who subsequently fare worse. The CRP may also correlate better with progress and regression of tumour than other, more specific, tumour markers. However, given the non-specific nature of the acute phase response and the limited number of studies performed so far, a definite role for CRP measurements in the management of cancer patients, other than in cases of intercurrent infection, has not yet been established.

Allograft rejection

In the era before routine immunosuppression with combined cyclosporin and steroid treatment, rejection episodes following renal allografting were generally associated with increased production of CRP. However, such treatment almost completely suppresses the CRP response in this situation. In contrast, the acute phase response of SAA is unaffected, and importantly, intercurrent infection still stimulates high levels of both CRP and SAA.

Conditions associated with minor elevation of serum CRP concentrations

Despite unequivocal evidence of active inflammation and/or tissue damage, the conditions listed in Table 4 are usually associated with only minor elevations of the serum CRP concentration, and in many cases it may even remain normal in the face of severe disease. The contrasts between systemic lupus erythematosus (SLE) and rheumatoid and other arthritides shown in Table 2, and between ulcerative colitis and Crohn's disease, are very striking. However, intercurrent microbial infection does provoke a major CRP response in all the conditions shown in Table 4, and this is of great value in diagnosis and management, especially in SLE and leukaemia. The basis of the apparently selective failure of the acute phase response of CRP (which is also shown by SAA) is not known, but presumably involves defect(s) in the pathways which mediate the acute phase response to autologous inflammation and tissue damage. The inbred mouse strain NZB/W, which spontaneously develops antinuclear autoimmune disease, behaves just like human SLE patients with respect to its acute phase responses and the phenomenon may thus be genetically determined. SAP knockout mice also spontaneously develop antinuclear autoimmune disease and do not handle chromatin degradation normally, indicating that pentraxins have a key role in these processes.

Pyrexia is common in SLE and may be caused by microbial infection or by activity of the lupus itself. Both SLE and its treatment predispose to infection, and steroids and immunosuppressives can mask the usual symptoms and signs of infection. Furthermore, infection can trigger exacerbations of SLE. This is a serious clinical situation and infection remains one of the most common causes of death in patients with SLE. CRP values of 60 mg/1 or more are very rare in SLE in the absence of infection whilst levels below 60 mg/1 are seen in patients with documented infection only when it is rather mild and often localized, for example to the skin or lower urinary tract. Differential diagnosis and management of fever in SLE are thus considerably improved by the measurement of serum CRP concentration (Fig. 4).

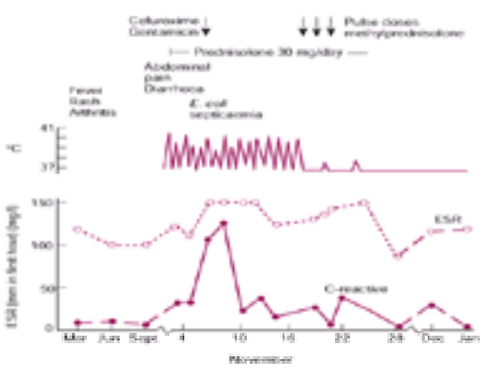

Fig. 4 A 12-year-old girl with a 3-year history of SLE; recurrent febrile episodes, polyarthritis, cutaneous vasculitis, and episodes of asymptomatic bacteriuria. Intermittent treatment was with prednisolone, azathioprine, and plasma exchange. Serum C-reactive protein was only marginally elevated throughout but ESR was persistently raised. Fever recurred with diarrhoea and abdominal pain. All microbial cultures were negative except for growth of *E. coli* from the urine. Despite oral cephalexin and prednisolone, her condition deteriorated with severe neutropenia, probably due to azathioprine. C-reactive protein rose from 36 to 101 and then 137 mg/l, and at this stage her blood culture grew *E. coli*. Intravenous antibiotics were given and the serum C-reactive protein level fell rapidly, but there was little clinical improvement. Active SLE appeared then to be the sole cause of the fever and this was confirmed by the development of a diffuse vasculitic rash and polyarthritis. Three pulse doses of methylprednisolone were given intravenously on successive days and produced a dramatic improvement in her clinical state with resolution of the fever. This case illustrates: (1) the differential response of the C-reactive protein to fever resulting from activity of SLE alone and fever due to bacterial infection; (2) the rapid response of the C-reactive protein both to the onset and to the effective treatment of serious bacterial infection; (3) the failure of ESR measurements to provide any useful information in this complex and rapidly evolving clinical situation. (Reproduced from Pepys MB, Langham JG, de Beer FC (1982). C-reactive protein in SLE. *Clinics in Rheumatic Diseases* **8**, 91–103, with permission.)

The reason why leukaemia patients fail to mount more than a modest CRP response, even during induction therapy when there is massive death of leukaemia cells, is not known, However, they do respond to infection. Since all febrile episodes in leukaemia must initially be treated as infective, the main value of CRP monitoring is to determine the response to therapy and assist in decisions about its duration. Acute or chronic graft-versus-host disease after bone marrow transplantion is usually associated with only a modest CRP response, if any. However, the immunosuppressive treatments used to prevent bone marrow rejection and to control graft-versus-host disease render the patients susceptible to intercurrent infections, often with unusual micro-organisms, and these are always associated with high levels of CRP. CRP monitoring therefore plays a valuable role in management in the post-transplant period.

Interpretation of clinical serum CRP measurements

Clinical measurements of serum CRP fall into two categories. First, routine measurements over the range 3 mg/l upwards in adult and general paediatric medicine. Secondly, high sensitivity measurements including the range up to 3 mg/l that are essential in neonatal medicine and for screening and prognostic investigation in adults with respect to atherothrombotic disease and osteoarthritis. The CRP response is not specific and CRP measurements on their own can never, therefore, be diagnostic of any particular condition. The CRP value can only be interpreted in the light of all other available clinical and laboratory information. Provided this is done it can make a most useful contribution to overall assessment of the patient and determination of the best management.

Routine CRP measurement

The applications fall into three main categories:

- Screening for organic disease
- Monitoring of extent and activity of disease:
  - infection
  - inflammation
  - malignancy
  - necrosis
- Detection and management of intercurrent infection.

Screening for organic disease

CRP production is a very sensitive response to organic disease. A normal CRP therefore eliminates many possible types of pathology and is a reassuring finding. Those serious conditions which only stimulate CRP production weakly if at all, for example SLE, ulcerative colitis, or leukaemia, are all readily recognized by clinical examination and other simple tests such as blood counts, rectal biopsy, or serology. The presence of a raised CRP is unequivocal evidence of active pathology though this may not necessarily be the cause of the complaint for which the patient presented. Such a finding, in the absence of other obvious abnormality, warrants a repeat CRP assay after a few days when a trivial cause such as upper respiratory tract infection will have resolved. Further investigation of a persistently raised CRP level will then depend on the severity of the complaint and other clinical findings.

Monitoring extent and activity of disease

Once the diagnosis is established, in those diseases which cause major elevation of the CRP, serial measurements reflect activity and response to treatment and can be used for monitoring. However, they can only be interpreted provided other possible intercurrent causes of an acute phase response, particularly infections, are excluded.

Detection and management of intercurrent infection

CRP production is a very sensitive response to most forms of infection and a raised level is thus a useful guide to the possible presence of infection in otherwise normal subjects or individuals with a primary condition which predisposes to infection. In disorders which themselves elevate the CRP concentration the decision as to whether infection is present or not must depend on clinical examination and other laboratory tests and the role of CRP testing is then to demonstrate rapidly and

objectively whether there is a response to whatever treatment is used. Effective antimicrobial therapy of infection is always associated with a prompt fall in the CRP whilst persistent CRP elevation indicates continuing infection and/or activity of the underlying disease. There is no other objective test which yields this sort of information so accurately. Changes in results of clinical examination and tests of organ function usually lag hours or days behind the CRP response.

CRP and body temperature

The acute phase response, which is best measured clinically by quantification of the serum CRP, is part of the systemic response of the body to disease. Monitoring of this same response by measurement of body temperature is an integral part of the physical examination and of patient management. CRP production is triggered by the same cytokines which cause fever, and the serum CRP concentration therefore may be considered in part to be a biochemical measurement of the body temperature. However, the CRP response is not susceptible to the many vagaries of thermoregulation itself and routine clinical measurement of body temperature. The precise numerical value of the CRP concentration and its changes over time reflect much more accurately than the temperature the intensity of the underlying stimulus. Furthermore there is often a CRP response in the absence of fever, especially in neonates and the elderly, though also at any age in many chronic inflammatory conditions, and a case therefore exists for the inclusion of a regular serum CRP chart together with the standard temperature chart in appropriate patients.

CRP or ESR?

The only other comparable, non-specific index of the presence of disease which is routinely measured is the erythrocyte sedimentation rate (ESR). The ESR reflects, in part, the intensity of the acute phase response, especially that of fibrinogen and the a-globulins, but is also largely determined by the concentration of immunoglobulins, which are not acute phase reactants. These proteins all have half-lives of days to weeks. The rate of change of the ESR is thus very much slower than that of the CRP level and it rarely reflects precisely the clinical status of the patient at the actual time of testing. ESR is also dependent on the number and morphology of the red cells, which bear no relation to the acute phase response. Finally, there is a significant diurnal variation in ESR, depending on food intake, which is not seen in the CRP. The ESR is therefore of limited use as an objective index of disease activity on which management decisions can be based. The dynamic range of the ESR is also much less than that of CRP and the precision and reproducibility of ESR measurements is poor compared to robust immunoassays for CRP. Thus, in all clinical situations which have been carefully evaluated, ranging from acute bacterial infections to the chronic remittent inflammatory diseases, such as Crohn's disease, rheumatoid arthritis and other inflammatory arthropathies, and systemic vasculitis in its various forms, frequent prospective measurements of CRP reflect disease activity very much more closely than measurements of the ESR. Finally, ESR does not provide the information given by the high sensitivity measurement of CRP, described below. However, the ESR remains a useful screening test for the detection of paraproteinaemias, especially multiple myeloma, which do not necessarily provoke an acute phase response.

High sensitivity CRP measurements

The limitations of conventional immunoassay technology for quantifying serum proteins imposed, until recently, a lower detection limit of about 5 mg/l in most routinely available methods. The advent of more sensitive assays has revealed important new indications for CRP measurement.

Neonatal medicine

Although newborns mount just as rapid and vigorous CRP responses as adults, their baseline values are lower; the median and range in normal cord blood are only 0.04 mg/l and 0.01 to 0.49 mg/l. Since infants can succumb to infection so rapidly, high sensitivity measurements are mandatory.

Atherosclerosis and coronary heart disease

In patients with severe, unstable angina admitted urgently to hospital, CRP values above 3 mg/l are significantly predictive of poor outcome, including death, acute myocardial infarction, or the need for urgent revascularization intervention. In patients undergoing coronary angioplasty, only those with raised CRP values mount an acute phase response to the procedure and the magnitude of this response predicts early reocclusion. Among outpatients with angina and also, remarkably, among healthy normal adult populations, those in the top quintile of the CRP distribution, that is with values above about 2.5 mg/l, have a two to five-fold increased risk of suffering a coronary event in future. Increased CRP production also predicts progression and atherothrombotic events in cerebrovascular and peripheral vascular disease, although the numbers of cases studied have been smaller.

The mechanisms underlying the relationship between even modestly increased CRP production and atherothrombotic events are not known. The CRP response may reflect the inflammation that is a major feature of atherosclerotic plaques, or it may be stimulated by low grade inflammation or infection elsewhere in the body, processes that are known to be associated with atherogenesis. Although CRP levels are associated with smoking, body mass index, hyperlipidaemia, and insulin resistance, all of which are risk factors for atherosclerosis and coronary heart disease, CRP values remain significantly prognostic of coronary events even after adjustment for these variables. It is therefore possible that, in addition to being a marker of inflammation, CRP itself may contribute to pathogenesis, perhaps through its interactions with lipids, lipoproteins, complement, and coagulation. Indeed CRP is detectable within atherosclerotic plaques. There is clearly much work to be done in this exciting new field but, regardless of the underlying mechanisms, the empirical results, from many large-scale independent studies in Europe and the United States, robustly show that high-sensitivity CRP measurements provide important prognostic information.

Osteoarthritis

Modest acute phase responses of CRP, within what was previously considered the normal range, are significantly associated with the presence and extent of osteoarthritis in middle-aged populations. Among affected subjects, the CRP values also predict future progression of the disease.

Serum amyloid A protein

SAA, an apolipoprotein of high-density lipoprotein particles, is a marked acute phase reactant, its concentration rising from normal levels of about 2 mg/l by as much as 1000 times. It is essential to monitor and control SAA levels in patients with reactive systemic, AA type amyloidosis (see Chapter 11.12.4). The other indication for routine SAA measurement is in renal allograft recipients, in whom the SAA response is the most sensitive marker of rejection episodes, despite suppression of the CRP response by immunosuppression with cyclosporin and steroids.

11.12.2 Metabolic responses to accidental and surgical injury

Roderick A. Little

Introduction

Accidental injury remains the principal cause of death and disability in those aged less than 45 years of age in the developed world. Also, as the threats of infectious disease and starvation have been reduced in parts of the 'third world', they have been replaced by injury; at the same time, motor vehicle and interpersonal violence have increased. Since such injuries involve predominantly the young, it can be calculated that in the loss to society of productive years of life, injury presents more of a challenge than cancer and cardiovascular disease.

Humans are also subjected to the planned injury of surgery, recovery from which may be prolonged. This consumes health service resources within and outside hospital and also delays return to employment and/or independence.

Attempts to reduce the burden of injury should emphasize prevention but it is also important to lessen its biological effects. A full description and explanation of the biological responses to injury is needed so that treatment can be properly directed. For example now that the metabolic responses to major injury, surgery, and infection have been shown to be very similar, 'generic' scientifically based measures rather than empirical *ad hoc* interventions are used in treatment.

The most important advance in the description of the metabolic response to injury was the recognition, by Sir David Cuthbertson in 1932, that the response did not involve unconnected reactions but rather followed an ordered pattern. He divided the response into an initial transient 'ebb', followed by a prolonged 'flow' phase.

Ebb phase

This was first described as a period of depressed vitality or metabolism and anuria which occurred during the first 1 to 2 days after injury. Subsequent analysis of the data from Cuthbertson's four patients reveals little evidence for a reduction in energy metabolism. However, his interpretation may have been influenced by previous experiments which showed an acute depression of metabolism after hind-limb muscle injury in anaesthetized cats. In these animals, the depression in metabolism was caused by a failure of tissue oxygen delivery—an unlikely occurrence in Cuthbertson's patients with single, lower-limb fractures.

It now seems that the ebb phase can be redefined as the early stage after trauma during which tissue energy production is not limited by a failure of oxygen delivery (Table 1). It is a complex neuroendocrine response, the magnitude of which depends on the generation of somatic afferent nociceptive stimuli arising from damaged tissues and the loss of intravascular volume. As well as eliciting a neurohumoral response, the nociceptive stimuli also inhibit central thermoregulation and cardiovascular reflex activity. Many aspects of this early response are reminiscent of the alerting response of the defence reaction or preparation for fight or flight. Thus, the arterial baroreceptor reflex is inhibited allowing concomitant increases in arterial blood pressure and heart rate.

In this initial phase, there is also mobilization of energy stores to fuel the anticipated increase in activity. The increases in plasma glucose concentration, which are directly related to the severity of injury, arise from the breakdown of glycogen stores in the liver and skeletal muscle. This breakdown is mediated by rises in the counter-regulatory hormones (the catecholamines, especially adrenaline, cortisol, and glucagon) which occur at this time, together with increases in antidiuretic hormone. The catecholamines may also be sufficient in the severely injured to inhibit intracellular glucose uptake and oxidation by suppressing the release of insulin. The increased activity of the sympathetic nervous system also stimulates lipolysis but the relationship between plasma concentrations of non-esterified fatty acids and severity of injury is complex. In particular, there may be stimulation of fatty acid re-esterification within adipose tissue by the raised plasma lactate that is associated with severe injury or impaired perfusion of the fat depots.

Although the main changes in protein metabolism are associated with the 'flow' phase, the acute phase plasma protein response is initiated early after injury. Hence, 6 h or so after tissue damage, plasma concentrations of the acute phase reactants (e.g. C-reactive protein and fibrinogen) rise. These rises are due to an increase in their hepatic synthesis, probably induced by interleukin-6 (IL-6). Plasma albumin concentrations often fall rapidly after injury, as a result of increased microvascular permeability rather than to a reduction in synthesis.

The role of the cytokines in mediation of the acute responses to injury remains controversial. While cytokines have been shown to mimic some of these responses, levels of plasma cytokines are not universally elevated immediately after injury. This may, of course, reflect their autocrine/paracrine rather than endocrine function. However, elevated plasma concentrations of the proinflammatory cytokines tumour necrosis factor-a (TNF-a), IL-b, IL-2, IL-6, and IL-8 occur after accidental injury. Also IL-6 levels have been directly related both to the severity of multiple trauma and to the magnitude of surgical trauma. IL-6 may also be involved in the activation of the hypothalamo–pituitary–adrenal axis by peripheral tissue injury, probably by means of the induction of cyclo-oxygenase products at the blood–brain interface (e.g. the circumventricular organs).

If the injury is not overwhelming, and with appropriate control of the airway, breathing, and circulation, the 'ebb' phase gives way to the 'flow' phase.

Flow phase

The main metabolic features of the flow phase are an increase in metabolic rate (hypermetabolism), due to catabolism (especially of skeletal muscle) and resistance to the anabolic effects of insulin (Table 2).

Hypermetabolism

There is said to be an increase in metabolic rate which is directly related to the severity of injury. Although such a relationship has been described for burned patients treated by exposure, it is not so clear after other injuries. One of the problems is that to describe a patient as hypermetabolic it is necessary that we define a normal metabolic rate for that individual; but what is a normal rate for someone who might be paralysed and ventilated, bedridden for a considerable time, receiving inadequate nutrition, and has suffered an acute reduction in body mass? All of these factors can reduce metabolic rate and thereby counteract any hypermetabolic stimuli associated with injury. It is also possible that in the most critically ill, energy expenditure may be limited by a failure of oxygen delivery. This may be the explanation for the finding of 'normal' metabolic rates in critically ill, septic patients.

What are the hypermetabolic stimuli alluded to above? There is an upward resetting of metabolic rate, perhaps triggered by a cytokine/prostanoid cascade, and there are increases in efferent sympathetic activity and substrate cycling (a process in which ATP is consumed without concomitant change in the amount of substrate or its metabolic products). Also, there is an extra organ—the wound—which contributes to whole body energy metabolism in two main ways. First, it can be the site of origin of the cytokine/prostanoid cascade mentioned above and, second, the wound is a consumer of glucose which it converts to lactate by aerobic glycolysis (an inefficient producer of ATP). The lactate produced is reconverted to glucose in the liver in an energy consuming process, thereby increasing hepatic oxygen consumption and blood flow. The evaporation of water from a burn wound or from an area of granulation tissue will also increase energy expenditure. The catabolism of lean tissue protein can also increase energy expenditure, but only in those with severe head injuries or very extensive burns is it likely to contribute more than 20 per cent to the total expenditure.

Protein metabolism

Whole body protein turnover is increased after injury with the balance between synthesis and breakdown being modified by the severity of injury and the influence of nutritional intake on synthesis. Thus, the severity of the injury increases both protein synthesis and breakdown. However, after the most severe injuries, the increase in breakdown predominates and cannot be counteracted by even the most aggressive nutritional support. It is now recognized that the increase in proteolysis in such catabolic conditions involves the ubiquitin–proteasome pathway. The increase in muscle protein catabolism is reflected by concomitant increases in the urinary excretion of nitrogen, 3-methylhistidine and, creatinine.

The most obvious site of net protein catabolism is skeletal muscle—although it also occurs in the respiratory muscles, the wall of the gut, and possibly the heart. Thus, in addition to problems with mobility, ventilation and the maintenance/restoration of enteral nutrition can also be compromised.

The increase in proteolysis provides amino acids as precursors for hepatic gluconeogenesis. The persistence of this glucose production at a time when plasma glucose and insulin concentrations are normal or raised can be considered as another facet of insulin resistance (see below). Plasma concentrations of several amino acids can fall at this time although their hepatic uptake is maintained by the increase in hepatic blood flow (see above). One amino acid that has received a lot of attention is glutamine, the intracellular concentration of which falls in skeletal muscle in response to injury. Glutamine is an important fuel for cells of the immune system, it is a precursor for the synthesis of glutathione (a free radical scavenger), has a role in nitric oxide metabolism, and has also been implicated in the maintenance of the integrity of the gut mucosal barrier, which may be compromised after injury.

Insulin resistance

Resistance to the 'anabolic' effects of insulin after injury is manifest in a several ways. For example hepatic glucose production, lipolysis, and net efflux of amino acids from skeletal muscle persist at plasma glucose and insulin concentrations which are inhibitory in uninjured subjects. Also the uptake of glucose into skeletal muscle is reduced, an impairment which involves glucose storage rather than oxidation.

The cause of injury-induced insulin resistance is unclear, although a role for the counter-regulatory hormones (cortisol, adrenaline, and glucagon) has been suggested. Whilst infusion of these hormones can induce insulin resistance in healthy individuals, the plasma concentrations needed are higher than those in injured/septic patients who are known to be insulin resistant. In this respect, the proinflammatory cytokines may have a role in modulating insulin sensitivity.

Plasma IL-6 concentrations in patients with cancer are positively correlated with the degree of insulin resistance and TNF-a has been implicated in the insulin resistance of diabetes and obesity. A role for IL-1 in the insulin resistance associated with endotoxaemia has also been suggested. The nature of the intracellular defect underlying insulin resistance remains to be elucidated but it may involve serine phosphorylation of insulin receptor substrate-1.

Manipulation of the metabolic response

Most efforts have been focused on trying to attenuate or reverse the loss of muscle mass. The administration of glutamine and anabolic agents such as growth hormone, insulin like growth factor (IGF), and oxandrolone have all been investigated.

Since glutamine plays such a central role in host defence mechanisms, there have been several studies of glutamine supplementation in, for example, surgical patients. These have shown preservation of intestinal mucosal integrity, enhanced immune function, and attenuation of the decrease in muscle intracellular glutamine concentration and protein synthesis. There have been fewer studies in critically ill patients, although one trial has shown that glutamine-supplemented parenteral nutrition improved 6-month survival.

The use of recombinant human growth hormone (rhGH) has produced conflicting results. Improvements in nitrogen balance have been reported in surgical, burned, and injured patients, and in the surgical group the improvement was accompanied by preservation of handgrip strength. In burned children, rhGH reduced the length of hospital stay, probably reflecting improved wound healing. However, other studies have failed to demonstrate an improvement in nitrogen balance and attenuation of muscle breakdown. The administration of IGF-1 in studies in animals and human volunteers were encouraging, but several randomized, controlled studies in catabolic patients have failed to demonstrate any protein-sparing effect.

Oxandrolone is a testosterone analogue with anabolic activity that has been shown to be of benefit to patients with severe malnutrition and alcoholic hepatitis. A trial in patients with severe burns has shown that oxandrolone combined with an increased protein intake significantly increased the rate of weight gain and improved subjective measures of muscle strength.

11.12.3 Familial mediterranean fever and other inherited periodic fever syndromes

P. N. Hawkins and D. R. Booth

The hereditary periodic fever syndromes are a group of multisystem disorders characterized by recurrent episodes of fever in association with inflammation that variably affects serosal linings, joints, and skin. They include familial Mediterranean fever, which is by far the most common, familial Hibernian fever, the hyperimmunoglobulin D syndrome, the Muckle–Wells syndrome, and familial cold urticaria. Although some of the individual features of these diseases overlap, there are distinctions in their mode of inheritance, their clinical features, and the frequency of symptoms. There has been substantial progress in elucidating the molecular basis of the hereditary periodic fever syndromes, which has proved to be surprisingly diverse and has opened several new avenues in inflammation research. Molecular analysis has already had a major impact on clinical diagnosis and the genetic defect in familial Hibernian fever has suggested a specific form of treatment. All of these disorders are compatible with normal life expectancy but since each of them is associated with a prominent, acute phase plasma protein response, potentially fatal systemic AA amyloidosis may develop unless the underlying inflammatory condition can be suppressed.

Familial Mediterranean fever

Familial Mediterranean fever (FMF) is an inherited, inflammatory disease that occurs most commonly in Jewish, Armenian, Turkish, and Middle Eastern Arab populations but also rarely in individuals of any ancestry. It is characterized by recurrent, acute attacks of fever, sterile peritonitis and pleurisy, arthritis, and erysipelas-like rashes lasting from 12 h to about 3 days, which in most cases can be prevented by regular prophylactic therapy with colchicine. The disorder is also known as recurrent polyserositis, periodic disease, Armenian disease, and other names besides, but the term familial Mediterranean fever is most commonly used. The recently identified gene responsible has been called *MEFV*, (Mediterranean fever), is located on chromosome 16 and appears to be expressed only in neutrophils. It encodes a hitherto uncharacterized protein called pyrin or marenostrin, and its discovery should enable the molecular basis of the disease to be unravelled. Analysis of *MEFV* has already revolutionized the diagnosis of FMF. About 30 mutations in *MEFV* have now been associated with FMF, and pairs of *MEFV* mutations, presumed to involve both alleles, can be found in most FMF patients. These findings accord with the autosomal recessive mode of inheritance that is usually evident clinically and which has long been recognized in population studies.

Pathogenesis and genetics

Pyrin, the uncharacterized protein product of *MEFV*, consists of 781 amino acids with a molecular weight of about 90 kDa. Messenger RNA for pyrin is found exclusively in neutrophils and their precursor cells. The amino acid sequence of pyrin contains zinc finger motifs, potential phosphorylation sites, and a B30.2 domain, all typical of several other proteins that act within the nucleus. Pyrin could therefore be a transcription factor and, if so, it could suppress the production of a proinflammatory molecule, or upregulate the transcription of an anti-inflammatory one. However, the same features are also found in some proteins acting outside the nucleus and which are involved in protein–protein interactions. It is likely that the *MEFV* mutations which cause FMF disrupt the structure of pyrin sufficiently to reduce its function, leading to inappropriate neutrophil activation and migration. The recurrent, acute clinical attacks, along with massive influx of neutrophils into serosal and synovial linings, would be consistent with bursts of relatively uncontrolled neutrophil activity. Patients with FMF often have prolonged periods of apparently normal health between their attacks, suggesting that reduced pyrin function has clinical consequences only in certain circumstances. Physical and emotional stress, menstruation, and diet have been reported to increase susceptibility to FMF attacks and the irregular nature of symptoms supports the notion that clinical attacks of FMF may be triggered by exogenous factors. The characteristic pattern of inflammation in serosal and synovial membranes, and the paucity of evidence in patients with FMF for exacerbation of other inflammatory processes in which neutrophils are involved, suggest that pyrin may regulate a rather specific facet of neutrophil behaviour.

The 30 or so *MEFV* mutations that are associated with FMF encode either single amino acid substitutions or deletions in the pyrin molecule. The mutations that commonly cause FMF are in exon 10 of the pyrin gene, and in exon 5 in some populations. Although a polymorphism in exon 2 encoding the pyrin variant E148Q may contribute to FMF in some cases, homozygosity for E148Q does not seem to be sufficient to cause FMF. Whilst it is inherently likely that different mutations will impair the function of a protein to differing extents, several findings indicate that the methionine residue at position 694 may be critical for the normal function of pyrin. Three different pathogenic exon 10 mutations involving M694 have been identified (M694V, M694I, and deletion M694) and individuals who are homozygous for M694V are reported to have particularly severe and early-onset FMF disease, as well as a greater propensity to develop AA amyloidosis. It is also noteworthy that simple heterozygous deletion of residue M694, which is likely to produce more severe structural disruption than an amino acid substitution, has been reported, by itself, to cause typical FMF in several British families. Recognition that *MEFV* mutations affecting a single allele may give rise to FMF suggests that a 50 per cent complement of normally functioning pyrin is not sufficient to prevent susceptibility to the disease. Severe disruption of a single *MEFV* allele by one or more mutations may therefore account for the rare reports of autosomal dominant FMF. However, transmission of FMF is pseudodominant in most families in which more than one successive generation is affected by the disease and this usually reflects consanguinity or a high incidence of the FMF trait in the population at risk. Up to one individual in seven in some Mediterranean regions is an FMF carrier, and the apparently 'mild' pyrin variant E148Q occurs very widely indeed. Pyrin E148Q has been identified in European whites, black Africans, Punjabi Indians, and Chinese populations, with an allele frequency of about 20 per cent in the latter two groups. The remarkable global prevalence of pyrin E148Q supports the hypothesis that the FMF trait conferred a survival benefit during evolution. Possible mechanisms for this include enhanced resistance to microbial infection mediated by non-specific upregulation of the inflammatory response. It is worth considering that the same process may have the potential to exacerbate chronic inflammatory disorders.

Clinical features

Patients with FMF typically present with acute attacks of fever, peritonitic abdominal pain, pleuritic chest pain, arthralgia, and rash in approximately this order of frequency. However, the pattern of tissue involvement varies substantially between patients, and even in the same patient on different occasions. Other features occasionally include myalgia, headache, orchitis, and cutaneous and renal vasculitis. The symptoms of FMF usually start in the first decade of life, and only five per cent of patients develop symptoms after 30 years of age, although the frequency and severity of attacks can alter substantially during the course of a patient's life.

A brief prodrome may occur after which the temperature rises to 38 to 40°C in almost every case. Peritonitis occurs in more than 90 per cent of cases and evolves over a few hours. It is readily misdiagnosed as acute appendicitis or some other surgical crisis. Many patients become confined to bed with severe pain and vomiting but these features can be quite mild or absent in other cases. Diarrhoea is unusual. Pleurisy occurs in about 50 per cent of patients, is typically unilateral, and can be associated with atelectasis or a small effusion. Involvement of joints also occurs in about half of the patients, and can range from polyarthralgia without overt soft tissue swelling to a more classical monoarticular synovitis affecting the knees or hips. The rash of FMF is less common but comprises very characteristic 10 to 15-cm, erysipelas-like, warm swollen lesions on the lower leg. Pericarditis, perhaps curiously, is rare. The acute crisis of FMF usually resolves in less than 3 days, and attacks tend to recur at irregular intervals of weeks or months. Direct long-term sequelae of FMF, such as serosal fibrosis and adhesions, occur rarely although a small proportion of patients do develop a chronic inflammatory arthritis that can lead to severe joint destruction. The most important and life-threatening long term consequence of FMF is AA amyloidosis (see below).

Investigations

No laboratory test is specific for FMF. The identification of *MEFV* clearly represents a major advance both in elucidating the molecular basis of the disease and for its diagnosis but the results of genetic testing in any individual must be interpreted with care. This is essential because individuals with *MEFV* mutations seem to differ

greatly in their susceptibility to developing FMF and many have subclinical inflammatory disease. They may also have some other, unrelated inflammatory disease that show symptom overlaps with FMF. Another practical problem is that *MEFV* is a relatively large gene spanning 10 exons, and limited screening for common mutations will fail to identify abnormalities in many patients, particularly in those with atypical ethnic backgrounds in whom rare or new mutations are more likely. Certainly, in the absence of an exon 10 mutation, the diagnosis of FMF is unlikely in patients from ethnic groups in which FMF typically occurs. However, even the most comprehensive analysis of the *MEFV* coding region has identified only single allele mutations in some patients with classical FMF and no mutations at all in a few cases. Thus, mutations in regulatory regions of *MEFV*, or indeed mutations in other genes, might contribute to the pathogenesis of the disease in some patients; alternatively, certain heterozygotes may be unusually susceptible to FMF. The results of *MEFV* genotyping should therefore be interpreted in light of each clinical presentation and ethnic origin.

Diagnostic clinical criteria for the evaluation of patients with features suggestive of FMF are well developed. During the clinical attacks of FMF, the number of neutrophils in peripheral blood may rise from normal levels by several fold. Some patients have a mild normochromic anaemia and polyclonal hyperglobulinaemia but the most striking serological feature of the disease is the magnitude of the acute phase plasma protein response that is evoked. During a typical clinical attack, the concentration of C-reactive protein generally exceeds 100 mg/l and may be greater than 250 mg/l; the plasma concentration of serum amyloid A protein often attains even higher levels, frequently exceeding 500 mg/l (normal less than 3 mg/l). Both C-reactive protein and serum amyloid A protein have half-lives in the circulation of less than 24 h, and their concentrations fall to healthy baseline values within several days of resolution of an acute episode. Serial monitoring of these sensitive and dynamic markers have shown that bursts of inflammation occur frequently in patients with FMF in the absence of symptoms, and even, to a lesser extent, among those taking regular colchicine therapy. Our own practice in a patient with suspected FMF is to measure the concentration of C-reactive protein and serum amyloid A protein on four or five occasions at 2-weekly intervals. In many cases, this will objectively document self-limiting 'periodic' bursts of inflammation. It is often useful to repeat this type of analysis during a therapeutic trial of colchicine.

Amyloidosis

AA amyloidosis is the most significant complication of FMF since it is unpredictable, progressive and potentially fatal. AA amyloid fibrils are derived from a 76 amino acid N-terminal cleavage fragment of the 104 residue serum amyloid A protein. Before the beneficial effect of colchicine in FMF was known, the lifetime incidence of AA amyloidosis was reported to be up to 30 per cent or more. The risk of developing amyloidosis appears to be greater among Sephardic Jews and Turks than among non-Sephardic Jews and Armenians. Some patients with FMF present with AA amyloidosis before they have experienced symptoms of the inflammatory disease, a situation often referred to as (pheno)type II FMF. The lack of a clear association between the severity of symptoms in FMF and the likelihood of developing AA amyloidosis, and the different incidence of amyloidosis among various ethnic groups has led some investigators to question the nature of the relationship. However, the features of AA amyloid in patients with FMF are identical to those in patients with every other type of chronic inflammatory disease, ranging from the composition of the amyloid fibril protein to the distribution and clinical consequences of the amyloid deposits. Although there are evidently unknown genetic or environmental factors that influence susceptibility to AA amyloidosis generally, acute phase production of serum amyloid A protein is the only absolute prerequisite for AA amyloid deposition. Systematic serial monitoring of serum amyloid A protein has confirmed that a major acute phase response frequently occurs in patients with FMF in the absence of symptoms, and the magnitude and duration of this is probably a very substantial determinant of the risk of developing amyloidosis. Evaluation of this risk is likely to become more refined when the significance of different *MEFV* mutations, serum amyloid A protein isotypes, and other factors is better understood, but for the time being all patients with FMF who have had uncontrolled inflammation, with or without symptoms, must be regarded as susceptible. *MEFV* analysis in patients with FMF complicated by AA amyloidosis, who have been evaluated in our own clinic, has demonstrated a wide spectrum and combination of mutations suggesting that amyloidosis is not restricted to any particular genotype.

AA amyloid deposition may be extensive without causing symptoms and can develop at any time from early childhood to late adult life. AA amyloid initially accumulates in the spleen, and functional hyposplenism may eventually develop. However, the most common mode of presentation is with non-selective proteinuria, nephrotic syndrome, and/or renal insufficiency. Acute renal failure may be precipitated by minor insults, and end-stage renal failure and its complications are the most frequent cause of death. Patients sometimes present with hepatosplenomegaly, occasionally without overt renal dysfunction, but renal deposits are nevertheless always present in such cases. The adrenal glands are involved in at least one-third of cases and the liver in a quarter. Although the function of these latter organs is often well preserved, hepatic amyloidosis is a sign of advanced and extensive disease and has a poor prognosis. Histological involvement of the gut is common, but tends only to cause symptoms in patients whose disease is generally very advanced. AA amyloidosis rarely ever causes overt cardiac disease. The prognosis is chiefly determined by the extent of amyloid at diagnosis and the effectiveness with which production of serum amyloid A protein can be suppressed by colchicine therapy. Proteinuria should be sought routinely in patients with FMF, and the suspicion of amyloid followed-up by renal or rectal biopsy and Congo-red staining. Serum amyloid P component scintigraphy is a sensitive and specific non-invasive method for imaging amyloid in visceral organs and can be used serially to monitor the deposits in a quantitative manner. Scintigraphic follow-up studies in more than 100 patients with AA amyloidosis, some of whom had FMF, have confirmed the findings of numerous clinical and histological case reports by demonstrating that the amyloid deposits frequently regress when production of serum amyloid A protein is reduced to normal healthy baseline levels. Routine monitoring of serum amyloid A protein should be an integral part of the management of all patients with AA amyloid and automated immunoassay systems for serum amyloid A protein are available, standardized on a World Health Organization International Reference Standard.

Treatment

The only effective treatment for FMF is colchicine, a serendipitous discovery made by Goldfinger in 1972. Regular prophylactic treatment with colchicine at a dose of 1 to 2 mg daily prevents or substantially reduces the clinical manifestations of FMF in at least 95 per cent of cases. A proportion of the remainder are poorly compliant or intolerant of the drug. Studies in which serum amyloid A protein has been monitored in FMF patients who have been rendered free of symptoms by colchicine therapy show that the subclinical inflammation is also substantially, but often not completely, prevented. Colchicine modulates neutrophil function by binding to tubulin in microtubules which inhibits motility and exocytosis of the intracellular granules and diminishes neutrophil chemotaxis *in vitro* and *in vivo*. However, colchicine is not generally effective in other acute or chronic inflammatory diseases, even in those in which neutrophils are recognized to have an important role. The mechanism by which colchicine exerts its beneficial effect in FMF, and how, if at all, it influences the pyrin pathway are not yet known.

Regular, long-term use of colchicine is advisable in every patient with FMF and mandatory in those with AA amyloidosis. Not only does this prevent amyloidosis from developing in the first place but established amyloid deposition will usually be halted by an adequate dose of the drug. Existing amyloid deposits may gradually regress. The clinical effects of amyloid may also resolve, particularly proteinuria in patients whose glomerular filtration is well preserved. FMF patients with end-stage renal failure due to AA amyloidosis are often excellent candidates for renal transplantation, since graft amyloid can also be prevented by colchicine prophylaxis. Although colchicine is an extremely toxic agent in large quantities, the small regular dose required for the treatment of FMF is generally well tolerated. The most frequent adverse effect of low-dose colchicine is diarrhoea, but this seldom prevents its use and sometimes responds to a lactose-free diet. Despite concerns about the antimitotic potential of colchicine, the drug does not appear to cause infertility or lead to birth defects, even when used throughout pregnancy, or have any other long-term adverse effect. The concentration of colchicine in breast milk is sufficiently low to permit breast feeding.

Colchicine is largely ineffective in the acute management of FMF attacks. Analgesics and intravenous fluid replacement are required in some patients but a low threshold for intravenous fluids should be the policy for FMF patients with AA amyloidosis since hypovolaemia can precipitate irreversible renal failure in these patients.

Familial Hibernian fever (tumour necrosis factor receptor associated periodic syndrome—TRAPS)

The term familial Hibernian fever was coined by Williamson in 1982, who described a large Irish family with a periodic fever syndrome inherited in an autosomal dominant manner. Affected individuals had intermittent bouts of fever, abdominal pain, painful erythematous rashes, arthralgia, and myalgia. Flares of the disease are very much less distinct than in FMF and patients frequently remain symptomatic for weeks or sometimes months on end. The clinical manifestations of inflammation are associated with a very intense acute phase response which can be sustained even when symptoms abate. Several affected individuals have developed AA amyloidosis. Only a handful of other families, most of Northern European ancestry, have been reported with similar syndromes but its genetic basis has recently been discovered. This is not only of major diagnostic value in autosomal dominant periodic fever syndromes, but it has also identified a novel mechanism of inflammation that suggests a specific therapeutic approach.

The disease is caused by at least 16 different missense mutations in the gene on chromosome 12 which encodes tumour necrosis factor receptor 1 (TNFRSF1A). Tumour necrosis factor (TNF) is a potent proinflammatory cytokine that is implicated very widely in inflammation. TNFRSF1A is expressed on the outer membrane of most cells in the body where it acts closely with TNF receptor 2 to bind TNF and lymphotoxin cytokines and signal the activation of a complex inflammatory pathway. This signalling can be turned off by enzymatic cleavage and shedding of the soluble, extracellular portion of TNFRSF1A from the cell surface into the blood. This has a dual effect since it disrupts the signalling mechanism and the soluble TNFRSF1A that is released can bind and neutralize TNF in the circulation. Many of the

mutations that have been identified in autosomal dominant periodic fever syndromes are thought to disrupt conserved disulphide bonds in the extracellular TNFRSF1A domain and interfere with the physiological negative feedback control mechanism. The plasma concentration of soluble TNFRSF1A is abnormally low in many patients with these diseases, and measurement of soluble TNFRSF1A (also known as p55 protein) may be a useful way of screening for the disorder. It is now widely accepted that the dominantly inherited fever syndromes associated with TNF receptor mutations should be classified as tumour necrosis factor receptor associated periodic syndromes (TRAPS).

This disorder responds partially to colchicine in some cases but can usually be suppressed by high doses of corticosteroids and other immunosuppressive agents. The genetic basis of the disorder suggests that specific blockade of TNF might be beneficial, and early experience with this approach has been promising.

Hyperimmunoglobulinaemia D periodic fever syndrome

The hyperimmunoglobulinaemia D periodic fever syndrome (HIDS) was first described in the Netherlands in 1984. It is inherited in an autosomal recessive manner and is characterized by intermittent, irregular attacks of abdominal pain and fever in association with an acute phase response and persistent elevation of the plasma concentration of immunoglobulin D. Attacks characteristically occur every 1 or 2 months and last for 3 to 7 days, but with considerable individual variation. Unlike FMF, the abdominal pain does not usually have the overt features of peritonitis, and is frequently associated with diarrhoea as well as vomiting. Lymphadenopathy occurs in most patients and arthralgia affecting the knees and ankles is present in about two-thirds of cases. Most families are of western European origin. The acute phase response in HIDS tends to be less intense than in the other inherited periodic fever syndromes described here, and this is likely to be the reason for an apparently very low risk of developing AA amyloidosis.

HIDS has lately been attributed to several mutations affecting both alleles of the gene on chromosome 12 encoding mevalonate kinase, *MVK*. This enzyme is involved in isoprenoid synthesis and catalyses the phosphorylation of mevalonate to 5-phosphomevalonate. The identified mutations have been shown to reduce its enzymatic activity. Different mutations in *MVK* are the cause of mevalonic aciduria, another inherited and much more severe multisystem disease. Excretion of mevalonic acid in the urine is increased constitutively in mevalonic aciduria, but only during the febrile episodes, if at all, in HIDS. The pathogenesis of these disorders, including the dysregulation of immunoglobulin D production, is not understood and, as in FMF, a previously unknown pathway that can profoundly regulate an aspect of the inflammatory response may be involved.

Muckle–Wells syndrome and familial cold urticaria

Muckle–Wells syndrome and familial cold urticaria are very rare, dominantly inherited, periodic fever syndromes. Fever and rash are prominent features of both conditions, and both can be complicated by AA amyloidosis. The original family described by Muckle and Wells in 1962 had progressive sensorineural deafness, although this does not occur in other cases. Arthralgia and poorly characterized limb pain occur in both disorders, and both conditions tend to start in early childhood. The skin rash, fever, and other symptoms in familial cold urticaria are triggered by exposure to cold. The frequency and pattern of symptoms is extremely variable but they can be present for very prolonged periods in both disorders. The search for the genetic basis of these two disorders, which evidently have a number of overlapping clinical features, has lately linked both of them to chromosome 1q44. It is therefore possible that Muckle–Wells syndrome and familial cold urticaria represent different phenotypic manifestations of the same mutation, or that they might be due to different mutations in the same gene. Phenotypic expression of familial cold urticaria can presumably be influenced by climatic conditions. We have lately evaluated a family with this syndrome that resides in a warm part of India, perhaps accounting for the very mild symptoms in most of the affected members. Treatment for these disorders centres mainly on corticosteroids and immunosuppressive drugs. A therapeutic trial of colchicine is, however, worthwhile, since it seems to be quite effective in a proportion of cases. Most patients with these syndromes have a normal life expectancy, although in the absence of a generally effective treatment, the outlook is poor for individuals who develop AA amyloidosis.

11.12.4 Amyloidosis

M. B. Pepys and P. N. Hawkins

Introduction

Amyloidosis is a disorder of protein folding, characterized by extracellular deposition of abnormal protein fibrils. The underlying molecular abnormalities may be either acquired or hereditary and about 20 different proteins can form clinically or pathologically significant amyloid fibrils *in vivo* (Table 1 and Table 2). Amyloid deposits also contain glycosaminoglycans, some of which are tightly associated with the fibrils, and also a non-fibrillar plasma glycoprotein, amyloid P component. Small, focal, clinically silent amyloid deposits in the brain, heart, seminal vesicles, and joints are a universal accompaniment of ageing. However, clinically important amyloid deposits usually accumulate progressively, disrupting the structure and function of affected tissues and leading inexorably to organ failure and death. No treatment yet exists which can specifically cause resolution, but intervention which reduces the availability of the amyloid fibril precursor proteins may lead to regression.

Clinical amyloidosis

Introduction

Amyloidosis occurs in many clinical disorders. Amyloid deposits in the brain and cerebral blood vessels are a central part of the pathology of Alzheimer's disease, which is the fourth most common cause of death in the Western world, whilst amyloid is present in the islets of Langerhans of the pancreas in all patients with type 2, maturity onset, diabetes mellitus. Amyloid deposition in the bones, joints, and periarticular structures eventually affects most patients who are on long-term haemodialysis for endstage renal failure and is the most frequent cause of serious morbidity among the approximately 800 000 such individuals worldwide. Systemic amyloidosis complicating myeloma and other B-cell dyscrasias, or chronic infections and inflammatory diseases, is very important because diagnosis is often difficult and the prognosis is poor, but effective treatments are increasingly available. Hereditary amyloidosis is very rare, except in a few geographic foci, but its diversity is remarkable. It is important because of its poor prognosis, the complexity of clinical management, the difficult genetic issues involved, and its considerable value as a model for understanding the pathogenesis of amyloid deposition.

Although there are some correlations between fibril protein type and clinical manifestations, there are also many forms of acquired and hereditary amyloidosis in which there is little or no concordance between the fibril protein, or the genotype of its precursor, and the clinical phenotype. There are evidently genetic and/or environmental factors, which are distinct from the amyloid fibril protein itself, which determine whether, when, and where clinically significant amyloid deposits form. The nature of these important determinants of amyloidogenesis is obscure. Furthermore, the mechanisms by which amyloid deposition causes disease are poorly understood. Whilst a heavy amyloid load is invariably a bad sign, there is often a poor correlation between the local amount of amyloid and the level of organ dysfunction. Active deposition of new amyloid is often associated with enhanced deterioration compared with stable long-standing deposits. Nascent or newly formed amyloid fibrils, generated *in vitro*, are also cytotoxic to cultured cells, whilst aged or *ex vivo* fibrils are generally inert, although it is not known how this relates to effects *in vivo*.

Reactive systemic (AA) amyloidosis

Associated conditions

AA amyloidosis occurs in association with chronic inflammatory disorders, chronic local or systemic microbial infections, and occasionally malignant neoplasms. In Western Europe and the United States the most frequent predisposing conditions are idiopathic rheumatic diseases (Table 3). Amyloidosis complicates up to 10 per cent of cases of rheumatoid arthritis and juvenile inflammatory arthritis, although for reasons that are not clear the incidence is lower in the United States than in Europe. Amyloidosis is exceptionally rare in systemic lupus erythematosus and related connective tissue diseases and in ulcerative colitis, in contrast to Crohn's disease. Tuberculosis and leprosy are important causes of AA amyloidosis, particularly where these infections are endemic. Chronic osteomyelitis, bronchiectasis, chronically infected burns, and decubitus ulcers as well as the chronic pyelonephritis of paraplegic patients are other well-recognized associations (Table 3). Hodgkin's disease and renal carcinoma, which often cause fever, other systemic symptoms, and a major acute phase response, are the malignancies most commonly associated with systemic AA amyloidosis.

Clinical features

AA amyloid involves the viscera but may be widely distributed without causing clinical symptoms. More than 90 per cent of patients present with non-selective proteinuria due to glomerular deposition, and nephrotic syndrome may develop before progression to endstage renal failure. Haematuria, isolated tubular defects, nephrogenic diabetes insipidus, and diffuse renal calcification occur rarely. Kidney size is usually normal, but may be enlarged, or, in advanced cases, reduced. Endstage chronic renal failure is the cause of death in 40 to 60 per cent of cases but acute renal failure may be precipitated by hypotension and/or salt and water depletion following surgery, excessive use of diuretics, or intercurrent infection, and may be associated with renal vein thrombosis. The second most common

presentation is with organ enlargement, such as hepatosplenomegaly or thyroid goitre, with or without overt renal abnormality, but in any case amyloid deposits are almost always widespread at the time of presentation. Involvement of the heart and gastrointestinal tract is frequent, but rarely causes functional impairment.

AA amyloidosis may become clinically evident early in the course of associated disease, but the incidence increases with duration of the primary condition. The mean duration of chronic rheumatic diseases such as rheumatoid arthritis, ankylosing spondylitis, or juvenile rheumatoid arthritis before amyloid is diagnosed is 12 to 14 years, although it can present much sooner. For most patients the prognosis is closely related to the degree of renal involvement and the effectiveness of treatment of the underlying inflammatory condition. In the presence of persistent, uncontrolled inflammation, 50 per cent of patients with AA amyloid die within 5 years of the amyloid being diagnosed; however, if the acute phase response can be consistently suppressed proteinuria can cease, renal function is retained, and the prognosis is much better. Availability of chronic haemodialysis and transplantation prevents early death from uraemia *per se*, but amyloid deposition in extrarenal tissues is responsible for a less favourable prognosis than for other causes of endstage renal failure.

Amyloidosis associated with immunocyte dyscrasia: monoclonal immunoglobulin light chain (AL) amyloidosis

Associated conditions

Almost any dyscrasia of cells of the B-lymphocyte lineage, including multiple myeloma, malignant lymphomas, and macroglobulinaemia, may be complicated by AL amyloidosis but most cases are associated with otherwise 'benign' monoclonal gammopathy. Amyloid occurs in up to 15 per cent of cases of myeloma, in a lower proportion of other malignant B-cell disorders, and probably in fewer than 5 per cent of patients with a 'benign' monoclonal gammopathy. In some cases deposition of AL amyloid may be the only evidence of the dyscrasia. A monoclonal paraprotein or free light chains can be detected in the serum or urine of only about 90 per cent of patients with AL amyloid, but detection of immunoglobulin gene rearrangement in the bone marrow or peripheral blood sometimes confirms a monoclonal gammopathy in the remaining cases. The paraprotein may also appear after presentation and diagnosis of the amyloid, and subnormal levels of some or all serum immunoglobulins or increased numbers of marrow plasma cells may provide less direct clues to the underlying aetiology. Until recently it has been the practice to diagnose apparently 'primary' cases of amyloidosis, with no previous predisposing inflammatory condition or family history of amyloidosis, as AL type by exclusion. However, it has lately been recognized that autosomal dominant hereditary non-neuropathic amyloidosis, particularly that caused by variant fibrinogen a-chain, may be poorly penetrant and of late onset, so that there may be no family history. The coincident occurrence of a monoclonal gammopathy may then be gravely misleading and it is essential to exclude by genotyping all known amyloidogenic mutations, and to seek positive immunohistochemical or biochemical identification of the amyloid fibril protein in all cases.

Clinical features

AL amyloid occurs equally in men and women, usually over the age of 50 but occasionally in young adults. It has a lifetime incidence, and is the cause of death, of between 0.5 and 1 per thousand individuals in the United Kingdom. The clinical manifestations are protean, as virtually any tissue other than the brain may be directly involved. Uraemia, heart failure, or other effects of the amyloid usually cause death within a year of diagnosis, unless the underlying B-cell clone is effectively suppressed.

The heart is affected in 90 per cent of patients with AL amyloid, in 30 per cent of whom restrictive cardiomyopathy is the presenting feature and in up to 50 per cent of whom it is fatal. Other cardiac presentations include arrhythmias and angina. Renal AL amyloid has the same manifestations as renal AA amyloid, but the prognosis is worse. Gut involvement may cause disturbances of motility (often secondary to autonomic neuropathy), malabsorption, perforation, haemorrhage, or obstruction. Macroglossia occurs rarely but is almost pathognomonic. Hyposplenism sometimes occurs in both AA and AL amyloidosis. Painful sensory polyneuropathy with early loss of pain and temperature sensation followed later by motor deficits is seen in 10 to 20 per cent of cases and carpal tunnel syndrome in 20 per cent. Autonomic neuropathy leading to orthostatic hypotension, impotence, and gastrointestinal disturbances may occur alone or together with the peripheral neuropathy, and has a very poor prognosis. Skin involvement takes the form of papules, nodules, and plaques usually on the face and upper trunk, and involvement of dermal blood vessels results in purpura occurring either spontaneously or after minimal trauma and is very common. Articular amyloid is rare but may mimic acute polyarticular rheumatoid arthritis, or it may present as asymmetrical arthritis affecting the hip or shoulder. Infiltration of the glenohumeral joint and surrounding soft tissues occasionally produces the characteristic 'shoulder pad' sign. A rare but serious manifestation of AL amyloid is an acquired bleeding diathesis that may be associated with deficiency of factor X and sometimes also factor IX, or with increased fibrinolysis. It does not occur in AA amyloidosis, although in both AL and AA disease there may be serious bleeding in the absence of any identifiable factor deficiency.

Senile amyloidosis

Some amyloid is present in all autopsies on individuals over 80 years of age but it is not known whether this contributes to the ageing process or whether it is an epiphenomenon that becomes clinically important only when it is extensive.

Senile systemic amyloidosis

Up to 25 per cent of old people have microscopic, clinically silent systemic deposits of transthyretin amyloid involving the walls of the heart and blood vessels, smooth and striated muscle, fat tissue, renal papillae, and alveolar walls. In contrast to most other forms of systemic amyloidosis, including hereditary transthyretin amyloid caused by point mutations in the transthyretin gene, the spleen and renal glomeruli are rarely affected. The brain is not involved. Occasionally more extensive deposits in the heart, affecting the ventricles and atria and situated in the interstitium and vessel walls, cause significant impairment of cardiac function and may be fatal. The transthyretin involved is probably usually of the normal wild type but cases with transthyretin variants have been described which may be hereditary.

Senile focal amyloidosis

Microscopic and clinically silent amyloid deposits of different fibril types, localized to particular tissues, are very commonly present in old people. Deposits of b-protein (see below) as amyloid in cerebral blood vessels and intracerebral plaques seen in 'normal' elderly brains may or may not be the harbinger of Alzheimer's disease had the patient survived long enough. Amyloid deposits are present in most osteoarthritic joints at surgery or autopsy, usually in close association with calcium pyrophosphate deposits, affecting the articular cartilage and joint capsule. However, neither the clinical significance of this age-associated articular amyloid nor its biochemical nature are known. The corpora amylacea of the prostate are composed of b_2-microglobulin amyloid fibrils. Amyloid in the seminal vesicles is derived from an as yet unidentified exocrine secretory product of the vesicle cells. Isolated deposits of cardiac atrial amyloid consist of atrial natriuretic peptide. Focal amyloid deposits commonly present in atheromatous plaques of elderly subjects contain fibrils composed of the N-terminal fragment of apolipoprotein A-I.

Cerebral amyloidosis

Introduction

The brain is a very common and important site of amyloid deposition (Table 4), although possibly because of the blood–brain barrier there are never any deposits in the cerebral parenchyma itself in any form of acquired systemic visceral amyloidosis. However, cerebrovascular transthyretin amyloid may occur in familial amyloid polyneuropathy due to the most common transthyretin variant (methionine for valine at residue 30), and oculoleptomeningeal amyloidosis is caused by other very rare transthyretin variants. The common and major forms of brain amyloid are confined to the brain and cerebral blood vessels with the single exception of cystatin C amyloid in hereditary cerebral haemorrhage with amyloidosis, Icelandic type, in which there are major though clinically silent systemic deposits.

Alzheimer's disease

By far the most frequent and important type of amyloid in the brain is that related to Alzheimer's disease, which is the most common cause of dementia and affects over 3 million individuals in the United States and a corresponding proportion of other Western populations. It is generally a disease of the elderly and its prevalence is therefore increasing. The clinical differential diagnosis of senile dementia and the positive identification of Alzheimer's disease are difficult and often of limited precision in life. However, intracerebral and cerebrovascular amyloid deposits are hallmarks of the neuropathological diagnosis. The amyloid fibrils are composed of b-protein (Ab), a 39- to 43-residue cleavage product of the large amyloid precursor protein. The vast majority of cases of Alzheimer's disease are sporadic but there are also families with an autosomal dominant pattern of inheritance and usually early onset. In about 20 families there are causative mutations in the *APP* gene for amyloid precursor protein on chromosome 21, and most other kindreds have mutations in the genes for presenilin 1 (chromosome 14) and presenilin 2 (chromosome 1). All these mutations are associated with increased production from amyloid precursor protein of Ab1–42, the most amyloidogenic form of Ab. Since all individuals

with Down's syndrome, that is trisomy 21, develop Alzheimer's disease if they survive into their forties, there is evidently a close link between amyloid precursor protein, Ab overproduction, Ab amyloidosis, and the pathogenesis of Alzheimer's disease, although it remains unclear whether or how Ab *per se*, or the amyloid fibrils that it forms, contribute to the neuronal loss which underlies the dementia. Synthetic amyloid b fibrils formed *in vitro* are markedly cytotoxic and cause the death of cultured cells by apoptosis and necrosis, but it is not clear to what extent these findings reflect phenomena that may be responsible for neurodegeneration *in vivo*. There is controversy about the correlation between the severity of dementia in Alzheimer's disease and the extent of amyloid angiopathy and plaques. Nevertheless the fact that patients with Alzheimer's disease caused by amyloid precursor protein and presenilin mutations have exactly the same neuropathology as sporadic cases, including tangles, argues strongly that the amyloid precursor protein and b-protein pathway can be of primary pathogenetic significance.

In addition to the Ab amyloid deposits in the brains of patients with Alzheimer's disease and Down's syndrome, there are also extensive 'amorphous' deposits of amyloid b throughout the brain. These do not stain with Congo red, and are detectable only by immunohistochemical staining. Their significance is unknown. They apparently precede the appearance of histochemically identifiable amyloid but are not necessarily the precursor of it because they are present in areas such as the cerebellum in which Ab amyloid is never seen. The non-fibrillar, non-amyloid protein apolipoprotein E is demonstrable in many amyloid deposits, including those of Alzheimer's disease. The *ApoE4* gene (chromosome 19), encoding one of the three isoforms of this apolipoprotein, is strongly associated with predisposition to develop Alzheimer's disease and with increased amounts of amyloid in the brain, but the underlying mechanisms are unknown.

Another neuropathological feature of Alzheimer's disease, and some other neurodegenerative conditions, is the neurofibrillary tangle located intracellularly within neuronal cell bodies and processes. These tangles have a characteristic ultrastructural morphology of paired helical filaments, and although they bind Congo red and then give the pathognomonic green birefringence of amyloid when viewed in polarized light, they are completely different structurally from amyloid fibrils. They are composed of an abnormally phosphorylated form of the normal neurofilament protein, tau.

Senile cerebral amyloidosis and amyloid angiopathy

The cerebral blood vessels contain Ab amyloid in up to 60 per cent of aged brains of non-demented individuals and there may also be focal intracerebral Ab amyloid plaques. These deposits are usually clinically silent and may or may not be harbingers of Alzheimer's disease, had the patients survived long enough. Sometimes the amyloid angiopathy is more extensive and it is a rare but important cause of cerebral haemorrhage and stroke, to be distinguished from atherosclerotic cerebrovascular disease.

Hereditary cerebral haemorrhage with amyloidosis: hereditary cerebral amyloid angiopathy

Icelandic type

Cerebrovascular amyloid deposits composed of a fragment of a genetic variant of cystatin C are responsible for recurrent major cerebral haemorrhages starting in early adult life in members of families originating in western Iceland. There is autosomal dominant inheritance and appreciable but clinically silent amyloid deposits are present in the spleen, lymph nodes, and skin. There is no extravascular amyloid in the brain and the neurological deficits, often including dementia, of surviving patients are compatible with their cerebrovascular pathology.

Dutch type

In families originating in a small region on the Dutch coast the autosomal dominant inheritance of recurrent normotensive cerebral hemorrhages starting in middle age is due to deposition of a genetic variant of Ab as cerebrovascular amyloid. There are also 'amorphous' Ab deposits in the brain and early senile plaques, without congophilic amyloid cores. Multi-infarct dementia occurs in survivors but some patients become demented in the absence of stroke. Amyloid outside the brain has not been reported.

Cerebral amyloid associated with prion disease

The neuropathology of a group of progressive, invariably fatal spongiform encephalopathies which are transmissible and in some cases are hereditary, sometimes includes intracerebral amyloid plaques and amyloid cerebral angiopathy. These diseases, sporadic and familial Creutzfeldt–Jacob disease, the familial Gerstmann–Sträussler–Scheinker syndrome, and kuru are caused by prions (PrP^{Sc}), conformational isoforms of the normal physiological cellular prion protein (PrP^{C}). The human diseases are closely related to the animal diseases scrapie of sheep and goats, transmissible encephalopathy of mink, elk, and male deer, and bovine spongiform encephalopathy. Variant Creutzfeldt–Jacob disease is apparently the result of transmission of bovine spongiform encephalopathy to humans. The significance of amyloid *per se* in these disorders is not clear, because it is not always detectable histologically and is not seen, for example, in fatal familial insomnia or in bovine spongiform encephalopathy, which is apparently a result of the transmission of ovine scrapie to cattle. When scrapie or its human counterparts are transmitted to experimental animals by inoculation of affected brain tissue the development of intracerebral amyloid depends on the strain of infectious agent and the genetic background of the recipient. Even when amyloid is present in the brain it is not seen elsewhere, for example in the spleen, although the latter is a rich source of the infective agent. However, when the infective agent is exhaustively and highly purified from brain or spleen it forms typical congophilic amyloid fibrils, composed of the proteinase-resistant subunit which is the prion, PrP^{Sc}, and when amyloid deposits are present in affected brains they immunostain with antiprion antibodies. The amyloid fibril protein is thus directly related to the cause of the encephalopathy but gross amyloid deposition is evidently not necessary for expression of disease. Neuronal damage may perhaps be caused by cytotoxic prefibrillar PrP^{Sc} aggregates, or indeed by other mechanisms entirely. This is a different situation from the extracerebral amyloidoses and from cystatin C and non-hereditary cerebral amyloid angiopathies, in which amyloid deposition is invariably present when there is clinical disease.

Hereditary systemic amyloidosis

Familial amyloid polyneuropathy

Familial amyloid polyneuropathy is an autosomal dominant syndrome with onset at any time from the second decade onwards, characterized by progressive peripheral and autonomic neuropathy and varying degrees of visceral involvement affecting especially the vitreous of the eye, the heart, kidneys, thyroid, and adrenals. There are usually amyloid deposits throughout the body involving the walls of blood vessels as well as the connective tissue matrix, and the pathology is due to these deposits. Apart from major foci in Portugal, Japan, and Sweden, familial amyloid polyneuropathy has been reported in most ethnic groups throughout the world. There is considerable variation in the age of onset, rate of progression, and involvement of different systems, although within families the pattern is usually quite consistent. There is remorseless progression and the disorder is invariably fatal. Death results from the effects and complications of peripheral and/or autonomic neuropathy, or from cardiac or renal failure.

Familial amyloid polyneuropathy is caused by mutations in the gene for the plasma protein transthyretin, formerly known as prealbumin, the most frequent of which causes a methionine for valine substitution at position 30 in the mature protein, but over 60 amyloidogenic mutations have been described. There is often little correlation between the underlying mutation and the clinical phenotype, which is evidently determined by other genetic and possibly also environmental factors, although in a few cases certain mutations are uniquely associated with particularly aggressive or relatively organ-limited disease. The amyloidogenic transthyretin mutations are not always penetrant, and asymptomatic methionine 30 homozygotes over the age of 60 have been reported. Rare kindreds with the apolipoprotein A-I arginine 26 variant, which usually causes non-neuropathic amyloidosis, may present with prominent peripheral neuropathy resembling transthyretin familial amyloid polyneuropathy.

Familial amyloid polyneuropathy with predominant cranial neuropathy

Originally described in Finland but now reported in other ethnic groups, this autosomal dominant hereditary amyloidosis presents in adult life with cranial neuropathy, lattice corneal dystrophy, and distal peripheral neuropathy. There may be skin, renal, and cardiac manifestations and microscopic amyloid deposits are widely distributed in connective tissue and blood vessel walls, although life expectancy approaches normal. The amyloid fibrils are derived from variants of the actin-modulating protein gelsolin, encoded by point mutations. Individuals homozygous for these mutations have severe renal amyloidosis in addition to the usual neuropathy.

Non-neuropathic systemic amyloidosis

In this rare autosomal dominant syndrome of major systemic amyloidosis without clinical evidence of neuropathy, the patterns of organ involvement and overall clinical phenotype vary between families. The kidneys are often most severely affected leading to hypertension and renal failure, but the heart, spleen, liver, bowel, connective tissue, and exocrine glands may all be involved. Following clinical presentation, usually from the second decade onwards, there is inexorable progression to death or organ failure requiring transplantation. Clinical presentation is usually in early adulthood, although in a few kindreds it may be as late as the sixth decade. The amyloid proteins identified so far are genetic variants of apolipoprotein A-I, lysozyme, and the a-chain of fibrinogen.

Cardiac amyloidosis

Cardiac amyloidosis, without overt involvement of other viscera or neuropathy, progressing inexorably to death, is associated with certain transthyretin gene mutations and is inherited as an autosomal dominant with variable penetrance (see Table 2). By far the most common variant is isoleucine 122 transthyretin which occurs in 4 per cent of African-Americans and frequently causes cardiac amyloidosis from the sixth decade onwards.

Familial Mediterranean fever

Familial Mediterranean fever is an autosomal recessive disorder caused by mutations in the gene on chromosome 16 that encodes a neutrophil-specific protein of unknown function, called pyrin or marenostrin. The disease is characterized by recurrent episodes of fever, abdominal pain, pleurisy, or arthritis, and predominantly occurs in non-Ashkenazi Jews, Armenians, Anatolian Turks, and Levantine Arabs. In Sephardi Jews of North African origin, and in the other ethnic groups except Armenians and to a lesser extent Ashkenazi Jews, untreated familial Mediterranean fever is eventually complicated in a high proportion of cases by typical systemic AA amyloidosis. Furthermore, some patients with familial Mediterranean fever present with AA amyloidosis before they have experienced any symptoms, and this is consistent with the recent finding that a substantial acute phase plasma protein response is frequently present even in asymptomatic individuals. The different incidence of amyloid in patients with familial Mediterranean fever from different ethnic groups is not wholly explained by their specific pyrin gene mutations, and is another illustration of the unknown genetic determinants of clinical amyloidosis.

Haemodialysis-associated amyloidosis

Almost all patients with endstage renal failure who are maintained on haemodialysis for more than 5 years develop amyloid deposits composed of b $_2$-microglobulin. These deposits are predominantly osteoarticular and are associated with carpal tunnel syndrome, large joint pain and stiffness, soft tissue masses, bone cysts, and pathological fractures. Renal tubular amyloid concretions may also form. The serious clinical problems associated with b $_2$-microglobulin amyloidosis constitute the major cause of morbidity in patients on long-term dialysis. Furthermore, in some such patients more extensive deposition occurs, most commonly in the spleen but also in other organs, and a few cases of death associated with systemic b $_2$-microglobulin amyloid have been reported. The b $_2$-microglobulin is derived from the high plasma concentrations which develop in renal insufficiency and which are not cleared by dialysis. This type of amyloid also occurs in patients on continuous ambulatory peritoneal dialysis and has even been reported in a few patients with chronic renal failure who had never been dialysed.

Endocrine amyloidosis

Many tumours of APUD cells which produce peptide hormones have amyloid deposits in their stroma. These are probably composed of the hormone peptides, and in the case of medullary carcinoma of the thyroid the fibril subunits are derived from procalcitonin. In insulinomas the amyloid fibril protein is a novel peptide first identified in that site and subsequently shown to be the fibril protein in the amyloid of the islets of Langerhans in type II, maturity onset, diabetes. This peptide is called islet amyloid polypeptide (and also amylin) and shows appreciable homology with calcitonin gene-related peptide. Islet amyloid polypeptide amyloid is an almost universal feature of the pancreatic islets in type II diabetes and becomes more extensive with increasing duration and severity of the disease. Although the amyloid itself is probably not initially responsible for the metabolic defect in this form of diabetes, it is likely that progressive amyloid deposition leading to islet destruction subsequently does contribute to the pathogenesis. The possible hormonal or other role of islet amyloid polypeptide itself, which is produced by the islet B cells, is also not yet clear.

Rare localized amyloidosis syndromes

Amyloid deposits localized to the skin occur in both acquired and hereditary forms. Primary localized cutaneous amyloidosis presents in adult life as macular or papular lesions, the fibrils of which may be derived from keratin. Hereditary cutaneous amyloid lesions are rare, of unknown fibril type, and are sometimes associated with other, non-amyloid, multisystem disorders. Amyloid deposits in the eye cause local problems in the cornea (corneal lattice dystrophy) or conjunctiva, whilst orbital amyloid presents as mass lesions which can disrupt eye movement and the structure of the orbit. In one such case the fibril protein has been identified as a fragment of immunoglobulin G heavy chain.

Localized foci of AL amyloid can occur anywhere in the body in the absence of systemic AL amyloidosis, the most common sites being the skin, upper airways and respiratory tract, and the urogenital tract. They may be associated with a local plasmacytoma or B-cell lymphoma producing a monoclonal immunoglobulin, but often the cells, which must be present to produce the amyloidogenic protein, are scattered inconspicuously in the affected tissue. The clinical problems caused by these space-occupying amyloidomas are usually cured by surgical resection, but this is not always possible.

Amyloid fibrils

Regardless of their very diverse protein subunits, amyloid fibrils of different types are remarkably similar: straight, rigid, non-branching, of indeterminate length, and 10 to 15 nm in diameter. They are insoluble in physiological solutions, relatively resistant to proteolysis, and bind Congo red dye producing pathognomonic green birefringence when viewed in polarized light. Electron microscopy reveals that each fibril consists of two or more protofilaments, the precise number varying with the fibril type. The X-ray diffraction patterns of all the different *ex vivo* amyloid fibrils, and of synthetic fibrils formed *in vitro*, that have been studied demonstrate the presence of a common core structure within the filaments, in which the subunit proteins are arranged in a stack of twisted antiparallel b-pleated sheets lying with their long axes perpendicular to the long axis of the fibril. Recent observations show that many different proteins, including molecules totally unrelated to amyloidosis *in vivo*, can be refolded after denaturation *in vitro* to form typical, stable, congophilic cross b fibrils. Although it is not clear why only the 20 or so known amyloidogenic proteins adopt the amyloid fold and persist as fibrils *in vivo*, a major unifying theme that is currently emerging is that in all cases studied the precursors are relatively destabilized. Even under physiological or other conditions they may encounter *in vivo*, they populate partly unfolded states, involving loss of tertiary or higher-order structure, that readily aggregate with retention of b-sheet secondary structure into protofilaments and fibrils. Once the process has started, seeding may also play an important facilitating role, so that amyloid deposition may progress exponentially as expansion of the amyloid template 'captures' further precursor molecules.

Amyloid fibril proteins and their precursors

Immunoglobulin light chain

AL proteins are derived from the N-terminal region of monoclonal immunoglobulin light chains and consist of all or part of the variable (V $_L$) domain. Intact light chains may occasionally be found, and the molecular weight therefore varies between about 8000 and 30 000 Da. The light chain of the monoclonal paraprotein is either identical to, or clearly the precursor of, AL isolated from the amyloid deposits.

AL is more commonly derived from l chains than from _ chains, despite the fact that _ chains predominate among both normal immunoglobulins and the paraprotein products of immunocyte dyscrasias. A new l-chain subgroup, l$_{VI}$, was identified first as an AL protein in two cases of immunocyte dyscrasia-associated amyloidosis before it had been recognized in any other form, and it has subsequently been observed in many more cases of AL amyloidosis. Furthermore, there is increasing evidence from sequence analyses of Bence Jones proteins of both _ and l type from patients with AL amyloidosis, and of AL proteins themselves, that these polypeptides contain unique amino acid replacements or insertions compared with non-amyloid monoclonal light chains. In some cases these changes involve replacement of hydrophilic framework residues by hydrophobic residues, changes likely to promote aggregation and insolubilization, and in others the monoclonal light chains from amyloid patients have been demonstrated directly to have decreased solubility and a greater propensity for precipitation than control non-amyloid proteins. The inherent 'amyloidogenicity' of particular monoclonal light chains has been elegantly confirmed in an *in vivo* model in which isolated Bence Jones proteins were injected into mice. Animals receiving light chains from AL amyloid patients developed typical amyloid deposits composed of the human protein whereas

animals receiving light chains from myeloma patients without amyloid did not.

AA

The AA protein is a single non-glycosylated polypeptide chain usually of mass 8000 Da and containing 76 residues corresponding to the N-terminal portion of the 104-residue serum amyloid A protein (SAA). Smaller and larger AA fragments, even some whole SAA molecules, have also been reported in AA fibrils. Serum amyloid A is an apolipoprotein of high-density lipoprotein particles and is the polymorphic product of a set of genes located on the short arm of chromosome 11. Serum amyloid A is highly conserved in evolution and is a major acute phase reactant in all species in which it has been studied. Most of the SAA in plasma is produced by hepatocytes in which the synthesis is under transcriptional regulation by cytokines, especially interleukin 1, interleukin 6, and tumour necrosis factor, acting via nuclear factor _B-like and possibly other transcription factors. After secretion it is rapidly associated with high-density lipoproteins from which it displaces apolipoprotein A-I. The circulating concentration can rise from normal levels of up to 3 mg/l to over 1000 mg/l within 24 to 48 h of an acute stimulus, whilst with ongoing chronic inflammation the level may remain persistently high. Certain isoforms of SAA, the products of different genes, are predominantly synthesized elsewhere in the body by macrophages, adipocytes, and certain other cells. Although they also associate with high-density lipoproteins, their acute phase synthesis is stimulated differently and they presumably have different functions. There is also a closely related family of high-density lipoprotein trace apoproteins which are not acute phase reactants and which have been designated 'constitutive SAAs', although they do not form amyloid.

Circulating SAA is the precursor of amyloid fibril AA protein, from which it is derived by proteolytic cleavage. Such cleavage can be produced by macrophages and by a variety of proteinases but since further cleavage of AA is readily demonstrable *in vitro* it is not clear why the AA peptide persists in amyloid. Furthermore, it is not known whether in the process of AA fibrillogenesis, cleavage of SAA occurs before and/or after aggregation of monomers. Persistent overproduction of SAA causing sustained high circulating levels is a necessary condition for deposition of AA amyloid but it is not known why only some individuals in this state get amyloid. In mice, only SAA2, one of the three major isoforms of murine SAA, is the precursor of AA in amyloid fibrils. Human SAA isoforms are more complex but homozygosity for particular types seems to favour amyloidogenesis, although there may also be ethnic differences.

The normal functions of SAA are not known, although modulating effects on reverse cholesterol transport and on lipid functions in the microenvironment of inflammatory foci have been proposed. A protein, homologous with SAA, produced by rabbit fibroblasts has been reported to act as an autocrine stimulator of collagenase production *in vitro*. Other reports of potent cell regulatory functions of isolated denatured delipidated SAA have yet to be confirmed with physiological preparations of SAA-rich high-density lipoproteins. Regardless of its physiological role, the behaviour of SAA as an exquisitely sensitive acute phase protein with an enormous dynamic range makes it an extremely valuable empirical clinical marker. It can be used to monitor objectively the extent and activity of infective, inflammatory, necrotic, and neoplastic disease. Furthermore, routine monitoring of SAA should be an integral part of the management of all patients with AA amyloid or disorders predisposing to it, as control of the primary inflammatory process in order to reduce SAA production is essential if amyloidosis is to be halted, enabled to regress, or prevented. Automated immuno-assay systems for SAA are available standardized to a World Health Organization international reference standard.

Transthyretin

Transthyretin, formerly known as prealbumin, is a normal non-glycosylated plasma protein, with a relative molecular mass of 54 980. It is composed of four identical non-covalently associated subunits each of 127 amino acids. It is produced by hepatocytes and the choroid plexus and is a significant negative acute phase protein. Each tetrameric molecule is able to bind a single thyroxine or triodothyronine molecule and up to 15 per cent of circulating thyroid hormone is transported in this way. Transthyretin also forms a 1:1 molecular complex with retinol-binding protein, which transports vitamin A.

Transthyretin is encoded by a single copy gene but is appreciably polymorphic and about 70 different point mutations encoding single-residue substitutions have been identified so far. Normal wild type transthyretin is an inherently amyloidogenic protein which forms the fibrils in senile systemic amyloidosis, and *in vitro* exposure to reduced pH is sufficient to generate transthyretin amyloid fibrils from the pure protein. Most of the variant forms of transthyretin have been associated with hereditary amyloidosis, and show decreased stability *in vitro* compared with the wild type. Transgenic mice expressing variant human transthyretin with a methionine 30 substitution develop extensive systemic amyloidosis, but no amyloid deposits have yet been reported in the peripheral nerves even when the transgene is expressed in the choroid plexus and transthyretin amyloid is deposited in the meninges and choroid plexus. This is another example of the important, unknown, factors, other than the presence of an amyloidogenic protein itself, that determine where and when clinical amyloidosis develops.

Individuals heterozygous for transthyretin mutations have a mixture of wild type and variant transthyretin monomers in their circulating transthyretin, and if they develop amyloidosis both forms are often present although the variant may predominate in the amyloid fibrils. Although cleavage fragments of transthyretin are commonly present, intact transthyretin subunits are also found and fibrillogenesis does not depend on an initial proteolytic step.

Ab

The fibril protein in the intracerebral and cerebrovascular amyloid of Alzheimer's disease, Down's syndrome, and hereditary amyloid angiopathy of the Dutch type is a 39- to 43-residue sequence derived by proteolysis from a high molecular weight precursor protein, the so-called amyloid precursor protein, encoded on the long arm of chromosome 21. Several isoforms of amyloid precursor protein (APP) are generated by alternative splicing of transcripts from the 19 exon gene, and yielding major forms: APP695, APP751, and APP770. These are each single-chain, multidomain glycoproteins with the 47 residues of the carboxy terminal within the cytoplasm, a 25-residue membrane-spanning region, and the rest of the molecule lying extracellularly. APP751 and APP770 contain a 56-residue Kunitz type serine proteinase inhibitor domain encoded by exon 7. Following glycosylation and membrane insertion, APPs are cleaved extracellularly by so-called APP secretase activity, close to the transmembrane sequence, releasing, in the case of the isoforms containing the proteinase inhibitor domain, a molecule known as proteinase nexin II, which avidly binds factor XIa, trypsin, and chymotrypsin as well as epidermal growth factor-binding protein and the g subunit of nerve growth factor. Although mRNA encoding APP695, which lacks the proteinase inhibitor domain, is the predominant species found in brain, whereas mRNA for APP751 is the most abundant in other tissues, 85 per cent of secreted APP in the brain is proteinase nexin II. Interestingly, APP secreted by a glial cell line is substantially glycosylated with chondroitin sulphate glycosaminoglycan chains. APP also undergoes high-affinity interactions with heparan sulphate. These observations suggest that APP may have important functions in cell adhesion, cell migration, and modulation of growth factor activities. APP proteinase nexin II is present in and released by platelets and probably functions in the clotting cascade.

The amyloidogenic amyloid b, encoded by parts of exons 16 and 17, corresponds to the part of the APP sequence which extends from within the cell membrane into the extracellular space. Secretase cleavage of APP to release the soluble form cannot therefore generate intact amyloid b itself, or larger fragments containing it. However, there is an alternative processing pathway for APP, in which it is taken up whole by lysosomes and cleaved to yield fragments that do contain the whole amyloid b sequence. Furthermore, APP cleaved at the *N*-terminus of amyloid b, and also free soluble amyloid b itself, are normally produced by cell lines and by mixed brain cells in culture and are present in the cerebrospinal fluid. However, the source of the amyloid b in the intracerebral amorphous deposits and of that which aggregates as amyloid fibrils in the brain and cerebral blood vessels is still not known. The 42-residue form of amyloid b is markedly the most amyloidogenic, and all the mutations in the APP and presenilin genes that are associated with hereditary Alzheimer's disease result in increased production of this amyloid b1–42. Increased availability of the precursor is thus responsible for amyloidogenesis, but the pathogenesis of neuronal damage and dementia remain unclear.

Cystatin C

Cystatin C (formerly called g-trace) is an inhibitor of cysteine proteinases, including cathepsins B, H, and L. It is encoded by a gene on chromosome 20 and consists of a single non-glycosylated polypeptide chain of 120 residues. It is present in all major human biological fluids at concentrations compatible with a significant physiological role in proteinase inhibition. The normal concentration in cerebrospinal fluid is 6.5 mg/l (range 2.7 to 13.7, $n = 34$), but is much lower (2.7 mg/l, range 1.0 to 4.7, $n = 9$) in patients with the Icelandic type of hereditary cerebral amyloid angiopathy in whom fragments of the glutamine 68 genetic variant of cystatin C form the amyloid fibrils. This reduced concentration is useful diagnostically and is evident even in presymptomatic carriers of the cystatin C gene mutation. The point mutation that causes the disease encodes a glutamine for leucine substitution in the mature protein and the amyloid fibril protein consists of the C-terminal 110 residues of the variant. This amino-terminally truncated form is not detectable in the cerebrospinal fluid of affected patients, suggesting that cleavage takes place either in close proximity to fibril deposition or is a postfibrillogenic event. The variant cystatin C is less stable than wild type and readily forms fibrils *in vitro*. It is not known whether cerebral haemorrhage in cystatin C amyloidosis is caused simply by the damaging effects of vascular amyloid deposition or whether deficiency in inhibitory capacity for cysteinase proteinases also plays a part.

Gelsolin

Gelsolin (mass 90 000 Da) is a widely distributed cytoplasmic protein which binds actin monomers, nucleates actin filament growth, and severs actin filaments. Alternative transcriptional initiation and message processing from a single gene on chromosome 9 are responsible for synthesis of a secreted form of gelsolin (mass 93 000 Da), which circulates in the plasma at a concentration of about 200 mg/l. Its function in the blood is not known but may be related to clearance of actin filaments released by dying cells. In the Finnish type of hereditary amyloidosis the amyloid fibril protein is a 71-residue fragment of variant gelsolin with asparagine substituted for aspartic acid at position 15, corresponding to residue 187 of the mature molecule, and the same mutation has been discovered in affected kindreds from different ethnic backgrounds. In one Danish family with the same phenotype there is a different mutation at the same nucleotide, predicting a tyrosine for aspartic acid substitution at residue 187. Synthetic and recombinant peptides including the asparagine for aspartic acid substitution at residue 187 are less soluble than the wild type sequence and readily form amyloid fibrils *in vitro*.

Apolipoprotein A-I

Apolipoprotein A-I is the most abundant apolipoprotein amongst the high-density lipoprotein particles and participates in their central function of reverse cholesterol transport from the periphery to the liver. Apolipoprotein A-I variants are extremely rare and may be phenotypically silent or may affect lipid metabolism. However, nine different variants of apolipoprotein A-I, including single- and multiple-residue substitutions and deletions, have been associated with amyloidosis. Although inherited as an autosomal dominant, and usually highly penetrant, there are marked variations in age and manner of presentation even in the same family and in different kindreds with the same mutation. The amyloid fibril protein consists, in all cases studied, of the first 90 or so N-terminal residues even when the causative variant residue(s) are more distal. Wild type apolipoprotein A-I is also amyloidogenic, forming the deposits associated with atheromatous plaques in the elderly, and the various amyloidogenic mutations presumably encode sequence changes that render apolipoprotein A-I less stable and/or more liable to cleavage to yield the fibrillogenic N-terminal fragment.

Lysozyme

Lysozyme is the classic bacteriolytic enzyme of external secretions, discovered by Fleming in 1922. It is also present at high concentration within articular cartilage and in the granules of polymorphs, and is the major secreted product of macrophages. Lysozymes are present in most organisms in which they have been sought, although their physiological role is not always clear. The complete structures of hen egg white and human lysozymes are known to atomic resolution and their catalytic mechanism, epitopes, folding, and other aspects of their structure–function relationship have been analysed exhaustively. This contrasts with the absence of detailed three-dimensional structural information on all other amyloid fibril proteins and their precursors except transthyretin and b $_2$-microglobulin. Lysozyme, unlike transthyretin and b_2-microglobulin, is not inherently amyloidogenic, and is therefore a valuable model for investigation of amyloid fibrillogenesis. There is only one copy of the lysozyme gene in the human genome and no disease is associated with lysozyme other than amyloidosis. The mutations which cause amyloid produce substitution of threonine for isoleucine at residue 56 in one family and histidine for aspartic acid at residue 67 in others. These dramatic changes in residues which are extremely conserved throughout the lysozyme and related a-lactal-bumin protein families, destabilize the native fold so that the variants readily populate partly unfolded states even under physiological conditions and spontaneously aggregate *in vitro*, and evidently also *in vivo*, into amyloid fibrils.

Islet amyloid polypeptide

Islet amyloid polypeptide (amylin) is a 37-residue molecule encoded by a gene on chromosome 12 and with 46 per cent sequence homology to the neuropeptide calcitonin gene-related peptide. Islet amyloid polypeptide is produced in the b cells of the pancreatic islets of Langerhans and is stored in and released from their secretory granules together with insulin. It has been reported to modulate insulin release, and to induce peripheral insulin resistance, vasodilatation, and lowering of plasma calcium but neither its physiological role nor its contribution to diabetes are yet known.

Amyloidogenicity of islet amyloid polypeptide depends on the amino acid sequence between residues 20 and 29, as shown by *in vitro* fibrillogenesis with synthetic peptides. The synthetic decapeptide IAPP20–29 and even the hexapeptide IAPP25–29, glycine–alanine–isoleucine–leucine–serine–serine, form amyloid-like fibrils *in vitro*, whereas other islet amyloid polypeptide fragments do not. There is also a correlation between conservation of this sequence and deposition of islet amyloid polypeptide amyloid in the islets of diabetic animals of different species. However, the role of the amyloid in diabetogenesis remains to be established. In the degu, a South American rodent, spontaneous diabetes is associated with islet amyloid composed of insulin, and xenogeneic insulin can also form amyloid in humans at sites of repeated therapeutic insulin injections.

b_2-Microglobulin

b_2-Microglobulin is a non-glycosylated, non-polymorphic single-chain protein of 99 residues with a single intrachain disulphide bridge (relative molecular mass 11 815) encoded by a single gene on chromosome 15. It becomes non-covalently associated with the heavy chain of major histocompatibility class I antigens and is required for transport and expression of the complex at the cell surface. Amino acid sequence homology places b $_2$-microglobulin in the superfamily including immunoglobulins, T-cell receptor a- and b-chains, Thy 1, major histocompatibility class I and II molecules, secretory component, etc. Its three-dimensional structure is a typical b-barrel with two antiparallel pleated sheets comprising three and four strands respectively, and closely resembles an immunoglobulin domain.

b_2-microglobulin is produced by lymphoid and a variety of other cells in which it stabilizes the structure and function of class I antigens at the cell surface. When these complexes are shed by cleavage of the heavy chain at the cell surface, free b $_2$-microglobulin is released. The circulating concentration of b $_2$-microglobulin is 1 to 2 mg/l and the protein is rapidly cleared by glomerular filtration and then catabolized in the proximal renal tubule. Impairment of renal function is associated with retention of b_2-microglobulin and increased circulating levels because there is no other site for its catabolism. Daily production of b $_2$-microglobulin is about 200 mg and in patients in endstage renal failure on haemodialysis, plasma b $_2$-microglobulin levels rise to and remain at levels of about 40 to 70 mg/l. Isolated unaltered b_2-microglobulin can form amyloid-like fibrils itself *in vitro*, and most studies of *ex vivo* b_2-microglobulin fibrils show the whole intact molecule to be the major subunit, although fragments and altered forms of b $_2$-microglobulin have also been reported.

Glycosaminoglycans

Amyloidotic organs contain more glycosaminoglycans than normal tissues and at least some of this is a tightly bound integral part of the amyloid fibrils. These fibril-associated glycosaminoglycans are heparan sulphate and dermatan sulphate in all forms of amyloid which have been investigated. Fibrils isolated by water extraction and separated from other tissue components contain 1 to 2 per cent by weight of glycosaminoglycan, none of which is covalently associated with the fibril protein. Interestingly, in systemic AA and AL amyloidosis, the only forms in which this has been studied so far, there is marked restriction of the heterogeneity of the glycosaminoglycan chains, suggesting that particular subclasses of heparan and dermatan sulphates are involved. Immunohistochemical studies demonstrate the presence of proteoglycan core proteins in all amyloid deposits, and that these are closely related to fibrils at the ultrastructural level. However, in isolated fibril preparations much of the glycosaminoglycan material is free carbohydrate chains and it is not yet clear whether this represents aberrant glycosaminoglycan metabolism related to amyloidosis or is just an artefact of postmortem degradation of core protein.

The significance of glycosaminoglycans in amyloid remains unclear, but their universal presence, intimate relationship with the fibrils, and restricted heterogeneity all suggest that they may be important. Glycosaminoglycans are known to participate in the organization of some normal structural proteins into fibrils and they may have comparable fibrillogenic effects on certain amyloid fibril precursor proteins. Furthermore the glycosaminoglycans on amyloid fibrils may be ligands to which serum amyloid P component, another universal constituent of amyloid deposits, binds.

Amyloid P component and serum amyloid P component

Amyloid deposits in all different forms of the disease, both in humans and in animals, contain the non-fibrillar glycoprotein amyloid P component. Amyloid P component is identical to and derived from the normal circulating plasma protein, serum amyloid P component, a member of the pentraxin protein family which includes C-reactive protein. Human serum amyloid P component is secreted only by hepatocytes, is a trace constituent of plasma (women: mean 24 mg/l, SD 8, range 8 to 55, n = 274; men: mean 32 mg/l, SD 7, range 12 to 50, n = 226), and is not an acute phase reactant. Nevertheless, apart from the fibrils themselves, amyloid P component is always by far the most abundant protein in all amyloid deposits.

Serum amyloid P component consists of five identical non-covalently associated subunits, each with a molecular mass of 25 462 Da, which are non-covalently

associated in a pentameric disc-like ring. The tertiary fold of the subunit is dominated by antiparallel b-sheets, forming a flattened b-barrel with jellyroll topology and a core of hydrophobic sidechains. This is the so-called 'lectin fold', shared with a variety of other animal, plant, and bacterial carbohydrate-binding proteins (lectins). Serum amyloid P component is a calcium-dependent ligand-binding protein, the best defined specificity of which is for the 4,6-cyclic pyruvate acetal of b- D-galactose, but it also binds avidly and specifically to DNA, to chromatin, to glycosaminoglycans, particularly heparan and dermatan sulphates, and to all known types of amyloid fibrils. This last is the interaction responsible for the unique, specific accumulation of serum amyloid P component in amyloid deposits. Aggregated, but not native, serum amyloid P component also binds specifically to C4-binding protein and fibronectin from plasma, although serum amyloid P component is not complexed with any other protein in the circulation. In addition to being a plasma protein, serum amyloid P component is also a normal constituent of certain extracellular matrix structures. It is covalently associated with collagen and/or other matrix components in the lamina rara interna of the human glomerular basement membrane and is present on the microfibrillar mantle of elastin fibres throughout the body.

No deficiency of serum amyloid P component has been described and it has been stably conserved in evolution. There is a single copy of its gene on chromosome 1, no polymorphism of the amino acid sequence, and the single biantennary oligosaccharide chain attached to asparagine at residue 32 is the most invariant glycan of any known glycoprotein. These indications that serum amyloid P component is likely to have important physiological function(s) have lately been confirmed by the finding that mice with targeted deletion of the gene for serum amyloid P component spontaneously develop marked antinuclear autoimmunity and immune complex glomerulonephritis. Studies of these serum amyloid P component knockout mice also show that serum amyloid P component is involved in host resistance to some infections and contributes to pathogenesis of others.

The serum amyloid P component molecule is highly resistant to proteolysis and, although not itself a proteinase inhibitor, its binding to amyloid fibrils *in vitro* protects them against proteolysis. Once bound to amyloid fibrils *in vivo*, serum amyloid P component persists for very prolonged periods and is not catabolized at all, in contrast to its rapid clearance from the plasma (half-life 24 h) and prompt catabolism in the liver. These observations suggest that serum amyloid P component may contribute to the persistence of amyloid deposits *in vivo*, and indeed serum amyloid P component knockout mice show retarded and reduced induction of experimental AA amyloidosis, confirming that serum amyloid P component is significantly involved in pathogenesis of amyloidosis.

Other proteins in amyloid deposits

A number of plasma proteins, other than the fibril proteins themselves and serum amyloid P component, have been detected immunohistochemically in some amyloid deposits. These include a_1-antichymotrypsin, some complement components, apolipoprotein E, and various extracellular matrix or basement membrane proteins. None of these match the universality, quantitative, or selective importance of serum amyloid P component, and their role, if any, in pathogenesis of amyloid deposition or its effects is not known.

Diagnosis and monitoring of amyloidosis

Introduction

Until recently amyloidosis was an exclusively histological diagnosis, and green birefringence of deposits stained with Congo red and viewed in polarized light remains the gold standard. Furthermore, immunohistochemical staining of amyloid-containing tissue is the simplest method for identifying the type of amyloid fibril present. However, biopsies provide extremely small samples and therefore can never provide information on the extent, localization, progression, or regression of amyloid deposits. A major advance in clinical amyloidosis has been the development of radiolabelled serum amyloid P component as a specific tracer for amyloid. Combined scintigraphic imaging and metabolic analysis using labelled serum amyloid P component have provided a wealth of new information on the natural history of many different forms of amyloid and their response to treatment.

Histochemical diagnosis of amyloid

Biopsy

Amyloid may be an incidental finding on biopsy of the kidneys, liver, heart, bowel, peripheral nerve, lymph node, skin, thyroid, or bone marrow. When amyloidosis is suspected clinically, biopsy of the rectum or subcutaneous fat is the least invasive. Amyloid is present in these sites in more than 90 per cent of cases of systemic AA or AL amyloidosis. Alternatively, a clinically affected tissue may be biopsied directly.

Congo red and other histochemical stains

Many cotton dyes, fluorochromes, and metachromatic stains have been used, but Congo red staining, and its resultant green birefringence when viewed with high-intensity polarized light, is the pathognomonic histochemical test for amyloidosis. The stain is unstable and must be freshly prepared every 2 months or less. A section thickness of 5 to 10 µm and inclusion in every staining run of a positive control tissue containing modest amounts of amyloid are critical.

Immunohistochemistry

Although many amyloid fibril proteins can be identified immunohistochemically, the demonstration of amyloidogenic proteins in tissues does not, on its own, establish the presence of amyloid. Congo red staining and green birefringence are always required and immunostaining may then enable the amyloid to be classified. Antibodies to serum amyloid A protein are commercially available and always stain AA deposits, similarly with anti-b $_2$-microglobulin antisera and haemodialysis-associated amyloid. In AL amyloid the deposits are stainable with standard antisera to _ or l in only about half of all cases, probably because the light chain fragment in the fibrils is usually the N-terminal variable domain, which is largely unique for each monoclonal protein. Immunohistochemical staining of transthyretin, Ab, and prion protein amyloid may require pretreatment of sections with formic acid or alkaline guanidine or deglycosylation.

Electron microscopy

Amyloid fibrils cannot always be convincingly identified ultrastructurally, and electron microscopy alone is not sufficient to confirm the diagnosis of amyloidosis.

Problems of histological diagnosis

The tissue sample must be adequate (for example, the inclusion of submucosal vessels in a rectal biopsy specimen), and failure to find amyloid does not exclude the diagnosis. The unavoidable sampling problem means that biopsy cannot reveal the extent or distribution of amyloid. Experience with Congo red staining is required if clinically important false negative and false positive results are to be avoided. Immunohistochemical staining requires positive and negative controls, including demonstration of specificity of staining by absorption of positive antisera with isolated pure antigens.

Non-histological investigations

Two-dimensional echocardiography showing small, concentrically hypertrophied ventricles, generally impaired contraction, dilated atria, homogeneously echogenic valves, and 'sparkling' echodensity of ventricular walls is virtually diagnostic of cardiac amyloidosis. However, clinically significant restrictive diastolic impairment may be difficult to detect even by comprehensive Doppler and other functional studies. Imaging after injection of isotope-labelled calcium-seeking tracers has poor sensitivity and specificity and is of no clinical use.

In cases of known or suspected hereditary amyloidosis the gene defect must be characterized. If amyloidotic tissue is available the fibril protein may be known and the corresponding gene can then be studied, but if no tissue containing amyloid is available, screening of the genes for known amyloidogenic proteins must be undertaken.

Biochemical and immunochemical screening tests for the presence in the plasma of amyloidogenic variant protein products of mutant genes also exist, for example for transthyretin and apolipoprotein A-I variants, but molecular genetic analysis of DNA is easier to perform and is the most direct approach. However, regardless of the DNA results, it is desirable, if possible, to also directly identify the respective protein in the amyloid.

Serum amyloid P component as a specific tracer in amyloidosis

The universal presence in amyloid deposits of amyloid P component, derived from circulating serum amyloid P component, is the basis for use of radioisotope-labelled serum amyloid P component as a diagnostic tracer in amyloidosis. No localization or retention of labelled serum amyloid P component occurs in healthy subjects or in patients with diseases other than amyloidosis (Fig. 1(a)). Radio-iodinated serum amyloid P component has a short half-life (24) in the plasma and is rapidly catabolized with complete excretion of the iodinated breakdown products in the urine. However, in patients with systemic or localized extracerebral amyloidosis, the tracer rapidly and specifically localizes to the deposits, in proportion to the quantity of amyloid present, and persists there without breakdown or modification (Fig. 1(b), Fig. 1(c)). For clinical purposes, highly purified serum amyloid P component is isolated from the plasma of single accredited donors and is oxidatively iodinated under conditions that preserve its function intact. The medium-energy, short half-life, pure gamma emitter ^{123}I is used for scintigraphic imaging, and the long half-life isotope ^{125}I is used for metabolic studies. The dose of radioactivity administered (less than 4 mSv) is well within accepted safety limits and more than 3000 studies have been completed without any adverse effects. In addition to high-resolution scintigraphs, the uptake of tracer into various organs can be precisely quantified and, together with highly reproducible metabolic data on the plasma clearance and whole body retention of activity, the progression or regression of amyloid can be monitored serially and quantitatively.

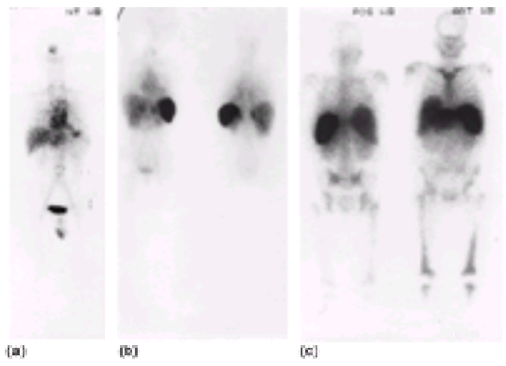

Fig. 1 Whole body scintigraphs 24 h after intravenous injection of ^{123}I-labelled human serum amyloid P component. (a) Anterior view of a normal control subject showing the distribution of residual tracer in the blood pool and radioactive breakdown products in urine in the bladder; note the absence of localization or retention of tracer anywhere in the body. (b) Posterior (left) and anterior (right) views of a patient with juvenile chronic arthritis complicated by AA amyloidosis. There is uptake of tracer in the spleen, kidneys, and adrenal glands, a typical distribution of AA amyloid in which the spleen is involved in 100 per cent of cases, kidneys in 75 per cent, and adrenals in 40 per cent. Note the reduced blood pool and bladder signal compared with (a). This patient, whose amyloid was diagnosed by renal biopsy 15 years ago when nephrotic syndrome developed, and who was then treated with chlorambucil, had been in complete remission for 10 years during which there had been no acute phase response. At the time of this scan there was no biochemical abnormality in blood or urine, despite the very appreciable amyloid deposits, illustrating the discordance between the presence of amyloid and clinical effects. (c) Posterior (left) and anterior (right) views of a patient with monoclonal gammopathy complicated by extensive AL amyloidosis. There is uptake and retention of tracer in the liver, spleen, kidneys, bone marrow, and soft tissues around the shoulder. This scintigraphic pattern of amyloid distribution is pathognomonic for AL amyloidosis; bone marrow uptake has not been seen in any other type. Note the complete absence of blood pool or bladder signal resulting from complete uptake of the tracer dose into the substantial amyloid deposits.

Important observations regarding amyloid (which have been made for the first time *in vivo*) include the following: the different distribution of amyloid in different forms of the disease; amyloid in anatomical sites not available for biopsy (adrenals, spleen); major systemic deposits in forms of amyloid previously thought to be organ-limited; a poor correlation between the quantity of amyloid present in a given organ and the level of organ dysfunction; a non-homogeneous distribution of amyloid within individual organs; and evidence for rapid progression and sometimes regression of amyloid deposits with different rates in different organs (Fig. 2). Examples of major regression of amyloidosis, when it has been possible to reduce or eliminate the supply of fibril precursor, are very encouraging. Studies with labelled serum amyloid P component thus make a valuable contribution to the diagnosis and management of patients with systemic amyloidosis, and these are available routinely for all known or suspected cases of amyloidosis in the National Health Service National Amyloidosis Centre at the Royal Free Hospital, London.

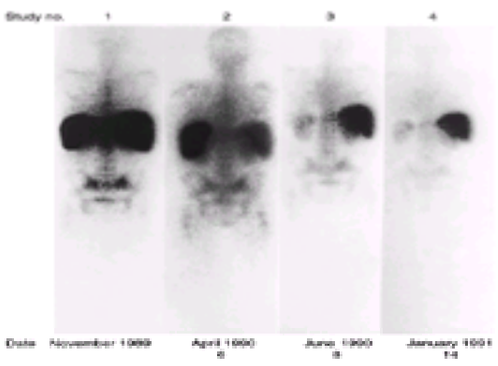

Fig. 2 Serial posterior whole body ^{123}I-serum amyloid P component scintigraphs of a man with AL amyloidosis complicating benign monoclonal gammopathy. At presentation, scan 1, there was uptake in the spleen, liver, and bone marrow, obscuring any possible renal signal. Chemotherapy was given before the second scan, which shows increased spleen uptake, reduced liver uptake, and some renal uptake, but no change in total amyloid load determined by measurements of the clearance and retention of the tracer (not shown). Subsequently he suffered from recurrent splenic infarction and splenectomy was performed. Thereafter, in scan 3, there was increased tracer uptake in liver, although a notably lower total amyloid load. Six months later, in scan 4, liver and kidney uptake, plasma clearance, and whole body retention of tracer were all reduced, indicating regression of amyloid. Clinically he was much improved and still remains well.

Management of amyloidosis

Although no treatments yet exist that specifically promote the mobilization of amyloid, there have been substantial recent advances in the management of systemic amyloidosis, in particular active measures to support failing organ function whilst attempts are made to reduce the supply of the amyloid fibril precursor protein. Serial serum amyloid P component scintigraphy in more than 1000 patients with various forms of amyloid has confirmed that control of the primary disease process, or removal of the source of the amyloidogenic precursor, usually results in regression of existing deposits and recovery or preservation of organ function. This strongly supports aggressive intervention, and relatively toxic drug regimes or other radical approaches can be justified by the poor prognosis. Such an approach, leading to reduced morbidity and improved survival, was the basis for the establishment of the National Health Service National Amyloid Centre. However, clinical improvement in amyloidosis is often delayed long after the underlying disorder has remitted, reflecting the very gradual regression of the deposits that is now recognized to occur in most patients. Continuing production of the amyloid precursor protein should be monitored as closely as possible long term, to determine the requirement for and intensity of treatment for the underlying primary condition. In AA amyloidosis this involves frequent estimation of the plasma SAA level, and in AL amyloidosis requires monitoring of proliferation of monoclonal plasma cells and immunoglobulin light chain production.

The treatment of AA amyloidosis ranges from potent anti-inflammatory and immunosuppressive drugs in patients with rheumatoid arthritis, to life-long prophylactic colchicine in familial Mediterranean fever, and surgery in conditions such as refractory osteomyelitis and the tumours of Castleman's disease. The alkylating agent chlorambucil can induce rapid and complete remission of inflammatory activity in many patients with rheumatoid and juvenile chronic arthritis, but its use must be considered very carefully since it is not licensed for this indication, it is potentially carcinogenic, and it causes infertility.

Treatment of AL amyloidosis is based on that for myeloma, although the plasma cell dyscrasias in AL amyloidosis are often very subtle. Prolonged low-intensity

cytotoxic regimes such as oral melphalan and prednisolone are beneficial in about 20 per cent of patients. Dose-intensive infusional chemotherapy regimes such as vincristine, doxorubicin (Adriamycin), and dexamethasone ('VAD'), and autologous peripheral blood stem cell transplantation are currently being evaluated with far more promising early results. However, very rigorous patient selection for transplantation is essential as the procedural mortality is high in individuals with multiple amyloidotic organ involvement, especially patients with autonomic neuropathy, severe cardiac amyloidosis, or a history of gastrointestinal bleeding, and in those aged over 55 years.

The disabling arthralgia of b_2-microglobulin amyloidosis may respond partially to non-steroidal anti-inflammatory drugs or corticosteroids, but even the most severe symptoms usually vanish rapidly following renal transplantation. The basis for this remarkable clinical response is unclear since although transplantation rapidly restores normal b_2-microglobulin metabolism, regression of b_2-microglobulin amyloid may not be evident for many years.

Hepatic transplantation is effective in familial amyloid polyneuropathy associated with transthyretin gene mutations since the variant amyloidogenic protein is produced mainly in the liver. Successful liver transplantation has now been reported in hundreds of patients with this condition and although the peripheral neuropathy usually only stabilizes, autonomic function can improve substantially and the associated visceral amyloid deposits have been shown to regress in most cases. Important questions remain about the timing of the procedure but, so far, early intervention seems advisable.

Supportive therapy remains critical in systemic amyloidosis, with the potential for delaying target organ failure, maintaining quality of life, and prolonging survival whilst the underlying process can be treated. Rigorous control of hypertension is vital in renal amyloidosis. Surgical resection of amyloidotic tissue is occasionally beneficial but, in general, a conservative approach to surgery, anaesthesia, and other invasive procedures is advisable. Should any such procedure be undertaken, meticulous attention to blood pressure and fluid balance is essential. Amyloidotic tissues may heal poorly and are liable to bleed. Diuretics and vasoactive drugs should be used cautiously in cardiac amyloidosis because they can reduce cardiac output substantially. Dysrhythmias may respond to conventional pharmacological therapy or to pacing. Replacement of vital organ function, notably dialysis, may be necessary and cardiac, renal, and liver transplant procedures have a role in selected cases.

Finally, a number of different therapies aimed specifically at inhibiting the formation of amyloid fibrils or promoting fibril regression are currently under development and will be evaluated clinically within the next few years. These approaches, directed at the generation of precursor proteins, the protein folding process, formed fibrils, glycosaminglycans, and serum amyloid P component, offer hope that in future amyloidosis may become a treatable condition.

11.13 a_1-Antitrypsin deficiency and the serpinopathies

David A. Lomas

Introduction

People of European descent are susceptible to disease arising from a genetic deficiency of the plasma protein a $_1$-antitrypsin. This is a 394 amino-acid, 52-kDa, acute-phase glycoprotein synthesized by the liver and macrophages and present in the plasma at a concentration of between 1.5 and 3.5 g/l. It functions as an inhibitor of a range of proteolytic enzymes but its primary role is to inhibit the enzyme neutrophil elastase. Activated neutrophil leucocytes release elastase to break down connective tissue at sites of inflammation. This breakdown is limited by the antielastase activity of a $_1$-antitrypsin, but if the plasma concentration of this protein falls below 40 per cent then unimpeded tissue destruction may ensue.

Genetic deficiency

a_1-Antitrypsin is subject to genetic variation resulting from mutations in the 12.2-kilobase (**kb**), 7-exon gene on the long arm of chromosome 14. Over 90 allelic variants have been reported and classified using the **Pi** (protease inhibitor) nomenclature that assesses a $_1$-antitrypsin mobility in isoelectric focusing analysis. Normal a_1-antitrypsin migrates in the middle (M) and variants are designated *A* to *L* if they migrate faster than M, and *N* to *Z* if they migrate more slowly. Many of these variants have been sequenced at the DNA level and shown to result from point mutations in the a $_1$-antitrypsin gene. For example, the *Z* allele results from the substitution of a positively charged lysine for a negative glutamic acid at position 342. The *S* allele results from the substitution of a neutral valine for a glutamic acid at position 264. It is clear that such mutations alter the overall charge of the protein and explain the changes in mobility seen on isoelectric focusing. Point mutations are inherited by simple Mendelian trait; the normal genotype is designated *PiMM* or *PiM*, a heterozygote for the *Z* gene is *PiMZ*, and a homozygote is *PiZZ* or *PiZ*.

The most clinically relevant variants are the *S* and *Z* alleles and the uncommon *Null* (non-production) gene. Approximately 8 per cent of people of Northern European descent are heterozygotes for the *S* variant (*PiMS*), although this can be as high as 28 per cent in parts of Southern Europe. The *Z* variant is less common and is found in 4 per cent of Northern Europeans (*PiMZ*), with 1 in 1700 being homozygotes (*PiZ*). a_1-Antitrypsin alleles are co-dominantly expressed, with each allele contributing to the plasma level of protein. Moreover, each of the deficiency alleles results in a characteristic decrease in the plasma concentration of a $_1$-antitrypsin; the *S* variant forms 60 per cent of the normal *M* concentration and the *Z* variant 10 to 15 per cent. Thus combinations of alleles have predictable effects, the *MZ* heterozygote has an a_1-antitrypsin plasma level of 60 per cent (50 per cent from the normal *M* allele and 10 per cent from the *Z* allele), the *MS* heterozygote 80 per cent, and the *SZ* heterozygote 40 per cent.

Molecular basis of a_1-antitrypsin deficiency

a_1-Antitrypsin functions by presenting its reactive-centre methionine residue on an exposed loop of the molecule such that it forms an ideal substrate for the enzyme neutrophil elastase (Fig. 1). The exact fit between enzyme and inhibitor causes them to form a tightly bound 1:1 complex that inhibits the enzyme and allows it to be eliminated from sites of inflammation. The *Z* mutation (342glutamic acid®lysine) results in normal translation of the gene, but 85 per cent of the *Z* a_1-antitrypsin is retained within the endoplasmic reticulum with only 10 to 15 per cent entering the circulation. The *Z* mutation distorts the relationship between the loop and the b-pleated A sheet that forms the major feature of the molecule (Fig. 1(a)). The consequent perturbation in structure allows the reactive-centre loop of one a $_1$-molecule to lock into the A sheet of a second (Fig. 1(b)) to form a dimer which then extends to form chains of loop-sheet polymers (Fig. 1(c)). The formation of these polymers is temperature- and concentration-dependent and is localized in the endoplasmic reticulum of the hepatocyte. These chains of polymers become interwoven to form the insoluble aggregates that are the hallmark of a $_1$-antitrypsin liver disease (Fig. 2 and Plate 1). *S* a_1-antitrypsin (342glutamic acid®lysine) and the rare *I* variant (39arginine®cysteine) also result in the formation of polymers but at a much slower rate than *Z*. Therefore these variants do not accumulate in the liver and cause only mild plasma deficiency.

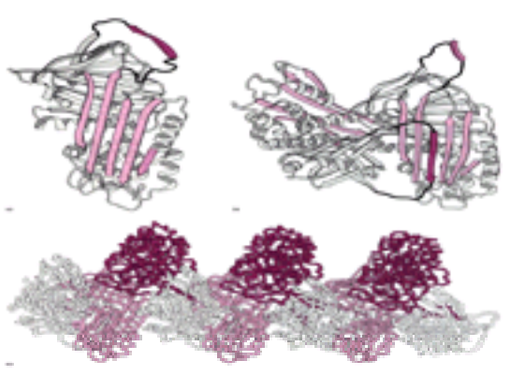

Fig. 1 The crystal structure of a $_1$-antitrypsin shows the reactive-centre loop (purple) held at the apex of the protein as a b-strand depicted as an arrow (a) The *Z* mutation opens the b-sheet A (pink) to allow the reactive loop of another molecule to insert to form a dimer (b) which can then extend to form long chains of polymers (c). In (c) white, pink, and purple represent different a $_1$-antitrypsin molecules linked together to form a polymer. (Figure prepared by Dr T. Dafforn, Cambridge Institute for Medical Research, and reproduced from *Nature Structure Biology* with permission.)

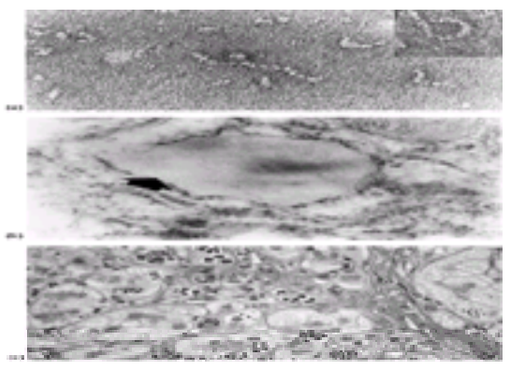

Fig. 2 (a) Electron microscopy of a chain of loop-sheet polymers isolated from a patient with a $_1$-antitrypsin deficiency. These polymers can form filaments or circlets

(inset) that tangle within the endoplasmic reticulum of the hepatocyte (b) to form the inclusions (arrowed) which are the hallmark of the disease. These intrahepatic inclusions are characteristically Periodic acid–Schiff (**PAS**)-positive and diastase-resistant (c) (see also Plate 1) and stain positive for a_1-antitrypsin on immunohistochemistry. ((a) and (b) reproduced from the *Journal of Biological Chemistry* and *Nature*, respectively, with permission.)

Clinical features

a_1-Antitrypsin deficiency and emphysema

The association between a_1-antitrypsin deficiency and the development of premature panlobular emphysema was first described by Laurell and Eriksson in 1963. Patients usually present with increasing dyspnoea and weight loss, with cor pulmonale and polycythaemia occurring late in the course of the disease. Chest radiographs typically show bilateral basal emphysema with paucity and pruning of the basal pulmonary vessels. Upper lobe vascularization is relatively normal. Ventilation–perfusion radioisotope scans and angiography also show abnormalities with a lower zone distribution. High-resolution computed tomography scans with 1 to 2 mm collimation are the most accurate method of assessing the distribution of panlobular emphysema and for monitoring the progress of the pulmonary disease, although this currently has little value outside clinical trials. Lung function tests are typical for emphysema with a reduced **FEV1/FVC** ratio (forced expiratory volume in 1 second/forced vital capacity), gas trapping (raised residual volume/total lung capacity ratio), and a low gas-transfer factor.

The association of a_1-antitrypsin with the development of premature emphysema has led to the wider conclusion that emphysema results from an imbalance between proteases and antiproteases within the lung. Undoubtedly the situation is more complex than a simple balance between elastase and a_1-antitrypsin, both in terms of the numbers of enzymes and inhibitors involved and the contribution of other mechanisms. Nevertheless, the elastase and a_1-antitrypsin balance clearly illustrates the processes involved in the development of emphysema and the interplay between the environmental and genetic factors that determine its onset.

Decline in lung function in individuals with a_1-antitrypsin deficiency

As with other tissues, there is a decline in the elasticity of the lungs with increasing age. Clinically, the most convenient measure of lung function is the FEV_1, which is approximately 3500 ml in young adults. After the age of 30 years in healthy non-smokers, the FEV_1 decreases by 35 ml/year, although there is considerable individual variation. By old age, most people will have an appreciable loss of lung function, but only occasionally in the non-smoker will this be clinically apparent. The assessment of symptomatic hospital patients has shown that the loss of FEV_1 may be accelerated to 80 ml/year in a *Z* a_1-antitrypsin homozygote. As a consequence there is a hastened but still variable onset of emphysema. In this study *PiZ* non-smokers were free from dyspnoea up to the age of 50 years, with the average age of death from respiratory disease being 67 years. Again there was considerable individual variation and, particularly in women, there was a good likelihood of a full lifespan without significant respiratory impairment. The outlook, however, was poor for the *PiZ* a_1-antitrypsin homozygote who was a heavy smoker, as the loss in FEV_1 increased to 300 ml/year. The onset of dyspnoea was approximately 30 years, with death from respiratory disease by the age of 50 years. More recently the Swedish, Danish, and NIH registries have reported a more favourable outcome. These registries include individuals identified by screening and family studies and are more representative of the disease process. They show a slower rate of decline in lung function in *PiZ* homozygotes who are non- or ex-smokers (approximately 50 ml/year). However, the studies reinforce the accelerated rate of decline in lung function in *PiZ* homozygotes who continue to smoke (70–132 ml/year).

a_1-Antitrypsin deficiency and liver disease

Z a_1-antitrypsin liver disease is characterized by the accumulation of diastase-resistant, Periodic acid–Schiff (**PAS**)-positive inclusions of a_1-antitrypsin in the periportal cells (Fig. 2(c)). This insoluble material accumulates within the endoplasmic reticulum of hepatocytes stimulating a massive increase in cellular degradative activity. The *PiMZ* individuals are able to degrade much of the abnormal a_1-antitrypsin, but not the *PiZ* homozygote in whom aggregation overwhelms the degradative process resulting in a_1-antitrypsin accumulation, hepatocellular damage, and cell death. The accumulation of a_1-antitrypsin within hepatocytes is also seen with two other rare mutations, S_{iiyama} (53phenylalanine®serine), which is the commonest cause of a_1-antitrypsin deficiency in Japan, and M_{malton} (52phenylalanine deletion), which is the commonest cause of a_1-antitrypsin deficiency in Sardinia. Both of these point mutations result in perturbations of a_1-antitrypsin and the ready formation of loop-sheet polymers. Cirrhosis has also been reported sporadically in *SZ* and *IZ* heterozygotes in whom the 'polymerogenic' *Z* and *S* or *I* a_1-antitrypsin can interlink to form chains of mixed SZ or IZ heteropolymers. The observation that polymer formation is temperature- and concentration-dependent may account for the variation in the number and density of liver inclusions between individuals. a_1-Antitrypsin is an acute-phase protein and, as such, undergoes a manifold increase in production in association with temperature increases of up to 41 °C. The increase in protein concentration and temperature during the inflammatory response favour polymerization, which in turn leads to inclusion formation and liver disease.

Neonatal jaundice and juvenile cirrhosis

Some 73 per cent of *Z* a_1-antitrypsin homozygote infants have a raised serum alanine aminotransferase level in the first year of life, but in only 15 per cent of people is it still abnormal by the age of 12 years. Similarly, the serum bilirubin level is raised in 11 per cent of *PiZ* infants in the first 2 to 4 months but falls to normal by 6 months of age. Cholestatic jaundice develops in 1 in 10 infants and 6 per cent develop clinical evidence of liver disease without jaundice. These symptoms usually resolve by the second year of life, but approximately 15 per cent of patients with cholestatic jaundice progress to juvenile cirrhosis. The reasons for this variable progression are unknown, but intercurrent illness and hormonal and genetic factors are likely to be involved. Indeed cholestatic jaundice in infancy is twice as common in boys than girls. The overall risk of death from liver disease in *PiZ* children during childhood is between 2 and 3 per cent.

Adult liver disease

All *PiZ* individuals have slowly progressive hepatic damage that is often subclinical and only evident as a minor degree of portal fibrosis. However, up to 50 per cent of *Z* a_1-antitrypsin homozygotes present with clinically evident cirrhosis and occasionally with hepatocellular carcinoma. The presence of *Z* a_1-antitrypsin deficiency, including the heterozygous *PiMZ* and *PiSZ* forms, should always be considered before making the diagnosis of cryptogenic cirrhosis.

Associated conditions

a_1-Antitrypsin deficiency is associated with an increased prevalence of asthma, panniculitis, Wegener's granulomatosis, pancreatitis, gallstones, and possibly bronchiectasis. There appears to be a reduced risk of cerebrovascular disease.

Diagnosis

The severe genetic deficiency of a_1-antitrypsin is readily diagnosed by low plasma levels and the virtual absence of the a_1-band on protein electrophoresis. As a_1-antitrypsin is an acute-phase protein, most laboratories will report levels with another acute-phase reactant, such as a_1-antitchymotrypsin, which allows the clinician to assess the likelihood of deficiency in the context of the inflammatory response. The acute-phase response raises the plasma level of a_1-antitrypsin, but never can the plasma level of the *PiZ* heterozygote reach the normal range. The deficiency variant is then assigned a Pi phenotype according to the migration of the protein on an isoelectric focusing gel.

Treatment

The treatment of a_1-antitrypsin deficiency depends largely on the avoidance of stimuli causing repeated pulmonary inflammation—primarily smoking. Patients with a_1-antitrypsin deficiency-related emphysema should receive conventional therapy with trials of bronchodilators and inhaled corticosteroids, pulmonary rehabilitation and, where appropriate, assessment for long-term oxygen therapy and lung transplantation. The role of lung volume-reduction surgery in this group is unclear as the

disease is basal rather than apical and resections of this region are technically more difficult. Mixed results have been reported in uncontrolled trials.

The lung disease results from a deficiency in the antielastase screen. This may be rectified biochemically by intravenous infusions of a $_1$-antitrypsin. Registry data suggest that individuals with a$_1$-antitrypsin deficiency and an FEV$_1$ of 35–49 per cent predicted may derive benefit from replacement therapy. The only controlled trial showed a non-significant trend towards reduced progression of emphysema in individuals receiving intravenous a $_1$-antitrypsin. a$_1$-Antitrypsin replacement therapy is currently unavailable in many European countries, including the United Kingdom. It is widely used in North America.

All *Z* homozygotes have some liver damage and, as such, would be wise to avoid alcohol abuse. The deduction that loop-sheet polymerization of a $_1$-antitrypsin complicates the acute-phase response highlights the importance of antipyretic agents in *PiZ* infants with antitrypsin deficiency. Although this has yet to be proven by clinical trials, there is anecdotal evidence that these intercurrent illnesses account for the variation in progression of liver disease in infants. Moreover, there is good reason to believe that conservative treatments to lessen pyrexia and the inflammatory response will be of value in reducing a $_1$-antitrypsin aggregation within hepatocytes and hence liver disease. *PiZ* homozygotes should be monitored for the persistence of hyperbilirubinaemia as this, along with deteriorating results of coagulation studies, indicates the need for liver transplantation. Parents with a child with severe *Z* a$_1$-antitrypsin liver disease may require genetic counselling. The likelihood of similar severe liver damage in a subsequent *Z* homozygote sibling is approximately 20 per cent.

The uncommon a$_1$-antitrypsin deficiency-associated panniculitis usually responds to dapsone, 100 to 150 mg daily, for 2 to 4 weeks, but occasionally it necessitates the administration of intravenous a$_1$-antitrypsin replacement therapy.

Other 'serpinopathies'

a$_1$-Antitrypsin is the archetypal member of a superfamily of proteins termed the *ser*ine *p*rotease *in*hibitors, or serpins, that have closely related structures and functions. These inhibitors control various inflammatory cascades, including coagulation (antithrombin), complement activation (C1-inhibitor), and fibrinolysis (a$_2$-antiplasmin). Pathological processes that underlie the deficiency of one member may account for deficiency of others. Indeed the process of polymer formation has also been reported in deficiency-mutants of antithrombin, C1-inhibitor, and a $_1$-antichymotrypsin. These polymers are inactive as proteinase inhibitors and so predispose the individual to thrombosis, angio-oedema, and chronic airflow obstruction disease, respectively. Moreover, polymerization also underlies a novel inclusion-body dementia that results from point mutations in a neurone-specific serpin, neuroserpin. The dementia, termed familial encephalopathy with neuroserpin inclusion bodies or FENIB, is inherited as an autosomal dominant trait with the inclusions of neuroserpin in the brain being PAS-positive and diastase-resistant, identical to those of *Z* a$_1$-antitrypsin in the liver. Heterozygotes with critical mutations develop early-onset dementia as the accumulated protein causes neuronal cell death. The recognition that serpin polymerization underlies all these disorders may allow the development of a common therapy.

12.1 Principles of hormone action

Mark Gurnell, Jacky Burrin, and V. Krishna K. Chatterjee

Definition

Endocrinology is the study of hormones secreted by glands or cells which, acting locally or at a distance, facilitate communication between cells and different organs thus co-ordinating their activities.

Classically, the production of hormones has been associated with specialized glands or tissues including the hypothalamus, pituitary, thyroid, parathyroids, gonads, pancreatic islet cells, adrenal glands, and placenta. It is now recognized that hormones are also produced by a range of other organs and tissues which are not considered to be classical endocrine glands. The heart is the primary source of atrial natriuretic peptide factor, which controls blood pressure and intravascular volume; endothelin and nitric oxide are derived from vascular endothelium and regulate vascular tone. Endocrine cells are distributed throughout the gastrointestinal tract and are a rich source of hormones such as cholecystokinin, gastrin, secretin, vasoactive intestinal peptide; many of these gastrointestinal hormones are also produced in the brain and central nervous system, where their role is less well understood. Erythropoietin, a circulating factor that stimulates erythropoiesis, is derived from the kidney. Adipose tissue has recently been shown to produce leptin, a circulating hormone which acts centrally to control appetite.

However, as understanding of intercellular communication has advanced, the lines of division that separate different physiological systems have become blurred. For example, neuroendocrinology represents intimate connections between the nervous and endocrine systems: peptide hormones produced in the brain exert effects via the hypothalamus to control hormone secretion from the pituitary gland; in the periphery, the sympathetic nervous system modulates hormone production by the adrenal medulla and pancreatic islets. Similarly, there are complex inter-relationships between the immune and endocrine systems: for example, glucocorticoid hormones exert powerful immunosuppressive effects; conversely, cytokines (for example, tumour necrosis factor-a and interleukin-6) produced by cells of the immune system markedly influence hormone secretion by glands such as the pituitary and adrenal.

Nature of hormones

In general, hormones can be classified into those that are based on proteins or peptides and those which are chemically derived. Small peptides include hypothalamic releasing factors produced by neuroendocrine cells, which act locally on the pituitary; larger polypeptides such as insulin or growth hormone are characteristically circulating hormones that act on more distant targets. Biogenic amines including catecholamines, dopamine, and serotonin (5-hydroxytryptamine) are derived from amino acids. The majority of protein and peptide hormones interact with membrane receptors located on the cell surface. Binding to membrane receptors activates downstream signalling pathways, leading to changes in cellular function which mediate responses to hormones.

A second class of hormones includes steroids and other lipophilic substances, which act by crossing the plasma membrane to interact with intracellular receptors. Steroid hormones are derived from cholesterol and include cortisol, progesterone, testosterone, and oestradiol. Vitamin D and retinoic acid, which are synthesized from dietary sources, and thyroid hormone produced by the modification of tyrosines in thyroglobulin, are structurally dissimilar to steroids but also act via nuclear receptors.

Development of endocrine glands

The hypothalamus develops from forebrain tissue adjacent to the third ventricle. Neurones secreting releasing factors send cellular processes which terminate in portal capillaries that perfuse the pituitary gland. The latter develops from ectoderm to form the adenohypophysis or anterior pituitary; the posterior pituitary or neurohypophysis is formed directly from axonal terminals of hypothalamic neurones that grow downward. The thyroid gland develops from endoderm in the floor of the oropharynx with the migration of cells caudally to its final position in the neck. During its descent, parafollicular C cells, derived from neural crest tissue within the ultimobranchial body and parathyroid glands from the third and fourth pharyngeal pouches, become incorporated into the thyroid gland. The adrenal glands comprise a steroid-secreting cortex developed from mesoderm, together with a catecholamine-producing medulla composed of chromaffin cells derived from neural crest. Germ cells within indifferent gonadal primordia differentiate to form the ovary, or in the presence of the Y chromosome-encoded sex determining gene (*SRY*), develop into testes. Endocrine cells of the pancreas are derived from endoderm and differentiate to form the islets of Langerhans. Various transcription factors that control the development of cells within endocrine glands and their differentiation to hormone biosynthesis are listed in Table 1.

Hormone synthesis, processing, and secretion

The organization of endocrine genes is homologous to those encoding many other proteins, although there are some characteristic features. Gene transcription is usually regulated by the promoter located in the upstream 5'-flanking region of the gene (Fig. 1). Typically, the promoter may contain three types of regulatory DNA sequence which are recognized by specific transcription factors: a hormone-response element (**HRE**) is recognized by nuclear receptors; a tissue-specific element (**TSE**) binds cell-specific transcription factors (see Table 1) which enhance the transcription of the hormone gene in a tissue-specific manner; a third class of response element mediates transcriptional activation in response to second messenger signalling pathways. A rise in intracellular cyclic AMP concentration leads to the phosphorylation of cyclic AMP response-element binding proteins (**CREBs**) which interact with CREs; cell-signalling pathways that activate protein kinase C induce the phosphorylation of the Fos–Jun (AP-1) transcription-factor complex which binds its cognate DNA regulatory sequence. Binding of transcription factors to regulatory DNA response elements, activates and stabilizes basal transcription factors (**BTFs**), promoting gene transcription and mRNA synthesis (Fig. 1).

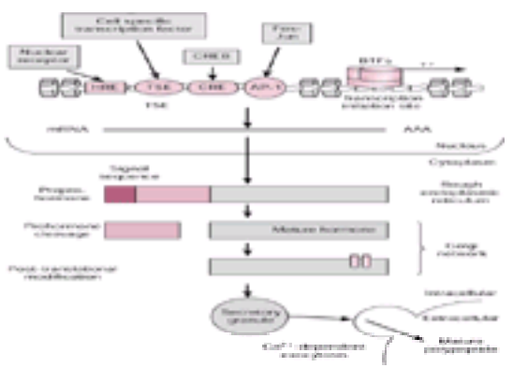

Fig. 1 Pathway of hormone synthesis, processing, and secretion.

Transcription of the gene generates mRNA, which undergoes translation in ribosomes leading to polypeptide synthesis. In some endocrine genes, alternate exon

splicing allows the substitution or removal of particular exons, such that peptides of differing sequence can be produced. For example, alternate splicing of the calcitonin gene in a tissue-specific manner directs the production of calcitonin in the C cells of the thyroid, whereas calcitonin gene-related peptide (**CGRP**) is produced preferentially in the brain.

Secreted polypeptide hormones incorporate a signal sequence at the amino terminus of the protein that directs its translocation across the endoplasmic reticulum where this sequence is cleaved (see Fig. 1). Many hormones are synthesized as larger polypeptides (prohormones) which undergo proteolytic cleavage to generate smaller functional peptides. Such proteolytic processing is mediated by specific proteases (prohormone convertase 1 and 2 (**PC1**, **PC2**)) which are highly expressed in cells of neuroendocrine lineage. Examples of hormone processing include the cleavage of proinsulin with removal of an internal C peptide to yield insulin, the active hormone. However, processing of the polypeptide precursor can also yield multiple functioning products. For example, pro-opiomelanocortin is cleaved by endopeptidases to yield adrenocorticotrophin (**ACTH**), melanocyte-stimulating hormone (**MSH**-a, -b, -g), b-endorphin, and lipocortin.

Hormones may also undergo post-translational modification such as amidation of neuropeptides or glycosylation. Modification of amino acids by the addition of carbohydrate side chains is a particular characteristic of the glycoprotein hormones (luteinizing hormone, follicle-stimulating hormone, thyroid-stimulating hormone, and human chorionic gonadotrophin) and such glycosylation affects both their biological activity as well as their half-life in the circulation (see Fig. 1).

Hormones such as growth factors and cytokines are not significantly concentrated within cells, but are released via small, clear, Golgi-derived transport vesicles that fuse with the plasma membrane, representing a 'constitutive' pathway of secretion. In contrast, many endocrine cells contain an additional 'regulated' secretory pathway, which allows the export of high concentrations of hormone stored in cytoplasmic dense-core vesicles. Chromogranin B, an acidic protein, and polypeptide proteases are additional constituents of secretory vesicles. Adrenal cells secreting catecholamine hormones contain chromaffin granules which include enzymes (for example, dopamine b-hydroxylase) that catalyse catecholamine biosynthesis. Dense-core vesicle exocytosis is mediated by a rise in intracellular calcium levels, which activates the cytoskeletal machinery, promoting vesicle translocation and docking with the plasma membrane (see Fig. 1). Cells secreting steroid hormones contain abundant mitochondrial and smooth endoplasmic reticulum which contain enzymes that mediate steroid biosynthesis. Mitochondrial side-chain cleavage enzyme converts cholesterol to pregnenolone. The latter is then converted to glucocorticoid, mineralocorticoid, or sex steroids dependent on the cell-specific expression of steroidogenic enzymes. Steroid hormones are not stored to any extent and are secreted constitutively.

Control of hormone production

The classical mechanism by which hormone-producing glands communicate is via **endocrine** pathways, whereby the products from one gland are secreted into the circulation (and exert effects on a different, distant target gland). Such endocrine pathways integrate the hypothalamus, pituitary, and various end-organs to control the production of major hormones (Fig. 2). Thus, peptide-releasing factors (for example, gonadotrophin-releasing hormone (**GnRH**), thyrotrophin-releasing hormone (**TRH**), growth-hormone releasing hormone (**GHRH**), and corticotrophin-releasing hormone (**CRH**)) from the hypothalamus, stimulate the production of trophic hormones from specific pituitary cell types; exceptions to this are somatostatin, which inhibits pituitary growth-hormone release, and dopamine, which is secreted continuously to inhibit prolactin secretion. The pituitary hormones act on end-organs to generate products, which, in turn, exert a negative feedback effect at both hypothalamic and pituitary levels to regulate their own synthesis. Tri-iodothyronine (T3) inhibits TRH and thyroid-stimulating hormone (**TSH**) production; gonadal steroids and inhibin negatively regulate hypothalamic GnRH and pituitary gonadotrophins; cortisol suppresses CRH and ACTH generation; circulating insulin-like growth factor-1 (**IGF-1**) inhibits GHRH and growth-hormone secretion (Fig. 2). Osmoreceptors in the hypothalamus sense changes in serum osmolality to control the release of vasopressin from the posterior pituitary.

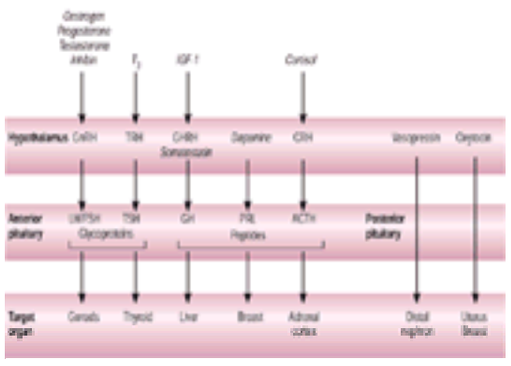

Fig. 2 Control of hormone production. Regulatory pathways integrating the hypothalamus, pituitary, and various end-organs. Hormones shown in italics exert inhibitory effects. Negative feedback regulation occurs at both hypothalamic and pituitary levels.

In addition to these endocrine control mechanisms, other types of local regulatory pathways are recognized. **Paracrine** regulation refers to factors that are released by one cell and act upon a nearby cell in the same tissue. For example, somatostatin produced by † cells in pancreatic islets inhibits the local production of insulin from b cells; in the testis, testosterone produced from Leydig cells exerts an effect on nearby Sertoli cells to enhance spermatogenesis. **Autocrine** control refers to a factor that acts upon the same cell in which it is produced. Examples include gonadotroph secretion of activin which stimulates the production of follicle-stimulating hormone (**FSH**) from the same cell; similarly, T cells produce interleukin-2 which acts to promote their own proliferation.

In addition to discrete hormonal responses, endocrine systems can respond to environmental stimuli by the integrated production of multiple hormones. For example, stress activates an array of pathways, with sympathetic activation mediating catecholamine release from the adrenals, and stimulation of the hypothalamus inducing multiple axes, resulting in the production of cortisol, growth hormone, prolactin, and vasopressin. The hormonal responses to starvation are also integrated by the hypothalamus. Here, diminished production of leptin rom adipose tissue inhibits hypothalamic GnRH and TRH secretion, with a consequent reduction in the production of both gonadal steroids and thyroid hormone to limit reproduction and energy expenditure.

In addition to the feedback regulatory mechanisms outlined above, many hormones are released in a rhythmic or pulsatile manner. Insulin is secreted in rapid (about every 10 min) pulses in response to changes in glucose concentration in the pancreatic b cell. Gonadotrophin-releasing hormone is secreted from the hypothalamus at a lower pulse frequency of every 1.5 to 3 h, stimulating similar pulses of pituitary luteinizing hormone (**LH**) and FSH release. This hormonal rhythm controls ovarian folliculogenesis and steroid production to establish the female reproductive and menstrual cycle. Pituitary growth-hormone secretion is regulated by pulses of stimulatory GHRH and inhibitory somatostatin from the hypothalamus that are out of phase with each other, corresponding to peaks and troughs of circulating growth hormone.

Many hormonal pathways are influenced by the light–dark cycle, with circadian variation in their circulating levels. For example, the hypothalamic–pituitary–adrenal axis exhibits most activity in the early morning with peak cortisol production, followed by a nadir in glucocorticoid levels in the evening. Sleep is another environmental regulator: puberty is associated with nocturnal surges of LH; growth-hormone secretion is also enhanced nocturnally and the release of vasopressin during sleep inhibits renal diuresis.

Hormone-binding proteins

Thyroid hormones and many steroids are transported in the circulation with serum-binding proteins. Thus, thyroxine (**T4**) and tri-iodothyronine (**T3**) are bound to thyroxine-binding globulin (**TBG**), albumin, and thyroxine-binding prealbumin. Cortisol and progesterone are bound to cortisol-binding globulin (**CBG**), while oestrogens and androgens are bound to sex-hormone-binding globulin (**SHBG**). The role of serum-binding proteins is to provide a reservoir of circulating hormone. The interaction of hormones with binding proteins is relatively weak compared to their affinity for receptors, enabling them to dissociate easily. Only free hormone interacts with its receptor to elicit a biological response. Hormone-binding proteins are produced by the liver, and their synthesis can be increased (for example, by oestrogens or in pregnancy) or decreased (for example, in liver disease) thereby affecting the circulating concentration of total hormones. Accordingly, wherever possible, the concentration of free hormones in the circulation (for instance, T4, T3) or urine (cortisol) should be measured. Some protein hormones also circulate associated with binding proteins, which may modulate their action. A range of insulin-like growth-factor binding proteins (**IGFBPs**) bind to IGF-1, with some inhibiting and others facilitating the action of this peptide on target-tissue receptors. Growth hormone circulates bound to the extracellular domain of its receptor derived by

cleavage from the membrane, with the complex prolonging the circulating half-life of the hormone.

Functions of hormones

The physiological roles of the major hormones can be broadly classified into three areas: control of growth and differentiation; maintenance of homeostasis; and regulation of reproduction. Some hormones have multiple functions and play a role in more than one area. In addition, some biological effects are mediated by the combined action of several different hormonal pathways. The principal actions of the major hormones are outlined in Table 2.

Linear growth is dependent on a complex interplay of many hormones and growth factors. Growth hormone plays a key role and exerts many of its effects by stimulating the hepatic production of IGF-1. Thyroid hormone also stimulates the epiphyseal growth plate in childhood, whereas production of sex steroids at puberty leads to epiphyseal closure. Other important actions of thyroid hormone include regulation of the basal metabolic rate, enhancement of myocardial contractility, and differentiation of the central nervous system.

The maintenance of homeostasis includes the control of metabolic pathways, fluid, electrolyte, and calcium balance, and regulation of blood pressure. Metabolic effects are mediated by several hormones: insulin lowers blood glucose by enhancing its cellular uptake and promotes glycogen synthesis; conversely, growth hormone, cortisol, glucagon, and adrenaline (epinephrine) act as counter-regulatory hormones to raise blood glucose. Glucagon and adrenaline stimulate glycogenolysis and, together with cortisol, promote gluconeogenesis. Other metabolic pathways are also influenced by these hormones: growth hormone and cortisol are lipolytic, whereas insulin mediates lipogenesis; insulin and growth hormone are also anabolic by promoting protein biosynthesis, whereas cortisol increases protein breakdown.

Circulating concentrations of ions and water balance are also under hormonal control. Vasopressin promotes water reabsorption via membrane channels (aquaporins) in the distal collecting ducts of the kidney; aldosterone acts at the renal distal convoluted tubule to stimulate sodium reabsorption and potassium excretion. Both parathyroid hormone (**PTH**) and vitamin D increase serum calcium levels; PTH mediates Ca^{2+} resorption from bone and kidney, whereas vitamin D acts on the gastrointestinal tract as well as these sites. Catecholamines and angiotensin-2 are potent vasoconstrictors and, together with cortisol, control blood pressure.

Hormones involved in reproduction exert effects from early in development. During embryogenesis, Müllerian-inhibiting substance (**MIS**) from the testis causes regression of female structures (uterus, fallopian tube), and testosterone promotes the development of the male structures (vas deferens, epididymis, seminal vesicles) derived from the Wolffian duct. Dihydrotestosterone promotes the development of male external genitalia. In both sexes, the gonadal axes are quiescent in childhood and become reactivated at puberty. Testosterone mediates virilization, secondary sexual characteristics, and spermatogenesis in the male; in females, ovarian production of oestrogen and progesterone induce secondary sexual features and control the menstrual cycle. In both sexes, gonadal steroids are required for the attainment of peak bone density at the end of puberty and its subsequent maintenance. During pregnancy, prolactin acts in concert with oestrogen to promote lactation; oxytocin stimulates uterine contraction at parturition and smooth muscle contraction in the mammary gland during suckling.

Hormone action

Hormones induce biological responses by interacting with receptors located either on the membrane or intracellularly in the cytoplasm or nucleus. Hormones bind to receptors with high affinity, such that low concentrations of free hormone associate and dissociate from receptors rapidly in a dynamic equilibrium. The interaction of hormones with receptors is usually highly specific, with individual receptors being highly selective for a single hormone even within a class of structurally related molecules (for example, steroid hormones). However, there are exceptions to this: parathyroid hormone (**PTH**) and parathyroid hormone-related peptide (**PTHRP**) share a common receptor and luteinizing hormone and chorionic gonadotrophin share another, generating similar biological responses; insulin and IGF-1 exhibit some degree of crossreactivity with their respective receptors; the mineralocorticoid receptor binds cortisol with equal or higher affinity than aldosterone.

Hormones that bind to membrane receptors act via effector proteins to activate second messenger signalling pathways. In turn, the second messengers stimulate a cascade of kinases, which then act upon target substrates in the cell membrane, the cytoplasm, or nucleus, to alter gene transcription or modulate a biochemical pathway, leading to a physiological response. Hormones that act through nuclear receptors are transported passively, or pumped actively, across the plasma membrane to interact with their targets. The hormone–receptor complex interacts with DNA sequences in target genes to either stimulate or repress their expression. The cellular actions of nuclear receptors are mediated by changes in target-gene transcription, altering mRNA synthesis, and in turn, the levels of protein product.

Signalling by membrane receptors

Membrane receptors can be divided into several groups (Table 3) depending on the signalling pathways that they utilize. The largest group consists of receptors with multiple transmembrane domains which are coupled to G-proteins; a second class of receptor contains an intracellular domain with tyrosine kinase activity; a number of hormones signal via membrane proteins that are homologous to cytokine receptors; a fourth class of hormone receptor contains an intracellular domain with serine or threonine kinase activity.

G-protein-coupled receptors (**GPCRs**) are characterized by seven separate hydrophobic domains that traverse the membrane phospholipid bilayer (Fig. 3(a)). They possess an extracellular domain of variable size, enabling further subclassification of these receptors: glycoprotein hormones or small molecule ligands (for example, calcium, g-aminobutyric acid (**GABA**)) interact with large amino-terminal extracellular domains; biogenic amines (for example, catecholamines, serotonin (5-hydroxytryptamine)) bind to residues that lie within the transmembrane domain; other polypeptide hormones interact with residues in both the extracellular and transmembrane domains. The intracellular domains of the receptor enable interaction with G-proteins.

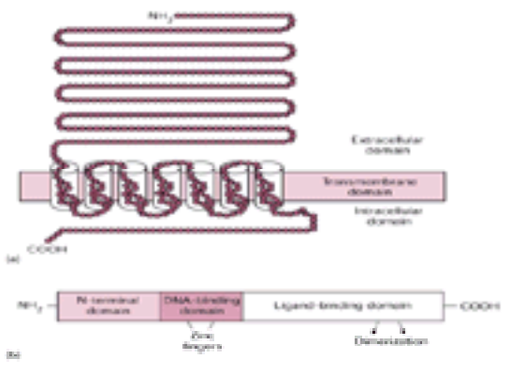

Fig. 3 Schematic representations of (a) G-protein-coupled receptor and (b) nuclear receptor illustrating their functional domains.

G-proteins typically form a heterotrimeric complex of a-, b-, and g-subunits that bind the guanine nucleotides GTP and GDP. The complex transduces signals from the receptor to downstream effectors such as adenylate cyclase, phospholipase C, or membrane voltage-dependent calcium channels. A family of different G-proteins (G_s, G_i, G_q, and others) exists with the ability to couple to different receptors and effectors, allowing a large array of potential receptor–G-protein–effector complexes, leading to diversity of cellular signalling.

A number of hormones signal via the cyclic AMP pathway (Table 4) and this mechanism is considered in further detail (Fig. 4). In the resting state, the G-protein complex is inactive and bound to GDP (Fig. 4(a)). Following hormone-binding to the receptor (Fig. 4(b)), the Ga-subunit binds GTP, becomes activated, and dissociates from the bg complex, to interact with adenylate cyclase (Fig. 4(c)). The latter converts ATP to the second messenger, cyclic AMP. This rise in the intracellular cyclic AMP level activates protein kinase A (**PKA**) which can phosphorylate a number of cellular targets: phosphorylation of a transcription factor, the cyclic AMP response-element binding protein (CREB), stimulates the transcription of genes containing CREs; other targets for PKA include enzymes in biochemical pathways or membrane ion channels.

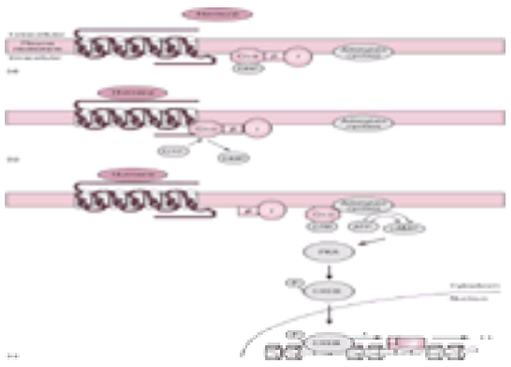

Fig. 4 G-protein-coupled receptor signalling via the cyclic AMP pathway.

At least two mechanisms serve to terminate signalling via a hormone–receptor complex. First, hydrolysis of GTP to GDP by the Ga-subunit promotes its reassociation with bg-subunits to reform an inactive complex; second, following hormone-binding, the G-protein-coupled receptors undergo phosphorylation of their intracellular domains by either PKA or other specific G-protein-coupled receptor kinases (**GRKs**). Such phosphorylation prevents further coupling to G-proteins and promotes receptor internalization. This receptor downregulation desensitizes the cell to hormone action, until further surface receptor is expressed.

Activation of their receptors by hormones such as somatostatin or dopamine is known to decrease intracellular cyclic AMP levels. Here, the hormone–receptor complex associates with a G-protein (Gi), whose a-subunit inhibits adenylate cyclase. Although many GPCRs signal via cyclic AMP, some receptors (for example, receptors for thyrotrophin-releasing hormone, gonadotrophin-releasing hormone, Table 4) are linked to different pathways. These receptors are coupled to G_q, whose a-subunit activates membrane phospholipase C (**PLC**) (Fig. 5). This enzyme catalyses the hydrolysis of phosphotidylinositol 4,5-bisphosphate (**PIP2**) to generate the second messengers inositol 1,4,5-triphosphate (**IP3**) and 1,2-diacylglycerol (**DAG**). IP_3 interacts with a specific receptor located on smooth endoplasmic reticulum, inducing the opening of intracellular channels and leading to a rise in cytoplasmic calcium levels (Fig. 5). Interaction of calcium with calmodulin (**CAM**), a cytoplasmic calcium-binding protein, activates a specific kinase (CAM kinase), which regulates a number of processes including hormone secretion, gene transcription, and metabolic enzymes. The rise in cellular calcium also facilitates DAG activation of protein kinase C (**PKC**), leading to phosphorylation of the Fos–Jun transcription-factor complex, inducing target-gene expression (Fig. 5). Hormones do not signal exclusively via a single pathway, with glycoprotein hormones and some peptides, for example, activating both cyclic AMP and phosphoinositide signalling (Table 4).

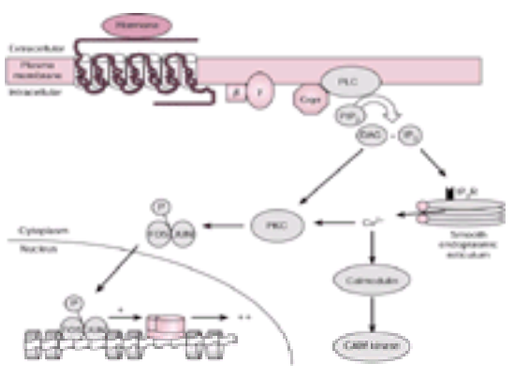

Fig. 5 G-protein-coupled receptor signalling via the phosphoinositide pathway.

The tyrosine kinase class of receptors is a diverse family that transduces signalling by insulin and IGF-1 as well as by epidermal, nerve, fibroblast, and platelet-derived growth factors. Growth-factor signalling differs from that of insulin, and the latter pathway will now be considered (Fig. 6). The interaction of insulin with its receptor promotes autophosphorylation of tyrosine residues in its cytoplasmic domains. In turn, this promotes the phosphorylation of substrates (for example, Shc and insulin-receptor substrate-1 (**IRS-1**)), followed by recruitment of adaptor proteins (Grb2/SOS). The Grb2/SOS complex recruits Ras, a GTP-binding protein. Ras activation induces signalling via a series of kinases (Raf, Mek, MAP kinase), culminating in the phosphorylation and activation of transcription factors that regulate target genes involved in mitogenesis or cellular differentiation. On the other hand, IRS-1 recruits phosphatidylinositol-3'-OH-kinase (PI3-kinase), which in turn activates protein kinase B. The latter mediates a number of the metabolic effects of insulin, enhancing translocation of a glucose transporter to the membrane to promote cellular glucose uptake, and activating enzymes involved in glycogen synthesis.

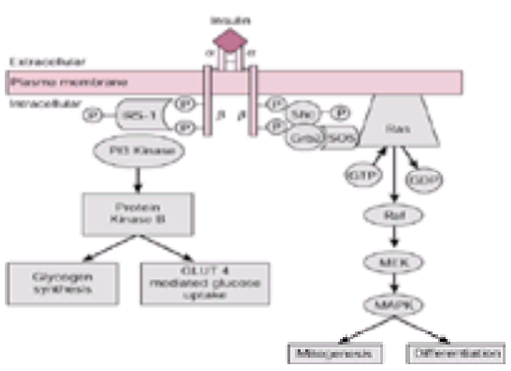

Fig. 6 Insulin action via its tyrosine kinase receptor and signalling cascade.

Hormones such as prolactin and GH interact uniquely with their receptors; a single polypeptide interacts simultaneously with two receptors promoting their dimerization (Fig. 7). The hormone–receptor complex recruits Janus kinases (**JAKs**) which phosphorylate **STATs** (signal transducers and activators of transcription). STATs translocate to the nucleus, interact with regulatory DNA elements, and promote target-gene transcription.

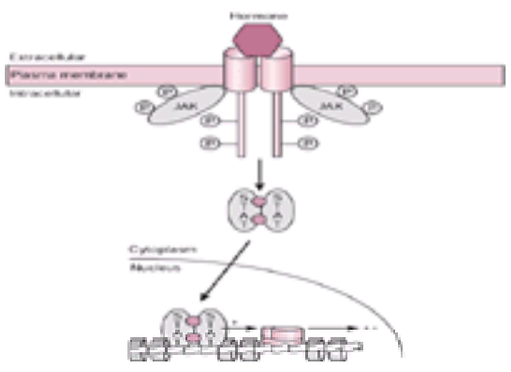

Fig. 7 Hormone signalling via the JAK–STAT pathway.

Activin and inhibin belong to the transforming growth-factor (**TGF**) class of peptides, which signal via a heterodimeric transmembrane-receptor complex with intrinsic protein serine/threonine kinase activity (Fig. 8). Here, hormone-binding promotes the association of two (type I, type II) surface receptors with differing properties. Subsequent transphosphorylation of the type I receptor by the intracellular kinase domain of the type II receptor leads to phosphorylation and dimerization of cytoplasmic Smad proteins. The Smad complex translocates to the nucleus to activate target-gene expression (Fig. 8).

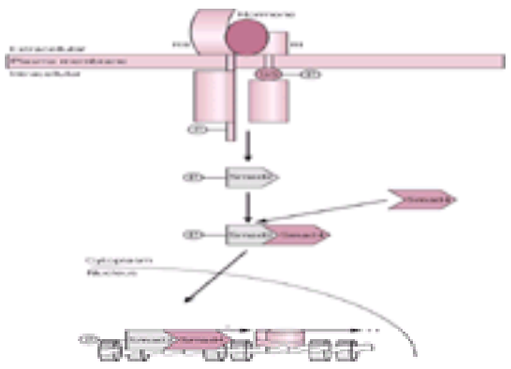

Fig. 8 Hormone signalling by the transforming growth-factor peptide family.

As described above, GPCR signalling is usually coupled to responses (for example, hormone secretion) by the Ga-subunit activation of cyclic AMP or phosphoinositide pathways. However, following receptor activation in some cellular contexts, the dissociated Gb/g-dimer subunit complex is also capable of stimulating effectors (for example, Ras, PI3-kinase), to enhance MAP kinase activity and elicit a mitogenic response.

Nuclear-receptor signalling

The nuclear receptors are a family of transcription factors that mediate the action of steroid and other lipophilic hormones. The human genome encodes approximately 60 to 70 different receptors, and it is clear that only a minority of these are targets for the action of major hormones (Table 5). The remainder comprise a large group classified as 'orphan receptors', reflecting the fact that either their ligands and/or physiological roles are still to be elucidated.

Based on homologies in their primary amino-acid sequence, nuclear receptors can be divided into distinct domains that mediate specific functions (Fig. 3(b)). A central DNA-binding domain contains cysteine-rich peptide motifs that chelate zinc to form two zinc fingers. The latter mediate receptor-binding to specific DNA sequences or hormone-response elements, usually located in target-gene promoters. The carboxy-terminal region of receptors encompasses their hormone-binding function as well as their ability to dimerize. Nuclear receptors can be divided into two major subclasses—the steroid receptors (homodimeric) and heterodimeric receptors—which differ in their mode of action.

Steroid receptors (for example, glucocorticoid, mineralocorticoid, [o]estrogen, progesterone, and androgen receptors (GR, MR, ER, PR, AR, respectively)) bind to hormone-response elements as homodimers (Fig. 9(b)). Some receptors (for example, GR, PR, AR) are bound to cytosolic heat-shock proteins. Hormone-binding to receptors promotes their dissociation from these, enabling translocation to the nucleus, dimerization, and interaction with DNA. In contrast, the thyroid, retinoic acid, and vitamin D receptors are constitutively nuclear and form heterodimers with a common partner (retinoid X receptor or **RXR**), to interact with DNA even in the absence of hormone or ligand (Fig. 9(a)). In some target-gene contexts, RXR can also form homodimers to mediate retinoid signalling.

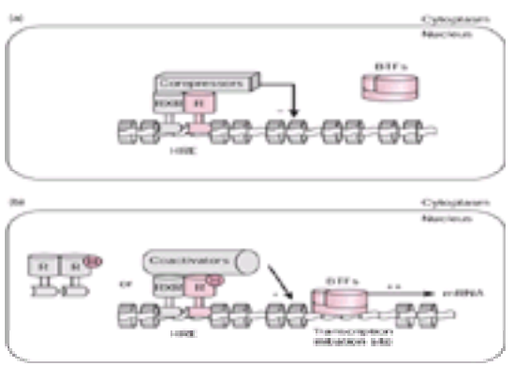

Fig. 9 Transcriptional regulation by nuclear receptors (a) In the absence of hormone, a subset of heterodimeric nuclear receptors (thyroid, retinoic acid) recruit co-repressors to inhibit gene transcription. (b) Hormone occupancy of homodimeric or heterodimeric receptors promotes their association with coactivators, leading to transcriptional activation.

In contrast to other transcription factors whose activity is controlled by post-translational modification (for example, phosphorylation), the hallmark of nuclear receptors is their ability to modulate gene expression in a hormone-dependent manner. Thus, in the absence of ligand, the thyroid and retinoic acid receptors actively silence target-gene transcription by recruiting a co-repressor complex of cofactors (Fig. 9(a)). For all nuclear receptors, hormone-binding induces a conformational change with dissociation of co-repressors and recruitment of coactivator proteins (Fig. 9(b)). This latter complex acts to relax the interaction between histone proteins and DNA in chromatin, thereby facilitating the access of basal transcription factors and RNA polymerase which induce gene transcription.

A further mechanism that controls signalling via nuclear receptors is regulation of the supply of their ligands to cells and tissues. Tri-iodothyronine, the ligand for the thyroid-hormone receptor (**TR**), is generated from circulating thyroxine by the action of type-1 or type-2 deiodinase enzymes expressed in the liver and central nervous system, respectively; the enzyme 5a-reductase converts testosterone to dihydrotestosterone in tissues of the male external genitalia. In contrast, the enzyme 11b-hydroxysteroid dehydrogenase type 2 catabolizes cortisol in renal cells, thereby enabling the mineralocorticoid receptor to respond selectively to aldosterone rather than to glucocorticoid, which it is also capable of binding to with high affinity.

Finally, in contrast to the classical effects of steroid hormones in modulating gene expression, recent evidence indicates that they can also modulate cellular functions such as hormone secretion or neuronal excitability within seconds or minutes. These rapid effects of steroid hormones occur independently of the genome, and are probably transduced by the same signalling pathways (for example, voltage-sensitive calcium channels) that mediate rapid responses to neurotransmitter hormones.

Genetic defects and endocrine disease

The majority of endocrine diseases can be divided into conditions of hormone excess, hormone deficiency, and hormone resistance. Defects in genes involved in hormone synthesis and action give rise to a spectrum of disorders (Table 6 and Table 7). Both germline gene defects causing inherited syndromes and somatic

mutations leading to acquired endocrine cellular dysfunction have been described.

Defects in developmental transcription factors are usually associated with endocrine gland hypoplasia: mutations in *HESX-1* cause optic and pituitary hypoplasia with agenesis of the corpus callosum; both *Pit-1* and *PROP-1* mutations disrupt the development of multiple pituitary cell types, resulting in a combination of hormone deficiencies; defects in *TTF-1*, *TTF-2*, and *PAX-8* result in thyroid dysgenesis manifesting as neonatal hypothyroidism; mutations in the *SRY* gene lead to failure of testis development and sex reversal in XY males.

Mutations in *DAX-1* or *SF-1*, orphan members of the nuclear-receptor family, disrupt both adrenal and gonadal development. Defects in other nuclear receptors (for example, VDR, TR, GR) are characterized by tissue resistance to their respective hormone ligands. Vitamin D resistance leads to rickets, together with abnormalities of skin differentiation, hair growth, and lymphocyte function, emphasizing its important extraskeletal actions. Point mutations in the androgen receptor are associated with a spectrum of phenotypes, ranging from complete feminization of XY individuals to mildly impaired virilization in men. In addition, expansion of a polyglutamine repeat sequence in the amino-terminal domain of AR is associated with adult-onset neuronal degeneration, leading to spinal and bulbar muscular atrophy. A homozygous defect in the oestrogen receptor in a male, led to failure of epiphyseal closure, resulting in tall stature together with severe osteoporosis. These manifestations suggest that testosterone effects on the male skeleton are, in part, mediated by its enzymatic conversion to oestrogens.

A growing number of disorders associated with defects in transmembrane receptors or their signalling intermediates have been described (Table 7). However, in addition to mutations that disrupt protein function, gain-of-function mutations causing constitutive activation of the receptor or signalling protein also occur. With G-protein-coupled receptors (GPCRs), diverse loss-of-function mutations, occurring most frequently in the extracellular domain, block hormone-binding or signalling, leading to insensitivity to hormone action. Such hormone resistance can lead to both hypofunction (for example, ACTH, TSH receptors) or hypoplasia (for example, LH, FSH receptors) of target glands expressing the receptor. Conversely, gain-of-function mutations in GPCRs typically occur in the third intracellular loop, causing constitutive activation of the receptor in the absence of hormonal ligand. Again, the functional consequence is either autonomous hyperfunction (for example, calcium, LH, FSH receptors) or excessive neoplastic proliferation (for example, TSH receptor, RET tyrosine-kinase receptor) of the target tissues in which the receptor is expressed (see Table 7). Constitutive activation of signal transduction may also result from G-protein mutations. Here, specific amino-acid substitutions in Gsa inhibit its intrinsic GTPase activity, and the GTP-bound protein constitutively activates adenylate cyclase leading to cyclic AMP accumulation. Somatic *Gsa* mutations occur in a proportion of pituitary growth-hormone secreting and thyroid adenomas; more widespread expression of a somatic *Gsa* mutation occurring early in development leads to polyostotic fibrous dysplasia, café-au-lait skin pigmentation, and hyperfunction of multiple endocrine glands, constituting the McCune–Albright syndrome. Similarly, germline, loss-of-function mutations which reduce cellular Gsa activity, are associated with resistance to multiple hormones, together with characteristic bone anomalies (Albright's hereditary osteodystrophy).

12.2 Disorders of the anterior pituitary

Paul J. Jenkins and Michael Besser

Historical introduction

The anterior pituitary gland, often termed the 'conductor of the endocrine orchestra' secretes six hormones of known function. These control many of the peripheral endocrine organs, between them regulating growth and development, sexual behaviour and the menstrual cycle, lactation, as well as the thyroid and adrenal glands. Hippocrates in 400 BC gave the first description of a prolactinoma in stating that 'if a woman who is neither pregnant nor has given birth produces milk, and menstruation has stopped...'. There are several descriptions of giants in the Old Testament, both as individuals and also as families, (Joshua XIV: 'Arba was a great man amongst the Anakim'); it is possible that Goliath was slain by David because of his bitemporal hemianopia resulting from a suprasellar growth hormone-secreting pituitary adenoma. However, despite these early descriptions, detailed knowledge of the physiology and pathophysiology of the anterior pituitary gland has only become apparent over the last 60 or 70 years and is continuing to expand.

The first major advance was the ability to purify pituitary hormones, detect their actions by bioassay, and then synthesize them. The development of radioimmunoassay in the 1960s allowed for their rapid and more precise measurement and the elucidation of their physiological role. In Oxford in the 1950s Harris demonstrated the control of anterior pituitary function by hypothalamic factors; these were later extracted from several hundred tons of porcine pituitaries, principally by Schally and Guillemin in the 1970s, leading to their being awarded the Nobel prize. The availability of these hypothalamic factors facilitated studies of their physiological effects in both normal subjects and patients with endocrine disorders. The development of modern imaging techniques such as computed tomography (**CT**) and magnetic resonance imaging (**MRI**) has greatly enhanced our ability to visualize the anatomy of the hypothalamic–pituitary region and allow the precise localization of pituitary lesions. In the 1980s the advent of molecular biological techniques allowed greater understanding of the control mechanisms at a molecular level as well as fuelling interest in potential treatments. In experienced hands, trans-sphenoidal surgery has become a safe and effective firstline treatment for most pituitary tumours thus avoiding the morbidity associated with craniotomy.

Anatomy and development

The hypothalamus is the true conductor of the endocrine orchestra since it controls the pituitary gland. It is derived from forebrain tissue on either side of the lower parts of the third ventricle. The floor comprises the optic chiasm and tracts, the pituitary stalk, and mamilliary bodies; anteriorly it is limited by the lamina terminalis and the anterior commissure, whilst posteriorly it blends with the midbrain. The pituitary gland (sometimes called the hypophysis) lies within the pituitary fossa of the sphenoid bone above the sphenoid sinus. On either side are the cavernous sinuses containing the internal carotid artery, the third, fourth, fifth (first, and second divisions), and sixth cranial nerves. Superiorly, the gland is covered by a layer of dura through which the stalk passes. Occasionally congenital enlargement of this gap allows the usual pulsations of cerebrospinal fluid to be transmitted through into the fossa compressing the pituitary and ballooning the fossa and giving rise to the 'empty sella syndrome'. The normal pituitary is approximately the size of a large pea and weighs 100 mg; its dimensions are approximately 10 mm transversely, 9 mm anteroposteriorly, and 6 mm vertically. During pregnancy it undergoes enlargement up to almost twice its normal size as it becomes engorged with prolactin-secreting mammotroph cells under the influence of oestrogen. (Fig. 1).

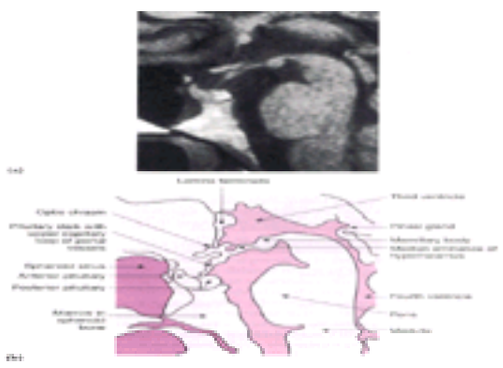

Fig. 1 Sagittal MRI scan of normal pituitary gland and an anatomical line drawing.

Embryologically and functionally the pituitary comprises two distinct parts. The epithelial portion which forms the anterior pituitary consists of the pars distalis and intermediate lobe; this originates from the stomodeal ectoderm of Rathke's pouch, which forms a vesicle that separates from the roof of the developing mouth. The neural portion which forms the posterior lobe, pituitary stalk, and infundibulum arises along with the rest of the hypothalamus from the diencephalic forebrain. Anterior pituitary cells also extend upwards to surround the neural tissue of the pituitary stalk forming the pars tuberalis.

The blood supply to the pituitary is in keeping with this dual origin. The anterior gland receives 80 to 90 per cent of its blood supply from the hypothalamo-hypophyseal portal veins which start as a plexus of capillaries in the median eminence/infundibulum of the hypothalamus, carrying blood and hypophyseotropic hormones down the stalk to bathe the cells of the anterior pituitary. The remaining blood supply is via the pituitary capsular vessels derived from the superior hypophyseal arteries. The neurohypophysis receives its blood supply from the inferior hypophyseal branches of the internal carotid artery. Venous drainage from the anterior pituitary is via the cavernous sinuses, principally into the petrosal sinuses and thence into the internal jugular veins.

Anterior pituitary differentiation and ontogeny is now known to be carefully regulated by tissue-specific transcription factors. The first marker of anterior pituitary differentiation is expression of the a subunit. Expression of prolactin, growth hormone, and thyroid-stimulating hormones in specific cells is controlled by the POU domain transcription factors Pit-I and Prop-I. Humans with mutations of Pit-I have a syndrome of short stature, congenital hypothyroidism, and prolactin deficiency.

General physiology and regulation

In common with all endocrine glands, secretion of anterior pituitary hormones is not autonomous. Each is subject to regulation by hypothalamic peptides and, with the possible exception of prolactin, subject to the fundamental endocrine regulatory mechanism of negative feedback by hormone from the target gland (Fig. 2; Table 1). This negative feedback control is at both the hypothalamic and pituitary levels and ensures precise homeostatic maintenance of physiologically appropriate hormonal secretion. Thus, failure of the primary gland results in reduced negative feedback and consequent increased hypothalamic and pituitary stimulation and secretion. Conversely, primary overactivity of the target gland results in increased negative feedback and diminished hypothalamic and/or pituitary stimulation. This central tenet

is fundamental to the laboratory interpretation of circulating hormonal levels and to the investigation of pituitary target gland disorders by means of either stimulatory or suppressive tests. In addition to this long-loop negative feedback, additional 'short-loop' feedback mechanisms exist between the pituitary and the hypothalamus.

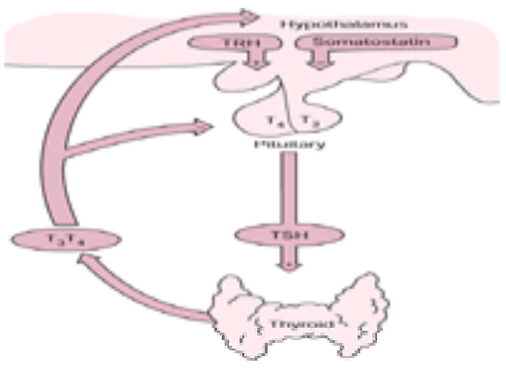

Fig. 2 Diagram of the hypothalamo-pituitary–thyroid axis showing negative feedback loops. TRH, thyrotrophin-releasing hormone; TSH, thyroid-stimulating hormone.

Pituitary hormones are synthesized as part of large precursor molecules; they are then cleaved into fragments which are secreted into the circulation. One fragment is the hormone concerned and the other cosecreted fragments have no known function as endocrine factors.

Causes of pituitary disease

Pituitary adenomas are the commonest cause of pituitary disease (Table 2); they can range from silent microadenomas to aggressive invasive tumours. Autopsy data suggest that the former may occur in up to 20 per cent of apparently normal people. Overall, clinically apparent pituitary tumours account for some 10 to 20 per cent of all intracranial tumours.

Pituitary tumours

With the advent of modern immunohistochemical techniques, the classification of pituitary adenomas has been simplified into that of the secreted hormone rather than the staining patterns of chromophobe, basophil, or acidophil adenomas resulting from periodic acid-Schiff staining (Table 2). Occasionally, despite these techniques, no tumour is visualized after trans-sphenoidal surgery even when the hormonal hypersecretion is cured postoperatively. Reasons for this may be that the tumour was so small it was missed on histological sectioning, the tumour was so small that it was not collected by the sucker during surgery, or the primary pathology was hypothalamic in origin.

Epidemiology of pituitary tumours

The annual incidence of clinically functioning pituitary tumours is estimated to be approximately 1 to 2 per 100 000 of the population. However, it is likely that this is an underestimate for two reasons: these are rare conditions which tend to be underdiagnosed and the incidence figures depend upon cancer registrations and not mortality data, which tend to be incomplete and are not universal. Despite these reservations, the following pituitary adenomas occur in decreasing order of frequency: non-functioning adenomas, prolactinomas, growth hormone-secreting, adrenocorticotrophic hormone (**ACTH**) secreting, thyroid-stimulating hormone secreting, and luteinizing hormone/follicle-stimulating hormone (**LH/FSH**) secreting tumours.

Clinical features of pituitary disease

The clinical features of pituitary dysfunction, usually resulting from a space occupying lesion, can be divided into local effects resulting from an expanding pituitary mass, anterior pituitary hormonal deficiency, and symptoms and signs of hormonal excess from hypersecretion of a pituitary hormone.

Local mass effects

An expanding mass within the pituitary fossa may give rise to headache, neuro-ophthalmological defects or facial pain according to the size and direction of expansion. Headaches usually result from dural stretching and are classically retro-orbital or bitemporal. They tend to be worse on waking and are relieved by analgesics; the somatostatin analogue octreotide may provide striking relief beyond any effect on hormone secretion, as it may have direct analgesic effects. Sudden catastrophic headaches may result from pituitary apoplexy. Very large pituitary masses may cause obstruction of the fourth ventricle or foramen of Munro resulting in hydrocephalus and expansion of the lateral ventricles. Rarely, inferior invasion and erosion of the sella floor may cause recurrent sinusitis or cerebrospinal fluid rhinorrhoea (confirmed by the presence of glucose in the fluid) and the risk of recurrent meningitis. Neuro-ophthalmological defects are common, particularly with macroadenomas, occurring in up to 60 per cent of such cases, although they are often asymptomatic. Although bitemporal hemianopia is the classic abnormality, any unilateral or bilateral visual field defect can occur depending on the site of impingement on the pathway of the optic nerve (Fig. 3). Lateral extension results in a squint from ocular nerve palsies. Extensive lateral invasion into the temporal lobe may result in temporal lobe epilepsy, whereas extensive superior extension may impinge upon the hypothalamus resulting in disorders of appetite, thirst, temperature regulation, and consciousness.

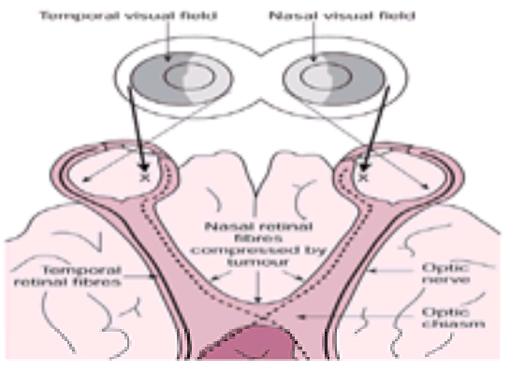

Fig. 3 Neuro-ophthalmological pathways and the classical bitemporal hemianopia that results from compression of the central optic chiasm by a pituitary tumour. However, any degree of unilateral or bilateral visual deficit can occur depending on the anatomical site of the lesion.

Hormonal deficiencies

Panhypopituitarism or varying degrees of loss of any of the six hormones may occur. Hypopituitarism resulting from a pituitary adenoma tends to occur in the sequential loss of LH, growth hormone, thyroid-stimulating hormone, and lastly ACTH and FSH. Thus, in adults the presenting clinical symptoms tend to be infertility, oligo/amenorrhoea, decreased libido, and erectile dysfunction. The clinical signs and phenotypic appearance reflect the loss of LH and growth hormone: there may be reduction of muscle bulk, decreased body hair, increased central adiposity, and small, soft testes. The facial appearance is almost pathognomonic—smooth skin with fine wrinkles, exaggerated by the loss of facial hair. Pallor may accompany ACTH deficiency. In children, hypopituitarism commonly presents with delayed puberty or impairment of growth. LH deficiency with preservation of growth hormone results in delayed fusion of the epiphyses of the long bones giving rise to a eunuchoid appearance, the span being greater than the height. Testicular size will depend on the stage of puberty prior to gonadotrophin failure and whether adrenarche,

influenced by ACTH-controlled adrenal androgen secretion, is maintained. Diabetes insipidus is almost never a presenting feature of primary pituitary tumours in either childhood or adults—it occurs most commonly in association with surgical treatment of pituitary adenoma.

Hormonal excess

If the pituitary adenoma is functioning, clinical symptoms and signs will also result from excess levels of either the secreted pituitary hormone itself, for example acromegaly (growth hormone), prolactin excess (prolactinoma), or from increased stimulation and secretion of the target gland hormone, for example Cushing's disease (ACTH), thyrotoxicosis (thyroid-stimulating hormone).

Evaluation of pituitary disease

The investigation of suspected anterior pituitary dysfunction requires the evaluation and integration in an appropriate clinical setting of: the presence of endocrine hyperfunction; the presence and degree of hypopituitarism; the radiological presence and extent of anatomical abnormalities; and assessment of neuro-ophthalmological function.

Hypothalamic pituitary function

Basal measurements

Measurements of basal levels of pituitary hormones with target gland hormone secretion are likely to be sufficient for the majority of cases of pituitary dysfunction, especially those involving thyroid-stimulating hormone, LH/FSH, and prolactin. It is only disorders of ACTH and growth hormone secretion that require dynamic investigation with stimulation or suppression tests according to the clinical scenario. Although the introduction of radioimmunoassays and then immunoradiometric assays revolutionized endocrine assessment, these have now largely been superseded by modern chemiluminescent assays which have the advantages of increased automation and sensitivity, avoidance of radioisotopes, and shorter assay time.

When interpreting any basal measurement of pituitary hormone, one needs to be aware of certain caveats:

1. Interpretation of all anterior pituitary hormonal levels, with the exception of prolactin, can only be made in the knowledge of the level of the primary target gland hormone.
2. The pulsatile nature of secretion of anterior pituitary hormones, especially ACTH, growth hormone, and LH/FSH, means that random isolated single levels may not be representative of overall secretion.
3. Specific factors such as time of day, stress, fed or fasting, asleep or awake, and stage of growth and pubertal development can all influence levels.

ACTH

Rapid proteolytic degradation in whole blood or frozen then thawed plasma, pulsatile secretion, and diurnal rhythm all need to be taken into account when measuring basal ACTH levels. In order to prevent degradation and thus uninterpretable results, plasma samples must be taken in an EDTA tube at 4 °C and immediately frozen. The time of day should be recorded (preferably 09.00) and samples should be taken from an in-dwelling cannula that has been *in situ* for at least 30 min in order to avoid the influence of stress. As ACTH is the prime regulator of cortisol secretion, a serum cortisol level (which does not require these logistical precautions) is a pragmatic measure of ACTH secretion; a 09.00 hour level of more than 200 nmol/l effectively excludes adrenal insufficiency under basal conditions, although it does not assess ACTH reserve (see later), whilst a 09.00 hour level of more than 550 nmol/l obviates the need for dynamic testing since the response to stress will be adequate.

Growth hormone

The markedly pulsatile secretion of growth hormone means that random levels of growth hormone are of very limited use. Furthermore, secretion is affected by nutritional status, being increased by amino acids. As it is a counter-regulatory hormone to insulin, levels are increased by hypoglycaemia and decreased by hyperglycaemia (the basis for its dynamic testing in situations of suspected oversecretion). There is also increased secretion during sleep (stages 3 and 4) and in response to stress. As a result of these factors, any meaningful assessment of growth hormone secretion requires dynamic testing. The action of growth hormone on tissues is classically mediated in an endocrine manner via hepatically derived circulating insulin-like growth factor I, although there is increasing evidence that most of its actions are effected through secretion of insulin-like growth factor I locally in the target tissues acting on cells adjacent to or the same as the cell of origin of insulin-like growth factor I (so-called paracrine or autocrine actions). Insulin-like growth factor II is not growth hormone dependent. A single serum level of insulin-like growth factor I has been claimed to represent an integrated index of growth hormone secretion, but it too is subject to separate influences and is discordant in up to 25 per cent of cases, particularly in adults. Thus, levels of insulin-like growth factor I in serum may be within the lower part of the normal range even though the patient has mild growth hormone deficiency. Growth hormone levels are markedly increased during puberty but decreased in pregnancy, due to the negative feedback on the pituitary by placental growth hormone, a variant of growth hormone produced by the placenta.

LH/FSH

More than for any other pituitary hormone, assays of LH/FSH must be interpreted with the simultaneous level of target gland hormone and the clinical scenario. In men a low testosterone in conjunction with low LH/FSH confirms the diagnosis of hypogonadotrophic hypogonadism rather than primary hypogonadism when LH/FSH levels would be high. In women the occurrence of the menstrual cycle is the definitive biological assay and excludes any deficiency. The occurrence of oligo/amenorrhoea requires measurement of gonadotrophins together with oestradiol, prolactin, and human chorionic gonadotrophin-b. Dynamic testing is very rarely required.

Prolactin

In the absence of pregnancy (during which levels rise markedly due to the action of increased oestrogen on the pituitary) a serum prolactin level of more than 4500 mU/l is almost always indicative of a prolactinoma. Mild elevations may be in response to stress and as such require repeated measurements. The large variety of causes of hyperprolactinaemia need to be considered (see later), particularly that due to coexisting drug therapy.

Thyroid-stimulating hormone

New ultrasensitive assays for thyroid-stimulating hormone have largely avoided the need for dynamic testing. A normal level of thyroid-stimulating hormone with a free thyroxine level in the normal range is indicative of euthyroidism. A subnormal level of thyroxine in conjunction with a normal or low thyroid-stimulating hormone (indicative of inadequate negative feedback) is strongly suggestive of secondary hypothyroidism. The commonly encountered low T_4 with an elevated thyroid-stimulating hormone is almost always indicative of primarily hypothyroidism, whilst conversely an elevated thyroxine or liothyronine level with a subnormal or undetectable thyroid-stimulating hormone confirms thyrotoxicosis. Secondary thyrotoxicosis as indicated by both an elevated thyroid-stimulating hormone and thyroxine level is very rare.

Dynamic endocrine testing

Where basal levels are inadequate or equivocal, dynamic endocrine tests will be required. The use of the combined anterior pituitary function test comprising LH-releasing hormone and thyrotrophin-releasing hormone is now no longer routinely used as it does not add to the clinical information obtained by basal hormone measurement. It is usually only disorders of the growth hormone and/or the ACTH axis that require either stimulatory or suppressive testing.

Insulin tolerance test

The insulin tolerance test remains the gold standard for assessing the AGTH/cortisol and growth hormone reserve. Its rationale is that insulin-induced hypoglycaemia is a marked stressor to hypothalamic neurones. A fall in blood glucose below 2.2 mmol/l invokes neuroglycopenic sympathetic stimulation, a stress reaction leading to

ACTH and cortisol release, which with catecholamines, glucagon, and growth hormone, act as counter-regulatory hormones liberating glucose from glycogen stores in the liver and returning blood glucose levels towards normal. Growth hormone is also released not only as a result of glucose levels falling below the neuroglycopenic threshold for stress induced release, but also in response to the subsequent stress.

Test procedure

The test must be performed in a properly equipped unit by well trained experienced personnel. In these circumstances it is an extremely safe and effective test. Contraindications are the presence of ischaemic heart disease, epilepsy or unexplained blackouts, a basal 09.00 cortisol level of less than 50 nmol/l (unless receiving exogenous glucocorticoids), and untreated hypothyroidism.

The patient should be fasted from midnight and the test performed at 09.00 hours. At least 30 min prior to this, an intravenous cannula is inserted. Blood is drawn for cortisol, growth hormone, and glucose analysis at 0, 30, 45, 60, 90 and 120 min. At 0 min 0.15 U/kg of soluble human insulin is injected intravenously (0.3 U/kg in insulin-resistant states such as acromegaly or Cushing's syndrome). Pulse rate and blood pressure along with the times of the characteristic features associated with hypoglycaemia are recorded with the blood samples. Symptoms and signs of hypoglycaemia usually occur between 30 and 45 min and comprise sweating, tachycardia, drowsiness, and hunger. Blood glucose must fall to less than 2.2 mmol/l and symptoms must be evident to be regarded as sufficient hypoglycaemic stress and to interpret the cortisol and growth hormone levels. A normal cortisol response is a rise to 580 nmol/l or more and growth hormone should increase to more than 20 mU/l. Failure to reach these levels indicates deficiency of ACTH and/or growth hormone. If the cortisol response is just subnormal, ACTH reserve may be adequate for day-to-day living but inadequate to cope with stresses such as illness or surgery and exogenous corticosteroid cover would be needed. A response to less than 450 nmol/l requires hydrocortisone replacement. Additionally all subnormal responses require a patient to carry a steroid card and MedicAlert bracelet.

An alternative to the insulin tolerance test to establish adequacy of ACTH/cortisol and growth hormone secretion in the presence of contraindications is the glucagon stimulation test (1 mg glucagon is given subcutaneously and sampling performed over 4 h) but the results are less consistent than with the insulin tolerance test.

The oral glucose tolerance test

As growth hormone secretion is inhibited by a rise in circulating glucose, the administration of exogenous oral glucose is used to confirm or exclude the diagnosis of acromegaly and remains the gold standard test for confirmation of this condition. The test is performed at 09.00 hours with the patient fasted from midnight. An intravenous cannula is inserted 30 min prior to the test and blood samples are drawn for analysis of glucose and serum growth hormone at –30, 0, 30, 60, 90 and 120 min. Glucose (75 g) dissolved in flavoured water (conveniently given as 370 ml 'Lucozade') is given to the patient immediately after the 0 min blood sample. In normal subjects, after oral glucose, serum growth hormone should be suppressed to undetectable levels (less than 0.5 mU/l). Failure to suppress is consistent with acromegaly, although it may also occur in diabetes mellitus, obesity, liver disease, and opiate dependence; in approximately 30 per cent of cases of acromegaly growth hormone levels paradoxically increase in response to glucose in this condition.

Pituitary imaging

The development of CT and subsequently MRI has revolutionized imaging of the pituitary gland, rendering the previous modalities of air encephalography and metrizamide cysternography obsolete. With their increasing availability, even the time-honoured skull radiograph has a limited role. These new techniques allow accurate visualization of the pituitary gland and, in the case of MRI, precisely delineates the extent of the surrounding invasion. If CT is used, imaging sections need to be thin (1.5 mm) and of high quality with multiplanar reconstructions; contrast should be given. Although CT is far more sensitive in demonstrating any calcification, as occurs commonly in craniopharyngiomas, MRI is nowadays the method of choice for delineating pituitary lesions. Its advantages are that it does not require ionizing radiation, it has the ability to image in any desired plane, and it shows the inherent contrast between tissues. Not only is it able to determine accurately the shape and dimensions of the anterior and posterior pituitary lobes (the latter has a high signal on T_1-weighted images in over 90 per cent of normal subjects) but it also delineates the hypothalamic region and optic chiasm. MRI allows accurate assessment of the size of pituitary adenomas, detecting lesions as small as 2 mm. It also determines the extent of any invasion superiorly, inferiorly, or laterally into the cavernous sinuses. On T_1-weighted images pituitary adenomas tend to be of lower signal intensity than the surrounding normal gland and enhance less briskly than the normal gland after injection with intravenous gadolinium contrast (Fig. 4).

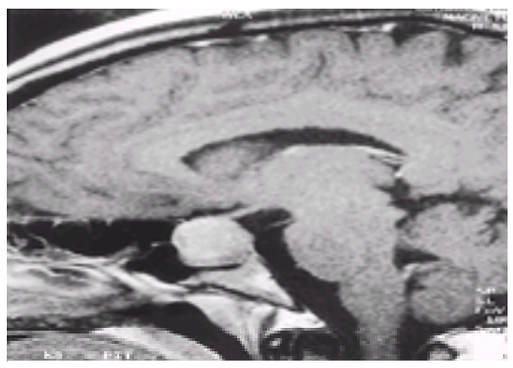

Fig. 4 MRI of a pituitary adenoma showing suprasellar extension and compression of the optic chiasm.

Neuro-opthalmological assessment

Neuro-ophthalmological assessment is mandatory in all cases of pituitary dysfunction. At the initial consultation visual acuity should be assessed with the use of Snellen charts and fundoscopy performed to exclude optic atrophy, retinal vein engorgement, or papilloedema from pressure on the visual pathways. Visual fields may be assessed by confrontation using a red pin. Patients with any clinical symptoms or evidence of compression of the optic chiasm from imaging studies require formal assessment of visual fields with Goldmann perimetery or visual evoked responses, stimulating each half-field in turn.

Although permanent loss of vision and/or visual field defects usually result from long-standing compression of the optic chiasm, the shorter the time of compression the easier and more complete is the reversal of any visual field deficit. Surgical decompression or shrinkage of prolactin-secreting tumours by medical therapy often results in rapid improvement in visual fields within hours or days, although the presence of optic atrophy reduces the likelihood of this occurring. Because onset is often insidious, patients may be unaware of any alteration in their vision, although once documented its presence requires them to inform the vehicle licensing authority as driving ability may be impaired. An exception to this usual gradual deterioration is pituitary haemorrhage when visual loss may be sudden with a loss of central vision and development of bitemporal field defects and possible ophthalmoplegia often accompanied by changes in mental function.

Pituitary surgery

With the exception of prolactinomas, for which medical therapy should be preferred as the primary therapy, trans-sphenoidal surgery is now regarded as the firstline treatment for pituitary adenomas. Originally performed by Harvey Cushing around 1910, the lack of adequate visualization prevented its reintroduction for routine use until the mid-1970s. In addition to its curative aim in pituitary adenomas, trans-sphenoidal surgery is also used where other treatments have failed, for example medical therapy in prolactinomas, and for debulking large tumours prior to irradiation. Pituitary apoplexy caused by significant haemorrhage into an adenoma is a neurosurgical emergency requiring prompt intervention. The most commonly used approach is with the patient in a semireclining position via a midline nasal route. Using a sublabial or direct nasal approach, the mucosa is cleaved off the nasal septum providing access to the sphenoid sinus with subsequent removal of the sellar floor. An endoscope is now in use. A less satisfactory alternative approach is via the ethmoidal sinus. Pituitary adenomas are usually soft and easily removed with curettes, although firmer and larger tumours may require piecemeal removal. The success of trans-sphenoidal surgery depends on a number of factors:

1. the size of the pituitary adenoma;
2. the degree of invasion into surrounding tissues, especially into the normal remaining pituitary gland, bone, meninges, and lateral extension into the cavernous sinuses;

3. the skill and experience of the surgeon; and
4. any previous therapy.

The aim is for selective adenectomy leaving sufficient functioning normal gland; in cases of microadenoma cure rates as high as 90 per cent can be achieved, although rates are usually much lower (in the region of 40 to 50 per cent) for macroadenomas. Visual field defects improve in approximately 80 per cent of patients.

Complications

In experienced hands, mortality is less than 1 per cent and is related to vascular complications, hypothalamic damage, or meningitis. Morbidity relates to local complications or endocrine dysfunction. Cerebrospinal fluid rhinorrhoea may occur and if persistent will require reoperation and sealing of the leak with autologous material such as fascia lata. The risk of meningitis can be minimized by the use of prophylactic antibiotics. Postoperative worsening of endocrine deficiency tends to increase with the size of the lesion and pre-existing hormonal deficiencies. Diabetes insipidus occurs in approximately 5 per cent of cases, though it is usually minor and transient; the exact prevalence depends on the stringency of the diagnostic criteria. The syndrome of inappropriate secretion of antidiuretic hormone is common, typically occurring transiently between the fifth and eighth postoperative days; it usually responds to fluid restriction.

While most macroadenomas, even those with a suprasellar extension of 2 or 3 cm, can often be substantially removed trans-sphenoidally, extremely large and more invasive pituitary tumours may require transfrontal removal. This approach is associated with additional risks of intracranial oedema/haemorrhage or damage to the optic nerve, frontal lobe, or hypothalamus.

Pituitary irradiation

With the advent of modern trans-sphenoidal techniques, pituitary irradiation tends to be reserved for patients who are either not fit enough to undergo surgery or in whom surgery is incompletely successful. In addition to so-called conventional megavoltage irradiation which has been in routine use since the mid-1960s, newer techniques of stereotactic or focused irradiation using one or a few large doses of irradiation have been introduced more recently.

Conventional irradiation uses a linear accelerator as the source; a cobalt source is less satisfactory. It is administered in a fractionated manner over 5 to 6 weeks with a total dose of 4500 cGy given in daily doses not exceeding 200 cGy. Irradiation should be via at least three portals (two temporal and one frontal) to prevent damage to the brain or optic chiasm. Modern CT techniques allow accurate planning and minimal variation in the daily dosage to surrounding structures. Widespread longstanding experience in this technique has revealed it to be both safe and effective. Hormone hypersecretion begins to decrease within 3 to 6 months with a rapid fall occurring within the first 2 years; thereafter there is a progressive exponential decline for up to 20 years. Thus most patients will be cured of their disease, although the time to achieve this varies. The use of this technique also dramatically reduces the risk of recurrence of both functioning and non-functioning adenomas. The major side-effect relates to the onset of hypopituitarism. In patients without preceding pituitary hypofunction, approximately 50 per cent will become deficient in growth hormone secretion after 5 years with slightly fewer becoming hypogonadal, followed much later (10 to 15 years) by deficiencies of ACTH and thyroid-stimulating hormone. These proportions increase with prior surgery. Thus any patient who has received pituitary irradiation requires lifelong careful follow-up. The other principal potential side-effect relates to damage to the optic chiasm, although this can be avoided by careful planning and keeping the daily fractionated dose to less than 200 cGy. Loss of cognitive function has been claimed to occur after irradiation, but does not occur if proper field planning and fractionated dosage is applied. The influence of prior surgery is also uncertain. Similarly there are reports of an increased incidence of secondary brain malignancies with a risk of perhaps 1 per cent at 20 years' post-irradiation. However, comparable control groups are difficult to obtain and it is likely that the predisposition to pituitary adenomas also predisposes to other cerebral tumours. The overall impression is that with careful radiotherapy the incidence of peripituitary second tumours is no greater in irradiated than non-irradiated patients with pituitary adenomas.

Stereotactic single high-dose pituitary irradiation using either the Gamma Knife (radiosurgery) or stereotactic multiple arc radiotherapy has received increasing attention in recent years, although long-term efficacy and safety data are not yet available. Care needs to be taken with tumours close to the optic chiasm. Initial impressions suggest that hypersecretory states fall to normal much earlier than after conventional radiotherapy but that hypopituitarism occurs just as often.

Individual pituitary hormones

ACTH

ACTH (adrenocorticotrophic hormone) is a 39-amino-acid peptide that is synthesized in the pituitary initially as part of a 231-residue peptide, pro-opiomelanocortin peptide. This then undergoes post-translational cleavage and modification before secretion. In the pituitary, pro-opiomelanocortin peptide is cleaved to b-lipotrophin, ACTH, a joining peptide, and an amino terminal fragment (Fig. 5). The biological activity of ACTH resides within its first 24 amino acids which are identical across species; synthetic $ACTH_{1–24}$ is used for clinical investigations. Pituitary secretion of melanocyte-stimulating hormone does not occur in humans; the increased pigmentation that is observed in conditions of ACTH excess is due rather to the melanocyte receptor stimulating properties of ACTH itself. ACTH G-protein coupled receptors are widely distributed in the adrenal cortex, predominantly in the zono fasiculata and reticularis. Upon binding of ACTH, cyclic AMP is generated which stimulates the synthesis and secretion of the glucocorticoid cortisol and the androgens androstenedione and dehydroepiandrostenedione. Mineralocorticoid secretion is largely controlled by the renin–angiotensin system. Long-term stimulation by ACTH acts to maintain adrenal size and growth, but there may be an additional, so far uncharacterized, hypothalamic–pituitary adrenocortical growth factors.

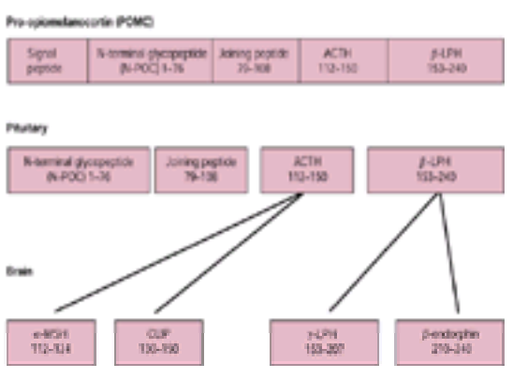

Fig. 5 Schematic representation of the pro-opiomelanocortin precursor protein and its subsequent tissue-specific cleavage products. LPH, lipotrophin; MSH, melanocyte-stimulating hormone; CLIP, coiticotrophinlike intermediate peptide.

Secretion of ACTH is tonically controlled by hypothalamic corticotrophin-releasing hormone, although arginine vasopressin also stimulates its release, particularly in response to stress. Cortisol feeds back negatively on the hypothalamus to inhibit the secretion of both of these factors, but also inhibits their actions at the pituitary directly; ACTH itself exerts negative feedback effects on the hypothalamus via a short loop. There are probably other physiologically important, as yet unidentified, ACTH-releasing hypothalamic hormones.

The secretion of ACTH is pulsatile but with a marked circadian rhythm. Secretory bursts start around 03.00 hours, are most frequent in the one to two hours before waking and the hour thereafter before declining progressively throughout the day to reach a nadir in the late evening, just before the normal time of sleeping. Secretion is predominantly controlled by the light–dark and sleep–wake cycles and is thus altered by time shifts—this accounts for at least some of the symptoms of jet lag. Secretion is also increased by major physical and psychological stress.

Conditions of ACTH deficiency

Isolated ACTH deficiency is rare; it more commonly occurs as a late component of the panhypopituitarism associated with pituitary adenomas, trans-sphenoidal surgery, or pituitary irradiation. Its symptoms are similar to those of Addison's disease but with two important differences: there is no pigmentation—indeed patients

are usually pale—and there is less risk of adrenal crises due to mineralocorticoid secretion being largely preserved. Patients typically complain of anorexia, malaise, loss of energy, and weight loss all of which contribute to them frequently being termed 'malingerers'. Severe cortisol deficiency may result in hypoglycaemia and predispose to circulatory collapse particularly during a supraimposed illness.

Conditions of ACTH excess

ACTH secretion is increased in both Addison's and Cushing's diseases (dealt with in other sections). It is also dramatically increased in the rare condition of Nelson's syndrome. This occurs in patients with Cushing's disease who have been treated by bilateral adrenalectomy. The loss of all negative feedback inhibition by cortisol can result in increasing growth of the pituitary adenoma with not only local invasion and mass effects, but also very high circulating ACTH levels which result in marked hyperpigmentation. Its incidence may be reduced by pituitary irradiation prior to adrenalectomy.

Treatment of ACTH deficiency

ACTH deficiency is best treated by glucocorticoid replacement. The standard regimen is 10 mg hydrocortisone on waking with a further 5 mg at lunchtime and 18.00 although this may need modifying according to the profile of measured serum cortisol throughout the day. Alternative regimes are prednisolone (5 and 2.5 mg) or dexamethasone (0.5 and 0.25 mg) although levels of either of these cannot be assayed in blood. It is essential that patients are educated to increase their dosage during illnesses or stress with at least a doubling of their oral medication. If vomiting occurs or during a perioperative period parenteral therapy will be required. Aldosterone production almost always remains adequate with ACTH deficiency unlike in primary adrenal insufficiency and fludrocortisone therapy is not needed.

Thyroid-stimulating hormone

The glycoprotein thyroid-stimulating hormone belongs in the same family as LH and FSH. Like other anterior pituitary hormones it is secreted in a pulsatile manner but with its effects mediated by circulating thyroxine and liothyronine from the thyroid gland. It is itself controlled by hypothalamic thyrotrophin-releasing hormone. Deficiency of thyroid-stimulating hormone almost never occurs in an isolated manner but occurs in conjunction with other pituitary hormone deficiencies.

Thyrotrophinomas

Thyrotrophin-secreting tumours (also known as TSHomas) are rare, comprising only 1 per cent of all pituitary tumours. Unlike primary thyroid gland diseases they have an equal sex incidence, with the majority presenting between the third and sixth decades of life, although cases at all ages have been recorded. Symptoms and signs result from the ensuing excess of thyroid hormone. As more than 90 per cent of the tumours are macroadenomas, visual field defects are common. Coexistant oversecretion of other pituitary hormones occurs in about 20 per cent of cases and is usually of growth hormone. Diagnosis is made on the basis of elevated circulating thyroxine with detectable or increased thyroid-stimulating hormone. The major differential diagnosis in such cases is the condition of resistance to thyroid hormone; distinguishing between the two requires both laboratory and radiological data. Generalized resistance to thyroid hormone is usually an autosomal dominant condition; however, when resistance to thyroid hormone is restricted to the pituitary it is often sporadic and patients are clinically hyperthyroid. In neither instance is a pituitary tumour present. Further differentiation is available with measurement of the a subunit of thyroid-stimulating hormone (and other glycoprotein pituitary hormones) and calculation of the a subunit/thyroid-stimulating hormone molar ratio; a ratio greater than 1.0, indicating oversecretion of the uncombined a subunit, is present in more than 90 per cent of thyrotrophin-secreting tumours, whilst a ratio of less than 1.0 is indicative of resistance to thyroid hormone.

Treatment

Surgery remains the initial treatment for the majority of cases of TSHomas, although the frequency of macroadenomas means that biochemical cure rates are only about 40 per cent. As almost all of these tumours express somatostatin receptors, the use of somatostatin analogues, for example octreotide, usually enables medical control of hypersecretion of thyroid-stimulating hormone to be achieved. This is often accompanied by a reduction in tumour size.

Gonadotrophins

The gonadotrophins LH (luteinizing hormone) and FSH (follicle stimulating hormone), together with thyroid-stimulating hormone and human chorionic gonadotrophin b comprise the family of glycoprotein anterior pituitary hormones. Whilst the a subunit is common to all these hormones, it is the b subunit that is unique to each and gives biological and immunological specificity. The actions of both LH and FSH are intimately involved with maintenance of libido and fertility; in women their secretion, subject to positive and negative feedback, controls ovarian gonadal secretion and the menstrual cycle. In men, LH controls testosterone production by the Leydig cells whilst FSH stimulates Sertoli cell spermatogenesis. Deficiency of gonadotrophin secretion is usually one of the earliest occurrences in pituitary tumours.

Gonadotrophinomas

Anterior pituitary tumours that secrete intact LH and/or FSH are termed gonadotrophinomas. Tumours secreting a subunit are more common, but as this is without biological effect and rarely measured in routine clinical settings these tumours are usually classified as non-functioning adenomas. Clinically both gonadotrophinomas and non-functioning adenomas usually tend to present in a similar manner with symptoms relating to a pituitary mass. In men, FSH-secreting tumours (known as FSHomas) cause testicular enlargement due to FSH-induced hypertrophy of the seminiferous tubules; as such the development of bilateral testicular enlargement should prompt investigation of a possible pituitary tumour.

The diagnosis of gonadotrophinomas is controversial; most clinicians require inappropriate elevation of serum LH and/or FSH. However, immunostaining of many clinically non-functioning adenomas will frequently demonstrate staining of either gonadotrophin or a subunit.

Treatment

Surgery is the main treatment for these tumours with adjunctive radiotherapy advocated by many clinicians to reduce the risk of recurrence. Medical therapy with long-acting gonadotrophin-releasing hormone agonists may reduce hormonal secretion, as may the use of somatostatin analogues, which may also result in tumour shrinkage.

Prolactin

Prolactin is a 199-amino-acid residue peptide that belongs to the same family as growth hormone with 16 per cent homology. Prolactin-secreting cells comprise approximately 10 per cent of the anterior pituitary cells in men but up to 30 per cent in multiparous women. Like other anterior pituitary hormones, prolactin is under the control of hypothalamic factors but is unique in that this comprises tonic inhibition by dopamine from the tuberoinfundibular neurones. Release also occurs after administration of thyrotrophin-releasing hormone and vasoactive intestinal peptide, which also occurs in the hypothalamus; although their physiological significance is clear in rodents it remains uncertain in humans. Prolactin synthesis is also strongly influenced by oestrogen which acts as a transcription factor for prolactin gene expression. Under this influence, concentrations are higher in premenopausal women than in men and increase during menarche and especially during pregnancy, when the gland may double in size and weight because of the increase in number of mammotroph cells. The causes of physiological and abnormal increased prolactin secretion are shown in Table 3. Following delivery, maternal levels decrease if breast feeding does not occur but remain elevated in response to suckling. Outside of lactation, nipple stimulation reflexly increases levels as does stress. Levels also increase in response to any disruption of the hypothalamic pituitary stalk or on administration of drugs that interfere with the synthesis or action of dopamine. Primary hypothyroidism may also cause levels to rise, falling again with thyroxine treatment (Table 3).

Action

Prolactin receptors, members of the cytokine superfamily, are widely distributed. Their predominant location is the mammary gland where their activation results in initiation and maintenance of lactation. During pregnancy, additional hormones are required for the development of the synthetic and secretory breast apparatus including oestrogen, insulin, cortisol, and placental mammotrophic hormones. However, the elevated oestrogen levels during pregnancy also inhibit lactation from the prepared prepuerperal breast, which occurs with their precipitous fall after delivery of the placenta. The actions of prolactin receptors at other sites is less clear. Direct effects on the hypothalamus inhibit pulsatile release of gonadotrophin-releasing hormone and thus gonadotrophin secretion, probably by increasing the inhibitory

opiate (endorphin) tone in the hypothalamus, resulting in impaired gonadal function. This is the basis for the contraceptive effect of lactation, which persists as long as prolactin levels are sufficiently high, maintained by the intensive reflex of breast feeding as the sole source of feeding the baby. It is also becoming increasingly clear that prolactin has widespread effects on immune functions as well as perhaps antiapoptotic actions in several tissues including the prostate.

Disorders of secretion

Absence of prolactin secretion rarely occurs on its own and is of unknown physiological significance other than precluding lactation. However, the usual coexistent loss of gonadotrophins and resultant infertility tends to precede this clinical effect.

Prolactinomas

Prolactinomas are the most common functioning anterior pituitary tumour encountered in clinical practice. They account for 25 to 30 per cent of pituitary adenomas and are much more common in women. The majority are sporadic, although occasionally they may be part of the multiple endocrine neoplasia type 1 syndrome. They may be either pure prolactin secreting or mixed somatomammotroph (growth hormone) tumours. They are of monoclonal origin. The clinical features can be divided into local mass effects or the effects of hyperprolactinaemia either on the breast or on the gonadotrophin-releasing hormone pulse generator. In premenopausal women the commonest symptoms are secondary oligo/amenorrhoea (in up to 95 per cent of patients), galactorrhoea (20 per cent), or infertility with regular cycles. Due to these symptoms, women tend to present earlier and thus the tumours are usually microadenomas. Although increased prolactin causes decreased libido and erectile dysfunction in men, these symptoms may be ignored and male patients, like postmenopausal women, present late with mass effects such as headaches, visual field defects, or involvement of other cranial nerves from cavernous sinus extension. Galactorrhoea is rare in men.

Treatment

In common with other pituitary tumours the aims of treatment are to reduce hormone secretion to normal, to reduce tumour size correcting visual field defects, and to restore normal anterior pituitary function.

Left untreated, the majority of microprolactinomas do not appear to undergo progressive enlargement. As such the need for treatment depends on the clinical situation and the patient's wishes. The introduction of the ergot-related synthetic dopamine agonist bromocriptine in 1971 revolutionized the treatment of prolactinomas. A variety of other dopamine agonists are now available, the only one with advantages being the long-acting cabergoline. All of these directly activate pituitary D_2 receptors, thereby mimicking endogenous hypothalamic dopaminergic action. They are highly effective in lowering prolactin levels, stopping galactorrhoea, and restoring normal gonadal function including fertility. They also have dramatic effects producing shrinkage of the tumour in 85 per cent of patients and improvement in visual fields. Disappearance of headaches is seen within days, and if imaging is repeated, shrinkage is confirmed within 4 to 6 weeks in most cases. Given these effects, it is mandatory that a serum prolactin level should be measured in all patients presenting with a visual field defect and a pituitary mass prior to surgery (normal levels are less than 400 mU/l or 20 ng/ml). A serum level of greater than 4000 mU/l (200 ng/ml) is indicative of a prolactinoma and introduction of dopamine agonist therapy will usually avoid the need for pituitary surgery. The usual starting dose for bromocriptine is 2.5 mg once daily taken during the main course of a bulk meal. This slows absorption and will minimize the side-effects of nausea and dizziness, although most patients experience tachyphylaxis and symptoms tend to settle with repeated dosages. An initial dose of cabergoline is 0.5 mg once weekly. Other side-effects include fatigue, headache, and nasal stuffiness. Most serious is psychosis which has been reported in approximately 1 to 2 per cent of patients, although more subtle psychiatric disturbances probably occur more often. A previous psychiatric history is therefore a contraindication to the use of this class of drugs. Most patients will require long-term therapy, although a significant proportion of microadenomas undergo spontaneous resolution/infarction and it is worthwhile having an intermittent trial off therapy from time to time. In the case of macroadenomas, pituitary irradiation is often advocated after initial shrinkage with dopamine agonists, in order to prevent recurrence. Occasional resistance to medical therapy may necessitate surgical intervention. While elevated levels lower than 4000 mU/l (200 ng/ml) may be found in patients with true prolactinomas, such levels may also be found in patients with pseudoprolactinomas. The term 'pseudoprolactinoma' is used for any peripituitary mass which interrupts delivery of dopamine to the normal pituitary via the pituitary stalk, i.e. a functional pituitary stalk section results and prolactin secretion from the normal gland is disinhibited. While prolactin levels as high as 6000 mU/l (300 ng/ml) have been described in association with prolactinoma, they are usually less than 2000 mU/l (100 ng/ml). While the clinical features in patients with pseudoprolactinomas may be identical, and are reversible with dopamine agonists, as in true prolactinomas, but pseudoprolactinomas do not shrink with medical therapy. Thus careful clinical supervision is needed during a trial of medical therapy for large tumours when prolactin levels are less than 6000 mU/l(300 ng/ml).

Hyperprolactinaema and pregnancy

As infertility is a common symptom of hyperprolactinaemia, it is likely that many women with prolactinomas will be trying to conceive whilst on dopamine agonists. Patients should be warned that they are likely to become fertile on treatment and the drug is usually stopped after confirmation of pregnancy. However, having been in use for nearly 30 years, it is clear that continued use of bromocriptine during pregnancy does not result in any adverse effects. Although there is less experience of cabergoline, there is no evidence to suggest that this should be any different.

During pregnancy, under the influence of increasing oestrogen levels, prolactinomas may enlarge like many peripituitary masses, especially meningiomas. Although the risk of this is small for microadenomas, there may be considerable expansion of macroadenomas. Such patients need very careful sequential monitoring for signs of chiasmal compression. In this event, reintroduction of medical therapy will shrink the mass and surgical intervention is rarely required. For patients with a macroadenoma, irradiation or trans-sphenoidal surgery has been advocated prior to attempting to conceive. Whilst this will reduce the risk of expansion during pregnancy, it may lead to growth hormone deficiency after some 5 years and gonadotrophin deficiency in about 50 per cent after 8 to 10 years.

Growth hormone

Human growth hormone is a 191-amino-acid single-chain protein containing two disulphide bonds. It is synthesized by cells located largely in the lateral part of the pituitary. Some 75 per cent circulates as a 22 kDa protein and 5 to 10 per cent as a smaller 20 kDa isoform with the remainder consisting of glycosylated and sulphated isoforms. Growth hormone is secreted in a marked pulsatile manner which is due to the integrated and co-ordinated effects of both stimulatory and inhibitory controlling hypothalamic hormones. Growth hormone-releasing hormone is a positive regulator of its synthesis whilst somatostatin (a 14-amino-acid peptide) is a potent inhibitor of both the frequency and amplitude of its secretory pulses. An additional positive regulator is the newly cloned growth hormone secretagogue 'ghrelin' which acts through a receptor which is distinct from that of growth hormone-releasing hormone. These regulatory peptides are themselves under numerous extrahypothalamic influences. Amino acids, sleep, stress, and a fall in blood glucose increase secretion of growth hormone; b antagonists are able to augment other stimulatory stimuli as do dopamine and cholinergic agonists, both of which are blocked by the cholinergic blockers. Oestrogen enhances the pulse amplitude of growth hormone. Thus secretion of growth hormone is subject to complex neuroregulatory control with levels increasing in response to several physiological stimuli (Table 4).

Overall growth hormone secretion is greater in females, with middle-aged women secreting approximately 45 µg in 24 h compared with 15 µg in men of equivalent age. Secretion increases from the time of puberty, peaking between 18 and 25 years, then inexorably falling to reach low levels after 60 years.

The growth hormone receptor

The growth hormone receptor is a 638-amino-acid receptor which is widely distributed throughout the body, being most abundant in the liver. It consists of extra- and intracellular domains; signal transduction requires dimerization of the receptor, which is facilitated by growth hormone binding. The identification of the specific high-affinity binding sites of the growth hormone molecule to the receptor has allowed their modification to provide specific modified growth hormone antagonists (see below). Signal transduction is via a number of pathways including activation of the JAK/STAT proteins, the insulin receptor substrate pathway and the MAP (mitogen-activated protein) kinase pathway. The complexity and variety of these pathways allows for the different anabolic/differentiative and proliferative effects of growth hormone in different tissues. Abnormalities of the growth hormone receptor occur in Laron's syndrome characterized by failure of growth and a distinct phenotypic appearance and high levels of growth hormone but low levels of insulin-like growth factor I.

Approximately 50 per cent of secreted growth hormone circulates bound to a growth hormone binding protein which consists of the cleaved extracellular domain of the transmembrane growth hormone receptor. Binding to this receptor fragment reduces the clearance rate of growth hormone thus prolonging its bioactivity. Growth hormone binding protein is absent, or abnormal, in Laron's syndrome and reduced or abnormal in other causes of insensitivity to growth hormone.

Actions of growth hormone

The actions of growth hormone can be divided into direct metabolic effects which act in the short term to increase glucose availability, regulate free fatty acids, and increase amino acid uptake, and powerful long-term effects on skeletal and soft tissue growth mediated via insulin-like growth factor I. Insulin-like growth factor I is a basic polypeptide of 70 amino acids (molecular weight 7.5 kDa) which was until recently thought to be synthesized almost solely by the liver. However, it is also synthesized by most tissues in response to growth hormone acting in a paracrine, autocrine, or juxtacrine manner. The circulating insulin-like growth factor I derived from the liver has little importance in determining the growth effects of growth hormone but is measured to reflect the overall functional status of growth hormone since tissue levels cannot be assayed. In the serum insulin-like growth factor I circulates bound to a group of binding proteins which also occur in tissue fluids; six have so far been identified. Insulin-like growth factor binding protein 3 is the predominant carrier of insulin-like growth factor I and its concentration is dependent on growth hormone itself; it thus plays a major role in regulating the bioactivity of insulin-like growth factor I. Insulin-like growth factor I acts via two specific receptors: type I, with a similar structure to that of the insulin receptor, has the greatest affinity for insulin-like growth factor I, whilst the structurally distinct type II receptor has the greatest affinity for insulin-like growth factor II. Insulin-like growth factor II is more important in the fetus and is not growth hormone dependent.

Disorders of growth hormone secretion

Acromegaly

The term acromegaly is derived from the Greek word summarizing its clinical manifestations: *akron*, extremity; *megas*, great. First described by Pierre Marie in 1886 it has an annual incidence of approximately 3 per million although this is almost certainly an underestimate. It is almost invariably due to a growth hormone-secreting pituitary tumour although very rare cases of ectopic secretion of growth hormone-releasing hormone from carcinoid tumours have been recorded. Approximately 5 per cent of cases are associated with multiple endocrine neoplasia type 1. Molecular analysis has revealed that approximately 50 per cent of cases are due to an activating mutation of the a subunit of the G-protein coupled receptor for growth hormone-releasing hormone.

Clinical features

Acromegaly affects both sexes equally, although its insidious onset means that the majority of patients are not diagnosed until the age of 40 to 60 years. Younger patients tend to have more aggressive disease and are detected earlier, although gigantism, occurring before fusion of the bony epiphyses, is a rare occurrence. In common with other pituitary tumours, the clinical manifestations can be related to the neighbouring effects of a local mass or to hypopituitarism, and to specific symptoms and signs relating to excessive secretion of growth hormone and insulin-like growth factor I (Table 5). The insidious onset means that the mean delay in diagnosis is about 7 years, although diagnosis may often take 10 to 20 years. In adults, the increase in soft tissue mass and skeletal effects are responsible for the clinical features including the classical coarse facial features, broad nose, and thick lips. Increase in the size of the mandible results in prognathism and interdental separation. Frontal bossing causes prominent supraorbital ridges. Sweating is one of the most prominent symptoms and the one most sensitive to growth hormone excess. Musculoskeletal symptoms are common, consisting of increased size and breadth of hands ('spade-like' hands) and feet; increasing ring size is common and is a sensitive index of excessive secretion of growth hormone. Degenerative arthropathy of the weight-bearing hips and knees is common, often necessitating joint replacement, and of the spine with pain and neurological pressure effects. Symptomatic carpal tunnel syndrome occurs in approximately half of patients and up to 80 per cent will have subclinical abnormalities. Thyroid enlargement is common resulting in a nodular goitre. Despite these signs the diagnosis is often overlooked.

Complications of acromegaly

Although originally regarded as a predominantly cosmetic disease, several epidemiological reviews have established that acromegaly is associated with significant morbidity and mortality. Early surveys revealed that over 50 per cent of patients died before the age of 60 years, principally due to cardiovascular and metabolic complications. With improved management of both these and the underlying disease, patients are now surviving longer. Reduction of mean serum levels of growth hormone to less than 5 mU/l (2 ng/ml) and/or a normal serum level of insulin-like growth factor I appear to be associated with a normal life expectancy.

Cardiovascular complications are a major source of morbidity and mortality. Although growth hormone in low doses may have a beneficial cardiac action, excessive amounts result in cardiomyopathy and increased left ventricular mass. Many patients develop arrythmias. Hypertension is a frequent complication requiring aggressive monitoring and management; it may persist despite lowering the levels of growth hormone. The increased cardiovascular risk factors also predispose to cerebral vascular ischaemic events. Due to the counter-regulatory properties of growth hormone on insulin, insulin resistance and impaired glucose tolerance is common often resulting in frank diabetes. This may be accompanied by a hypertriglyceridaemia. Increase in the soft tissues of the larynx and tongue can result in obstructive sleep apnoea which often requires domiciliary nocturnal continuous positive pressure airway ventilation. Anaesthetic intubation for any surgical intervention is more difficult (Table 6).

The question of increased risk of malignancy in acromegaly has been controversial for many years, but recent studies have confirmed that there is an increased risk of premalignant colonic tubulovillous adenomas and colorectal carcinoma. Although comparison with comparable control groups is difficult, this increased risk of colorectal cancer appears to be at least threefold. It appears to be an age-related complication with adenomas occurring after the age of 40 years and carcinomas occurring in or after the sixth decade. Although the precise mechanisms remain uncertain it is associated with elevated levels of insulin-like growth factor I which might both increase proliferation of epithelial cells and inhibit their apoptotic response to local environmental factors such as bile salts. These patients require regular colonoscopic screening, although their associated colonomegaly makes this technically challenging. There is a suggestion that acromegaly also predisposes to breast cancer and some circumstantial evidence indicates that elderly male patients should also be screened for prostatic neoplasia.

Aims of treatment

Although the aims of treatment are the same as those for any pituitary tumour, there has been controversy as to the level of reduction of growth hormone that should be considered as a satisfactory therapeutic aim. Epidemological surveys suggest that a normal life expectancy is associated with a mean serum growth hormone level of less than 5 mU/l (2 ng/ml) and/or a normal level of insulin-like growth factor I, although reference tends to be made to a 'safe' level of growth hormone rather than a cure, since physiological responses to growth hormone rarely return to normal. Larger epidemiological studies are required to confirm and refine these findings.

Treatment of acromegaly

Surgery: Trans-sphenoidal surgery remains the firstline therapy for the majority of patients. It is a safe operation with low morbidity. Its success rate depends on the size of the pituitary tumour, the presurgical levels of growth hormone, and the experience of the surgeon. Safe levels of growth hormone are achieved in 60 to 80 per cent of patients with microadenomas and 30 to 40 per cent of patients with macroadenomas.

Radiotherapy: Pituitary irradiation is a very effective means of reducing secretion of growth hormone. It tends to be reserved for patients in whom levels of growth hormone remain elevated after surgery. Its efficacy depends on the preirradiation level with approximately a 50 per cent fall occurring in the first 2 years but with an exponential decline thereafter which may continue for 15 to 20 years. The majority of patients therefore eventually achieve safe levels of growth hormone with a mean interval of 5 to 7 years being required. Normalization of insulin-like growth factor I occurs in over 50 per cent of patients by 10 years. Focused radiotherapy probably results in a more rapid fall. Medical therapy is required during the interim period.

Medical therapy: For many years dopamine agonists provided the only medical therapy for acromegaly. However, unlike in prolactinomas, the response rate is relatively poor with less than 10 per cent of patients achieving safe levels of growth hormone. Furthermore, the doses required are usually very much higher than in prolactinomas with a consequent increased frequency of side-effects. The introduction of the synthetic somatostatin analogue octreotide in the early 1980s provided an enormous advance in medical therapy. Natural somatostatin has a half-life of approximately 80 s and thus cannot be used therapeutically unless by continuous intravenous infusion. Octreotide by contrast has a prolonged effect lasting 6 to 8 h and thus thrice daily subcutaneous injections provide reasonably stable concentrations of drug in the plasma. Using this regimen, growth hormone is suppressed in more than 90 per cent of patients, but only approximately 60 per cent achieve safe levels and 50 per cent a normal level of insulin-like growth factor I. The usual total daily dose ranges from 150 to 600 µg, although occasional patients may require higher doses. There is evidence that octreotide may also shrink the adenoma in many patients, although this effect is not nearly as dramatic or complete as that seen in prolactinomas following therapy with a dopamine agonist. There is no consistent evidence that such shrinkage may aid subsequent surgery. Although generally well tolerated, the predominant side-effects are local pain at the site of injection and gastrointestinal—abdominal cramps, flatulence, and bulky or fluid stools are common although they tend to resolve with time. In the longer term, there is an increased frequency of gallstones which is due to both an inhibition of gall bladder

contractility and increased bacterial deconjugation of bile acids as a result of prolonged intestinal transit time. Atrophic gastritis is another long-term complication. More recently, subcutaneous octreotide has been superseded by the development of somatostatin analogue depot formulations, of which there are currently two, octreotide LAR and lanreotide SR, both of which are administered intramuscularly. The former is available at variable doses of 10, 20, or 30 mg and is administered every 4 or 6 weeks, whilst lanreotide SR is available as a 30 mg dose administered every 14 days or less. Their efficacy is similar to subcutaneous octreotide but with the obvious advantage of increased convenience for the patient. Pegvisomant is an entirely new medical therapy for acromegaly. It is a recombinant modified growth hormone molecule that has increased affinity to one receptor binding site but with a different modification of the other binding site that prevents receptor dimerization. Its conjugation to polyethylene glycol increases its molecular size and prolongs its half-life; it is given as a subcutaneous daily injection. Phase 3 clinical trials have shown it to be extremely effective, with over 90 per cent of patients achieving a normal level of insulin-like growth factor I. The fact that it is a modified growth hormone molecule means that it interferes with most growth hormone assays and thus this measurement cannot be used as a marker of efficacy. Indeed, growth hormone levels actually rise with this medication but to date there is no evidence of pituitary tumour growth. Whether pegvisomant will become a firstline treatment in acromegaly remains to be determined.

Growth hormone deficiency

Although long realized to be vitally important in children, the role and widespread influence of growth hormone in adult physiology has only become apparent over the last decade. It is now clear that not only does growth hormone have widespread functions, but its deficiency in the adult is associated with significant morbidity and mortality. Based on indirect evidence of the frequency of pituitary disease, the annual incidence of adult onset growth hormone deficiency is estimated to approximately 10 per million. In adults, pituitary adenomas remain the commonest cause, although iatrogenic causes, especially irradiation, are also common. In children, approximately 70 per cent of cases are idiopathic. As many of these children have a normal growth hormone axis on subsequent retesting in their teens and adulthood, the pathogenesis might be due to deficiency of hypothalamic growth hormone-releasing hormone or failure or delayed maturation of the hypothalamic–pituitary axis.

Clinical features

Growth hormone does not appear to be necessary for intrauterine growth and most children with congenital or childhood onset growth hormone deficiency tend to present with a falling off of growth velocity and failure to grow, which if unchecked leads to short stature. Bone age is delayed but with a normal weight for height. Thus, early detection requires accurate growth and weight charts.

Over the last 10 years, there have been a large number of studies detailing the effects of growth hormone deficiency, and in the case of adults it is now clear that these patients have a distinct phenotype (Table 7).

The impairment of psychological well-being and quality of life is probably the most important symptom of growth hormone deficiency. Its occurrence has been validated by a variety of questionnaires including the Nottingham Health Profile, the Psychological and General Well-Being Schedule, and the General Health Questionnaire, as well as a specific assessment of growth hormone deficiency. Consistent findings using these measures are decreased energy and mood, increased emotional lability and social isolation, increased anxiety, and reduced overall energy levels and vitality. These measures show significant improvement with administration of growth hormone in about 85 per cent of cases, which in some patients is dramatic. Lack of effect may reflect psychological dysfunction related to previous surgery or irradiation.

Growth hormone deficiency is associated with a reduction of lean body mass of approximately 7 to 8 per cent and an increase in fat mass of the same amount. This tends to be in a central distribution resulting in increased waist–hip ratio. There is decreased fluid volume comprising total body water. Administration of growth hormone will reverse all of these changes with an increase in lean body mass of up to 5 kg, predominantly skeletal muscle, and a corresponding reduction of fat mass with a consequent decreased waist–hip ratio. There is an increase in total body water. One of the most important effects of growth hormone appears to be a significant reduction in bone mineral density, with several studies showing an increase in osteoporotic fractures. Although recombinant growth hormone increases bone mineral density, it takes a minimum of 12 months for the effect to be measurable (using dual-energy X-ray absorptiometry scanning) and as yet there are no studies showing a consequent reduction in the rate of osteoporotic fractures. Impaired muscle strength and exercise performance is a frequent symptom and sign of growth hormone deficiency. Maximum oxygen uptake is reduced to approximately 80 per cent of that of age-, sex-, and height-matched controls. Whilst it improves with administration of growth hormone, not all measures of strength and muscle function are restored to normal and several years of treatment may be required.

Growth hormone deficiency has been associated with a two- to threefold increased mortality relating to vascular disease. Possible mechanisms might be related to the demonstrated increased thickness of the arterial intima and atherosclerotic plaques of carotid arteries, as well as the increased risk factors for ischaemic heart disease such as body mass, total cholesterol and low-density lipoprotein, and reduction in high-density lipoprotein. Metabolic effects of insulin resistance and hyperinsulinaemia with decreased carbohydrate metabolism might also be important. The abnormal lipid profile improves with growth hormone treatment, although an associated increase in lipoprotein (a), which is proposed to be an independent risk factor for atherosclerosis, remains of some concern.

Growth hormone deficiency is associated with impaired cardiac function comprising decreased left ventricular mass, impaired systolic function, and reduced ejection fraction. Whilst there is anecdotal evidence of dramatic increases in cardiac performance, the majority of studies have shown considerably milder effects on increased ventricular mass, stroke volume, and cardiac output.

Treatment of adult growth hormone deficiency

The aims of treatment are to improve and normalize the abnormalities associated with growth hormone deficiency. At present, most endocrine units only offer growth hormone replacement to patients who have a severe growth hormone deficiency (i.e. a peak growth hormone response of less than 9 mU/l after insulin-induced hypoglycaemia) and who are symptomatic or have abnormal metabolic/bone investigations. It is not yet routinely administered to all patients with growth hormone deficiency. In part this is due to its cost (in 2000 approximately £5000 per annum). There is, however, growing interest in the role of recombinant growth hormone therapy in the frail elderly with a view to improving their functional capacity, as it is suggested that the physiological decrease in growth hormone secretion in the elderly might be responsible for the associated changes in body composition. At present, however, trials of growth hormone administration in these patients are limited and there is obvious concern about the long-term safety issues (see below). Amongst patients in whom growth hormone treatment is indicated, the development and widespread availability of recombinant growth hormone has avoided the risk of transmission of Creutzfeldt–Jacob disease which was associated with the use of pituitary-derived natural growth hormone before 1985. The development of modern cartridge pens has also facilitated its administration, which is usually as a once daily subcutaneous injection in a manner similar to insulin. Currently, childhood doses are calculated according to body weight with the end point being growth velocity. Early studies in adults also used a weight-based regimen but the doses tended to be supraphysiological with an increased incidence of side-effects. It is now clear that individual dose titration should be performed with an initial daily dose of 0.8 U (0.3 mg). which is subsequently titrated according to the serum values of insulin-like growth factor I. The aim is to restore serum insulin-like growth factor I to the upper half of the age-matched normal range. This gradual titration ensures a more physiological replacement and minimizes the side-effects. The average maintenance dose in men is 0.8 U (0.3 mg) whilst in women it is higher at 1.2 U (0.4 mg). Regardless of the final dose, it has become clear that a minimum of 6 months' treatment is required to establish whether or not benefit has occurred.

Side-effects

Too large an initial dose, or too rapid an increase, results in sodium and water retention and thus oedema, weight gain, and carpal tunnel syndrome. There may be changes in glucose metabolism and alterations in cortisol metabolism such that hypopituitary patients taking hydrocortisone may need adjustment of their dose. Hypopituitarism seems to be associated with a reduced incidence of malignancy and there is a theoretical possibility that this might be increased back to normal, particularly as several epidemiological studies have demonstrated serum insulin-like growth factor I to be a risk factor for prostate, breast, and colorectal cancer. These safety issues will be clarified by continual analysis of the on-going long-term surveillance programmes that have been established, although there is no current evidence supporting this theoretical concern.

Craniopharyngiomas

Craniopharyngiomas are rare tumours with an incidence of approximately 1 to 2 per million population, but constitute the commonest intracranial tumour of childhood. They are derived from remnants of Rathke's pouch and as such arise within or above the pituitary fossa. They usually contain both cystic and solid components with the cyst containing oily fluid that is rich in human chorionic gonadotrophin b. Although histologically these tumours are benign, they are often locally invasive with a

strong tendency to recur. Their frequent involvement of the hypothalamus, pituitary, and optic pathways means that the clinical symptoms may be severe. Over half the cases occur in childhood when growth failure is the predominant complaint; presenting symptoms in adults include amenorrhoea and decreased libido. Hypothalamic symptoms, which are often most disabling, include obesity, hyperphagia, diabetes insipidus, and disturbances of sleep. In addition, as the tumours tend to be large, symptoms of a space occupying lesion and visual symptoms are common.

A unique feature is the frequent presence of calcification within the tumour, which aids in its diagnosis as it is visible on both skull radiographs and CT scans. MRI is optimal for visualizing the cystic components and for determining the extent of local invasion but does not show the calcification. There exists considerable controversy about the optimal treatment of these tumours. Early series tended to favour radical resection in order to reduce the chances of recurrence. However, such an approach, particularly in childhood, results in considerable damage to the optic apparatus and hypothalamus with an increased mortality and morbidity. Many units now favour the subtotal removal with postoperative irradiation. Recurrence of cysts is often dealt with by drainage and the insertion of yttrium-90 seeds into the cyst cavity.

Lymphocytic hypophysitis

Although not described until 1962, lymphocytic hypophysitis is increasingly recognized as a cause of pituitary dysfunction. It is an autoimmune disease with more than 90 per cent of cases occurring in women, often in relation to pregnancy when it occurs in the late third trimester or puerperium. However, men and patients of any age can be affected. Histologically, the disease is characterized by infiltration of the pituitary by lymphocytes and plasma cells with the formation of follicles containing germinal centres. There is subsequent destruction of the gland and fibrosis. Lymphocytic hypophysitis tends to present in either of two ways. In pregnancy, there is often a rapidly expanding pituitary mass presenting with headaches and visual failure. Alternatively, outside of pregnancy there may be an insidious onset of hypopituitarism. Diabetes insipidus occurs in approximately 10 per cent of cases. The major differential diagnosis is that of Sheehan's syndrome, although it is highly likely that many cases previously ascribed to Sheehan's syndrome were due to hypophysitis. Unlike pituitary adenomas, the destruction of pituitary cells in hypophysitis tends to affect corticotrophs and thyrotrophs predominantly, with deficiency of ACTH and/or thyroid-stimulating hormone occurring in approximately 80 per cent of patients. There are no specific radiological features, with both CT and MRI showing a varying appearance: the pituitary mass may appear hypo- or isointense with variable enhancement. More than 50 per cent show suprasellar extension.

The treatment for this condition is controversial. As there have been numerous reports of spontaneous resolution, particularly during pregnancy, the development of a pituitary mass in the third trimester or puerperium may warrant a conservative approach, although careful monitoring of visual fields is essential. Some endocrinologists familiar with this condition advocate a trial of steroids, although evidence of their efficacy remains anecdotal. Outside of pregnancy, the differential diagnosis of a pituitary mass is broad and trans-sphenoidal surgery is indicated both to remove the mass and to obtain a histological diagnosis. Although it is an autoimmune disease, there are no specific antibodies available for its diagnosis; however, the presence of antithyroid or other organ-specific antibodies is frequent.

12.3 Disorders of the posterior pituitary

John Newell-Price and Michael Besser

Anatomy

The posterior pituitary lies immediately dorsal and caudal to the anterior pituitary gland and is an extension of the ventral hypothalamus. The major function of the posterior pituitary is the release of the nonapeptide peptide hormones arginine vasopressin (AVP) and oxytocin. These are synthesized in the magnocellular neurones of the supraoptic and paraventricular nuclei of the hypothalamus, and pass by axonal transport, to be stored in nerve endings in the posterior pituitary (Fig. 1). Efferent fibres from these nuclei also project to the median eminence, the brainstem, the floor of the third ventricle, and the spinal cord. Afferent fibres arise from osmoreceptors adjacent to, but separate from, the supraoptic and paraventricular nuclei, probably in the organum vasculosum of the lamina terminalis or subfornicial organ rostrally in the hypothalamus; signals are also received from the brainstem, and from the vagus and glossopharyngeal nerves that receive input from the pharynx and baroreceptors of the heart and great vessels. All these fibres carry the sensory signals modulating AVP and oxytocin release.

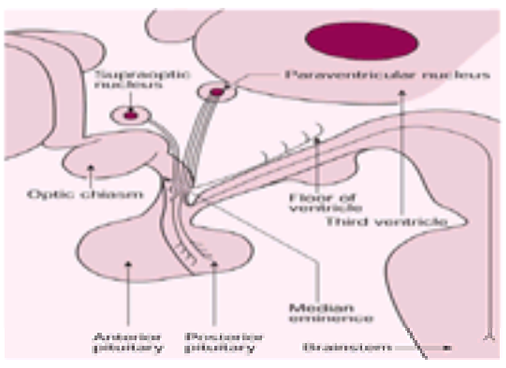

Fig. 1 Schematic representation of the neuronal pathways from the paraventricular and supraoptic nuclei. The nerves project to the posterior pituitary, the median eminence, the floor of the third ventricle, and the brainstem. Afferent fibres from the osmoreceptors and thirst centre are shown. (Reproduced from Besser GM and Thorner MO, 1994, with permission.)

Vasopressin and oxytocin

Vasopressin and oxytocin have molecular weights of 1087 Da and 1007 Da, respectively. The genes for both these hormones are located on chromosome 20q13 in close physical proximity. Each peptide is synthesized as a 145-amino acid precursor comprising a signal peptide, the peptide hormone AVP or oxytocin, and their specific neurophysin—I for oxytocin and II for AVP. The AVP precursor has, in addition, a glycoprotein at the C-terminus. AVP and oxytocin are composed of a six-member disulphide ring with a three-amino acid tail (Fig. 2). The differing amino acids at positions 3 and 8 have a profound effect on the biological action. In the synthesizing nuclei, granules are formed containing the precursor complex of neurophysin and oxytocin or vasopressin. During axonal transport processing cleaves off the active hormone from the neurophysin, and the products are stored in the nerve termini in the posterior pituitary. On firing of the nerves, AVP or oxytocin together with the relevant neurophysin are released into the systemic circulation. Most AVP circulates as free hormone and has a half-life of approximately 10 min. AVP is principally cleared by the liver and kidneys, whilst oxytocin is cleared in these sites and in the uterus.

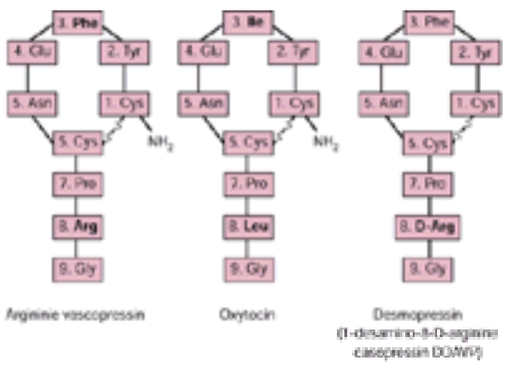

Fig. 2 The structure of vasopressin, oxytocin, and desmopressin. Amino acid differences are highlighted in bold.

Arginine vasopressin

Physiology

Actions of arginine vasopressin

At least three distinct receptors, V1a, V1b, and V2, mediate the actions of AVP. Each of these is a member of the superfamily of seven-transmembrane-domain, G-protein-coupled receptors. The first two signal by inositol-phosphate pathways, whilst the V2 receptor activates adenylate cyclase with an increase in intracellular cAMP. The V2 receptor is expressed almost exclusively in the collecting tubules of the kidney. When AVP binds to the receptor, an increase in intracellular cAMP results in the insertion of a water-conducting channel (aquaporin 2) into the apical membrane of the collecting duct. This allows water to pass from the lumen of the tubule along a concentration gradient into the cell, and then into the renal interstitium, via the AVP-independent aquaporin channels that are constitutionally active in the basolateral cell membrane, thus accounting for the antidiuretic action of AVP. Activation of the V1a receptor in vascular smooth muscle results in vasoconstriction and increases blood pressure but at much higher blood concentrations. Activation of the V1b receptor in the anterior pituitary, in synergy with corticotropin-releasing hormone (**CRH**), is involved in the release of ACTH, but the vasopressin involved in ACTH release derives predominantly from the paraventricular nuclei and represents a separate neuroanatomical system.

Control of arginine vasopressin secretion

There are three principal stimuli to AVP release—a rise in circulating osmolality, a drop in blood pressure, and a stressful event. An increase in plasma osmolality is sensed in the osmoreceptor cells, and this is the major physiological stimulus to the secretion of AVP. There is a tight linear positive correlation between the plasma osmolality and the release of AVP, and a similar relationship holds between osmolality and thirst, which is probably sensed in a centre distinct from, but adjacent to, the osmoreceptor. A loss of extracellular water will stimulate vasopressin secretion to conserve water, accompanied by thirst and a drive to drink. In combination, these processes maintain the plasma osmolality within the narrow range of 285 to 295 mOsmol/kg (Fig. 3). An increase in the plasma sodium concentration is a greater stimulus to AVP secretion than other solutes, and in humans maximum antidiuresis is achieved at plasma vasopressin concentrations between 2 and 4 pmol/l. After ingestion of fluid, there is a fall in the plasma vasopressin levels before a change in the osmolality, which is presumed to occur via a pharyngeal reflex that inhibits AVP release.

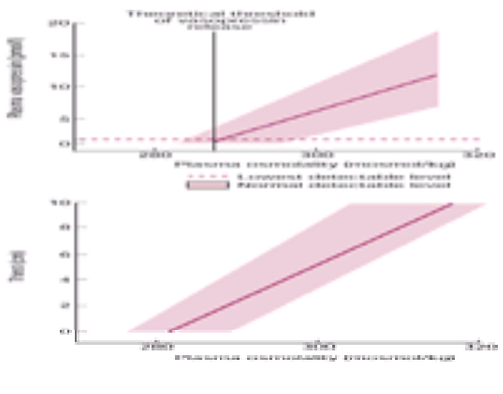

Fig. 3 The relationship between plasma osmolality and plasma arginine vasopressin concentration, and between plasma osmolality and thirst. AVP concentrations and thirst sensation rise in a linear fashion in relation to plasma osmolality. (Reproduced from Besser GM and Thorner MO, 1994, with permission.)

AVP release after a fall in blood pressure, as after haemorrhage, is sensed by baroreceptors in the heart, aorta, and the great vessels. The accompanying water retention helps, together with the sodium retention that follows aldosterone release, to restore the blood volume. AVP is also released under non-specific stress, particularly if associated with nausea or vomiting.

Disorders of arginine vasopressin secretion

Diabetes insipidus

Polyuria with dilute urine may result from vasopressin deficiency (cranial diabetes insipidus, **DI**), resistance to the actions of AVP (nephrogenic DI), and excessive fluid drinking (primary polydipsia). The causes of diabetes insipidus are shown in Table 1. Simple destruction or removal of the posterior pituitary gland, or damage to the distal part of the pituitary stalk, usually results in a temporary DI lasting for 6 weeks to 6 months, since the proximal nerve endings grow out to find systemic capillaries in any scar formed and begin direct secretion again. Upper stalk, median eminence, or more extreme hypothalamic damage results in permanent diabetes insipidus.

An individual deficient in AVP will pass approximately 40 ml/kg of urine in 24 h (between 3 and 20 litres), leading to the clinical features of polyuria, polydipsia, nocturia, and in children nocturnal enuresis. In the complete absence of AVP the maximally dilute urine has an osmolality of approximately 50 mOsmol/kg. As long as there is free access to water, normovolaemia and normonatraemia are maintained by an intact thirst centre. Glucocorticoids are necessary for adequate free-water clearance by the kidneys. Thus if there is a coexistent ACTH deficiency because of a hypothalamic or pituitary lesion, diabetes insipidus may not become manifest until the institution of corticosteroid replacement therapy. It the thirst centre is destroyed as part of the hypothalamic lesion, dangerous dehydration may ensue.

Familial causes are very rare and have been documented as being due to mutations in either the gene encoding the signal peptide or neurophysin molecule, but not of the gene for the AVP peptide itself. Interestingly, symptoms are not usually present at birth but gradually develop between 1 and 6 years of age. It is hypothesized that the changes resulting from such mutations interfere with correct protein folding, and cause retention of a mutant peptide within the neurones which then undergo degeneration, with diabetes insipidus becoming manifest when approximately 80 per cent have been destroyed. Diabetes insipidus is very rarely a presenting feature of an anterior pituitary tumour, although it is frequent after surgical treatment. Therefore, if DI is present at diagnosis of a pituitary mass lesion this should alert the clinician to possible primary hypothalamic lesions such as craniopharyngioma or germinoma.

Differential diagnosis of diabetes insipidus

In a normal individual the plasma osmolality will range from 285 to 295 mOsmol/kg, but urine can be concentrated to more than twice the concentration of plasma. Significant diabetes insipidus is excluded if the urine to plasma (U:P) osmolality ratio is more than 2 to 1, provided that the plasma osmolality is no greater than 295 mOsmol/kg. In diabetes insipidus, despite the raised plasma osmolality, the urine is inappropriately dilute with a U:P ratio below 2. Any cause of polyuria will give a relative resistance to the actions of AVP since the renal medullary concentrating gradient will be washed out. Furthermore, hypercalcaemia or hypokalaemia cause resistance to the actions of vasopressin, possibly by decreasing the level of cAMP within renal tubular cells. The commonest investigation used to discriminate normality from the various causes of diabetes insipidus is the water-deprivation test (Table 2).

There are no contraindications to this test in the fully hydrated patient. Before the test can be performed and adequately interpreted both the thyroid function and adrenal reserve must be normal, or the patient must be on replacement therapy. Impaired renal function, hypercalcaemia, and hypokalaemia need to be excluded. It is important that covert drinking is avoided and that the individual is continuously monitored to prevent severe dehydration. The patient is allowed free access to water overnight to avoid dehydration and the test is started in the morning. Drinking is not allowed for 8 h. Urine and plasma osmolality are followed and close adherence to a defined protocol is essential for safety (Table 2).

Interpretation of the water-deprivation test

A normal response is for the urine volume to gradually fall with fluid deprivation, with a increase in osmolality and a U:P osmolality ratio above 2 towards the end of the test; but the plasma osmolality should remain below 295 mOsmol/kg. In cranial diabetes insipidus there is little rise in urine osmolality, the U:P ratio is less than 2, and frequently the plasma osmolality rises above 295 mOsmol/kg. However, following desmopressin the urine concentrates normally, whereas in nephrogenic diabetes insipidus there is no rise in urine osmolality following desmopressin. Primary polydipsia often gives results that are difficult to interpret since the patient may be water-overloaded at the start of the test, and in addition has a decreased medullary concentrating gradient in the kidney. The combination of these two factors often results in U:P ratios of less than 2 at the end of the test and with a plasma osmolality of less than 285 mOsmol/kg, the threshold for AVP secretion.

In circumstances where the plasma osmolality does not rise above 295 mOsmol/kg, it is still possible that vasopressin secretion is abnormal despite a U:P ratio above 2. Unfortunately this may occur in mild cases of cranial and nephrogenic diabetes insipidus (DI), and in primary polydipsia causing diagnostic confusion. One excellent means to further investigate these patients is to give a 5 per cent hypertonic saline infusion and then measure plasma AVP levels; patients with cranial DI will demonstrate low levels of AVP, whilst the levels of AVP will be increased in those with nephrogenic DI. However, AVP is only measured in a few centres and an alternative is an extended water-deprivation test.

The extended water-deprivation test may be performed in mild cases and if the results from the standard water-deprivation test are equivocal. This is similar to the standard test except that the patient starts somewhat dehydrated, avoiding drinking from 18.00 h the day before the test, which is then started the next morning. Water deprivation is continued until the urine osmolality reaches a plateau (less than 30 mOsmol/kg increase between three consecutive samples), and then desmopressin 2 µg intramuscular is given and the patient allowed to drink. In normal subjects, endogenous AVP secretion under these circumstances is sufficient to maximally concentrate the urine so that no further increase in osmolality is seen after desmopressin. A urine osmolality rise of 9 per cent or more after desmopressin suggests partial cranial DI. Primary polydipsia is suggested when urine concentrates normally if the plasma osmolality rises above 290 mOsmol/kg before desmopressin, with

no further rise following desmopressin in the presence of polydipsia and polyuria.

Treatment of cranial diabetes insipidus

Desmospressin is a synthetic analogue of AVP with high selectivity for the V2 receptor and a prolonged half-life, giving it profound antidiuretic properties and, at antidiuretic doses, little pressor activity. In adults the normal daily dose by intranasal spray is between 10 and 40 µg in divided doses. It is essential to instruct the patient carefully in the administration of the spray so that it may be adequately absorbed from the olfactory mucosa. Oral preparations allow for easier administration, but variability in the bioavailability between patients means that the oral dose may range between 100 and 600 µg daily (and occasionally more) in divided doses. In the perioperative period, or in critically ill patients, it may be necessary to administer desmopressin parenterally at doses of between 1 and 4 µg daily. The main side-effect is hyponatraemia if excess fluid is ingested or administered. Patients should be encouraged to drink only in response to their thirst to avoid water intoxication. All other pharmaceutical treatments are inferior.

Individuals with cranial diabetes insipidus and an intact thirst centre usually do not present particular management problems. However, in the presence of destructive hypothalamic lesions the thirst centre may also be damaged and management of water balance is frequently difficult. In adipsic patients this is best achieved by setting a fixed dose of desmopressin and weighing them when they are normovolaemic. These individuals will then need to be instructed to maintain their daily weight by drinking, taking into account insensible losses, and in hotter climates this may involve twice-daily weighing. In some circumstances, an automated audible reminder to drink may be necessary if hypothalamic damage has affected the patient's memory.

Nephrogenic diabetes insipidus

Nephrogenic diabetes insipidus has diverse causes (Table 1). Congenital nephrogenic diabetes insipidus typically presents with profound polyuria and hypernatraemia from birth, in contrast to congenital cranial diabetes insipidus. The condition needs urgent recognition since repeated episodes of hypernatraemia with polyuria, vomiting, constipation, fever, irritability, and a failure to thrive may result in long-term cognitive impairment. The drive to drink may impair eating and lead to delayed growth. The X-linked condition is associated with mutations of the V2 receptor, whilst in autosomal recessive disease there is deficiency of aquaporin. Other than direct mutational analysis, infusion of desmopressin may allow discrimination between the two types: in the autosomal recessive condition there will be an increase in blood pressure, and in circulating Von Willebrand factor and factor 8 to two to threefold the basal level. As these effects are dependent on intact V2 receptor signalling they will not be seen in the X-linked form.

Treatment of nephrogenic diabetes insipidus

Drugs such as lithium should be withdrawn if possible. Thiazide diuretics reduce the urine output by enhancing sodium excretion to the expense of water and decreasing glomerular filtration rate. Amiloride may need to be coadministered to avoid hypokalaemia. Cyclo-oxgenase inhibitors such as indometacin may also be of benefit.

Syndrome of inappropriate antidiuresis (SIADH)

Excessive and inappropriate secretion of vasopressin either from the posterior pituitary or from ectopic sources, such as small-cell lung cancer, results in inappropriately concentrated urine, dilute plasma, and hyponatraemia with continuing renal sodium excretion. Since there are many causes of hyponatraemia the diagnosis of SIADH should only be entertained in the absence of oedema-forming states, hypovolaemia, or hypotension, and when renal and adrenal function are normal (Table 3). Typically, the condition is asymptomatic during the initial stages, especially if the fall in the serum sodium level is slow. Rapid onset of hyponatraemia is associated with confusion, drowsiness, convulsions, coma, and death. Symptoms are uncommon until the serum sodium falls to 120 mmol/l or less, or the plasma osmolality drops below 268 mOsmol/kg. In cases where vasopressin is secreted from an ectopic source, such as small-cell lung cancer, there is a complete disassociation of the concentration of plasma vasopressin from plasma osmolality. In contrast, in certain central nervous system conditions vasopressin is secreted in a regulated fashion but inappropriately at a low plasma osmolality. This is in keeping with an osmostat that is set at a lower level. Pragmatically, however, the management of the metabolic disturbance is the same whatever the cause. States associated with sodium depletion must be excluded. The urinary sodium concentration will be very low in patients with a low body sodium concentration, unless they are on diuretics, whereas it will be normal or high in those with SIADH.

Management of the syndrome of inappropriate antidiuresis

It is clear that the underlying cause will require treatment on its own merits. Fluid restriction is the cornerstone of treatment: Fluid restriction to between 500 and 750 ml/24h usually reverses any adverse clinical features and restores the circulating sodium level and osmolality to normal. The use of hypertonic saline infusions is very rarely required and only if severe drowsiness or convulsions are experienced, which are unresponsive to fluid restriction and if the serum sodium is around 100 mmol/l. Hypertonic saline should only be administered under close supervision to avoid rapid increases in the plasma sodium concentration and the risk of central pontine myelinolysis. The plasma sodium concentration should rise by no more than 0.5 mmol/l per hour. Drugs such as demeclocycline, which induce nephrogenic diabetes insipidus, may be helpful but the effects are often short lasting.

Oxytocin

Actions of oxytocin

Oxytocin binds to its specific cell-surface receptor expressed predominantly in the myometrial cells of the uterus and breast, and the ductal and epithelial cells of the breast. Expression of the receptor is increased by oestrogen, and receptor numbers increase during pregnancy. In the gravid uterus the myometrial cells are probably maintained in a tonic state of relaxation by the levels of cAMP induced by the actions of placental corticotropin-releasing hormone (CRH). The oxytocin receptor signals via phospholipase C; an increase in intracellular calcium causes phosphorylation of the CRH receptor, resulting in its desensitization and decoupling of CRH receptor signalling. The combined effect of these processes is to stimulate myometrial contraction. This is utilized in obstetric practice where infusions of synthetic oxytocin are used to initiate and sustain labour.

Control of oxytocin secretion

Cervical distension causes the release of oxytocin, which may be involved in the onset of parturition in the human as it is in lower species. In lactating women the release of oxytocin is stimulated by suckling, which then causes contraction of the myoepithelial cells within the breast alveoli and milk ejection.

12.4 The thyroid gland and disorders of thyroid function

Anthony P. Weetman

Structure of the thyroid gland

Development

The human thyroid develops as a diverticulum in the pharyngeal floor around 3 weeks of gestation. This median anlage moves caudally, remaining connected to the pharynx via the thyroglossal duct, which subsequently is obliterated when the thyroid begins to expand as two distinct lobes, around 2 months of gestation. The foramen caecum marks the point in the tongue where the thyroid develops and there is sometimes an upward extension of thyroid tissue from the isthmus, the pyramidal lobe, arising from the lower part of the thyroglossal duct. At the same time, the lateral anlage ultimobranchial bodies, derived from the fifth branchial pouches, fuse with the developing thyroid to which they contribute the parafollicular calcitonin-secreting clear (C) cells. Synthesis of thyroid hormone begins at week 11, at the same time as thyroid stimulating hormone (TSH) production by the pituitary. There is significant maternal-to-fetal thyroxine (T4) transfer so that babies with no endogenous thyroid hormone production are nonetheless largely protected from the adverse effects of fetal hypothyroidism on development of the brain, lung, and skeleton. Preterm infants of less than 27 weeks gestation have immature thyroid function and their neurological development may be improved by temporary thyroxine supplementation.

Anatomy and histology

The adult thyroid weighs 15 to 20 g and each lobe is around 4 cm in length and 2 cm in width, although the right lobe is often larger than the left. The isthmus connecting the two lobes lies just below the cricoid cartilage. The blood supply on each side is derived from the external carotid artery via the superior thyroid artery and from the subclavian artery via the inferior thyroid artery. There is adrenergic and cholinergic innervation which regulates blood flow. The thyroid is attached to the trachea by connective tissue and the recurrent laryngeal nerves lie between the trachea and the posterior aspect of the lobes.

The gland is made up of lobules, each comprising 20 to 40 spherical follicles. The follicles vary considerably in size, but average 200 μm in diameter, and are made up of a single layer of thyroid follicular epithelial cells (Fig. 1). The cells are cuboidal when quiescent and columnar when active, and have a microvillous apical membrane. The follicular lumen contains colloid, the principal constituent of which is the glycoprotein thyroglobulin, secreted by the thyroid cells. Each follicle is surrounded by a rich capillary network. C cells lie scattered between follicular epithelial cells or in the intersititium, and account for around 1 per cent of the epithelial mass.

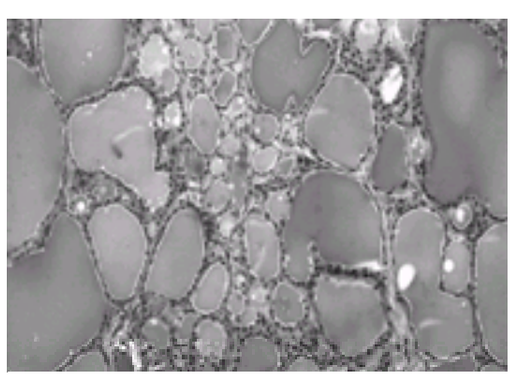

Fig. 1 Photomicrograph showing the histology of a normal thyroid. Thyroid epithelial cells are arranged in follicles containing colloid. (Original magnification ×200; photomicrograph by courtesy of Dr K. Suvarna.)

Thyroid hormone synthesis and metabolism

Synthesis and secretion

Thyroid hormone synthesis requires iodide uptake and oxidation, iodination of certain tyrosine molecules on thyroglobulin, and coupling of the iodotyrosines to form the thyroid hormones triiodothyronine (T3) and T4 (Fig. 2). Iodide is actively transported into the thyroid cell by the Na^+/I^-symporter, which is also expressed in breast tissue and the salivary glands. Perchlorate, thiocyanate, and pertechnetate are also transported by the same symporter and these anions can competitively inhibit iodide uptake. The recommended daily intake of iodine is 150 µg for adults (200 µg during pregnancy) but there is wide variation in actual intake, with many countries having borderline or frankly deficient intakes of less than 50 to 100 µg, while in Western Europe and North America intake is excessive (up to 750 µg/day).

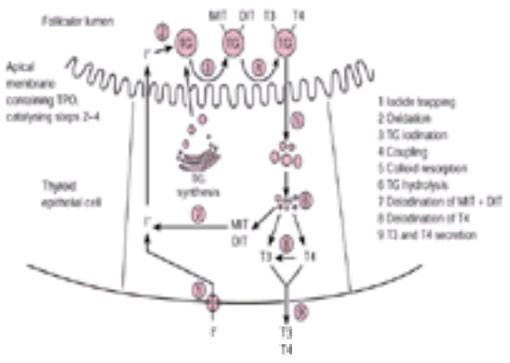

Fig. 2 Steps in the synthesis of thyroid hormones. TG = thyroglobulin, TPO = thyroid peroxidase, MIT = monoiodotyrosine, DIT = diiodotyrosine.

Iodide is oxidized by thyroid peroxidase, a haem-containing enzyme located at the apical border of the thyroid cell, and is rapidly incorporated into tyrosine residues to form monoiodotyrosine and diiodotyrosine. Thyroid peroxidase is also responsible for the coupling of these iodotyrosines, with different sites in the thyroglobulin molecule being responsible for the formation of T3 or T4. Normally, each thyroglobulin molecule contains 3 to 4 T4 molecules, but only 20 per cent of thyroglobulin molecules contain a T3 molecule. Thyroglobulin acts as slow turnover reservoir for thyroid hormone, thus ensuring maximum use is made of often scarce dietary iodine. Around a 7-week supply of T4 is contained in the normal thyroid. Thyroid hormone is released from the gland after endocytosis of colloid and lysosomal hydrolysis of the thyroglobulin to yield T4 and T3, which are secreted from the basal membrane into the capillaries in a ratio of 10:1. Released iodotyrosines are deiodinated for iodide recycling.

Thyroid hormone transport

Up to 90 per cent of the total T3 in the circulation is derived from peripheral conversion of T4 to T3 by deiodinase enzymes (see below) rather than thyroid secretion. Only 0.03 per cent of T4 and 0.3 per cent of T3 in the circulation exist as free hormone, able to diffuse into tissues. The remainder is protein bound. T4 binds predominantly to thyroxine-binding globulin, and to a lesser extent to transthyretin (or prealbumin); a little is bound to albumin. T3 binds to thyroxine-binding globulin and albumin, with little bound to transthyretin. Alteration in the concentration or binding capacity of thyroid hormone binding proteins can produce major changes in total but not free thyroid hormone levels (Table 1).

Metabolism of thyroid hormone

The half-life of T4 in the circulation is 7 days, contrasting with the much shorter half-life of T3 (24 h). The most important metabolic pathway for T4 is outer ring (5') deiodination to T3 (Fig. 3). This is catalysed by type 1 and 2 deiodinase, while type 3 deiodinase catalyses inner ring (5) deiodination leading to hormone inactivation. Type 1 deiodinase can also catalyse inner ring deiodination of T3 and T4. All three enzymes have a selenocysteine moiety as the active catalytic site. Type 1 deiodinase is expressed predominantly in the liver, kidney, thyroid, and brain, type 2 in the pituitary, brain, placenta, skeletal muscle, and heart (tissues critically dependent on thyroid hormone for development or function), and type 3 in the brain, placenta, and skin. The type 1 deiodinase is largely responsible for the generation of circulating T3 from T4, whereas T3 generated by the type 2 enzyme mainly provides intracellular T3 at specific sites.

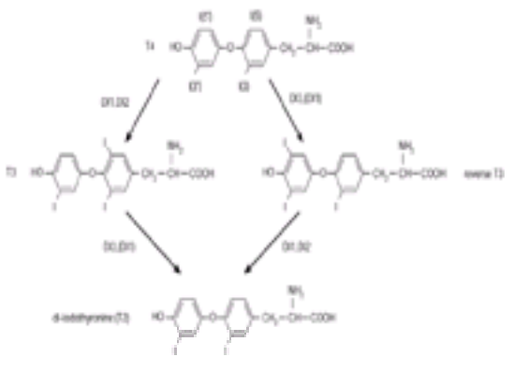

Fig. 3 Main deiodination pathway for thyroid hormones. DI = deiodinase enzyme; parentheses denote a minor contribution. Deiodination of T3 also yields 3,5-T2 and deiodination of reverse T3 also yields 3',5'-T2. T2 is further deiodinated to monoiodothyronine and thyronine.

Around 40 per cent of T4 is metabolized to T3 and 40 per cent is converted to reverse T3 by the type 3 deiodinase. This same enzyme is responsible for the main metabolic pathway for T3 which is converted to 3,3'-dioiodothyronine. Starvation, trauma, and drugs (propylthiouracil, amiodarone, glucocorticoids, propranolol) impair T4 to T3 conversion and must be borne in mind in interpreting tests of thyroid function (see below). In addition to deiodination, a small proportion of thyroid hormone is metabolized by conjugation of the phenolic hydroxyl group with sulphate or glucuronic acid, which increases water solubility and allows urinary and biliary excretion. Biliary iodothyronine glucuronides can be reabsorbed, constituting an enterohepatic cycle.

Thyroid hormone action

Thyroid hormone acts as a transcription regulatory factor, mediated by T3 binding to nuclear receptor isoforms which belong to the same superfamily as steroid and retinoic acid receptors. All such receptors possess a conserved DNA-binding domain, containing two zinc fingers which interact with specific DNA response elements, and a hormone-binding domain. Alternative splicing results in two pairs of thyroid hormone receptor (Fig. 4) whose tissue expression varies during development. Thyroid hormone receptors bind to DNA as homodimers or heterodimers (with the retinoid X receptor). Without ligand, basal gene transcription is inhibited by a corepressor. When T3 binds, homodimers dissociate, releasing corepressor and allowing gene transcription; the stable heterodimer binds coactivators in the presence of T3 with the same outcome. The a2 thyroid hormone receptor does not bind T3 and may act as a natural inhibitor of receptor activity. Knockout mice devoid of all known thyroid hormone receptors have an abnormal pituitary–thyroid axis and impaired growth and bone maturation, but not the severe manifestations of complete hypothyroidism, indicating the potential for other mechanisms of thyroid hormone action.

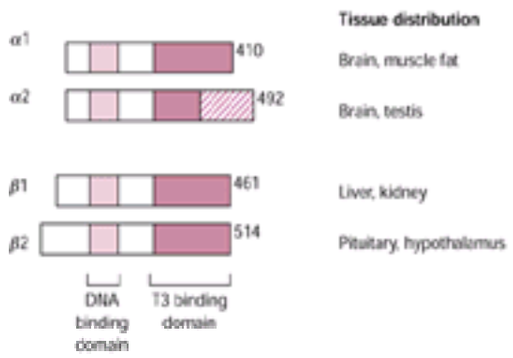

Fig. 4 Structure of the thyroid hormone receptors. The numbers indicate the amino acid content. Homologous areas are shaded; the lack of homology in the T3-binding domain of the a2 receptor (hatched area) prevents T3 binding and the function of this receptor is unknown.

Regulation of thyroid function

The main regulator of thyroid function is TSH (thyrotropin), secreted by thyrotrophs in the anterior pituitary in response to the tripeptide thyrotropin-releasing hormone (TRH), derived from the hypothalamic supraoptic and paraventricular nuclei. Thyroid hormones exert a classical negative feedback effect on thyrotrophs; the acute effect is mediated by T3 in the pituitary which is derived from T4 by type 2 deiodination. Thyroid hormones also inhibit hypothalamic TRH synthesis. TRH-stimulated TSH secretion is inhibited by dopamine and somatostatin, while a-adrenergic activation stimulates TSH release. Cytokines, particularly interleukin-1, interleukin-6, and tumour necrosis factor, inhibit TSH synthesis and may be responsible for the suppression of TSH seen in severe illness.

Within the thyroid, TSH binds to the G protein-coupled TSH receptor, leading to intracellular signalling predominantly via cyclic AMP. TSH increases iodide transport and organification, endocytosis of colloid and thyroid hormone secretion, as well as thyroid follicular epithelial cell division. Autoregulatory mechanisms can modulate thyroid function when TSH levels are constant. The most important is iodine intake. Increased iodide transport transiently decreases organification and reduces thyroid hormone synthesis (the Wolff–Chaikoff effect); after several weeks under normal conditions, the thyroid escapes and resumes hormone production. Sudden increases in iodine intake can also block thyroid hormone release acutely. In iodine deficiency, thyroid hormone production is switched to preferential T3 synthesis, but this effect is largely TSH-mediated rather than autoregulatory.

Laboratory investigation of thyroid function

Determining thyroid status

The introduction of sensitive immunoradiometric assays for circulating TSH, with a detection level of 0.1 mU/l or less, has transformed the evaluation of thyroid status. A normal TSH level rules out primary thyroid dysfunction. Low levels of thyroid hormones elevate TSH as a result of negative feedback, while excessive thyroid hormone suppresses TSH. The TRH test for detecting low TSH levels is now redundant. Besides primary thyroid disorders, other conditions may alter TSH levels and must be borne in mind when using TSH as a screening test for thyroid dysfunction (Table 2), as must the possibility of secondary (pituitary or hypothalamic) disturbances of thyroid function.

It is therefore essential to confirm thyroid status when TSH levels are abnormal, or when pituitary or hypothalamic abnormalities are possible, by measuring circulating thyroid hormone levels. Methods which measure total T3 or T4 are prone to artefacts caused by abnormal thyroid hormone binding (Table 1), although in the absence of such abnormalities these tests are reliable. When altered binding is suspected or found, compensation can be made by calculation of the free T3 or free T4 index. These indices are derived from the total hormone levels and measurement of the differential distribution of radiolabelled T3 between unoccupied protein binding sites in the sample and an absorbent resin (hence the term resin uptake test). Thyroxine-binding globulin levels can also be measured directly.

However, the ready availability of immunoassays for free T3 and free T4 has generally supplanted these methods. The immunoassays rely on the ability of a radiolabelled thyroid hormone analogue to bind to thyroid hormone antibody but not to plasma binding proteins. The analogue then competes for antibody binding with the free thyroid hormone in the sample. Despite initial concerns about the theoretical basis and performance of such assays, recent improvements allow generally reliable estimation of free thyroid hormones. In cases of doubt, free hormone levels can be measured by physical separation from bound hormone, using ultracentrifugation or equilibrium dialysis.

Several indirect methods can be used to determine thyroid status. The thyroidal uptake of radioiodine (^{123}I, ^{131}I) or ^{99m}Tc-pertechnetate is increased in hyperthyroidism and decreased in hypothyroidism, but can be affected by excessive dietary iodine and destructive processes in the thyroid, so that uptake is low when the patient is thyrotoxic (see Destructive thyroiditis below). Serum thyroglobulin is raised in hyperthyroidism of all types but is also raised in destructive thyroiditis and thyroid cancer. Its main role in investigation is follow-up of treated thyroid cancer (see Chapter 12.5). A number of non-specific tests have also been used to determine end organ responses to thyroid hormones, including basal metabolic rate, tendon relaxation time, and serum levels of cholesterol, ferritin, sex hormone-binding globulin, and liver enzymes.

Thyroid function in non-thyroidal illness and pregnancy

Assessing thyroid function in severely ill patients often reveals abnormalities termed the sick euthyroid syndrome. Many of the changes are due to cytokine release, but therapeutic agents such as dopamine and glucocorticoids also contribute, as do unknown factors. Any major, acute illness or starvation can result in a decrease in circulating T3 (total and free) with normal levels of T4 and TSH. Reverse T3 levels rise. The severity of the illness correlates with the magnitude of the fall in T3, and in very sick patients total T4 levels also fall. Analogue-based free T4 assays generally produce normal results but sometimes high or low values occur. In 10 to 15 per cent of sick individuals, TSH levels are abnormal (raised or lowered). Psychiatric illness can be associated with raised total and free T4 levels with normal T3.

There is no proven benefit from thyroid hormone administration in the sick euthyroid syndrome and the hormone changes may be protective, limiting catabolism (although this view is regularly challenged). The importance of these alterations lies in their potential to cause diagnostic confusion. Thyroid function tests should only be requested in ill patients when thyroid disease is genuinely suspected. Abnormal thyroid function tests due to the sick euthyroid syndrome return to normal after recovery and therefore repetition of testing is the simplest way to confirm the reason for unusual results.

Pregnancy also affects thyroid function testing. The most obvious change is the rise in thyroxine binding globulin, which elevates total but not free T3 and T4 levels. In addition, the reference ranges for free T3 and T4 are higher than normal in the first half of pregnancy, because placental human chorionic gonadotropin (hCG), at high levels, acts as a weak stimulator of the TSH receptor. There is a reciprocal fall in TSH levels during the first trimester, but TSH returns to normal in the second trimester as hCG levels decline. Occasionally, these changes are sufficient to cause transient 'gestational' hyperthyroidism, associated with hyperemesis gravidarum. Antithyroid drugs are usually unnecessary in this condition, and attention should be directed to controlling the vomiting and giving parenteral fluids. Renal clearance of iodine is increased in pregnancy, leading to maternal and neonatal goitre and mild hypothyroidism in areas where iodine intake is marginal (50 µg/day). These complications can be prevented by supplemental iodine, 150 to 200 µg/day.

Determining the cause of thyroid dysfunction

The most frequent cause of thyroid dysfunction in iodine-sufficient areas is autoimmunity and the simplest test for this is measurement of thyroid autoantibodies, particularly those directed against thyroid peroxidase (the 'microsomal' antigen). Antibodies against thyroglobulin are also easily measured but are almost always accompanied by thyroid peroxidase antibodies, so testing for the latter alone is usually adequate. Different methods, including haemagglutination, immunofluorescence, radioimmunoassay, and enzyme-linked immunosorbent assay, give different prevalence rates for thyroid autoantibodies. Almost all patients with autoimmune hypothyroidism, and around 75 per cent with Graves' disease, have thyroid peroxidase antibodies. Generally lower levels are found in 5 to 15 per cent of healthy women and 2 per cent of men, and in slightly higher proportions of patients with nodular goitre and thyroid cancer, and results therefore need to be interpreted carefully. Individuals with positive thyroid autoantibodies but normal thyroid function are at increased risk of developing autoimmune hypothyroidism (around 2 per

cent per year).

Thyroid imaging by scintiscanning is useful in determining the aetiology of thyroid disease when this is not obvious clinically, particularly in hyperthyroidism and ectopic thyroid tissue. Its role in the evaluation of a solitary thyroid nodule is considered in Chapter 12.5. ^{99m}Tc is usually used as it has a short half life (6 h) which allows safe administration of high activity and rapid scanning. ^{123}I is not as readily available but is also preferable to ^{131}I, especially in children, as it too has a short half life and does not emit beta radiation. ^{131}I imaging is particularly useful in planning treatment of thyroid cancer and localization of metastases. The place of ultrasound imaging is less clear. The technique allows accurate determination of thyroid size, which may be useful in follow-up of goitre, and can help to determine the nature of an atypical neck mass. Its role in evaluating nodular thyroid disease is considered in Chapter 12.5. CT scanning is particularly valuable in determining the extent of a retrosternal goitre and assessing tracheal compression (Fig. 5). In contrast, a standard chest radiograph can be misleading in evaluating tracheal compression, particularly in the anterior–posterior plane.

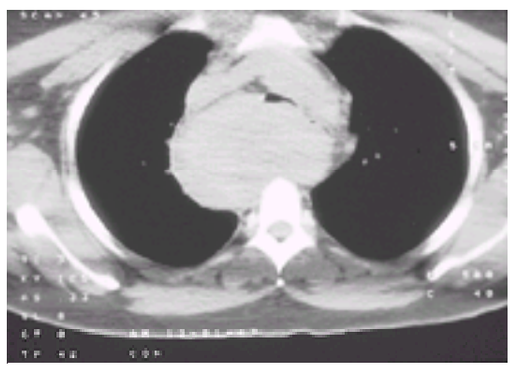

Fig. 5 CT scan of the chest in a patient with a large retrosternal goitre causing tracheal compression.

Goitre

The distribution of thyroid size in any population forms a continuous, positively skewed curve, whose shape depends on the age, sex, and country of residence of the individuals assessed. Hence a precise definition of goitre is impossible. Ultrasound is the most accurate method to assess thyroid size and estimates of goitre prevalence based on inspection and palpation underestimate the true frequency. However, simple schemes, such as that used by WHO/UNICEF, are useful in field studies of goitre prevalence:

- Grade 0 = no visible or palpable thyroid
- Grade 1 = thyroid enlargement that is palpable but not visible when the neck is in the neutral position
- Grade 2 = thyroid enlargement which is both visible and palpable with the neck is in the neutral position
- Grade 3 = goitre visible at a considerable distance

Of the many causes of goitre (Table 3), those associated with disturbances of thyroid function are considered later. The remainder can be classified broadly as endemic and sporadic non-toxic goitres.

Endemic goitre

Prevalence

Goitre is said to be endemic when the prevalence exceeds 10 per cent in children aged 6 to 12 years, although this figure is arbitrary and it has recently been suggested that a prevalence of more than 5 per cent should be used.. Over 200 million people are affected world-wide, especially in the Himalayas, Andes, and parts of Africa, although Eastern and Southern Europe are also involved.

Aetiology

The main cause is iodine deficiency, with goitre prevalence exceeding 30 per cent in areas with very low iodine intakes (<30 µg/day). However, endemic goitre is not exclusively related to iodine deficiency. Naturally occurring goitrogens, such as those in vegetables of the cabbage family and in cassava, exaggerate the effects of iodine deficiency by the action of thiocyanates and cyanoglucosides, respectively, on iodine transport. Where selenium and iodine deficiency coincide, thyroid cell destruction and gland fibrosis minimize goitre formation. In Japan, endemic goitre actually results from iodine excess, as well as goitrogens in seaweed, and in Kentucky, chemical pollution of water is goitrogenic.

Clinical presentation

Diffuse goitre is more frequent in girls, and gradually becomes nodular with age and increasing iodine deficiency. Endemic goitres can be massive but give few compressive symptoms. In areas of marginal iodine deficiency, such as Belgium, goitre only appears, and is then modest, when demands on thyroidal iodide metabolism are increased during puberty or in pregnancy.

The major impact of endemic goitre and iodine deficiency on health is the association with endemic cretinism. Two forms of cretinism can be delineated in separate geographical areas, but there is considerable overlap. Firstly, when maternal iodine intake is severely reduced, causing hypothyroidism, there is reduced placental transfer of T4 to the fetus, resulting in a profound neurological deficit in the infant, with mental deficiency, deafness, speech defects, and spastic gait. Secondly, hypothyroidism in the infant after birth produces the typical cretin features, in particular stunted growth. The thyroid in cretins may be enlarged or atrophic and it is clear from field studies that iodine deficiency alone cannot account for the multiple forms of endemic cretinism.

Management

Iodine supplementation is perhaps the simplest and cheapest of remedies and the condition it prevents has devastating consequences; it is sobering that iodine deficiency still persists. There are few complications from iodine supplementation, although thyrotoxicosis may result in a variable proportion of individuals (the Jod–Basedow phenomenon), some of whom have avoided this previously through lack of sufficient iodine. It is political, social, and economic inertia which are at the heart of continuing iodine deficiency. Effective programmes are best targeted at women intending pregnancy and children. Iodization of salt or bread is widely used in developed nations, but intramuscular or oral iodized oil as a single annual dose, or iodination of drinking water, is preferable in areas where distribution of iodized foodstuffs is a problem.

Sporadic goitre

Prevalence

Goitre occurs in around 5 per cent of the iodine-sufficient population and is four times more common in women. However, the prevalence varies with area and generally declines with age; over 60 per cent of goitres found in adolescents regress over the next 20 years. The character also changes over time, from a diffuse (sometimes called simple) goitre to a multinodular goitre. The presentation of single thyroid nodules is dealt with in Chapter 12.5, but it is worth mentioning here that solitary thyroid nodules increase in frequency with age.

Aetiology

The aetiology of sporadic goitre is largely unknown. Unidentified goitrogens may be responsible in a few patients, and in others, mild iodine deficiency in infancy may initiate goitrogenesis which persists despite a subsequently normal iodine intake. A large proportion are probably the result of mild defects in hormone synthesis; compensatory growth ensures normal thyroid function and current tests cannot identify the nature of the defect. Familial clustering of sporadic goitre supports this idea. Although TSH is the most obvious thyroid growth factor, TSH levels by definition are normal in sporadic goitre, which may therefore be the result of other autocrine and paracrine growth factors (e.g. insulin-like growth factor-1, epidermal growth factor, fibroblast growth factor). A role for growth stimulating autoantibodies has also been suggested, but remains controversial.

Progression to a multinodular goitre occurs when unencapsulated nodules form in a long-standing diffuse goitre. These nodules contain colloid-rich, polyclonal follicles, and are usually distinct from adenomas, which are encapsulated and derived from a single thyroid follicular cell with a somatic mutation conferring growth advantage. However, some goitres contain both nodules and adenomas, suggesting a spectrum of pathological changes. Because thyroid follicular cells are heterogeneous, nodules generally develop with varying degrees of function, giving rise to 'hot' and 'cold' areas on scintiscanning with radioiodine. Some nodules develop autonomy and may eventually cause hyperthyroidism, completing the evolution from non-toxic to toxic multinodular goitre (see below). Other nodules undergo degeneration with haemorrhage, fibrosis, and cyst formation.

Clinical presentation

Patients usually seek attention because of the appearance of the neck or a sensation of pressure or discomfort. Equally, they may be unaware of a long standing small goitre which is noticed on examination. Careful palpation is sufficient to distinguish true goitre, which moves on swallowing, from a prominent pad of fat over the front of the neck. Very large goitres can cause dysphagia or even stridor when the trachea is compressed, but these symptoms are uncommon. Venous compression at the thoracic inlet is even rarer; this sign is exacerbated by asking the patient to raise her arms (Pemberton's sign). Pain in the thyroid, which radiates to the jaw, is uncommon and suggests either destructive thyroiditis (see below) or haemorrhage into a cyst in a multinodular goitre. In the latter, the pain is usually unilateral, acute, and associated with a rapid change in thyroid size; symptoms resolve spontaneously in a few days.

Investigations

Thyroid function should be assessed by checking TSH levels, and then free T3 and T4 levels if the TSH is abnormal, to rule out goitre associated with thyroid dysfunction. The presence of thyroid peroxidase antibodies is also useful as a marker of an underlying autoimmune thyroiditis, which occurs in 10 to 20 per cent of multinodular goitres. Imaging, in my view, has only a limited place in the investigation of sporadic goitre, although in many centres, scintiscans and ultrasound are widely used. Ultrasound is useful in determining thyroid size accurately and may reassure an anxious patient that the thyroid is not enlarging. In most cases it is not necessary. Thyroidal uptake of radioisotopes (especially ^{99m}Tc) is indicated if destructive thyroiditis is suspected as a cause of goitre. Otherwise, the major role for imaging is to ensure there is no tracheal compression or intrathoracic/retrosternal component in a patient with suggestive symptoms, and a CT scan is then the preferred investigation (Fig. 5).

Treatment

Most patients with euthyroid sporadic goitre do not require treatment. Neck discomfort or cosmetic concerns may prompt intervention but it is necessary to take a careful history to ensure that discomfort or difficulty swallowing is indeed caused by the goitre. There is no cost–benefit analysis which shows the superiority of any single treatment. Thyroxine, given at doses to maintain slightly suppressed TSH levels (0.1 to 0.3 mU/l), leads to a reduction in goitre size in up to 60 per cent of patients but is unlikely to have any effect on a very nodular goitre or when the TSH level is already low (so-called subclinical hyperthyroidism, discussed below). There are concerns about the long-term effects of suppressive doses of thyroxine on the heart and skeleton, and treatment must be continued long-term to maintain any improvement.

Radioiodine has recently been used in some centres, with doses of ^{131}I ranging from 600 to 3400 MBq (hospitalization is required for doses greater than 800 MBq). Goitre size is usually reduced by more than 50 per cent at 2 years, and most of the improvement occurs within 2 to 3 months. Tracheal compression by a goitre can be treated with ^{131}I, despite theoretical concerns over acute worsening due to a radiation thyroiditis. However, there are as yet no long-term follow-up data on such patients, although hypothyroidism certainly occurs in 20 to 40 per cent by 5 years.

Surgery is used in other centres, and is particularly indicated for severe tracheal compression or retrosternal goitres, and if there is any suspicion of malignancy. Subtotal thyroidectomy is undoubtedly effective, but goitre may recur in around 20 per cent of patients within 10 years and does not seem avoidable by giving thyroxine replacement. Complications, including recurrent laryngeal nerve damage, hypoparathyroidism, and hypothyroidism, are more likely with the biggest goitres, near total thyroidectomy, and reoperation.

Hypothyroidism

Introduction

Impaired production of thyroid hormones is usually due to a primary abnormality of thyroid gland or iodine deficiency; occasionally it is secondary to pituitary or hypothalamic disorders, dealt with in Chapter 12.2 and Chapter 12.3. The onset of primary hypothyroidism is gradual and may be detected when the TSH is elevated (to compensate for impaired thyroid output) but the free thyroid hormone levels are normal. This state is subclinical hypothyroidism. As thyroid damage continues, TSH levels rise further but free T4 levels fall. The TSH at this stage is usually greater than 10 mU/l, symptoms become apparent, and the patient is said to have overt or clinical hypothyroidism.

Aetiology

The causes of hypothyroidism are listed in Table 4. The commonest cause world-wide is iodine deficiency, discussed in the preceding section. In iodine sufficient areas, autoimmune hypothyroidism and thyroid damage after radioiodine or surgical treatment for hyperthyroidism are the major causes.

Epidemiology

The prevalence of overt hypothyroidism in Caucasians is around 2 per cent in women and 0.2 per cent in men, with a mean age of 60 at diagnosis. Subclinical hypothyroidism is even more common (6 to 8 per cent of women and 3 per cent of men). Around 4 per cent of these individuals progress to overt hypothyroidism annually if thyroid peroxidase antibodies accompany the elevated TSH. Half this number progress in the absence of thyroid peroxidase antibodies. Focal lymphocytic infiltration of thyroid, associated with thyroid autoantibody positivity, occurs in up to 15 per cent of healthy women and 2 per cent of men without an elevated TSH, representing the earliest manifestation of thyroid autoimmunity; 2 per cent of these people progress to overt hypothyroidism annually. Congenital hypothyroidism occurs in about 1 in 4000 births and this high frequency has led to the widespread introduction of neonatal screening.

Pathogenesis

Autoimmune hypothyroidism is primarily the result of autoreactive T-cell-mediated cytotoxicity directed against thyroid follicular cells. Cytokines derived from the locally infiltrating T cells, macrophages, and dendritic cells impair thyroid cell function and enhance T-cell-mediated cytotoxicity. The role of thyroid autoantibodies in thyroid cell destruction is unclear, but thyroid peroxidase antibodies fix complement and may cause secondary damage. In 10 to 20 per cent of patients, antibodies which block the TSH receptor are partially or wholly responsible for hypothyroidism and transplacental passage of these antibodies (but not thyroid peroxidase antibodies) occasionally causes transient neonatal hypothyroidism. Genetic and environmental factors are involved in the aetiology but, as with most autoimmune disorders, the complex interaction of these factors has so far prevented a full understanding. Polymorphisms in the HLA-DR and CTLA-4 genes are associated with autoimmune hypothyroidism, and a high iodine intake may be an important environmental factor in some cases.

Congenital hypothyroidism is caused by thyroid aplasia or hypoplasia in 60 per cent of cases and in 30 per cent there is an ectopic gland. Mutations in thyroid-specific

transcription factors have been found in some of these cases. In the remaining 10 per cent, hypothyroidism is due to dyshormonogenesis (Table 4).

Clinical features

The cardinal features in adults with hypothyroidism are shown in Table 5. However, the ready availability of reliable screening tests for hypothyroidism, especially TSH assays, has led to the recognition of many patients in whom there are only vague or non-specific symptoms, such as tiredness, weight gain, and poor concentration. The differential diagnosis is accordingly vast but the high frequency of hypothyroidism should prompt its exclusion when any suggestive features are present, particular in middle aged women with chronic fatigue or depression.

Autoimmune hypothyroidism may present with a goitre (Hashimoto's thyroiditis) or without (atrophic thyroiditis or primary myxoedema). When present, the goitre is of variable size but is often hard and irregular, sometimes giving rise to suspicion of a malignancy, which then requires exclusion by fine needle aspiration biopsy. Primary lymphoma of the thyroid is a rare but important association (Chapter 12.5). Thyroid pain due to autoimmune thyroiditis is also a rare complication. Patients may notice a Hashimoto goitre before any thyroid dysfunction has developed and annual follow-up is then needed.

The most dramatic presentation of hypothyroidism is myxoedema coma, which is fortunately rare. In addition to the usual features, there is hypothermia (as low as 23°C) and coma, sometimes with seizures. Mortality is 50 per cent even with intensive treatment. Patients are typically elderly and either previously undiagnosed or poorly compliant with medication. There is generally an additional precipitant, such as respiratory depression due to drugs, chest infection, heart failure, stroke, blood loss, or exposure to cold.

Autoimmune hypothyroidism is frequently associated with other autoimmune conditions. In the type 2 autoimmune polyglandular syndrome, autoimmune thyroid disease (hypothyroidism or Graves' disease) is associated with type 1 diabetes mellitus and/or Addison's disease. This syndrome is autosomal dominant with variable penetrance. In the rare, autosomal recessive type 1 autoimmune polyglandular syndrome (chronic mucocutaneous candidiasis, Addison's disease, and hypoparathyroidism), autoimmune hypothyroidism is found in 5 to 10 per cent of patients. Other common associations include pernicious anaemia, vitiligo, and alopecia areata and there is a significant excess of autoimmune hypothyroidism in coeliac disease, dermatitis herpetiformis, chronic active hepatitis, rheumatoid arthritis, systemic lupus erythematosus, and Sjögren's syndrome. Breast cancer patients and individuals with Down's and Turner's syndromes have a higher than expected frequency of thyroid autoimmunity. Around 5 per cent of patients with thyroid-associated ophthalmopathy, discussed later in this chapter, have autoimmune hypothyroidism and 15 per cent of patients with Graves' disease successfully treated with antithyroid drugs develop hypothyroidism 10 to 20 years later. This relationship with Graves' disease is further emphasized by rare patients who oscillate between hyper- and hypothyroidism over a period of months. The likely explanation is fluctuation in the relative levels of TSH receptor stimulating and blocking antibodies, but the cause of these changes is unknown.

Juvenile hypothyroidism is uncommon. The features of adult hypothyroidism (Table 5) may be present, but the diagnosis is usually suggested by retarded growth and dentition, and an infantile face. Myopathy with muscle enlargement is common. Puberty is usually delayed, yet sometimes is precocious. Congenital hypothyroidism is typically unrecognizable at birth but, if not identified by screening, gives rise to prolonged jaundice, failure to thrive, impaired growth, feeding difficulties, constipation, and hypotonia. Left untreated, even for a few weeks after birth, there is permanent neurological damage, resulting in intellectual impairment.

Pathology

In Hashimoto's thyroiditis there is a prominent diffuse and focal lymphocytic infiltrate with germinal centre formation. The thyroid follicles show varying degrees of destruction and little or no colloid. The remaining thyroid follicular cells have an increased number of mitochondria, giving rise to oxyphil metaplasia (Askanazy or Hürthle cells). There is a variable degree of fibrosis. In atrophic thyroiditis, fibrosis is the most prominent feature, with a less obvious lymphocytic infiltrate than in Hashimoto's thyroiditis. Thyroid follicles are usually sparse, reflecting the later stage at which this form of autoimmune hypothyroidism is diagnosed. Whether there is a natural progression from Hashimoto's to atrophic thyroiditis is unclear, although the goitre usually decreases with thyroxine replacement.

Laboratory diagnosis

Measuring the serum TSH is the first step in diagnosing hypothyroidism, with the important caveat that this approach will miss most cases of secondary hypothyroidism in which the serum TSH measured by immunoassays may be low, normal, or even slightly raised, due to the secretion of bioinactive forms of the hormone. If secondary hypothyroidism is suspected, for instance in the follow-up of a patient with treated pituitary disease, it is essential to check the free T4 level. The TSH is elevated in other settings besides primary overt hypothyroidism (Table 2). It is therefore important to confirm the diagnosis by measuring the free T4 in all samples in which the TSH is elevated. Measurement of free T3 adds nothing to the diagnosis, especially as values may be within the reference range in a quarter of hypothyroid patients, due to extrathyroidal conversion of T4.

If myxoedema coma is expected, it is essential that treatment is initiated immediately without awaiting confirmation of the diagnosis. These patients often have dilutional hyponatraemia, hypoglycaemia, and electrocardiography changes (low voltage, prolonged QT interval, flat or inverted T waves, and heart block). Other non-specific features which may be found in any patient with hypothyroidism are elevation in serum liver and muscle enzymes (the raised creatine phosphokinase particularly may cause unnecessary concern), raised cholesterol, and anaemia. The anaemia is usually normocytic or macrocytic, but microcytosis occurs when hypothyroidism is accompanied by menorrhagia.

The aetiology is usually easily established. In the absence of a history of treated hyperthyroidism or iodine exposure, the majority of juvenile or adult onset primary hypothyroidism in iodine-sufficient countries is due to autoimmune hypothyroidism. Transient hypothyroidism due to destructive thyroiditis is considered later. The diagnosis of autoimmune hypothyroidism is confirmed by the presence of thyroid peroxidase antibodies, usually at high levels, although occasionally these antibodies are absent. Cytological diagnosis of Hashimoto's thyroiditis is possible using fine needle aspiration biopsy, but is only necessary if there is uncertainty over the cause of a nodular goitre.

Once congenital hypothyroidism is diagnosed by routine testing after birth, it is usual to initiate thyroxine immediately. Treatment can then be stopped without neurological consequences at age 3 to 4 years to establish that life-long thyroxine replacement is necessary. At this time, the aetiology can be established by scintiscanning and/or ultrasound. Dyshormonogenesis, suspected when there is detectable thyroid tissue and a family history, requires specialized investigation to establish the diagnosis and increasingly this is possible by direct analysis of gene mutations. The commonest of these defects is Pendred's syndrome in which there are mutations in the pendrin gene encoding a chloride/iodide transporter present in the thyroid and cochlea, leading to goitre, mild hypothyroidism, and deafness. The thyroid abnormalities usually appear in the second or third decade, rather than at birth. The diagnosis can be made easily by the perchlorate discharge test, which shows an excessive decline of radioactivity in the thyroid when potassium perchlorate is given 2 to 3 h after allowing the thyroid to take up a tracer dose of radioiodine.

Treatment

In adult patients without heart disease and below the age of 60, treatment can begin with the estimated replacement dose of thyroxine. If there is no remaining thyroid tissue (indicated by a very high TSH and very low or undetectable free T4), the full replacement dose is 1.6 µg thyroxine/kg body weight, which is around 100 to 150 µg/day. In practice, the typical starting dose is 50 to 100 µg thyroxine daily, the lower dose being reserved for patients with mild to moderate biochemical abnormalities. Dosage changes should be based on TSH levels measured 2 to 3 months after starting treatment, the main goal of treatment being to normalize the TSH. A similar period is required to assess the effect of any change to the dosage, made as 25 or 50 µg increments or decrements depending on how abnormal the TSH is. Treatment is usually straightforward, although if there is only partial thyroid failure when treatment is begun, the dose of thyroxine may require adjustment over many months.

Once on a full replacement dose, TSH levels should be checked at intervals of 1 to 3 years, depending on their stability. Fluctuating or elevated TSH levels in a previously stable patient, or thyroxine requirements in excess of 200 µg/day, usually indicate compliance problems. It is important to rule out malabsorption or abnormal thyroxine kinetics caused by drugs: cholestyramine, ferrous sulphate, lovastatin, aluminium hydroxide, rifampicin, amiodarone, carbamazepine, and phenytoin all alter the absorption or clearance of T4. A common cause for poor compliance is worsening angina. Optimization of antianginal treatment is then required, although some patients may simply prove intolerant of full thyroxine replacement if their coronary artery disease is extensive and irremediable. It is important to remind poorly compliant patients that, because of the long half-life of thyroxine, missed tablets should always be taken and that this is safe.

In the elderly, or in individuals with heart disease, the usual starting dose is 25 µg thyroxine daily (or on alternate days when there is severe angina). Dosage should

be increased slowly with increments of 12.5 to 25 µg thyroxine. Proportionately higher doses of thyroxine are needed during the first year of life than in adults, and the starting daily dose of thyroxine for congenital hypothyroidism is 10 µg/kg body weight. There is a continuing debate on the benefit of thyroxine in subclinical hypothyroidism. It is reasonable to commence thyroxine when subclinical hypothyroidism is coupled with the presence of thyroid peroxidase antibodies, as there is a high risk of progression to overt hypothyroidism. Modest improvements in mental function and lipid levels occur when thyroxine is given to some patients with subclinical hypothyroidism, but long-term studies on the benefits of treatment have not been conducted. At present, it seems reasonable to offer a 3-month trial of thyroxine to thyroid peroxidase antibody-negative patients with subclinical hypothyroidism. If the patient notices an improvement in the symptoms which prompted thyroid function testing, thyroxine is continued, but is stopped if there is no benefit. All patients with subclinical hypothyroidism or positive thyroid peroxidase antibodies should be offered annual testing for the development of overt hypothyroidism.

Another problem is posed by the occasional patient with overt hypothyroidism who continues to feel unwell or who fails to lose weight after the TSH is normalized with thyroxine replacement. It can take around 3 months from achieving full replacement for all symptoms to disappear, and weight gained during hypothyroidism will generally only be lost by following an appropriate diet. It is sensible to ensure that the TSH level is in the lower half of the reference range and sometimes a small increment of thyroxine can achieve this, improving symptoms but not suppressing the TSH. More controversial is the treatment of such patients with higher doses of thyroxine which suppress the TSH. This approach may resolve symptoms but at the risk of atrial fibrillation due to subclinical thyrotoxicosis. The other recognized adverse effect of excessive thyroxine is a decrease in bone mineral density, particularly in postmenopausal women who have previously had hyperthyroidism and therefore already have a low skeletal mass. However, the changes in bone mineral density are modest and no increase in fracture rate has been reported as a result of thyroxine given at supraphysiological doses. It should be emphasized that, in the absence of coronary artery disease, thyroxine has no adverse effects when given at doses which return TSH levels to normal.

Treatment of myxoedema coma consists of thyroid hormone replacement, treatment of any precipitating factor, and supportive therapy. If an intravenous preparation is available, 500 µg thyroxine is given as a single intravenous bolus; the same dose can be given by a nasogastric tube but absorption may be slow. Thereafter, 50 to 100 µg thyroxine is given daily. An alternative is to use triiodothyronine, which has the theoretical benefit of not needing conversion for its activity, but the potential disadvantage of excessive doses causing cardiac arrhythmias. The usual dose is 10 µg triiodothyronine every 4 to 6 h, and it can be given intravenously or by nasogastric tube. Some centres combine thyroxine (200 µg) with triiodothyronine (25 µg) as a single bolus. Patients usually require ventilation initially but external warming should be avoided as it may provoke cardiac failure through peripheral vasodilation and increased oxygen consumption. Instead, space blankets are used. Intravenous infusion of hypertonic saline or glucose may be required to correct metabolic problems. Parenteral hydrocortisone is given at doses of 50 mg every 6 h to treat the reversible decline in adrenal reserve which occurs in marked hypothyroidism. If infection is suspected as a precipitant, broad spectrum antibiotics should be used early.

Prognosis

Thyroxine treatment is usually life-long and, properly taken, restores normal health and lifespan. Occasional patients may discontinue thyroxine and remain euthyroid. Errors in initial diagnosis account for some of these; in others, a spontaneous decline in TSH receptor blocking antibody levels may be responsible. There is no easy means of ascertaining whether a patient continues to need thyroxine, short of stopping it and measuring the TSH 6 weeks later. As remission is uncommon, and of uncertain duration, few endocrinologists at present attempt withdrawal.

Special problems in pregnant women

Untreated hypothyroidism impairs fertility and increases the risk of miscarriage. Children born to such mothers have varying degrees of intellectual impairment. It is therefore essential that thyroxine replacement is monitored closely in women with hypothyroidism who intend to become or who are pregnant. Ideally the TSH and free T4 should be checked prior to conception, once pregnancy is confirmed, and at the beginning of the second and third trimesters. The requirement for thyroxine can increase by 50 to 100 per cent during pregnancy but reverts to normal after delivery. There are no implications for breast feeding.

Areas of uncertainty or needing further research

There has been a recent revival of the concept that thyroid hormone replacement should consist of both thyroxine and triiodothyronine, based on the observation that deiodinase activity varies between tissues, suggesting that in some organs the level of the active thyroid hormone, T3, is insufficient when only thyroxine is given. The short half-life of triiodothyronine makes it alone unsuitable for replacement. Improvements in mental function in a trial of 50 µg of the daily dose of thyroxine with 12.5 µg triiodothyronine have been modest and short-term, and further work is needed. Because hypothyroidism is frequent, routine screening of certain groups or even the entire population has been advocated (Table 6) but the cost–benefit of setting up new screening programmes is unclear. If widely adopted, screening will turn up many individuals with subclinical hypothyroidism, for whom the benefits of early treatment with thyroxine have not yet been fully established.

Thyrotoxicosis

Introduction

Thyrotoxicosis is defined as the state produced by excessive thyroid hormone. Hyperthyroidism exists when thyrotoxicosis is caused by thyroid overactivity but there are several types of thyrotoxicosis which are not due to hyperthyroidism, the most obvious being administration of excessive thyroxine.

Aetiology

The causes of thyrotoxicosis are shown in Table 7. Graves' disease is responsible for 60 to 80 per cent of cases and nodular thyroid disease (toxic multinodular goitre and toxic adenoma) accounts for most of the rest. Destructive thyrotoxicosis is dealt with in the next section.

Epidemiology

The prevalence of thyrotoxicosis is Caucasians is 2 to 3 per cent in women and 0.2 to 0.3 per cent in men. The peak age of onset for Graves' disease is between 20 to 50, whereas toxic multinodular goitre occurs more often in later life.

Pathogenesis

Graves' disease is caused by TSH receptor stimulating antibodies, clearly demonstrated by the occurrence of transient, neonatal thyrotoxicosis in babies born to mothers with Graves' disease whose antibody levels are high enough for transplacental transfer to affect the fetus. As with autoimmune hypothyroidism, genetic factors, including HLA-DR and CTLA-4 gene polymorphisms, are associated with the disease; the concordance rate in monozygotic twins is about 20 per cent and much less in dizygotic twins. A high iodine intake, smoking, and stress have all been identified as environmental factors, but in many patients the genetic and environmental triggers remain elusive. Smoking is a major risk factor for the development of thyroid-associated ophthalmopathy. These eye signs are due primarily to swelling of the extraocular muscles, the result of fibroblast activation by cytokines released by infiltrating T cells and macrophages, leading to glycosaminoglycan accumulation, oedema, and fibrosis. The close correlation between ophthalmopathy and thyroid disease is best explained by an unidentified, shared orbital and thyroid autoantigen.

Toxic multinodular goitre evolves from a non-toxic sporadic goitre (see above) and is particularly likely when iodine intake increases, either gradually as a result of changes in the diet, or acutely when iodine-containing agents (amiodarone, some contrast media) are given. More than 50 per cent of toxic adenomas are due to a somatic activating mutation in the genes encoding the TSH receptor or the associated Gsa protein, and a similar but unknown mechanism leading to constitutive activation of a clone of thyroid cells must underlie the remainder.

Clinical features

The typical features of thyrotoxicosis from any cause are shown in Table 8, but their presence and severity depend on the duration of disease and the age of the patient. Occasionally there are paradoxial manifestations, such as the weight gain which can occur in up to 10 per cent of patients when the increase in appetite exceeds the effects of increased metabolism, and apathetic or masked thyrotoxicosis in the elderly which mimics depression. The most dramatic but rare presentation

is thyrotoxic crisis or storm, with a mortality of 20 to 30 per cent even with treatment. Patients typically are previously undiagnosed or partially treated, and have an acute exacerbation of thyrotoxicosis precipitated by acute illness (infection, stroke, diabetic ketoacidosis) or trauma, especially directly to the thyroid (surgery or radioiodine). Exact diagnostic criteria for thyrotoxic crisis are not agreed and its frequency is sometimes exaggerated. There is marked fever (>38.5°C), delirium or coma, seizures, vomiting, diarrhoea, and jaundice, death being caused by arrhythmias, heart failure, or hyperthermia.

The differential diagnosis of thyrotoxicosis includes any cause of weight loss, anxiety, and phaeochromocytoma, but simple biochemical testing can readily distinguish thyrotoxicosis from these conditions. Once the diagnosis of thyrotoxicosis is made, it is essential to determine the cause (Table 7), as this determines treatment. Graves' disease is usually clinically distinctive; there is a small to moderate, diffuse, firm goitre and around a half of these patients have signs of thyroid-associated ophthalmopathy (Table 9, Fig. 6). There may be evidence of another autoimmune disorder, in the patient or her family, with the same associations as autoimmune hypothyroidism described above. Less than 5 per cent of patients have pretibial myxoedema, which is better called thyroid dermopathy as it can occur anywhere, especially after trauma (Fig. 7 and Plate 1). These patients almost always have moderate to severe ophthalmopathy and 10 to 20 per cent have clubbing (thyroid acropachy). Thyroid dermopathy most commonly occurs as non-pitting plaques with a pink or purple colour but no inflammatory signs. Nodular and generalized forms, the latter mimicking elephantiasis, also occur. Hyperplasia of lymphoid tissue, including splenomegaly and thymic enlargement, is sometimes found in Graves' disease.

Fig. 6 Thyroid-associated ophthalmopathy (a) upper lid retraction, periorbital oedema, and scleral injection; (b) chemosis (conjunctival oedema) and proptosis.

Fig. 7 Thyroid dermopathy (pretibial myxoedema) affecting the lateral aspect of the shin and the dorsum of the foot; the patient also had thyroid acropachy. (See also Plate 1.)

The absence of these features of Graves' disease and the presence of a multinodular goitre strongly suggest toxic multinodular goitre, although nodular thyroid disease is so common that occasional patients with Graves' disease may cause confusion when their thyrotoxicosis arises in a pre-existing multinodular gland. In toxic adenoma, the solitary thyroid nodule is usually readily palpable. Other, rare causes of thyrotoxicosis can usually be easily identified from the history and biochemical investigations.

Pathology

In Graves' disease, there is thyroid hypertrophy and hyperplasia. The follicles show considerable folding, contain little colloid, and are composed of tall columnar cells. Gland vascularity increases. There is a focal and diffuse lymphocytic infiltrate and lymphoid hyperplasia may occur in the lymph nodes, spleen, and thymus. These changes are all reversed by antithyroid drugs. Toxic multinodular goitre comprises a mixture of areas of follicular hyperplasia and nodules filled with colloid. There is a variable degree of fibrosis, haemorrhage, and calcification. Toxic adenomas are encapsulated and cellular, sometimes with little evidence of follicle formation, and occasionally containing unusual cell forms suggesting malignant change. However, capsular invasion is absent and this is the cardinal feature which distinguishes a follicular adenoma from carcinoma.

Laboratory diagnosis

Measuring the serum TSH is the simplest way to exclude primary thyrotoxicosis. A normal or slightly raised TSH level can rarely be associated with hyperthyroidism in the case of a TSH-secreting pituitary adenoma. A low TSH level is not always the result of thyrotoxicosis (Table 2). Therefore the diagnosis of thyrotoxicosis must be confirmed by measuring thyroid hormone levels. Free hormone assays are preferable to those for total hormone, to eliminate binding protein effects (Table 1). Measuring only free T4 alone is adequate in most cases of thyrotoxicosis, which can be confirmed by the presence of a suppressed TSH and elevated free T4 level. However, in up to 5 per cent of patients, only free T3 levels are elevated (T3 toxicosis), especially during the earliest phase of the disorder. Therefore, if both free T3 and T4 are not measured routinely by a laboratory, it is essential to request free T3 analysis in any sample showing a suppressed TSH but normal free T4 level. Rarely, the free T4 is elevated but the free T3 is normal. This arises when Graves' disease or nodular thyroid disease is precipitated by the administration of excess iodine (the Jod–Basedow phenomenon).

Although it is possible to measure TSH receptor stimulating antibodies and thus prove the existence of Graves' disease in a thyrotoxic patient, these assays are cumbersome or expensive, and at present therefore are not widely used. Almost as much information can be gained by measuring thyroid peroxidase antibodies which are present in around 75 per cent of patients with Graves' disease. In cases of diagnostic uncertainty, a thyroid scintiscan will demonstrate a diffuse goitre with high isotope intake in Graves' disease and reveal nodular thyroid disease as well as ectopic thyroid tissue in the extremely rare struma ovarii. In destructive and factitious thyrotoxicosis, the thyroid scan shows virtually no isotope uptake and the diagnosis of factitious thyrotoxicosis can be confirmed by measuring serum thyroglobulin levels, which are suppressed in contrast to the raised levels in all other causes of thyrotoxicosis. When a TSH-secreting pituitary adenoma is suggested biochemically, the diagnosis is made by demonstrating both an elevated level of the a-subunit common to glycoprotein hormones including TSH and a pituitary tumour on CT, or preferably MR, imaging. Prolonged thyrotoxicosis can cause a number of non-specific biochemical abnormalities, especially abnormal liver function tests, hypercalcuria, and elevated serum levels of ferritin. Less commonly, serum calcium and phosphate may be raised, glucose intolerance or diabetes may occur, and rarely there may be a microcytic anaemia or thrombocytopenia.

Treatment

Definitive diagnosis is the most important determinant of treatment selection for thyrotoxicosis. In particular, antithyroid drugs only achieve a cure in Graves' disease. When due to a subacute or silent thyroiditis, discussed below, spontaneous resolution of thyrotoxicosis is expected and symptomatic treatment with b-blockers such as propranolol, 20 to 80 mg three times daily, is indicated. Although b-blockers will rapidly alleviate symptoms in all types of hyperthyroidism, definitive treatment is

also necessary, and when euthyroidism is restored, b-blockers can be gradually withdrawn.

There are three types of treatment for Graves' disease: antithyroid drugs, radioiodine (^{131}I), and surgery. Local policy and patient age dictate the order of their use. For young or middle aged adults, antithyroid drugs are generally used initially in Europe and Japan, whereas radioiodine is preferred in North America. Surgery is particularly useful in patients with a large goitre, but is less frequently used in North America than elsewhere. The local availability of an experienced surgeon is crucial. There is more international agreement over the preferential use of radioiodine for a recurrence after antithyroid drugs and as first line treatment in the elderly with Graves' disease.

The main antithyroid drugs used in Europe are carbimazole and its active metabolite methimazole, whereas propylthiouracil is preferred in North America. There is little to choose between them in normal practice, as all exert their principal action by inhibiting iodide oxidation and organification by thyroid peroxidase. Propylthiouracil additionally inhibits the activity of type 1 deiodinase, reducing T3 formation in many tissues, but this activity is only of clinical importance in very severe hyperthyroidism, and more frequent dosing is necessary with this drug.

Two regimens are used to avoid antithyroid drug-induced hypothyroidism and achieve the best chance of remission, which occurs in 40 to 60 per cent of patients and is inversely proportional to dietary iodine intake. The first method is to titrate the dose of antithyroid drug, giving carbimazole (or methimazole) 20 mg two or three times daily, and then lowering the dose every 3 to 4 weeks or so, based on free T4 measurements, until a maintenance dose of 5 to 10 mg once daily is achieved. Equivalent starting and maintenance doses of propylthiouracil are 100 to 200 mg three times daily and 50 mg once or twice daily. Maximum remission rates occur after 18 to 24 months of treatment.

The second regimen is to start with the same dose of antithyroid drug but then to add thyroxine 100 µg daily after 3 to 4 weeks when free T4 levels are usually becoming normal, rather than lowering the dose of drug. Thereafter the patient is maintained on 40 mg carbimazole or methimazole once daily (alternatively, 100 to 150 mg propylthiouracil three times daily) and thyroxine, the latter being adjusted if necessary 4 weeks after starting to achieve normal free T4 levels. The block–replace regimen achieves the same remission rate as the titration regimen within 6 months; continuation beyond this time is not necessary but can be used if a patient wishes to ensure euthyroidism for a particular period of time. Patients with the biggest goitres almost always relapse after antithyroid drug treatment, but unfortunately there are no reliable predictors of which other patients will relapse, and therefore it is usual practice to follow patients closely (for example every 3 months) in the first year after stopping treatment. Thereafter, an annual check of thyroid function is warranted as recurrence occurs in 10 to 20 per cent 1 to 5 years after treatment, and autoimmune hypothyroidism may supervene in around 15 per cent.

The side-effects of antithyroid drugs are shown in Table 10; most occur in the first 3 months of treatment and there is a moderate dose dependency. Substituting propylthiouracil for carbimazole or vice versa usually reverses the common side-effects but further antithyroid drugs should be avoided if bone marrow disturbance develops. Lower doses of antithyroid drugs can be used in areas of low iodine intake. Lithium and potassium perchlorate have antithyroid actions and are alternatives when antithyroid drugs are not tolerated but these drugs are difficult to use, their side-effects are serious and they are given as a last resort. Anticoagulation with warfarin should be considered in all patients with atrial fibrillation; only 50 per cent of patients revert to sinus rhythm when euthyroidism is restored. In the remainder, attempts at cardioversion should be made, ideally when hyperthyroidism has been definitively treated with radioiodine. Digoxin is useful to control atrial fibrillation acutely but higher doses than normal are needed in the thyrotoxic state.

There are several dosage methods for radioiodine administration, which aim to achieve maximum cure rates with the minimum of subsequent hypothyroidism. Accurate dosimetry based on uptake tests has now largely fallen out of favour, as the results have been little or no better than more empirical methods of dose calculation. A simple formula is to give 200 MBq ^{131}I for a small goitre, 400 MBq for a large goitre, and 600 MBq for Graves' disease complicated by heart failure, but local policies vary, not least because less ^{131}I is needed when iodine intake is low. Around 5 to 10 per cent of patients treated this way require a second dose of ^{131}I, while hypothyroidism rates are 10 to 20 per cent after one year and 5 to 10 per cent annually thereafter. An alternative approach, based on the premise that hyperthyroidism is much more serious than predictable hypothyroidism, has been to attempt deliberate ablation of the thyroid with a fixed dose of 600 MBq ^{131}I. Even with this dose, some patients require a second treatment. Close follow-up is needed in the first year after treatment, and an annual test of thyroid function thereafter is recommended. Transient cytoplasmic, rather than nuclear, damage may cause hypothyroidism in the first 2 to 3 months after ^{131}I treatment, which then resolves. It is usual to delay a second dose of ^{131}I for at least 4 to 6 months after the first, as hyperthyroidism is controlled only slowly by radiation-induced nuclear damage. Antithyroid drugs or b-blockers are useful in the interim.

Radioiodine is contraindicated in pregnancy and breast feeding. There are no teratogenic risks if men or women attempt conception 4 months or more after treatment. Overall mortality rates from cancer are not increased by radioiodine, although there is a theoretical risk of an increase in the frequency and aggressiveness of thyroid cancer in children and adolescents, which makes many endocrinologists reluctant to use ^{131}I in this group, unless other treatments fail or are rejected. Another concern is the precipitation of thyrotoxic crisis by ^{131}I, but in practice this must be rare. To minimize the risk, antithyroid drugs can be given for up to 4 or more weeks prior to radioiodine, particularly in the elderly who are at special risk. Thyroid-associated ophthalmopathy may appear or worsen after radioiodine, especially if the patient smokes. A 3-month tapering course of prednisolone, starting with 40 mg daily at the time of ^{131}I administration, will prevent such worsening but an extended course of antithyroid drugs, with scrupulous maintenance of euthyroidism, may well be preferable until the orbital disease becomes inactive.

Surgery for Graves' disease consists of subtotal or near total thyroidectomy, and in the best centres achieves cure in more than 98 per cent of patients but with a hypothyroidism rate similar to radioiodine. Lower rates of hypothyroidism are inevitably associated with a higher recurrence rate. Patient preference is the main determinant of when surgical treatment is used to treat relapses after antithyroid drugs. Euthyroidism must be achieved with a further course of these drugs prior to surgery to avoid thyrotoxic crisis. Stable iodine (e.g. Lugol's iodine three drops three times daily) is often also given for 7 to 10 days prior to surgery, to block hormone synthesis acutely. Specific complications of surgery include haemorrhage leading to laryngeal oedema, damage to the recurrent laryngeal nerves, and hypoparathyroidism. These problems occur in less than 1 per cent of cases in experienced hands and the last two are often transient.

The management of thyroid-associated ophthalmopathy is summarized in Table 11. Symptoms and signs are usually mild to moderate, although still capable of creating considerable anxiety and disturbance of social function. Severe ophthalmopathy is fortunately rare (1 to 5 per cent of cases) and requires specialist ophthalmological management. Signs usually stabilize 12 to 18 months after onset, and may improve thereafter in 30 to 50 per cent of patients, although improvement is less likely for marked proptosis or diplopia. Corrective surgery for diplopia or cosmetic problems should only be considered in this stable phase. Thyroid dermopathy is left untreated and may resolve spontaneously. Surgical removal usually worsens the situation and, when troublesome, the best treatment is topical, high potency corticosteroids. Octreotide may also be beneficial.

Toxic multinodular goitre is usually managed by radioiodine treatment. Antithyroid drugs will control the hyperthyroidism but relapse is inevitable when the drugs are stopped. Long-term use of antithyroid drugs may be indicated in the very old or frail, or when incontinence poses an insuperable problem for the safe disposal of excreta after ^{131}I. The therapeutic dose of ^{131}I used for toxic multinodular goitre is generally higher than for Graves' disease (600 to 800 MBq) because there is uneven uptake of the isotope and usually a large goitre. Surgery is sometimes used as an alternative in patients with a retrosternal goitre or if there is any suspicion of a malignancy. Toxic adenoma is also usually treated with ^{131}I and the rate of subsequent hypothyroidism is low because the function of the normal thyroid issue is suppressed at the time the patient is hyperthyroid and therefore receives little irradiation. When there is a large (>5 cm) nodule or in young patients (<20 years) surgical excision is preferable and subsequent hypothyroidism is uncommon. Treatment of rare forms of primary hyperthyroidism is by surgical removal of the source of thyroid hormone or radioiodine. TSH-secreting pituitary adenomas causing secondary hyperthyroidism are usually treated by transphenoidal surgery, with radiotherapy for any residual tumour. Octreotide can also be used to lower TSH secretion.

Thyrotoxic crisis is a medical emergency whose management consists of antithyroid treatment, identification and treatment of any underlying precipitant, and supportive measures. Propylthiouracil is given as a loading dose of 600 mg and then 250 mg four times daily, either orally, by stomach tube, or per rectum. Carbimazole or methimazole are less effective alternatives, as they do not reduce T4 deiodination. Stable iodine blocks thyroid hormone synthesis and release but is safe to give only when iodine organification is arrested by propylthiouracil. Lugol's iodine, 5 drops four times daily, is given orally or by stomach tube 1 h after the first dose of propyl-thiouracil; ipodate 500 mg twice a day is an alternative. Control of the heart rate is central to managing the heart failure which frequently occurs, and in all but the most severe cases propranolol should be given (40 mg orally or 2 mg intravenously every 4 h), with careful monitoring of ventricular function. Diuretics and digoxin are used as needed. Plasmapheresis, dialysis, or cholestyramine (to interrupt the enterohepatic circulation of thyroid hormones) may be useful in extreme cases. Supportive measures include dexamethasone 2 mg four times daily, which also inhibits T4 to T3 conversion, oxygen, cooling, and intravenous fluids.

Prognosis

Although spontaneous remission occurs in Graves' disease, its exact frequency is unknown and is unlikely to be more than 10 per cent, with no guarantee of

persistence. Remission does not occur in other types of hyperthyroidism. Mortality rates in untreated hyperthyroidism are also uncertain but are probably around 30 per cent. Even after successful treatment, there is a three-fold increased risk of death from osteoporotic fracture and a 1.3-fold increased risk of death from cardiovascular disease and stroke. It is important that the patient with Graves' disease understands that the course of ophthalmopathy is independent of the thyroid disorder; eye signs appear one or more years before or after the onset of hyperthyroidism in a quarter of patients and progression of the orbital disease frequently occurs despite restoration of euthyroidism.

Special problems in pregnant women

Graves' disease during pregnancy is often treated with propylthiouracil, as carbimazole and methimazole have been associated with fetal aplasia cutis, but some dispute the significance of this association. The block–replace regimen is contraindicated in pregnancy, as preferential placental transfer of antithyroid drug will cause fetal hypothyroidism. Instead, the dose of antithyroid drug should be titrated to the lowest dose which results in maternal free T4 levels in the upper part of the reference range. TSH receptor stimulating antibodies decline during pregnancy and it is usually possible to stop treatment at the beginning of the third trimester. Subtotal thyroidectomy can be performed in the second trimester for women intolerant of antithyroid drugs.

Transplacental passage of TSH receptor antibodies causes fetal and neonatal thyrotoxicosis in 1 to 5 per cent of mothers with Graves' disease and can be predicted by demonstrating a high level of these antibodies in the maternal circulation at the beginning of the third trimester. Poor intrauterine growth and a high fetal heart rate also suggest this diagnosis. Fetal thyrotoxicosis is treated by giving the mother antithyroid drugs and the neonate requires treatment for 1 to 3 months after delivery. Failure to treat untrauterine and neonatal thyrotoxicosis causes low birth weight, premature closure of the sutures, and intellectual impairment. Breast feeding is safe with low doses of antithyroid drugs, but when high doses are needed (e.g. 20 mg or more carbimazole daily), thyroid function should be checked every 1 to 2 weeks in the baby. Patients with Graves' disease who have entered remission prior to or during pregnancy have an increased risk of relapse around 3 to 6 months after delivery, and should be offered thyroid function testing at this time.

Areas of uncertainty or needing further research

The pathogenesis of thyroid-associated ophthalmopathy is poorly understood, and remains an obstacle to developing better treatments. Outcome after antithyroid drug treatment in Graves' disease cannot yet be predicted but improved assays for TSH receptor antibodies may permit better assessment in the near future. Antithyroid drugs modulate the autoimmune response favourably in those patients whose Graves' disease remits, indicating the potential for more specific immunotherapy aimed at the cause of the disease, that would be preferential to present treatments which merely block or destroy the thyroid.

The evolution of hyperthyroidism is gradual and patients with multinodular goitre in particular are now recognized at the stage of subclinical hyperthyroidism, that is with a low or suppressed TSH but normal free T3 and T4 levels. Their optimum management is uncertain. There is a two to three-fold increased risk of atrial fibrillation over 10 years in subclinical thyrotoxicosis, as well as deleterious effects on bone mineral density, but no clinical trials have been performed to show a clear benefit from early intervention. Many endocrinologists simply follow such patients carefully, electing to treat when overt hyperthyroidism is shown by an abnormal free T3 level (T3 usually increases before T4). However, in the elderly with known cardiac disease, there is an increasing tendency to use radioiodine for sustained subclinical hyperthyroidism.

Destructive thyroiditis

Acute thyroiditis is rare and usually caused by bacterial infection of the thyroid via a pyriform sinus connecting the gland with the oropharynx. There is severe thyroid pain with fever and malaise, but thyroid function is rarely disturbed. Diagnosis is made by fine needle aspiration biopsy, with culture of the specimen, and treatment consists of antibiotics, surgical drainage of any abscess, and excision of the sinus which is identified by barium swallow.

Subacute (or de Quervain's) thyroiditis is due to thyroid infection by any of a number of viruses, especially mumps, Coxsackie, influenza, adenoviruses, and echoviruses. The most prominent symptom is pain in the thyroid, often radiating to the ears. A small, tender goitre can be palpated which is usually diffuse, but there can be asymmetrical involvement. Systemic upset with fever is variable but sometimes profound, and symptoms of a prodromal viral infection several weeks earlier may be recalled. There is a granulomatous thyroid inflammation with follicular destruction and the release of thyroid hormones often results in a transient thyrotoxicosis, lasting 1 to 4 weeks. Continuing thyroid destruction then leads to a phase of hypothyroidism once stored hormone is depleted. This lasts 4 to 12 weeks before euthyroidism is restored, but relapses occur in 10 to 20 per cent of cases. Sometimes only one phase of thyroid disturbance is seen. Confirmation of the clinical diagnosis is made by finding an elevated erythrocyte sedimentation rate (ESR) and low or absent radioiodine uptake by the thyroid. Thyroid function requires continuous monitoring as the disease evolves. Mild cases may resolve spontaneously with aspirin as symptomatic treatment, but most patients benefit from prednisolone 40 to 60 mg daily, which rapidly alleviates the pain. The dose is tapered over 6 to 8 weeks, depending largely on symptoms. Propranolol may be useful for thyrotoxic symptoms, and temporary thyroxine replacement is sometimes needed during the hypothyroid phase.

Silent thyroiditis is an autoimmune disorder in which there is a transient but painless thyroid destruction, giving rise to the same kind of thyroid function disturbances as subacute thyroiditis. As well as the absence of thyroid pain, there is no sign of a systemic inflammatory response (including a normal ESR) and the two conditions are therefore readily distinguished. The commonest setting for silent thyroiditis is in the postpartum period in a women with positive thyroid peroxidase antibodies and a mild underlying autoimmune thyroiditis, exacerbated for unknown reasons at this time. Such postpartum thyroiditis is common, being detectable in up to 5 per cent of women 3 to 6 months after delivery when repeated biochemical testing is done, although in many of these women the changes in thyroid function are mild and asymptomatic. Postpartum thyroiditis is three times more common in type 1 diabetes mellitus. Thyroid uptake tests are useful in the postpartum period to distinguish thyrotoxicosis due to postpartum thyroiditis from Graves' disease. ^{99m}Tc is used in preference to ^{131}I and only requires cessation of breast feeding for a day. Treatment is with propranolol for thyrotoxic symptoms and thyroxine for hypothyroidism. Thyroxine should be withdrawn 1 year after delivery and thyroid function tested 6 weeks later, as 90 per cent of women recover normal thyroid function. However, annual follow-up is needed as around 20 per cent of these women have permanent hypothyroidism 5 years later. The condition usually recurs in subsequent pregnancies.

Amiodarone inhibits T4 deiodination, and in all amiodarone-treated patients free T4 levels are in the upper half of the reference range or mildly elevated. Several months to years after starting amiodarone, however, effects on the thyroid may become manifest. In patients with mild thyroid dysfunction, especially autoimmune thyroiditis and positive thyroid peroxidase antibodies, the excessive iodine released from the drug causes hypothyroidism. This is treated as usual with thyroxine. Paradoxically, the high level of iodine causes hyperthyroidism in other subjects who are predisposed to this because of an underlying multinodular goitre or incipient Graves' disease (Jod–Basedow phenomenon). This is called type 1 amiodarone-induced thyrotoxicosis (AIT); type 2 AIT is due to thyroid destruction via drug-induced lysosomal activation. Colour-flow Doppler thyroid scanning shows an increase in vascularity in type 1 but not type 2 AIT, while serum IL-6 levels may be elevated in type 2 but not type 1 AIT. Mixed forms sometimes make an exact diagnosis impossible.

Treatment of AIT can be difficult and biochemical changes are often out of proportion to the symptoms. Amiodarone should be stopped if possible but often this cannot be done and in any case the drug has a very long half-life. Antithyroid drugs are often ineffective in type 1 AIT and potassium perchlorate may need to be added, 200 mg four or five times daily. There is a high frequency of agranulocytosis (up to 1 per cent) with this drug. Prednisolone is also used at doses of 40 to 60 mg daily, and is particularly helpful in type 2 AIT. Thyroidectomy is another alternative in severe cases.

Thyroid hormone resistance syndrome

Mutations in one allele of the b thyroid hormone receptor gene (Fig. 4) cause thyroid hormone resistance (homozygous mutation is lethal). The mutations affect the hormone binding domain and the mutant receptor inhibits the activity of normally encoded receptors, so called dominant negative inhibition, resulting in an autosomal dominant pattern of inheritance. The condition is usually discovered during screening for a goitre but children may sometimes present with short stature, hyperactivity, or mild learning difficulties. Thyrotoxic features in some patients were originally ascribed to selective pituitary resistance to thyroid hormone, leading to increased thyroid hormone secretion and therefore thyrotoxicosis in the peripheral tissues. However, the same receptor mutations occur in generalized and pituitary resistance syndromes, and although differential tissue expression of receptor subtypes presumably underlies the occasional expression of thyrotoxic signs and symptoms, the exact molecular basis is unknown.

The diagnosis is suggested by the presence of a normal or elevated TSH with elevated free T3 and T4 levels. Non-specific biochemical changes of thyrotoxicosis, such as elevated ferritin, sex hormone binding globulin, and liver enzymes, are absent. The main differential diagnosis is a TSH-secreting adenoma. Thyroid hormone resistance can be confirmed by direct mutational analysis. Treatment is usually not required as reducing thyroid hormone levels to normal causes hypothyroidism. If

thyrotoxic symptoms do occur, treatment is with b-blockers or thyroid hormone analogues (e.g. triac) aimed at lowering TSH secretion.

12.5 Thyroid cancer

Anthony P. Weetman

Thyroid cancer is by far the most common endocrine malignancy but it constitutes less than 1 per cent of all cancers. Most thyroid cancers arise in the follicular epithelial cells of the thyroid and may be differentiated or undifferentiated (Table 1). Tumours of the parafollicular C cells (medullary carcinoma) and other malignancies such as lymphoma and sarcoma behave in a different fashion from thyroid follicular epithelial cancers and are dealt with at the end of this chapter.

Primary thyroid follicular epithelial tumours

Aetiology

Excessive stimulation of the thyroid by thyroid-stimulating hormone accounts for the higher proportion of follicular carcinomas compared with papillary carcinomas in iodine-deficient areas. The thyroid-stimulating antibodies of Graves' disease do not increase the risk of developing thyroid cancer, but incidental thyroid tumours that arise in this disorder may behave more aggressively because of activation of thyroid-stimulating hormone receptors. Low-dose external beam radiation (10–1500 cGy) to the head and neck increases the risk of papillary thyroid cancer over 10 to 30 years. Higher thyroid radiation doses, including those arising from radio-iodine given for treatment of hyperthyroidism, are not associated with an increased risk of malignancy because thyroid cells are destroyed rather than transformed. However, death from thyroid cancer, which is an unusual outcome, may be slightly increased by radio-iodine treatment, suggesting an effect of radiation on tumour dedifferentiation. In Belarus and Ukraine, the incidence of papillary carcinomas in children and young adults has increased 5 to 10 years after the disastrous release of radio-iodine and other radionuclides from the Chernobyl nuclear reactor. This is ascribed to the potent mutagenic effects of radio-iodine on the growing thyroid gland.

Familial forms of papillary and follicular carcinomas exist but are unusual (less than 5 per cent of cases). There are associations with familial adenomatosis polyposis, including the Gardner's syndrome variant, Cowden's disease (multiple hamartoma syndrome), Peutz–Jehgers syndrome, and ataxia-telangiectasia.

Papillary carcinomas do not arise from hyperplastic nodules or adenomas. In about one-third of these tumours one of five distinct rearrangements of the *ret* proto-oncogene, a member of the receptor tyrosine kinase family, occurs. The resulting chimaeric oncogenes are termed *ret/PTC* (for papillary thyroid carcinoma). *ret/PTC3* is particularly linked to radiation. In 10 to 20 per cent of papillary cancers there is oncogenic activation of the *trk* gene.

Follicular carcinomas probably arise, at least in some cases, from follicular adenomas. Activation of the *ras* oncogene occurs in both these tumours (and in some papillary thyroid cancers) and they share cytogenetic abnormalities, especially on chromosome 3. Rarely follicular carcinomas are associated with activating mutations of the thyroid-stimulating hormone receptor and Gsa protein (encoded by the *gsp* gene), similar to those found in toxic adenoma. Anaplastic carcinoma may arise in a papillary or follicular carcinoma and is associated with inactivating mutations of the p53 tumour suppressor gene.

Epidemiology

Papillary microcarcinomas are less than 1 cm in diameter and occur in 4 to 36 per cent of autopsy specimens; they are more frequent in areas of high iodine intake. Clearly most of these do not become malignant. Excluding tumours which are found coincidentally, the annual incidence of thyroid follicular epithelial cancer is around 4 per 100 000. In iodine-sufficient countries, papillary carcinoma accounts for more than 80 per cent of these; follicular carcinoma constitutes about 10 per cent, and anaplastic carcinoma 5 to 10 per cent. Women are two to four times more likely to develop thyroid cancer than men; the peak incidence is between 30 and 50 years of age.

Clinical features

Most patients present with an asymptomatic thyroid nodule: this may be noticed by themselves or relatives—sometimes the nodule is detected during physical examination for another complaint. The difficulty for diagnosis arises because thyroid nodules are frequent and only about 5 per cent of palpable thyroid nodules are malignant. Diffuse or multinodular thyroid enlargement occurs in around 10 per cent of the population, and is four times more common in women than men. Solitary thyroid nodules occur in up to 5 per cent of the population and are usually hyperplastic or colloid nodules. The remaining 5 to 20 per cent of nodules are neoplastic but this figure includes follicular adenomas as well as malignant tumours.

It can be seen that determining which thyroid nodules are malignant poses a great difficulty, which has been exacerbated by the widespread use of ultrasound examination of the neck. Up to 60 per cent of adult thyroids have nodules detectable by high-resolution ultrasound scanning. If these nodules are impalpable and there are no other associated features, such ultrasound findings can be ignored. However, a palpable thyroid nodule should always be properly evaluated. Another problem is determining which, if any, nodules warrant investigation in a multinodular goitre. It seems reasonable to investigate further if there have been any new symptoms (see below) or if one nodule is larger than the others.

There are usually no symptoms or signs to indicate that a solitary thyroid nodule is malignant because most tumours progress slowly and present before disease is advanced. Age and sex are important considerations, since a malignancy is more likely in a solitary nodule when the patient is a child or adolescent, is over 60 years old, or is a man between the ages of 20 and 60 years. Previous exposure to radiation and a family history of thyroid cancer should also arouse suspicion. A carcinoma is more likely if the nodule has grown recently or is hard, irregular, or fixed on palpation. Clinical assessment should include careful examination of the cervical, submental, and supraclavicular lymph nodes. Late-presenting features include hoarseness, dysphagia, or dyspnoea which may indicate local invasion, but these symptoms can occasionally occur with an enlarging benign goitre. Rarely the diagnosis only becomes apparent when metastatic disease is detected in bone or lung.

The relatively indolent presentation of papillary and follicular thyroid carcinoma contrasts with that of anaplastic carcinoma in which a rapidly enlarging and fixed thyroid mass occurs, sometimes with local pain. Extension to the oesophagus, trachea, and/or recurrent laryngeal nerves is frequent and the overlying skin may also be infiltrated.

Pathology

There are several variants of papillary thyroid carcinoma united by their characteristic cytological features. The nuclei are large, clear ('Orphan Annie', after the eyes of the cartoon character), and have longitudinal grooves and invaginations of cytoplasm (Fig. 1). Two-thirds of tumours are unencapsulated and display papillary and follicular structures, the remainder comprise the encapsulated, follicular, tall cell, sclerosing, and clear cell variants.

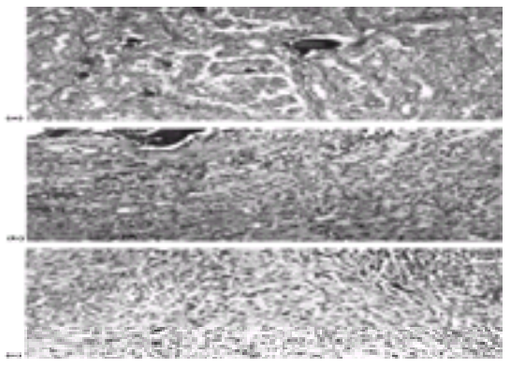

Fig. 1 Histopathological features of thyroid follicular epithelial carcinoma: (a) papillary carcinoma, with psammoma bodies and typical nuclear appearance; (b) metastatic follicular carcinoma, eroding vertebral bone; (c) anaplastic carcinoma showing pleomorphic spindle cells. (All sections, original magnification ×200; photomicrographs by courtesy of Dr K. Suvarna.)

The encapsulated variant has a better prognosis than average and the tall cell variant a worse prognosis. Half of papillary carcinomas contain degenerate calcified papillae, termed psammoma bodies. The tumour is multicentric in up to 80 per cent of cases if the resected thyroid is examined carefully. Metastasis is via the lymphatics and local lymph nodes are infiltrated in 40 to 50 per cent of cases (more in young patients). Distant metastases are found in less than 5 per cent of patients at presentation: the lung is the most common site.

Follicular carcinoma is characterized by follicular differentiation with a solid growth pattern and without the nuclear features of papillary carcinoma. The tumour is encapsulated but there is invasion of the capsule and vessels (Fig. 1). This invasion is the crucial feature which distinguishes follicular carcinoma from follicular adenoma, self-evidently a distinction only possible by histological examination. Minimally and widely invasive subtypes are recognized, the latter having a worse prognosis. When 75 per cent or more of the tumour cells exhibit oxyphilic staining due to mitochondrial accumulation, this is termed a Hürthle cell carcinoma, which probably also has a worse prognosis. Lymph node metastases are unusual, as is multicentricity in the thyroid. Metastasis occurs via the bloodstream, typically to bone and lungs.

When follicular differentiation is poor or absent, the tumour is classified as an insular carcinoma with a poor prognosis. In anaplastic carcinoma there is no capsule, the cells are atypical, including spindle, multinuclear, and squamoid forms, and mitoses are frequent (Fig. 1).

Diagnosis

Thyroid epithelial cancers generally fail to affect thyroid function. However, this should be evaluated in all patients presenting with a thyroid nodule: a low circulating level of thyroid-stimulating hormone strongly suggests an autonomous benign nodule. Anaplastic carcinoma may occasionally cause hypothyroidism, but the most frequent cause of an elevated level of thyroid-stimulating hormone with a hard, nodular thyroid is Hashimoto's thyroiditis. Some Hashimoto glands are so irregular that a malignancy may be suspected. There is no increased or decreased risk of thyroid epithelial carcinoma in Hashimoto's thyroiditis, but thyroid lymphoma almost always occurs in association with autoimmune thyroiditis. Therefore any dominant or atypical area in a Hashimoto goitre requires careful evaluation. Thyroid peroxidase and/or thyroglobulin antibodies occur in about one-quarter of patients with thyroid follicular epithelial carcinoma, coincident with the presence of a lymphocytic infiltrate which, in turn, is associated with a more favourable prognosis. Although the serum thyroglobulin concentration is extremely useful in follow-up, as discussed below, this investigation is useless in diagnosis: levels may not be elevated with some cancers and, even when elevated, cannot be causally distinguished from those which occur in benign adenoma, multinodular goitre, Graves' disease, or destructive thyroiditis.

In the past solitary thyroid nodules were investigated by radionuclide and/or ultrasound imaging but neither technique is able to diagnose malignancy accurately. Radionuclide scanning can be performed with $^{99}Tc^{m}$ pertechnetate or radio-iodine (^{123}I or ^{131}I), with similar information being obtained from either nuclide. Most thyroid cancers fail to take up radionuclide ('cold' nodules), but the more frequent benign lesions such as colloid nodules, cysts, adenomas, and thyroiditis behave similarly. About 20 per cent of nodules have normal or increased radionuclide uptake. Malignancy cannot be excluded with these appearances, however. The only exception is when the nodule is 'hot' and the surrounding thyroid tissue fails to take up radionuclide, indicating the presence of a toxic adenoma which is almost invariably benign. This type of nodule will cause suppression of thyroid-stimulating hormone and will be suspected from routine testing of thyroid function. In summary, radionuclide scanning adds little to diagnosis.

The use of ultrasound is more controversial. Cystic nodules have a lower risk of malignancy than those which are solid, but thyroid cancer cannot be reliably excluded by ultrasound. Predicting the presence of malignancy based on the echo pattern of the tumour, and more recently using colour-flow Doppler, may be successful in up to 80 per cent of cases but this depends on considerable experience. As well as the poor specificity of ultrasound, the technique is so sensitive that many small unsuspected nodules will be uncovered, complicating the evaluation. Ultrasound is useful for accurate measurement of thyroid and nodule size, which can be helpful in monitoring patients and in guiding biopsy, although this procedure is usually performed without imaging.

Fine needle aspiration biopsy is undoubtedly the current technique of choice for investigation of a thyroid nodule. Local anaesthetic is not needed because the procedure causes little discomfort. It is usual to take two to six biopsies to increase the sample yield. Essentially three diagnoses are possible: benign (65–75 per cent of specimens), malignant (5 per cent), and indeterminate (20–30 per cent), but an experienced cytopathologist is needed to obtain reliable results. Papillary carcinoma is readily diagnosed by fine needle aspiration biopsy, and medullary carcinoma and lymphoma can also be detected by use of immunohistochemical staining.

Follicular carcinomas cannot be distinguished cytologically from a follicular adenoma, and these tumours account for the bulk of needle aspiration specimens labelled indeterminate (or suspicious). Open biopsy and histological examination is the only secure diagnostic method in this setting. About 15 per cent of biopsies reported in experienced centres are considered unsuitable for diagnosis. It is relatively simple to repeat the biopsy but a persistently equivocal biopsy should be grounds for considering surgery, since malignant tumours will be found in about half of the cases. A cyst may be aspirated during biopsy. If this fails to reaccumulate and no lesion remains palpable, a malignancy is highly unlikely, but recurrence of a cyst may indicate malignant disease and require surgery for definitive diagnosis. Overall, the sensitivity and specificity of fine needle aspiration biopsy is greater than 90 per cent.

Treatment

Surgical excision

A total or near total thyroidectomy should be performed since papillary carcinomas are often bilateral and removal of thyroid tissue facilitates subsequent ablation by radio-iodine. There is controversy regarding surgery for low-risk unifocal papillary carcinomas (those less than 5 cm in diameter, especially in young patients) but bilateral resection is associated with a lower rate of local recurrence than unilateral total lobectomy. In papillary carcinoma, the ipsilateral central lymph nodes should be dissected, as should all palpable nodes.

After surgery, radio-iodine is usually administered to remove any remaining thyroid tissue, which then allows thyroglobulin or ^{131}I total body scanning to be used in follow-up to detect metastases. This treatment also destroys occult carcinoma and, by scanning after ablation, metastatic disease is revealed. Local policies vary, but in most centres an ^{131}I scan is performed 1 to 2 months after surgery and an ablation dose of 1100 to 3700 MBq ^{131}I is given, depending on the size of the remnant. In 15 to 30 per cent of patients a second treatment dose of ^{131}I is necessary to achieve ablation. Iodine exposure, including iodine-containing contrast media, may prevent accumulation of ^{131}I during treatment.

In patients whose tumour is less than 1.5 cm in diameter, excision alone without radio-iodine ablation is indicated. Whether all other patients require ablation is controversial. Clinical staging scores (see below) may help to identify other low-risk patients who do not require ablation excision.

Radio-iodine therapy

High levels of stimulation by thyroid-stimulating hormone are required to produce maximum uptake of ^{131}I; this is achieved by a period of 30 to 45 days without thyroxine replacement and can thus lead to the development of severe hypothyroid symptoms. The short action of tri-iodothyronine, 20 µg three times daily, as a replacement is therefore preferable in the weeks before scanning and ^{131}I treatment, because only 2 weeks are needed when this is stopped to increase endogenous thyroid-stimulating hormone. Even this short period without thyroid hormone may be troublesome for the patient and recombinant thyroid-stimulating hormone suitable for intramuscular administration is now available and can be given without cessation of thyroid hormone replacement.

Long-term thyroid replacement therapy

The third aspect of treatment is to maintain the patient for life on thyroxine at doses sufficient to suppress levels of thyroid-stimulating hormone to 0.1 mU/litre or less, because thyroid-stimulating hormone is a growth factor for thyroid carcinoma. The optimum level of thyroid-stimulating hormone is unknown, but higher levels can be accepted in those patients known to be disease-free for several years, compared with newly treated patients. In almost all patients, satisfactory suppression of thyroid-stimulating hormone can be achieved without inducing thyrotoxic symptoms. The effective thyroxine dosage is 2.2 to 2.8 µg/kg body weight.

Anaplastic carcinoma is rapidly fatal. The tumour does not take up radio-iodine. Surgery has a limited role in relieving obstructive symptoms and external beam radiotherapy is useful in palliation. The place of chemotherapy (usually doxorubicin combined with other drugs) is unclear.

Follow-up

Lifelong follow-up is necessary for papillary and follicular cancer because recurrence may occur many years after apparent cure. As well as monitoring the concentration of thyroid-stimulating hormone and performing careful neck palpation, serum thyroglobulin should be measured. Detectable levels of thyroglobulin after thyroid ablation indicate persistent or recurrent disease. In many centres, thyroglobulin levels are checked when the patient is not taking thyroxine replacement, as the rise in thyroid-stimulating hormone will stimulate thyroglobulin production and exaggerate any increase. This is particularly useful in high-risk patients: in those at low risk (see next section), it is reasonable to measure thyroglobulin without withdrawing thyroxine.

If thyroglobulin is detectable, the patient should have a total body ^{131}I scan and any recurrent disease can then be treated with a therapeutic dose of 3700 MBq ^{131}I. Many centres also perform a total body scan at 6 to 12 months after initial ablation, but repeated routine scans thereafter have now been superceded by measurement of thyroglobulin. The only exception is in the patient with thyroglobulin antibodies which interfere with many assays for thyroglobulin. If this is the case, repeated scans are the only way to ensure that the patient remains free of disease.

For metastatic disease, usually in the lung, treatment with radio-iodine can be repeated every 4 to 6 months, but there is little benefit above a cumulative dose of 18 500 MBq. Bone metastases may respond to ^{131}I or external beam radiotherapy. The best survival in metastatic thyroid cancer occurs in young patients with small metastases, indicating the overall value of early treatment for this disease.

Prognosis

At least seven scoring systems have been advocated to assess prognosis in papillary and follicular carcinoma. These take into account the age and sex of the patient, tumour characteristics (especially size, extension, and metastases), and completeness of excision. An example of the predictive power of such scoring is shown in Table 2. The risk of death increases with age, especially after 60, while tumour recurrence is commonest in those aged under 20 and over 60. Men have a worse prognosis than women, but the difference is small.

With proper treatment the rate of recurrence of papillary carcinoma is about 15 per cent, and the cause-specific death rate is approximately 5 per cent at 20 years. In other words, 85 per cent of these patients present with features of the group with the best prognosis, for instance achieving a score of less than 6 in the system described in Table 2. In follicular carcinoma, the cause-specific survival rate is 80 per cent at 20 years after treatment and 70 per cent at 30 years. However, in the subgroup with metastases at presentation the 10-year survival is only 20 per cent. The median survival time for anaplastic carcinoma is 4 to 12 months and those with distant metastases at presentation have a median survival time of only 3 months.

Prevention

In the event of a nuclear accident, prompt administration of stable iodine prevents the uptake of inhaled and ingested radioactive iodine isotopes. Emergency arrangements should be in place close to nuclear installations to provide for distribution of potassium iodate tablets, and arrangements for the United Kingdom are detailed in the Department of Health document PL/CMO (93) 1.

Special problems in pregnancy

A solitary nodule in a pregnant woman should be evaluated by fine needle aspiration biopsy. If the biopsy suggests malignancy, surgery can be undertaken in the second or third trimester, but if the nodule is discovered late in the third trimester, it is probably best to defer surgery until after delivery.

Medullary carcinoma of the thyroid

This accounts for 5 to 10 per cent of all thyroid cancers. About 80 per cent are sporadic with a peak incidence at 40 to 50 years of age. Hereditary autosomal dominant forms occur as part of multiple endocrine neoplasia type 2A or 2B or as isolated familial medullary carcinoma. These forms are associated with germline point mutations in the *ret* proto-oncogene and preneoplastic C cell hyperplasia (Table 3).

The pathological findings are of an encapsulated tumour with round, spindle shaped, or polyhedral cells arranged in a variety of patterns that have no prognostic significance. There is variable fibrosis and three-quarters of tumours show marked deposition of amyloid—a feature associated with a good prognosis. Heterogeneous staining for calcitonin, a hormone of C cells, is associated with a poorer outcome, reflecting dedifferentiation. Even the smallest medullary tumours may be associated with local lymph node metastases.

The presentation of sporadic medullary carcinoma is typically with a solitary thyroid nodule, accompanied by cervical lymphadenopathy in 50 per cent of cases. Lung, liver, or bone metastases are present at diagnosis in 10 per cent of cases. Symptoms due to local invasion or the paraneoplastic production of polypeptides and prostaglandins (flushing, diarrhoea, and Cushing's syndrome) are less common presenting features.

The diagnosis is often apparent from fine needle aspiration biopsy. Basal serum calcitonin concentrations are almost invariably elevated and confirm the diagnosis. There is controversy over the utility of routine serum calcitonin measurement in the work-up of all thyroid nodules: most centres perform aspiration biopsy initially. Newly diagnosed patients should be screened for other evidence of multiple endocrine neoplasia and a careful family history is also essential. In particular, phaeochromocytoma occurring as part of an inherited cancer syndrome must be excluded before surgery.

Testing genomic DNA for *ret* mutations in the germline is now widely available and should ideally be carried out on leucocyte DNA from all new patients. The absence of the most common mutations, coupled with a negative family history and the absence of C-cell hyperplasia or multicentric tumours in the resected thyroid, indicates that further family testing is not warranted. When a *ret* mutation is detected, there is a clear benefit from family testing, as prophylactic thyroidectomy in affected individuals improves outcome. However, there are some kindreds in whom familial medullary carcinoma occurs without a recognizable *ret* mutation and family screening must then be undertaken annually, up to the age of 35 to 40 years, using pentagastrin-stimulated serum calcitonin measurements as a guide to the presence of the inherited abnormality.

Medullary carcinoma should be treated by total thyroidectomy, with dissection of the central and other involved lymph nodes; this may require a second completion operation if the diagnosis is not made at the outset. Thyroxine replacement is needed at physiological doses rather than doses which suppress thyroid-stimulating hormone. After surgery the patient should be monitored by measurement of serum calcitonin concentration. Cure, defined as a persistently normal calcitonin level,

occurs in only about one-third of patients, but 80 to 90 per cent of patients in whom there is an elevated calcitonin level and only nodal disease survive for 10 years. The best management of persistent disease is unclear, but local recurrence with identifiable lymph node involvement should be dealt with surgically. Radiotherapy and chemotherapy have a variable and at best partial effect. Profuse (secretory) watery diarrhoea is frequently a troublesome feature of extensive disease; this may respond to treatment with loperamide, but somatostatin analogues, for example octreotide, may be needed.

Age, stage and size of tumour, and completeness of surgical removal are important prognostic features. Familial medullary carcinoma has the best outcome; in contrast, the tumour associated with multiple endocrine neoplasia type 2B is very aggressive. The overall 10-year survival is 70 to 80 per cent.

Primary thyroid lymphoma

Less than 5 per cent of thyroid malignancies are non-Hodgkin's B-cell lymphoma. The peak incidence is between 50 and 80 years of age, and women are affected three times more frequently than men. The typical presentation is a rapidly enlarging thyroid mass in a patient with Hashimoto's thyroiditis. The clinical features may suggest anaplastic carcinoma. The diagnosis can be made by fine needle aspiration biopsy and confirmed by large needle or open biopsy. Accurate staging is then necessary to plan treatment, which is with external beam radiotherapy and anthracycline-based chemotherapy. Intensive treatment has produced 8-year survival rates approaching 100 per cent.

12.6 Parathyroid disorders and diseases altering calcium metabolism

R. V. Thakker

Calcium homeostasis

Most of the total of 1 kg of calcium in the healthy adult is present within the crystal structure of bone mineral and less than 1 per cent is in soluble form in the extracellular and intracellular fluid compartments. In the extracellular fluid compartment about half of the total calcium is ionized and the rest is principally bound to albumin or complexed with counter-ions. Ionized calcium concentrations range from 1.17 to 1.33 mmol/l, and the total serum calcium concentration ranges from 2.12 to 2.62 mmol/l. Measurements of free ionized calcium are not often undertaken because they are difficult; most laboratories report total serum calcium concentration for routine clinical use. However, the usual 2:1 ratio of total to ionized calcium may be disturbed by disorders such as metabolic acidosis, which reduces calcium binding by proteins, or by changes in protein concentration, caused by cirrhosis, dehydration, venous stasis, or multiple myeloma. In view of this, total serum concentrations are adjusted, or 'corrected', to a reference albumin concentration; thus, the corrected serum calcium may be related to a reference albumin concentration of 41 g/l and, for every 1 g/l of albumin above or below the reference value, the calcium is adjusted by 0.016 mmol/l, respectively. For example a total serum calcium of 2.70 mol/l with an albumin concentration of 47 g/l would be equivalent to a corrected serum calcium of 2.60 mmol/l, thereby correcting the initial apparent hypercalcaemic value to a normal value.

The extracellular concentration of calcium is closely regulated (Fig. 1) within the narrow physiological range that is optimal for those cellular functions that are affected by calcium. Indeed both hypercalcaemia and hypocalcaemia impair the function of many different organ systems. Regulation of extracellular calcium takes place through complex interactions (Fig. 2) at the target organs of the major calcium regulating hormone, parathyroid hormone (PTH), and vitamin D and its active metabolites, 1,25-dihydroxy (1,25$(OH)_2$) vitamin D. The parathyroid glands secrete PTH at a rate that is appropriate to, and depending upon the prevailing extracellular calcium ion concentration. Parathyroid gland disorders cause either hypercalcaemia or hypocalcaemia and these can be classified according to whether they arise from an excess of PTH, its deficiency, or insensitivity to its effects (Table 1, Fig. 2).

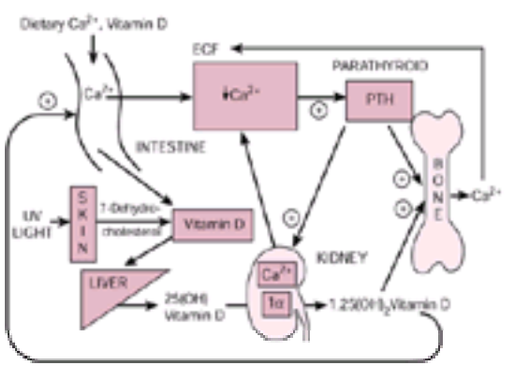

Fig. 1 Regulation of extracellular fluid (ECF) calcium (Ca^{2+}) by parathyroid hormone (PTH) action on kidney, bone, and intestine. A decrease in ECF Ca^{2+} is sensed by the calcium-sensing receptor (Fig. 2), and this leads to an increase in PTH secretion which predominantly acts directly on kidney and bone that possess the PTH-receptor (PTHR, Fig. 2). The skeletal effects of PTH are to increase (+) osteoclastic bone reabsorption but as osteoclasts do not have PTHRs, this action is mediated via the osteoblasts, which do have PTHRs and in response release cytokines and factors that activate osteoclasts. In the kidney, PTH stimulates (+) the 1a hydroxylase (1a) to increase the conversion of 25-hydroxy vitamin D (25(OH)D) to the active metabolite 1,25-dihydroxy vitamin D (1,25$(OH)_2$D). In addition, PTH, increases (+) the reabsorption of Ca^{2+} from the renal distal tubule and inhibits the reabsorption of phosphate from the proximal tubule, thereby leading to hypercalcaemia and hypophosphataemia. PTH also inhibits Na^+–H^+ antiporter activity and bicarbonate reabsorption, thereby causing a mild hyperchloraemic acidosis. The elevated 1,25$(OH)_2$D acts on the intestine to increase (+) absorption of dietary calcium and phosphate, and it is important to note that PTH does not appear to have a direct action on the gut. Thus, in response to hypocalcaemia and the increase in PTH secretion, all of these direct and indirect actions of PTH on the kidney, bone, and intestine will help to increase ECF Ca^{2+}, which in turn will act via the calcium-sensing receptor to decrease PTH secretion.

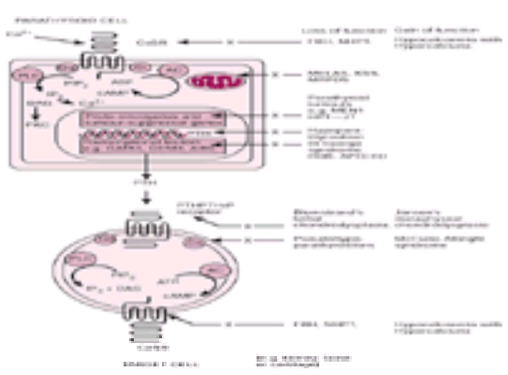

Fig. 2 Schematic representation of some of the components involved in calcium homeostasis. Alterations in extracellular calcium are detected by the calcium-sensing receptor (CaSR), which is a 1078 amino acid G-protein coupled receptor. The PTH/PTHrP-receptor, which mediates the actions of PTH and PTHrP, is also a G-protein coupled receptor. Thus, Ca^{2+} and PTH and PTHrP involve G protein-coupled signalling pathways and interaction with their specific receptors can lead to activation of Gs, Gi, and Gq, respectively. Gs stimulates adenylcyclase (AC) which catalyses the formation of cAMP from ATP. Gi inhibits AC activity. cAMP stimulates PKA which phosphorylates cell-specific substrates. Activation of Gq stimulates PLC, which catalyses the hydrolysis of the phosphoinositide (PIP_2) to inositol triphosphate (IP_3), which increases intracellular calcium, and diacylglycerol (DAG), which activates PKC. These proximal signals modulate downstream pathways, which result in specific physiological effects. Abnormalities in several genes, which lead to mutations in proteins in these pathways, have been identified in specific disorders of calcium homeostasis (Table 1). Adapted from Thakker RV, (2000). Parathyroid disorders. Molecular genetics and physiology. In: Morris PJ, Wood WC, eds. *Oxford Textbook of Surgery*, 2nd edn, pp. 1121–9. Oxford University Press, Oxford.

The *PTH* gene is located on chromosome 11p15 and consists of three exons (transcribed regions) which are separated by two introns. Exon 1 of the *PTH* gene is 85 bp in length and is untranslated whereas exons 2 and 3 code for the 115 amino acid pre-proPTH peptide. Exon 2 is 90 bp in length and encodes the initiation (ATG)

codon, the prehormone sequence and part of the prohormone sequence. Exon 3 is 612 bp and encodes the remainder of the prohormone sequence, the mature PTH peptide, and the 3' untranslated region. The 5' regulatory sequence of the human *PTH* gene contains a vitamin D response element 125 bp upstream of the transcription start site, which down-regulates *PTH* mRNA transcription in response to vitamin D receptor binding. *PTH* gene transcription (as well as PTH peptide secretion) is also dependent upon the extracellular calcium concentration, although the presence of a specific upstream 'calcium response element' has not yet been demonstrated.

The mature PTH peptide is secreted from the parathyroid chief cell as an 84 amino acid peptide; however, when the *PTH* mRNA is first translated it is as pre-proPTH peptide. The 'pre' sequence consists of a 25 amino acid signal peptide (leader sequence) which is responsible for directing the nascent peptide into the endoplasmic reticulum to be packaged for secretion from the cell. The 'pro' sequence is six amino acids in length and, although its function is less well defined than that of the 'pre' sequence, it is also essential for correct PTH processing and secretion. After the 84 amino acid mature PTH peptide is secreted from the parathyroid cell, it is cleared from the circulation with a short half-life of about 2 min, via non-saturable hepatic uptake and renal excretion.

PTH shares a receptor with PTH-related peptide (PTHrP); this PTH/PTHrP receptor (Fig. 1) is a member of a subgroup of the G protein-coupled receptor family. The PTH/PTHrP receptor gene is located on chromosome 3p21–p24 and is expressed in kidney and bone, where PTH is its predominant agonist. Expression of the PTH/PTHrP receptor also occurs in the brain, heart, skin, lung, liver, and testis where is mediates the actions of PTHrP. Mutations involving the genes that encode these proteins and receptors in this calcium regulating pathway (Fig. 2) are associated with hypercalcaemic and hypocalcaemic disorders (Table 1).

Hypercalcaemia

Clinical features and investigations

The clinical presentation of hypercalcaemia varies from a mild, asymptomatic, biochemical abnormality detected during routine screening to a life-threatening medical emergency. In general, the presence or absence of symptoms correlates with the severity and rapidity of onset of the hypercalcaemia. Thus, symptoms do not usually develop when serum calcium is below 3.00 mmol/l and are invariably present when the hypercalcaemia exceeds 3.50 mmol/l. However, there is a considerable variability and some patients may be symptomatic with mild hypercalcaemia (2.65–2.90 mmol/l). Although there are many causes of hypercalcaemia (Table 2), the signs and symptoms of hypercalcaemia are similar, regardless of aetiology. Indeed the clinical manifestations of hypercalcaemia involve several organ systems that include the renal, musculoskeletal, gastrointestinal, neurological, and cardiac systems (Table 3), and many of these have been referred to as 'moans, groans, pains, and stones'. Investigations should be directed at confirming the presence of hypercalcaemia and establishing the cause (Table 2).

The causes of hypercalcaemia can be classified according to whether serum PTH concentrations are elevated (i.e. primary hyperparathyroidism) or low (i.e. not due to a parathyroid tumour). Primary hyperparathyroidism and malignancy are the most common causes and account for more than 90 per cent of patients with hypercalcaemia. Detailed clinical history and examination will usually help to differentiate between these two diagnoses. In primary hyperparathyroidism, the hypercalcaemia is often less than 3.00 mmol/l, asymptomatic, and may have been present for months or years. If symptoms, for example nephrolithiasis, are present then they have usually been present for several months. However, in malignancy, the patients are usually acutely ill, often with neurological symptoms, the hypercalcaemia is more than 3.00 mmol/l, and the cancer (e.g. lung, breast, or myeloma) is often readily apparent. Hypercalcaemia from causes other than primary hyperparathyroidism or malignancy may also occur (Table 2) and a careful history (e.g. for vitamin D ingestion, drugs, renal disease) and examination (e.g. for thyrotoxicosis, adrenal disease, granulomatosis diseases), together with appropriate investigations (Table 4) are essential for establishing the diagnosis.

Management of hypercalaemia

The management of hypercalcaemia depends on the severity of the hypercalcaemia and the presence of symptoms. Thus, asymptomatic patients with mild hypercalcaemia, that is serum calcium below 3.00 mmol/l, do not usually need urgent treatment. However, a patient with severe hypercalcaemia, that is a serum calcium above 3.50 mmol/l, would require treatment regardless of symptoms, whilst a patient with moderate hypercalcaemia, that is a serum calcium in the range 3.00 to 3.50 mmol/l, would require urgent treatment if symptomatic. Before instituting treatment, it is always important to consider the underlying causes (Table 2) and to initiate investigations (Table 4).

The acute management of hypercalcaemia involves general measures to enhance hydration and diuresis, and specific measures using drugs to lower serum calcium. Dehydration due to hypercalcaemic symptoms, for example anorexia, nausea, vomiting and polyuria because of defective urinary concentration, is very common and patients may require 5 to 10 l of 0.9 per cent sodium chloride over a 24 to 48-h period. This vigorous hydration with normal saline may lower serum calcium by 0.25 to 0.75 mmol/l; it enhances urinary calcium excretion by increasing glomerular filtration and reducing proximal and distal renal tubular reabsorption of calcium and sodium. This saline diuresis may need adjuvant therapy with a loop diuretic, for example frusemide 20 to 100 mg to control complications due to volume overload, especially in the elderly and those with impaired cardiovascular and renal function. Saline diuresis may lead to hypokalaemia, hypomagnesaemia, and electrolyte imbalance, which will need correction.

If saline diuresis is not successful, and particularly if the hypercalcaemia is very severe, then more specific measures, for example dialysis and/or drugs, will be required. The drug of choice is pamidronate, which is a potent bisphosphonate that is administered parenterally. A recommended regimen is to administer 60 to 90 mg intravenously as a single infusion. Other bisphosphonates, for example etidronate and clodronate and other agents such as mithramycin, calcitonin, and gallium nitrate, have also been used in the past. Glucocorticoid therapy (e.g. hydrocortisone 120 mg/day in three divided doses) is particularly effective when the hypercalcaemia is mediated by the actions of 1,25-dihydroxy vitamin D, for example in granulomatosis disease or lymphoma (Table 2), or myeloma. Once the acute management of hypercalcaemia has been completed, then appropriate treatment for the underlying cause, for example parathyroidectomy for primary hyperparathyroidism, needs to be undertaken.

Hypercalcaemic diseases

Hypercalcaemia may arise through one more of three mechanisms: increased bone resorption, increased gastrointestinal absorption of calcium, and decreased renal calcium excretion. For example: lytic bone metastases cause increased bone resorption; thiazide diuretics lead to a decrease in calcium excretion; and excessive PTH will either directly or indirectly, by increasing 1,25-dihydroxy vitamin D production, stimulate bone resorption and calcium absorption from the gut and renal tubules. The hypercalcaemic diseases may be classified according to whether serum PTH concentrations are elevated or reduced (Table 2). In addition, hypercalcaemia may also be classified as being due to: an excess of PTH (e.g. primary or tertiary hyperparathyroidism) from parathyroid tumours; an excessive production of PTHrP; a defect in the PTH receptor (i.e. the PTH/PTHrP receptor); an excess production of down-stream mediators, for example 1,25-dihydroxy vitamin D; or an altered set point in the calcium-sensing receptor (Fig. 2).

Hyperparathyroidism

Hyperparathyroidism is characterized by high concentrations of serum immunoreactive PTH, and three types, referred to as primary, secondary, and tertiary, are recognized. Primary and tertiary hyperparathyroidism are associated with hypercalcaemia (Table 2), whereas secondary hyperparathyroidism is associated with hypocalcaemia (see below). Primary hyperparathyroidism may arise as an isolated endocrinopathy or as part of a multiple endocrine neoplasia (MEN) syndrome, and tertiary hyperparathyroidism usually arises in association with chronic renal failure.

Primary hyperparathyroidism

Primary hyperparathyroidism, which affects 1 in 1000 adults, is one of the two most common causes of hypercalcaemia and is due to an excessive secretion of PTH from one or more parathyroid tumours. In 80 per cent of patients this tumour is a solitary parathyroid adenoma, and in 15 per cent to 20 per cent of patients hyperplasia involving all four parathyroids is present. Parathyroid carcinoma accounts for less than 0.5 per cent of patients with primary hyperparathyroidism. Primary hyperparathyroidism usually occurs between the ages of 40 to 65 years, and is three times more common in females than males. The underlying causes of primary hyperparathyroidism are largely unknown, but abnormalities of several genes have been identified. Thus, abnormalities of the *cyclin D1* (*CCNDI*), *retinoblastoma*, *calcium-sensing receptor* (*CaSR*), *MEN type 1* (*MEN1*), and *type 2* (*MEN2*) genes together with other genes, yet to be identified, on chromosomes 1p and 1q (Table 1) are associated with the development of some parathyroid tumours.

Clinical features

Many patients with primary hyperparathyroidism will be asymptomatic and the hypercalcaemia, which is usually mild, will have been detected by chance at the time of biochemical screening for other reasons. However, it is important to note that nearly half the patients will have subtle neuromuscular symptoms such as fatigue and weakness and this becomes apparent only in retrospect after a successful parathyroidectomy.

Symptomatic hypercalcaemia (Table 3) predominantly affects the skeletal, renal, and gastrointestinal systems; peptic ulcers and pancreatitis may develop. The skeletal changes of osteitis fibrosa cystica due to subperiosteal resorption of the distal phalanges (Fig. 3), tapering of the distal clavicles, a 'salt and pepper' appearance of the skull, bone cysts, and brown tumours of the long bones are now identified in less than 5 per cent of patients. However, osteopenia, as assessed by bone mineral density, occurs in 25 per cent of patients. Renal stone disease (nephrolithiasis and nephrocalcinosis) occurs in 20 per cent of patients and hypercalciuria occurs in 30 per cent of patients; renal impairment may complicate this disease.

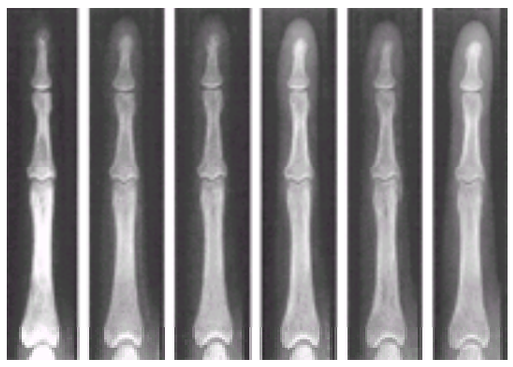

Fig. 3 Renal osteodystrophy over a 9-year period in a patient with chronic renal failure. Marked periosteal erosions were seen (a) despite treatment with 1a-hydroxy cholecaliferol, and a resolution was observed following dialysis (b). Note the vascular calcification. One year later a relapse was noted with periosteal erosions (c) and the use of calcitriol resolved these (d). Unfortunately, a relapse occurred 2 years later (e), and following renal transplantation a marked resolution was observed (f).

Investigations

In the presence of hypercalcaemia, the finding of elevated circulating PTH concentrations establishes the diagnosis, as the PTH will be elevated in approximately 90 per cent of patients with primary hyperparathyroidism, who will invariably have hypercalcaemia. However, it is important to make sure that the immunoradiometric (IRMA) and immunochemiluminometric (ICMA) assays for PTH are being used to measure the intact molecule, rather than the older radioimmunoassays which were not as reliable. The only other hypercalcaemic disorders in which PTH may occasionally be elevated are those related to familial benign hypocalciuric hypercalcaemia (FBH or FHH), immobilization, or lithium or thiazide use (Table 2), and a careful history and a cessation of drug use will help to exclude these possibilities. About one-third of patients with primary hyperparathyroidism will have a low serum phosphate and in the others it will be in the lower range of normal. In addition, some patients will have a small increase in serum chloride concentration and a concomitant decrease in bicarbonate concentration. Serum alkaline phosphatase activity may be elevated in some patients, and urinary calcium excretion is increased in 30 per cent of patients. The circulating 1,25-dihydroxy vitamin D concentration is elevated in some patients with primary hyperparathyroidism although it is not of diagnostic value as it is also elevated in other hypercalcaemic disorders such as sarcoidosis and lymphomas. The serum 25-hydroxy vitamin D concentration is within the normal range. Densitometric scanning is of use in detecting early skeletal changes. Patients with primary hyperparathyroidism develop reduced bone mineral densities (osteopenia) primarily of the cortical bone (e.g. distal third of forearm) rather than the cancellous bone (e.g. lumbar spine). The hip bones, which are an equal mixture of cortical and cancellous bone, show intermediate reductions in bone mineral density. Overall, the risk of bone fractures in patients with mild primary hyperparathyroidism is similar to those in matched, normal controls. However, successful parathyoidectomy does lead to an increase in bone mineral density over a 6 to 12-month period and this continues for up to 10 years. Indeed, bone mineral density measurements are used in the evaluation of patients with primary hyperparathyroidism and in deciding conservative as opposed to surgical management (Table 5).

Preoperative localization to define the site(s) of the parathyroid tumours may be undertaken. The non-invasive tests consist of ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI), and scintigraphy with technetium-99m sestamibi. Sestamibi scintigraphy has now become established as the best and most convenient localization test; this can be performed with computed tomographic techniques (SPECT) to give a three-dimensional image with greater anatomical resolution. It is important to note that there is an appreciable incidence of false positive rates with all the non-invasive localization procedures and so a confirmation using two methods is preferable. Invasive localization tests consist of arteriography and selective venous sampling for PTH in the veins draining the thyroidal region. These tests are time-consuming, expensive, difficult, and dependent on the skill of the radiologist. It is generally accepted that these preoperative localization tests are indicated in those patients who have had previous neck surgery. However, their role in patients who have not had prior surgery remains to be established and at present the preferences and expertise of the local medical, radiology, and surgery teams usually determine the use of venous sampling procedures.

Management and treatment

Parathyroidectomy, which is the definitive cure, is a generally successful and safe procedure if undertaken by an experienced surgeon. Thus surgery is recommended for symptomatic patients and for those who have skeletal and renal complications. However, the decision to recommend surgery, which does have a small risk, may be difficult in asymptomatic patients, who may constitute over 50 per cent of patients with primary hyperparathyroidism. The natural history of primary hyperparathyroidism in most patients is to progress slowly or not at all. For example amongst asymptomatic patients, only 25 per cent will have progressive disease, which is usually manifested as a decrease in bone mineral density during a 10-year period. This has lead to a controversy regarding the indications for surgery, and guidelines have been provided by the Consensus Development Conference on the Management of Asymptomatic Primary Hyperparathyroidism (Table 5). However, these guidelines may not exclusively influence the decision for or against surgery and a careful evaluation and assessment of the risks and benefits is considered by most medical and surgical teams in conjunction with the patient. Clearly, some patients will not wish to continue living with a curable disease and will prefer surgery despite the guidelines (Table 5), whilst other patients will decline surgery, despite having guideline indications for surgery, because they may have coexisting medical conditions that make them feel that the risks of surgery are too great.

Patients who do not undergo parathyroidectomy should be evaluated clinically, and also monitored for serum calcium, creatinine, and PTH at 6 to 12-monthly intervals, and for bone mineral density and nephrolithiasis at 12-monthly intervals. In addition, the following medical guidelines are recommended. First, they should avoid dehydration and remain ambulant. Second, the dietary intake of calcium should be moderate, that is at or below 1000 mg/day, and thiazide diuretics should be avoided. Finally, they should avoid herbal and tonic remedies that may contain Vitamin D or A. These measures may help and at present an effective and safe drug for the treatment of primary hyperparathyroidism is not available. Drugs that have been used include oral phosphate, oestrogens in postmenopausal women, and the bisphosphonates—alendronate and clodronate. Phosphate is not used because of concerns related to soft tissue ectopic calcification, and although oestrogen does increase bone density in postmenopausal women, it has little effect on the serum calcium and PTH concentrations. The bisphosphonates inhibit bone resorption and do reduce serum calcium. However, these effects are not sustained. A more targeted approach using drugs that alter the function of the calcium sensing receptor, CaSR (see below), is being evaluated, and these calcimimetic agents may provide a medical therapy; for example use of such an agent has been shown to reduce serum calcium and PTH in postmenopausal women with asymptomatic primary hyperparathyroidism.

Uraemic hyperparathyroidism

Serum PTH levels rise in response to hypocalcaemia and this secondary hyperparathyroidism usually resolves with treatment of the underlying cause of hypocalcaemia (Table 6). However, in chronic renal failure the secondary hyperparathyroidism may persist for a longer time, and eventually the parathyroid cells gain an autonomous function, secreting excessive PTH despite hypercalcaemia; this state is referred to as tertiary hyperparathyroidism (Table 2). The cause of progression from the early, presumably polyclonal, secondary hyperplasia of the parathryoids to the later, presumably monoclonal, tumours is not understood and appears to involve genes other than those involved in the aetiologies of the sporadic and familial forms of primary hyperparathyroidism (Table 1).

Clinical features and treatment

In chronic renal failure, the ensuing phosphate retention and decreased production of 1,25-dihydroxy vitamin D result in hypocalcaemia and secondary hyperparathyroidism. This combination of biochemical abnormalities results in a severe bone disease that shows combined features of hyperparathyroidism and vitamin D deficiency (i.e. osteomalacia). Thus in renal osteodystrophy, bone erosions (Fig. 3) and osteomalacia are simultaneously observed. Treatment is based on correcting the hypocalcaemia, for example with oral administration of calcium salts, which also ameliorates the hyperphosphataemia by chelating phosphate in the intestines, and with calcitriol (1,25-dihydroxy vitamin D). The use of the most appropriate phosphate binder is not well established but it is clear that aluminium-containing compounds are to be avoided. Aluminium in these preparations and as a contaminant of dialysis solutions contributed in the recent past to the osteomalacic osseous disease and other aspects of metal toxicity in patients with renal failure (e.g. hypochromic anaemia and encephalopathy). Early treatment of the metabolic disturbance will prevent or delay the onset of severe secondary hyperparathyroidism and tertiary hyperparathyroidism, which requires parathyroidectomy.

Familial primary hyperparathyroidism

Primary hyperparathyroidism is most frequently encountered as a non-familial disorder. However, approximately 10 per cent of patients with primary hyperparathyroidism will have a hereditary form which may either be part of the multiple endocrine neoplasia type 1 (MEN1) and type 2 (MEN2) syndromes, or part of the hereditary hyperparathyroidism–jaw tumour (HPT-JT) syndrome. In addition, hereditary primary hyper-parathyroidism may develop as a solitary endocrinopathy and this has also been referred to as familial isolated hyperparathyroidism (FIHP). Investigations of these hereditary and sporadic forms of primary HPT have helped to identify some of the genes and chromosomal regions that are involved in the aetiology of parathyroid tumours (Table 1). FIHP has been reported in several kindreds, and some have been shown to harbour mutations of the MEN1 gene whilst in other families linkage to polymorphic loci from chromosome 1q21–q31, the region of the HPT-JT syndrome, has been shown. In addition, analysis of parathyroid tumours from FIHP patients has revealed loss of heterozygosity (LOH) involving chromosome 1q21–q31 loci. FIHP located on chromosome 1q21–q31 has been reported to be associated with a high incidence of early-onset parathyroid carcinomas. These familial syndromes associated with parathyroid tumours will be briefly reviewed.

Multiple endocrine neoplasia type 1 (MEN 1)

MEN1 is characterized by the combined occurrence of tumours of the parathyroids, pancreatic islet cells, and anterior pituitary. Parathyroid tumours occur in 95 per cent of MEN1 patients, and the resulting hypercalcaemia is the first manifestation of MEN1 in about 90 per cent of patients. Pancreatic islet cell tumours occur in 40 per cent of MEN1 patients and gastrinomas, leading to the Zollinger–Ellison syndrome, are the most common type and also the important cause of morbidity and mortality in MEN1 patients. Anterior pituitary tumours occur in 30 per cent of MEN1 patients, with prolactinomas representing the most common type. Associated tumours, which may also occur in MEN1, include adrenal cortical tumours, carcinoid tumours, lipomas, angiofibromas, and collagenomas. The gene causing MEN1, which is located on chromosome 11q13 and represents a putative tumour suppressor gene, consists of 10 exons that encode a 610 amino acid protein, referred to as 'MENIN'. The majority (>80 per cent) of the germ line *MEN1* mutations in families are inactivating. MENIN has been shown to be located in the nucleus, where it directly interacts with the N-terminus of the AP1 transcriptional factor JunD. MENIN suppresses JunD-activated transcription and thus MENIN acts via the transcriptional regulation pathway to control cell proliferation.

Multiple endocrine neoplasia type 2 (MEN2)

MEN2 describes the association of medullary thyroid carcinoma (MTC), phaeochromocytomas, and parathyroid tumours. Three clinical variants of MEN2 are recognized—MEN2a, MEN2b, and MTC-only. MEN2a is the most common variant, where the development of MTC is associated with phaeochromocytomas (50 per cent of patients), which may be bilateral, and parathyroid tumours (20 per cent of patients). MEN2b, which represents 5 per cent of all MEN2 cases, is characterized by the occurrence of MTC and phaeochromocytoma in association with a Marfanoid habitus, mucosal neuromas, medullated corneal fibres, and intestinal autonomic ganglion dysfunction leading to multiple diverticulae and megacolon. Parathyroid tumours do not usually occur in MEN2b. MTC-only is a variant in which medullary thyroid carcinoma is the sole manifestation of the syndrome. The gene causing all three MEN2 variants was mapped to chromosome 10cen–10q11.2, a region containing the c-*RET* proto-oncogene which encodes a tyrosine kinase receptor with cadherin-like and cysteine-rich extracellular domains and a tyrosine kinase intracellular domain. Specific mutations of c-*RET* have been identified for each of the three MEN2 variants. Thus in 95 per cent of patients, MEN2a is associated with mutations of the cysteine-rich extracellular domain and mutations in codon 634 (Cys®Arg) account for 85 per cent of MEN2a mutations. MTC-only is also associated with missense mutations in the cysteine-rich extracellular domain and most mutations are at codon 618. MEN2b is associated with mutations in codon 918 (Met®Thr) of the intracellular tyrosine kinase domain in 95 per cent of patients. Mutational analysis of c-*RET* to detect mutations in codons 609, 611, 618, 634, 768, and 804 in MEN2a and MTC-only, and codon 918 in MEN2b, has been used in the diagnosis and management of patients and families with these disorders.

Hyperparathyroidism–jaw tumour (HPT-JT) syndrome

The HPT-JT syndrome is an autosomal dominant disorder characterized by the development of parathyroid tumours and fibro-osseous jaw tumours. In addition, some patients may also develop Wilms' tumours, renal cysts, renal hamartomas, renal cortical adenomas, papillary renal cell carcinomas, pancreatic adenocarcinomas, testicular mixed germ cell tumours with a major seminoma component, and Hurthle cell thyroid adenomas. It is important to note that the parathyroid tumours may occur in isolation and without any evidence of jaw tumours, and this may cause confusion with other hereditary hypercalcaemic disorders such as MEN1, familial benign hypercalcaemia (FBH), which is also referred to as familial hypocalciuric hypercalcaemia (FHH), and FIHP. HPT-JT can be distinguished from FBH, as in FBH serum calcium concentrations are elevated from the early neonatal or infantile period whereas in HPT-JT such elevations are uncommon in the first decade. In addition, HPT-JT patients, unlike in FBH, will have associated hypercalciuria. The distinction between HPT-JT patients and MEN1 patients, who have only developed the usual first manifestation of hypercalcaemia (>90 per cent of patients), is more difficult and is likely to be influenced by the operative and histological findings and the occurrence of other characteristic lesions in each disorder. It is noteworthy that HPT-JT patients will usually have single adenomas or a carcinoma, whilst MEN1 patients will often have multiglandular parathyroid disease. The distinction between FIHP and HPT-JT in the absence of jaw tumours is difficult but important as HPT-JT patients may be at a higher risk of developing parathyroid carcinomas. These distinctions may be helped by the identification of additional features, and a search for jaw tumours, renal, pancreatic, thyroid, and testicular abnormalities may help to identify HPT-JT patients. The jaw tumours in HPT-JT are different from the brown tumours observed in some patients with primary hyperparathyroidism, and do not resolve after parathyroidectomy. Indeed ossifying fibromas of the jaw are an important distinguishing feature of HPT-JT from FIHP, and the occurrence of these may occasionally precede the development of hypercalcaemia in HPT-JT patients by several decades. The gene causing HPT-JT has been mapped to chromosome 1q25–q31.

Malignancy

The hypercalcaemia of malignancy is usually due to increased bone resorption, which may either be directly due to skeletal metastases or indirectly due to tumour-production of a humoral factor that stimulates osteoclastic bone resorption. The cancers that typically metastasize to produce lytic bone lesions are from the breast, lymphomas, or multiple myeloma (Table 2). The cancers that are typically associated with the humoral hypercalcaemia of malignancy (HHM) are squamous carcinomas of the lung, oesophagus, cervix, vulva, skin, head, or neck, but other types from the kidney, bladder, ovary, and breast may also occur. HHM accounts for up to 80 per cent of patients with malignancy-associated hypercalcaemia. The most common factor causing HHM is parathyroid hormone related peptide (PTHrP), which can be measured in the serum by immunoassay. However, these assays are relatively insensitive and the failure to detect serum PTHrP does not exclude the diagnosis of HHM. Patients with HHM generally have hypercalcaemia associated with lower or undetectable serum PTH levels, marked hypercalcaemia, and a reduced plasma 1,25-dihydroxy vitamin D level. Therapy of HHM is aimed at: (1) reducing the tumour load by surgery, radiotherapy, and/or chemotherapy; (2) reducing osteoclastic bone resorption by use of bisphosphonates or calcitonin; and (3) increasing renal calcium clearance by a saline diuresis.

Granulomatous disorders

Several granulomatous disorders are associated with hypercalcaemia (Table 2) and this is invariably associated with elevated circulating concentrations of 1,25-dihydroxy vitamin D, which is due to extrarenal synthesis. Sarcoidosis is the most frequently encountered granulomatous disorder associated with hypercalcaemia and 10 per cent of patients with sarcoidosis will have hypercalcaemia and about one-half will become hypercalciuric. The finding of raised serum angiotensin converting enzyme (ACE) activity may help in confirming the diagnosis. Glucocorticoids (e.g. 40 to 60 mg of prednisolone) decrease 1,25-dihydroxy vitamin D production and restore the calcium concentration to normal. Failure to achieve normal serum calcium concentrations within 10 days of glucorticoid therapy (e.g. hydrocortisone 40 mg, three times per day), which is referred to as the steroid suppression test, should suggest the coexistence of another cause for the hypercalcaemia, for example primary hyperparathyroidism or malignancy.

Endocrine causes of hypercalcaemia other than hyperparathyoidism

Several non-parathyroid disorders (Table 2) are associated with hypercalcaemia and these include thyrotoxicosis, phaeochromocytoma, Addison's disease, VIPomas, familial benign hypocalciuric hypercalcaemia, Jansen's disease, and William's syndrome.

Thyrotoxicosis

Mild hypercalcaemia (<3.00 mmol/l) frequently accompanies thyrotoxicosis, which leads to increased bone turnover and resorption. The hypercalcaemia may respond to treatment with b-adrenergic blockers.

Familial benign hypocalciuric hypercalcaemia and neonatal primary hyperparathyroidism

Familial benign hypercalcaemia (FBH), which is also referred to as familial hypocalciuric hypercalcaemia (FHH), is an autosomal dominant disorder with a high degree of penetrance, that is characterized by lifelong asymptomatic hypercalcaemia in association with an inappropriately low urinary calcium excretion (i.e. calcium clearance to creatinine clearance ratio <0.01). A normal circulating parathyroid hormone (PTH) concentration and mild hypermagnesaemia are also typically present. Although most patients with FBH are asymptomatic, chondrocalcinosis and acute pancreatitis have occasionally been observed. In addition, children of consanguineous marriages within FBH kindreds have been observed to have life-threatening hypercalcaemia due to neonatal primary hyperparathyroidism (NHPT). NHPT is defined as symptomatic hypercalcaemia with skeletal manifestations of hyperparathyroidism in the first 6 months of life. NHPT children often present in the first few days or weeks of life with failure to thrive, dehydration, hypotonia, constipation, rib cage deformities, and multiple fractures due to bony undermineralization. Children with NHPT often require urgent parathyroidectomy, which corrects the PTH-dependent hypercalcaemia and bone demineralization. FBH is due to heterozygous inactivating mutations of the calcium sensing receptor (CaSR) and NHPT is often associated with inactivating homozygous CaSR mutations (Fig. 2). However, NHPT has also been observed in children where only one parent had clinically apparent FBH, and many other NHPT patients appear to be sporadic, that is both parents have normal serum calcium concentrations. In such NHPT patients with heterozygous CaSR mutations, the mutant CaSR may exert a dominant negative action on the normal CaSR. The human CaSR is a 1078 amino acid cell surface protein which is expressed in parathyroids, thyroid cells, and kidney, and is a member of the family of G-protein coupled receptors. The *CaSR* gene is located on chromosome 3q21–q24.

Jansen's disease

Jansen's disease is an autosomal dominant disease that is characterized by short-limbed dwarfism, due to metaphyseal chondrodysplasia, and severe hypercalcaemia and hypophosphataemia, despite normal or undetectable serum levels of PTH. These abnormalities are associated with activating mutations of the PTH receptor (Fig. 2) and thus this represents a PTH-independent activation of the PTH receptor (PTHR). Two different mutations of the PTHR have been identified, and these involve codon 223 (His®Arg) and codon 410 (Thr®Pro). Expression of the mutant receptors in COS-7 cells resulted in constitutive, ligand-independent accumulation of cAMP, while the basal accumulation of inositol phosphates was not increased. These findings provide a likely explanation for the abnormalities observed in mineral homeostasis and growth plate development in this disorder.

William's syndrome

William's syndrome is an autosomal dominant disorder characterized by supravalvular aortic stenosis, elfin-like facies, psychomotor retardation, and infantile hypercalcaemia. The underlying abnormality of calcium metabolism remains unknown but abnormal 1,25-dihydroxy vitamin D_3 metabolism or decreased calcitonin production have been implicated, although no abnormality has been consistently demonstrated. Hemizygosity due to a microdeletion at the *ELASTIN* locus on chromosome 7q11.23 in over 90 per cent of patients with the classical William's phenotype has been demonstrated. This microdeletion has been reported to involve another gene, designated *LIM-KINASE*, that is expressed in the central nervous system. The calcitonin receptor gene has been localized to chromosome 7q21 and close to the region deleted in William's syndrome. However, the calcitonin receptor gene was not involved in the deletion found in four patients with William's syndrome, indicating that it is unlikely to be implicated in the hypercalcaemia of such children. While the involvement of the *ELASTIN* and *LIM-KINASE* genes in the deletions of William's syndrome patients can explain the respective cardiovascular and neurological features of this disorder, it seems possible that another, as yet uncharacterized, gene that is within this contiguously deleted region is likely to be involved to explain the abnormalities of calcium metabolism.

Drugs

Several drugs (Table 2) can cause hypercalcaemia by different mechanisms. Compounds containing vitamins D and A are common and frequently associated with hypercalcaemia. The use of thiazide diuretics is often associated with hypercalcaemia. The hypercalcaemia appears to be largely renal in origin, as thiazides enhance distal renal tubular calcium reabsorption. Hypercalcaemia reverses rapidly with discontinuation of the drug.

The milk-alkali syndrome was first described in the 1930s, generally in the context of ulcer treatment with large quantities of milk together with sodium bicarbonate. Today, the responsible agent is usually calcium carbonate, although consumption of large quantities of dairy products (milk, cheese, and yoghurt) may still contribute. Classical features include moderate to severe hypercalcaemia with alkalosis and renal impairment. The amount of calcium ingested by patients with this syndrome is usually 5 to 15 g/day. Treatment consists of: (1) discontinuing the ingestion of the calcium containing compounds(s) and antacids; (2) rehydration; and (3) saline diuresis.

Hypocalcaemia

Clinical features and investigations

The clinical presentation of hypocalcaemia (serum calcium <2.12 mmol/l) ranges from an asymptomatic biochemical abnormality to a severe, life-threatening condition. In mild hypocalcaemia (serum calcium 2.00–2.12 mmol/l), patients may be asymptomatic. Those with more severe (serum calcium <1.9 mmol/l) and long-term hypocalcaemia may develop: acute symptoms of neuromuscular irritability (Table 7); ectopic calcification (e.g. in the basal ganglia, which may be associated with extrapyramidal neurological symptoms); subcapsular cataract; papilloedema; and abnormal dentition. Investigations should be directed at confirming the presence of hypocalcaemia and establishing the cause. Hypocalcaemia (Table 6) can be classified by cause, according to whether serum parathyroid hormone (PTH) concentrations are low (i.e. hypoparathyroid disorders) or high (i.e. disorders associated with secondary hyperparathyroidism). Hypocalcaemia is most commonly caused by hypoparathyroidism, a deficiency or abnormal metabolism of vitamin D, acute or chronic renal failure, or hypomagnesaemia. In hypoparathyroidism, serum calcium is low, phosphate is high, and PTH is undetectable; renal function and concentrations of the 25-hydroxy and 1,25-dihydroxy metabolites of vitamin D are usually normal. The features of pseudohypoparathyroidism are similar to those of hypoparathyroidism except for PTH, which is markedly increased. In chronic renal failure, which is the most common cause of hypocalcaemia, phosphate is high and alkaline phosphatase, creatinine, and PTH are elevated; 25-hydroxy vitamin D_3 is normal and 1,25-dihydroxy vitamin D_3 is low. In vitamin D deficiency osteomalacia, serum calcium and phosphate are low, alkaline phosphatase and PTH are elevated, renal function is normal, and 25-hydroxy vitamin D_3 is low. The most frequent artifactual cause of hypocalcaemia is hypoalbuminaemia, such as occurs in liver disease or the nephrotic syndrome.

Management of acute hypocalcaemia

The management of acute hypocalcaemia depends on the severity of the hypocalcaemia, the rapidity with which it developed, and the degree of neuromuscular irritability (Table 7). Treatment should be given to symptomatic patients (e.g. with seizures or tetany) and asymptomatic patients with a serum calcium of less than 1.90 mmol/l who are at high risk of developing complications. The preferred treatment for acute symptomatic hypocalcaemia is calcium gluconate, 10 ml 10 per cent w/v (2.20 mmol of calcium) intravenous, diluted in 50 ml of 5 per cent dextrose or 0.9 per cent sodium chloride and given by slow injection (>5 min); this can be repeated as required to control symptoms. Serum calcium concentrations should be assessed regularly. Persistent hypocalcaemia may be managed acutely by administration of a calcium gluconate infusion; for example, dilute 10 ampoules of calcium gluconate, 10 ml 10 per cent w/v (22.0 mmol of calcium), in 1 litre of 5 per cent dextrose or 0.9 per cent sodium chloride, start infusion at 50 ml/h and titrate to maintain serum calcium concentrations in the normal range. Generally, 0.3 to 0.4 mmol/kg of elemental calcium infused over 4 to 6 h increases serum calcium by 0.5 to 0.75 mmol/l. If hypocalcaemia is likely to persist, oral vitamin D therapy (see below) should also be administered. In hypocalcaemic patients who are also hypomagnesaemic, the hypomagnesaemia must be corrected before the hypocalcaemia

will resolve. This may occur in the postparathyroidectomy period or in patients with severe malabsorption, for example those with established coeliac disease.

Management of persistent hypocalcaemia

The two main agents available for the treatment of hypocalcaemia are supplemental calcium, about 10 to 20 mmol calcium 6 to 12 hourly, and vitamin D preparations. Patients with hypoparathyroidism seldom require calcium supplements after the early stages of stabilization with vitamin D. A variety of vitamin D preparations have been used. These include: vitamin D_3 (cholecalciferol) or vitamin D_2 (ergocalciferol), 25 000 to 100 000 units (1.25–5 mg/day); dihydrotachysterol (now seldom used), 0.25 to 1.25 mg/day; alfacalcidol (1a-hydroxycholecalciferol), 0.25 to 1.0 µg/day; and calcitriol (1,25-dihydroxy cholecalciferol), 0.25 to 2.0 µg/day. In children, these preparations are prescribed in doses based on body weight. Cholecalciferol and ergocalciferol are the least expensive preparations but have the longest durations of action and may result in prolonged toxicity. The other preparations, which do not require renal 1a-hydroxylation, have the advantage of shorter half-lives and thereby minimize the risk of prolonged toxicity. Calcitriol is probably the drug of choice because it is the active metabolite and, unlike alfacalcidol, does not require hepatic 25-hydroxylation. Close monitoring (at about 1–2-week intervals) of the patient's serum and urine calcium concentrations are required initially, and at 3 to 6-monthly intervals once stabilization is achieved. The aim is to avoid hypercalcaemia, hypercalciuria, nephrolithiasis, and renal failure. It should be noted that hypercalciuria may occur in the absence of hypercalcaemia.

Hypocalcaemic diseases

Hypocalcaemic diseases (Table 6) may arise because of a destruction of the parathyroid glands, failure of parathyroid gland development, or reduced PTH secretion or PTH-mediated actions in target tissues. Thus, these diseases may be classified as being due to a deficiency of PTH, a defect in the PTH-receptor (i.e. the PTH/PTHrP receptor), or an insensitivity to PTH caused by defects down-stream of the PTH/PTHrP receptor (Fig. 2). The diseases may also be classified as being part of the hypoparathyroid disorders, of the calcium sensing receptor abnormalities, or of the pseudohypoparathyroid disorders.

Hypoparathyroidism

Hypoparathryoidism is characterized by hypocalcaemia and hyperphosphataemia, which are the result of a deficiency in parathyroid hormone (PTH) secretion or action. Serum concentrations of immunoreactive PTH are low or undetectable and the concentrations of 1,25-dihydroxy vitamin D_3 are usually in the low normal to low range but alkaline phosphatase activity is unchanged. The daily urinary excretion of calcium is reduced, although the fractional excretion of calcium is increased. Nephrogenous cyclic adenosine monophosphate (cAMP) excretion is low and renal tubular reabsorption of phosphate is elevated. Urinary cAMP, plasma cAMP, and urinary phosphate excretion increase markedly after administration of exogenous bioactive PTH (Chase–Aurbach and Ellsworth–Howard tests). Hypoparathyroidism may result from agenesis (e.g. the DiGeorge syndrome) or destruction of the parathyroid glands (e.g. following neck surgery, in autoimmune diseases), from reduced secretion of PTH (e.g. neonatal hypocalcaemia or hypomagnesaemia), or resistance to PTH (which may occur as a primary disorder (e.g. pseudohypoparathyroidism or secondary to hypomagnesaemia). In addition, hypoparathyroidism may occur as an inherited disorder (Table 1) that may either be part of a complex congenital defect (e.g. DiGeorge syndrome), or as part of a pluriglandular autoimmune disorder, or as a solitary endocrinopathy, which has been referred to as isolated or idiopathic hypoparathyroidism. Hypoparathyroidism may also complicate iron storage disease, especially secondary haemochromatosis in children and adolescents. In thalassaemic children, destruction of the parathyroids is associated with ill health and frank tetany, which may elude diagnosis and effective treatment unless hypoparathyroidism is suspected.

Isolated hypoparathyroidism

Isolated hypoparathyroidism may either be inherited or it may be acquired by damage to the parathyroids at surgery, by infiltrating metastases, or systemic disease (Table 6).

Inherited hypoparathyroidism

Patients with inherited forms of hypoparathyroidism may develop hypocalcaemic seizures in the neonatal or infantile periods and require life-long treatment with oral vitamin D preparations, for example calcitriol. Autosomal dominant, autosomal recessive, and X-linked recessive inheritances for hypoparathyroidism have been observed (Table 1). Some of the autosomal forms are due to mutations of the *PTH* gene, the calcium sensing receptor (see below), and the transcriptional factor *GCM2* (glial cells missing 2).

Acquired forms of hypoparathyroidism

Hypoparathyroidism may occur after neck surgery, irradiation, or because of infiltration by metastases or systemic disease, for example haemochromatosis, amyloidosis, sarcoidosis, Wilson's disease, or thalassaemia (Table 6). Surgical damage to the parathyroids occurs most commonly after a radical neck dissection, for example laryngeal or oesophageal carcinoma treatment, a total thyroid resection, or after repeated parathyroidectomies for multigland disease (e.g. in MEN1 or MEN2, see above). Hypocalcaemic symptoms begin 12 to 24 h postoperatively and may need treatment with oral or intravenous calcium. Parathyroid function often returns, but persistent hypocalcaemia requires treatment with vitamin D preparations.

Neonatal hypoparathyroidism resulting in hypocalcaemia may occur in the baby of a mother with hypercalcaemia caused by primary hyperparathyroidism. Maternal hypercalcaemia results in increased calcium delivery to the fetus, and this fetal hypercalcaemia suppresses fetal PTH secretion. Postpartum, the infant's suppressed parathyroids are unable to maintain normocalcaemia. The disorder is usually self-limiting, but occasionally therapy may be required. In addition, the feeding of cow's milk, which has a high phosphate content, to babies may also result in hypocalcaemia in some children.

Functional hypoparathyroidism may result from severe hypomagnesaemia (<0.40 mmol/l), which may be due to a severe intestinal malabsorption disorder (e.g. Crohn's disease) or a renal tubular disorder. It is associated with hypoparathyroidism because magnesium is required for the release of PTH from the parathyroid gland and also for PTH action via adenyl cyclase. Magnesium chloride, 35 to 50 mmol intravenously in 1 litre of 5 per cent glucose or other isotonic solution given over 12 to 24 h may be repeatedly required to restore normomagnesaemia.

Complex syndromes associated with hypoparathyroidism

Hypoparathyroidism may occur as part of a complex syndrome which may either be associated with a congenital developmental anomaly or with an autoimmune syndrome. The congenital developmental anomalies associated with hypoparathyroidism include the DiGeorge, the HDR (hypoparathyroidism, deafness, and renal anomalies), the Kenney–Caffey and Barakat syndromes, and also syndromes associated with either lymphoedema or dysmorphic features and growth failure (Table 1).

DiGeorge syndrome

Patients with the DiGeorge syndrome (DGS) suffer from neonatal hypoparathyroidism, T-cell immunodeficiency, congenital heart defects, and deformities of the ear, nose, and mouth (e.g. cleft lip and/or palate). Children with DGS often die from infections related to the immunodeficiency. The disorder arises from a congenital failure in the development of the derivatives of the third and fourth pharyngeal pouches with resulting absence or hypoplasia of the parathyroids and thymus. Most cases of DGS are sporadic but an autosomal dominant inheritance of DGS has been observed and an association between the syndrome and an unbalanced translocation and deletions involving chromosome 22q11.2 have also been reported. In some patients, deletions of another locus on chromosome 10p13–p14 have been observed in association with DGS and this is referred to as DGS type 2 (DGS2), whilst patients with the 22q11.2 deletions are referred to as DGS type 1 (DGS1). Studies of the DGS1 deleted region on chromosome 22q11.2 have revealed three genes (referred to as *RNEX40*, *NEX2.2-NEX3*, and *UDFIL* to be involved). However, although these are involved in the chromosomal deletions, the mechanisms by which they lead to the varied manifestations of DGS remain to be elucidated.

Hypoparathyroidism, deafness, and renal anomalies (HDR) syndrome

HDR is an autosomal dominant disorder in which patients often have asymptomatic hypocalcaemia with undetectable or inappropriately normal serum concentrations of PTH, and normal brisk increases in plasma cAMP in response to the infusion of PTH. Bilateral, symmetrical, sensorineural deafness involving all frequencies occurs, and the renal abnormalities consist mainly of bilateral cysts that compress the glomeruli and tubules and lead to renal impairment. Cytogenetic abnormalities

involving chromosome 10p14–10pter have been identified in HDR patients. HDR patients do not have immunodeficiency or heart defects, which are key features of DGS2, and indeed there are two non-overlapping regions; thus, the DGS2 region is located on 10p13–14 and HDR on 10p14–10pter. HDR patients have a haploinsufficiency of the zinc finger transcription factor GATA3.

Mitochondrial disorders associated with hypoparathyroidism

Hypoparathyroidism has been reported to occur in three disorders associated with mitochondrial dysfunction: the Kearns–Sayre syndrome (KSS), the MELAS syndrome, and a mitochondrial trifunctional protein deficiency syndrome (MTPOS). Kearns–Sayre syndrome is characterized by progressive external ophthalmoplegia and pigmentary retinopathy before the age of 20 years, and is often associated with heart block or cardiomyopathy. The MELAS syndrome consists of a childhood onset of mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes. In addition, varying degrees of proximal myopathy can be seen in both conditions. Both the Kearns–Sayre and MELAS syndromes have been reported to occur with insulin dependent diabetes mellitus and hypoparathyroidism, and mitochondrial gene abnormalities have been identified in some patients. Mitochondrial trifunctional protein deficiency is a disorder of fatty acid oxidation that is associated with peripherial neuropathy, pigmentary retinopathy, and acute fatty liver degeneration in pregnant women who carry an affected fetus. Hypoparathyroidism has been observed in one patient with trifunctional protein deficiency.

Kenney–Caffey syndrome

Hypoparathyroidism has been reported to occur in over 50 per cent of patients with the Kenney–Caffey syndrome, which is associated with short stature, osteosclerosis, and cortical thickening of the long bones, delayed closure of the anterior fontanel, basal ganglia calcification, nanophthalmos, and hyperopia. Parathyroid tissue could not be found in a detailed post mortem examination of one patient and this suggests that hypoparathyroidism may be due to an embryological defect of parathyroid development. The molecular genetic defect has not been identified.

Additional familial syndromes

Single familial syndromes in which hypoparathyroidism is a component have been reported (Table 1). Thus, an association of hypoparathyroidism, renal insufficiency, and developmental delay has been reported in one Asian family in whom autosomal recessive inheritance of the disorder was established. The occurrence of hypoparathyroidism, nerve deafness, and a steroid-resistant nephrosis leading to renal failure, which has been referred to as the Barakat syndrome, has been reported in four brothers from one family, and an association of hypoparathyroidism with congenital lymphoedema, nephropathy, mitral valve prolapse, and brachytelephalangy has been observed in two brothers from another family. Molecular genetic studies have not been reported from these two families. A syndrome in which hypoparathyroidism was associated with severe growth failure and dysmorphic features has been reported in twelve patients from Saudi Arabia. Consanguinity was noted in 11 of the 12 patients' families, the majority of which originated from the Western province of Saudi Arabia. This syndrome, which is inherited as an autosomal recessive disorder, has also been identified in families of Bedouin origin and homozygosity and linkage disequilibrium studies have located this gene to chromosome 1q42–q43.

Blomstrand's disease

Blomstrand's chondrodysplasia is an autosomal recessive disorder characterized by early lethality, dramatically advanced bone maturation, and accelerated chondrocyte differentiation. Affected infants, who usually have consanguineous unaffected parents, develop pronounced hyperdensity of the entire skeleton with markedly advanced ossification, that results in extremely short and poorly modelled long bones. Mutations of the PTH/PTHrP receptor that impair its function are associated with Blomstrand's disease. Thus, it seems likely that affected infants will, in addition to the skeletal defects, have abnormalities in other organs, including secondary hyperplasia of the parathyroid glands, presumably due to hypocalcaemia.

Pluriglandular autoimmune hypoparathyroidism

This syndrome (Fig. 4) comprises of hypoparathyroidism, Addison's disease, candidasis, and two or three of the following: insulin-dependent diabetes mellitus, primary hypogonadism, autoimmune thyroid disease, pernicious anaemia, chronic active hepatitis, steatorrhoea (malabsorption), alopecia (totalis or areata), and vitiligo. The disorder has also been referred to as either the autoimmune polyendocrinopathy candidasis ectodermal dystrophy (APECED) syndrome or the polyglandular autoimmune type 1 syndrome. Antibodies directed against the adrenal, thyroid, and parathyroid glands are detected in the sera of some patients. The polyglandular autoimmune type 2 syndrome is characterized by adrenal insufficiency, insulin-dependent diabetes mellitus, and thyroid disease, and does not involve hypoparathyroidism. APECED, which has an autosomal recessive inheritance, has a high incidence in Finland and amongst Iranian Jews. The *APECED* gene, which has been located to chromosome 21q22.3, encodes a 545 amino acid protein that contains motifs suggestive of a transcriptional factor and includes a nuclear localization signal, two zinc-finger motifs, a proline-rich region, and three LXXLL motifs. The gene is referred to as *AIRE* (autoimmune regulator); six *AIRE* mutations have been reported in APECED families and a codon 257 (Arg®Stop) mutation was the predominant abnormality in 82 per cent of the Finnish families.

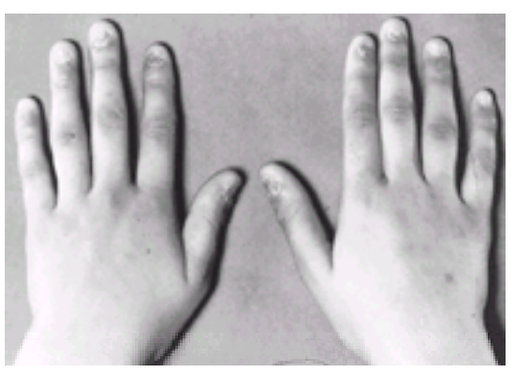

Fig. 4 Moniliasis and hyperpigmentation of the hands, particularly over the knuckles, is seen in this 8-year-old patient with hypoparathyroidism and Addison's disease. The patient also had vitiligo, and thus had some of the features of the polyglandular autoimmune syndrome type 1. Reproduced with permission from Thakker RV. Hypocalcaemic disorders. In: Thakker RV, Wass JAH, eds (1997). *Endocrine Disorders, Medicine*, vol. 25, pp. 68–70. The Medicine Group (Journals) Ltd, Abingdon, Oxon.

Calcium-sensing receptor (CaSR) abnormalities

The CaSR, which is located in the plasma membrane of the cell (Fig. 2), is at a critical site to enable the cell to recognize changes in extracellular calcium concentration. Thus, an increase in extracellular calcium leads to CaSR activation of the G-protein signalling pathway, which in turn increases the free intracellular calcium concentration and leads to a reduction in transcription of the *PTH* gene. CaSR mutations that result in a loss of function are associated with familial hypocalciuric hypercalcaemia (see above). However, CaSR missense mutations that result in a gain of function (or added sensitivity to extracellular calcium) lead to hypocalcaemia with hypercalciuria. These hypocalcaemic individuals are generally asymptomatic and have serum PTH concentrations that are in the low–normal range, and because of the insensitivities of previous PTH assays in this range such patients have often been diagnosed to be hypoparathyroid. In addition, such patients may have hypomagnesaemia. Treatment with vitamin D or its active metabolites to correct the hypocalcaemia in these patients results in marked hypercalciuria, nephrocalcinosis, nephrolithiasis, and renal impairment. Thus, these patients need to be distinguished from those with hypoparathyroidism.

Pseudohypoparathyroidism (PHP)

Patients with pseudohypoparathyroidism (PHP), which may be inherited as an autosomal dominant disorder, are characterized by hypocalcaemia and hyperphosphataemia due to PTH resistance rather than PTH deficiency. Five variants are recognized on the basis of biochemical and somatic features (Table 8) and three of these—PHP type Ia (PHPIa), PHP type 1b (PHPIb), and pseudopseudohypoparathyroidism (PPHP)—will be reviewed in further detail. Patients with PHPIa exhibit PTH resistance (hypocalcaemia, hyperphosphataemia, elevated serum PTH, and an absence of an increase in serum and urinary cyclic AMP and urinary

phosphate following intravenous human PTH infusion), together with the features of Albright's hereditary osteodystrophy (AHO), which includes short stature, obesity, subcutaneous calcification, mental retardation, round facies, dental hypoplasia, and brachydactyly (i.e. shortening of the metacarpals (Fig. 5), particularly the third, fourth, and fifth). In addition to brachydactyly, other skeletal abnormalities of the long bones and shortening of the metatarsals may also occur. Patients with PHPIb exhibit PTH resistance only and do not have the somatic features of AHO, whilst patients with PPHP exhibit the somatic features of AHO in the absence of PTH resistance. The absence of a normal rise in urinary excretion of cyclic AMP excretion after an infusion of PTH in PHPIa indicated a defect at some site of the PTH receptor–adenyl cyclase system (Fig. 2). This receptor system is regulated by at least two G proteins, one of which stimulates (Gsa) and another which inhibits (Gia) the activity of the membrane-bound enzyme that catalyses the formation of the intracellular second messenger cyclic AMP. Interestingly, patients with PHPIa may also show resistance to other hormones, for example thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH), that act via G-protein coupled receptors. Inactivating mutations of the Gsa gene (referred to as *GNAS1*), which is located on chromosome 20q13.2, have been identified in PHPIa and PPHP patients. However, *GNAS1* mutations do not fully explain the PHPIa or PPHP phenotypes, and studies of PHPIa and PPHP that occurred within the same kindred revealed that the hormonal resistance is parentally imprinted. Thus, PHPIa occurs in a child only when the mutation is inherited from a mother affected with either PHPIa or PPHP; and PPHP occurs in a child only when the mutation is inherited from a father affected with either PHPIa or PPHP. *GNAS1* mutations have not been detected in PHPIb, which has been considered to be due to a defect of the PTH/PTHrP receptor. However, studies of the PTH/PTHrP receptor gene and mRNA in PHPIb patients have not identified mutations, and linkage studies in four unrelated kindreds have mapped the PHPIb locus to chromosome 20q13.3, a location that also contains the *GNAS1* gene. In addition, parental imprinting of the genetic defect was observed and this is similar to the findings in kindreds with PHP-type Ia and/or PPHP. Two possible explanations for these observations have been proposed. First, PHPIb maybe due to a defect in a tissue- or cell-specific enhancer, or promoter, of the *GNAS1* gene and this may affect, directly or indirectly, the expression levels of the Gsa-specific transcripts. Or, second, PHPIb may be caused by a defect in a gene close to the *GNAS1* gene which is transcribed only from the maternal allele and affects PTH/PTHrP receptor or Gsa expression and/or function in some renal cells.

Fig. 5 Radiograph of both hands of a patient with pseudohypoparathyroidism type 1a. The patient has a normal right hand, but there is shortening of the left fourth metacarpal (brachydactyly). Metatarsals may be similarly shortened. Reproduced with permission from Thakker RV. Hypocalcaemic disorders. In: Thakker RV, Wass JAH, eds (1997). *Endocrine Disorders, Medicine*, vol. 25, pp. 68–70. 12.7.1 Disorders of the adrenal cortex

P. M. Stewart

Introduction

Three main types of hormone are produced by the adrenal cortex—glucocorticoids (cortisol, corticosterone), mineralocorticoids (aldosterone, deoxycorticosterone), and sex steroids (mainly androgens). The biochemical pathways involved in their synthesis are shown in Fig. 1. Glucocorticoids are secreted in relatively high amounts (cortisol 10 to 20 mg/day) from the zona fasciculata under the control of ACTH, whilst mineralocorticoids are secreted in low amounts (aldosterone 100 to 150 µg/day) from the zona glomerulosa under the principal control of angiotensin II. Classic endocrine feedback loops are in place to control the secretion of both hormones—cortisol inhibits the secretion of both corticotrophin-releasing factor and ACTH from the hypothalamus and pituitary, respectively, and the aldosterone-induced sodium retention inhibits renal renin secretion.

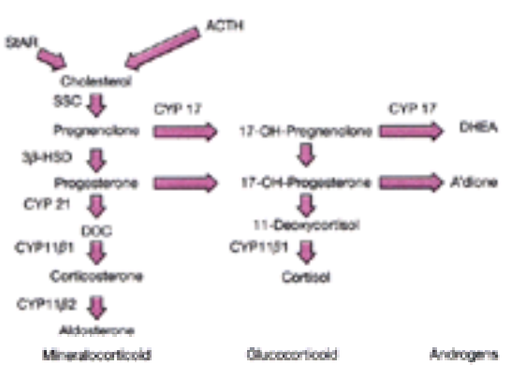

Fig. 1 Pathways of adrenocortical steroid biosynthesis.

Within the adrenal cortex, cholesterol is taken up from circulating cholesterol bound to low-density lipoprotein and an initial, rate-limiting step in adrenal steroidogenesis is the uptake of cholesterol by mitochondria dependent upon a recently characterized protein, steroidogenic acute regulatory protein (or StAR). Thereafter, the functional zonation of the adrenal cortex is achieved in part through the discrete expression and regulation of the final steroidogenic enzymes—aldosterone synthase, expressed in the glomerulosa, and 11b-hydroxylase in the fasciculata (Fig. 1).

Aldosterone acts physiologically to stimulate sodium transport across epithelial cells in the distal nephron, colon, and salivary gland. This involves the interaction of aldosterone with the mineralocorticoid receptor and the induction of the basolateral sodium–potassium ATPase pump and the apical sodium channel. This is mediated through the induction of a novel gene, serum- and glucocorticoid-induced kinase (sgk). The mineralocorticoid receptor, however, is non-selective *in vitro*; paradoxically cortisol and aldosterone have the same intrinsic affinity for this receptor, raising the question as to how aldosterone is the preferred mineralocorticoid *in vivo*. This selectivity is achieved at a prereceptor level through the expression of an enzyme, 11b-hydroxysteroid dehydrogenase type 2 (**11b-HSD2**), which efficiently inactivates cortisol to cortisone allowing aldosterone to occupy the mineralocorticoid receptor. Inhibition of 11b-HSD2 results in cortisol, conventionally regarded as a glucocorticoid, acting as a potent mineralocorticoid.

Glucocorticoids have more diverse and extensive roles than mineralocorticoids, regulating sodium and water homeostasis, glucose and carbohydrate metabolism, inflammation, and stress. These effects are mediated by the interaction of cortisol with the ubiquitous glucocorticoid receptors and the induction or repression of target gene transcription.

Adrenocortical diseases are relatively rare, but part of their importance lies in their relative ease of diagnosis and the availability of effective therapy. The diseases are most readily classified on the basis of whether there is hormone excess or deficiency (Table 1). In most instances this excess or deficiency arises from abnormal secretion of hormones. However, the defect may also relate to a change in corticosteroid metabolism (for example glucocorticoid-suppressible hyperaldosteronism, liquorice ingestion) or to defective receptors (for example glucocorticoid resistance).

Glucocorticoid excess–Cushing's syndrome

Harvey Cushing first described a case of the 'polyglandular syndrome' secondary to pituitary basophilia in 1912 and linked this to bilateral adrenal hyperplasia several years later. The first case of an adrenal adenoma was probably reported by H.G. Turney in 1913 (Fig. 2).

Fig. 2 H. G. Turney's case of Cushing's syndrome before and after developing the condition.

Definition

Cushing's syndrome comprises the symptoms and signs associated with prolonged exposure to inappropriately elevated levels of free plasma glucocorticoid (Fig. 2). This definition thus takes into account the elevated corticosteroid levels that may be found in severely depressed patients but which appear to be appropriate to the condition and also the increased total (but normal free) glucocorticoid levels found when there is an increase in circulating cortisol-binding globulin (for example in patients on oestrogen therapy). The use of the term glucocorticoid in the definition covers both endogenous (cortisol) and exogenous (such as prednisolone, dexamethasone) excess.

Classification of Cushing's syndrome

The condition is most readily classified into ACTH-dependent and ACTH-independent causes (Table 2). The term Cushing's syndrome is used to describe all causes whilst that of Cushing's disease is reserved for cases of pituitary-dependent Cushing's syndrome.

ACTH-dependent causes

Cushing's disease

When iatrogenic causes are excluded, the most frequent cause of Cushing's syndrome is Cushing's disease, which accounts for approximately 70 per cent of cases. The adrenal glands show bilateral adrenocortical hyperplasia with widening of the zona fasciculata and reticularis.

Cushing himself raised the question as to whether his disease was a primary pituitary condition or secondary to an abnormality in the hypothalamus. The release of ACTH from the pituitary is controlled by corticotrophin-releasing factor (**CRF**) acting synergistically with arginine vasopressin. If there was hypothalamic dysfunction in Cushing's disease, it might be expected that one or other of these would be produced in excess, yet measurement of CRF in both the circulation and cerebrospinal fluid has shown that the levels are low. This would suggest that CRF is not involved, but patients with Cushing's disease show an exaggerated ACTH response to CRF, suggesting that there may be an enhanced sensitivity of corticotrophs to this factor. However, *in vitro* experiments with microadenomas from patients with Cushing's disease have not confirmed this. By contrast there is some evidence for enhanced arginine vasopressin production in Cushing's disease and this might interact with CRF to promote tumour growth and ACTH release.

Whether or not the hypothalamus has an initiating role, there is abundant evidence that at presentation the condition is pituitary, rather than hypothalamus, dependent. In over 90 per cent of cases the disease is due to a pituitary adenoma of monoclonal origin; basophil hyperplasia is very uncommon. Selective surgical removal of the microadenoma usually results in cure with a very low recurrence rate.

Ectopic corticotrophin-releasing factor (CRF) production

This is a very rare cause of pituitary-dependent Cushing's disease. However, cases have been described in which a tumour (for example medullary thyroid, prostate carcinoma) has been shown to contain CRF but not ACTH. It has been suggested that ectopic CRF production may explain the metyrapone responsiveness and suppression with high-dose dexamethasone found in some patients with the ectopic ACTH syndrome.

Ectopic ACTH syndrome

Cushing's syndrome may be associated with non-pituitary tumours producing ACTH, most commonly a small-cell carcinoma of the bronchus (Table 3). These conditions are described further in Chapter 12.11.

Macroscopic nodular adrenal hyperplasia

In about 20 to 40 per cent of patients with Cushing's disease there is bilateral adrenocortical hyperplasia associated with one or more nodules. These may be up to several centimetres in diameter. Such nodules are a trap for the unwary (see below) as they may be mistaken for primary adrenal tumours.

ACTH-independent causes

Adrenal adenoma and carcinoma

With the exclusion of iatrogenic Cushing's syndrome, adrenal adenomas are responsible for about 10 per cent of cases and carcinomas for about the same. Carcinomas are the most common cause of Cushing's syndrome in children. The aetiology of these tumours is unknown.

Carney's syndrome

This is an autosomal dominant condition comprising mesenchymal tumours (especially atrial myxomas), spotty skin pigmentation, peripheral nerve tumours, and various endocrine tumours, one of which may lead to Cushing's syndrome. The adrenals then contain multiple, small, pigmented nodules. The condition has been described as pigmented multinodular adrenocortical dysplasia. It does not appear to be ACTH dependent and recent evidence suggests that the condition results because of mutations in the regulatory subunit R1A of protein kinase A.

McCune–Albright syndrome

In this condition fibrous dysplasia and cutaneous pigmentation may be associated with pituitary, thyroid, adrenal, and gonadal hyperfunction. The adrenal hypersecretion may produce Cushing's syndrome. The underlying abnormality is a somatic mutation in the a-subunit of the stimulatory G protein which is linked to adenyl cyclase. The mutation results in the G protein being constitutively activated (that is, in the adrenal mimics constant ACTH stimulation). Adrenal nodular formation may occur.

Aberrant receptor expression

Recently patients have been described with nodular hyperplasia, ACTH-independent Cushing's syndrome, and enhanced adrenal responsiveness to gastric inhibitory polypeptide (**GIP**). The biochemical clues were the presence of subnormal morning levels of plasma cortisol and a rise in cortisol after food. This food-dependent form of Cushing's syndrome resulted from the normal increase in GIP after eating. The adrenocortical tissue of these patients responded *in vitro* to low doses of GIP,

whereas there was no such effect in normal adrenal cortex, suggesting that in some unknown manner adrenal GIP receptors are linked to steroidogenesis in these patients. Not surprisingly, the clinical syndrome is related to food intake. Fasting can produce adrenal insufficiency. It remains to be seen whether abnormalities of adrenal sensitivity to GIP play a subtle role in other types of Cushing's syndrome. Similarly Cushing's syndrome due to a cortisol-secreting adrenal adenoma has recently been attributed to aberrant expression of receptors for interleukin 1.

Alcohol-associated pseudo-Cushing's syndrome

In the original description of this syndrome, urinary and plasma cortisol levels were elevated and were not suppressed with dexamethasone. Plasma ACTH has been found to be normal or suppressed. The frequency and pathogenesis of this condition remain unknown but a 'two-hit' hypothesis has been put forward to explain its aetiology. Chronic liver disease irrespective of the cause is associated with impaired cortisol metabolism, but in alcoholics this is associated with an increase in cortisol secretion rate, rather than concomitant suppression in the face of impaired metabolism. With abstinence from alcohol the biochemical abnormalities rapidly revert to normal.

Clinical features of Cushing's syndrome

The classic features of Cushing's syndrome with centripetal obesity, moon face, hirsutism, and plethora are well known following Cushing's initial description in 1912 (Fig. 2 and Fig. 3). However, this gross clinical picture is not always present. The signs and symptoms in patients with Cushing's syndrome are listed in Table 4 together with the most discriminatory features distinguishing Cushing's from simple obesity. Weight gain and obesity were the commonest symptom and sign, but the distribution of fat was not invariably centripetal; a 'buffalo hump' was present in about half the patients.

Fig. 3 Typical facies of a patient with Cushing's syndrome before and after treatment.

Gonadal dysfunction is very common, with menstrual irregularity in females and loss of libido in males. Hirsutism is frequently found in female patients, as is acne.

Psychiatric abnormalities have been reported in all series of patients with Cushing's syndrome regardless of cause. Depression and lethargy are among the commonest problems, but poor concentration, paranoia, and overt psychosis are also well recognized. Lowering of plasma cortisol by medical or surgical therapy usually results in a rapid improvement in the psychiatric state.

Most patients with long-standing Cushing's syndrome have lost height because of osteoporotic vertebral collapse. This can be assessed by measuring the patient's height and comparing it with their span; in normal subjects these measurements should be equal. Pathological fractures, either spontaneous or after minor trauma, are not uncommon. Rib fractures, in contrast to those of the vertebrae, are often painless. The radiograph appearances are typical, with exuberant callus formation at the site of the healing fracture.

The plethoric appearance of the patient with Cushing's syndrome is caused by thinning of the skin and is not due to true polycythaemia. In those with a high concentration of haemoglobin, the red cell mass is usually normal and the polycythaemia due to a reduced plasma volume.

The typical red-purple livid striae of the syndrome are found most frequently on the abdomen but may also be present on the upper thighs and arms. They are very common in younger patients and less so in those over 50.

Myopathy and bruising are two of the most discriminatory features of the syndrome. The myopathy involves the proximal muscles of lower limb and shoulder girdle. Complaints of weakness such as inability to climb stairs or get up from a deep chair are relatively uncommon, but observation of whether the patient can rise from a crouching position often reveals the problem. Bruising of the skin is often extensive and occurs with unknown or trivial trauma.

Hypertension is another prominent feature; even though epidemiological data show a strong association between blood pressure and obesity, hypertension is much more common in patients with Cushing's syndrome than in those with simple obesity.

Pigmentation is rare in Cushing's disease but common in the ectopic ACTH syndrome. However, in some pituitary tumours there is abnormal processing of the pro-opiomelanocortin (POMC) precursor molecule, with resulting pigmentation.

Infections are more common in patients with Cushing's syndrome. In many instances these are asymptomatic as the normal inflammatory response may be suppressed. Reactivation of tuberculosis has been reported. In the skin, fungal infection is frequently found. Glucose intolerance may be a predisposing factor, with overt diabetes being present in up to one-third of patients in some series.

Ocular effects may include raised intraocular pressure, chemosis, and exophthalmos (present in up to one-third of patients in Cushing's original series). Cataracts, a well-recognized complication of corticosteroid therapy, seem to be uncommon, except as a complication of diabetes.

Special features of Cushing's syndrome

Cyclical cushing's syndrome

Of particular clinical interest has been a group of patients with cyclical Cushing's syndrome, characterized by periods of excess cortisol production (for example, 40 days) followed by intervals of normal cortisol production (for example, 60 to 70 days). Some of these patients demonstrate a paradoxical rise in plasma ACTH and cortisol when treated with dexamethasone, and occasional patients show benefit with dopamine agonist (bromocriptine) or serotonin antagonist (cyproheptadine) therapy. Most patients have been thought to have pituitary-dependent disease and in many of these patients basophil adenomas have been removed, some with long-term cure. However, cortisol secretion may show some evidence of cyclicity in other causes of Cushing's syndrome, notably the ectopic ACTH syndrome.

Children

In children all the above features occur, but growth arrest is almost invariable. The dissociation between height and weight on the growth chart is obvious. It is important to try to obtain previous growth data so as to be able to calculate growth velocity. If the patient is growing along the same centile line, then the diagnosis of Cushing's syndrome is highly unlikely. In addition to glucocorticoid-induced growth arrest, androgen excess may result in precocious puberty.

Pregnancy

Pregnancy is rare in women with Cushing's syndrome because of associated amenorrhoea due to androgen excess or hypercortisolism. However, approximately 100

such cases have been reported, 50 per cent of which are due to adrenal adenomas. A few cases of true pregnancy-induced Cushing's syndrome have been reported with regression postpartum. In these cases the aetiology is unknown. Establishing a diagnosis and cause can be difficult; normal pregnancy is associated with a threefold increase in plasma cortisol due to increased production rates and increases in cortisol-binding globulin. Urinary free cortisol also rises and dexamethasone does not suppress plasma cortisol to the same degree as the non-pregnant state. Untreated the condition has a high maternal and fetal morbidity and mortality. Adrenal and/or pituitary adenomas should be excised. Metyrapone, which is not teratogenic, has been effective in many cases in controlling the hypercortisolism.

Adrenal carcinomas

In addition to the normal features resulting from glucocorticoid excess, the patient may present with other problems relating to (i) the tumour, for instance abdominal pain from the primary tumour or with secondary deposits, or (ii) the secretion of other steroids, such as androgens or mineralocorticoids. Thus, in females, in addition to hirsutism, there may be other features of virilization, with clitoromegaly, breast atrophy, deepening of the voice, temporal recession, and severe acne.

Ectopic ACTH syndrome

If this is due to a small-cell lung carcinoma, the clinical presentation more commonly resembles Addison's disease than Cushing's syndrome. The patients are very commonly pigmented and have lost weight, but the association of this with hypokalaemic alkalosis and glucose intolerance should alert the clinician. Patients with benign tumours, such as bronchial carcinoids which produce ACTH, present with the typical features of Cushing's syndrome.

Investigation of patients with suspected Cushing's syndrome

There are two stages in the investigation of a patient with suspected Cushing's syndrome: (1) Does the patient have Cushing's syndrome? (2) If the answer to (1) is yes, then what is the cause? Unfortunately many investigators fail to make this distinction and ill-advisedly use tests that are relevant to question (2) to try to answer question (1). In particular it is essential that radiological investigations are not undertaken until Cushing's syndrome has been confirmed biochemically. The principal diagnostic tests are listed in Table 5.

Diagnostic tests

Circadian rhythm of plasma cortisol

In normal subjects, plasma cortisol concentrations are at their highest first thing in the morning and reach a nadir at around midnight (less than 100 nmol/l). This circadian rhythm is lost in patients with Cushing's syndrome such that in the majority of patients the 09.00 h level of plasma cortisol is normal but nocturnal levels are raised. Random morning levels of plasma cortisol are therefore of little value in making the diagnosis. In addition, various factors such as stress of venepuncture, intercurrent illness, and admission to hospital may result in normal subjects losing their circadian rhythm. It is therefore good practice not to measure plasma cortisol until the patient has been in hospital for 48 h.

Very few laboratories have developed methods for the measurement of free levels of plasma cortisol. As more than 90 per cent of plasma cortisol is protein bound, the results of the conventional assay will be affected by drugs or conditions which alter levels of cortisol-binding globulin. Thus oestrogen therapy or pregnancy may elevate cortisol-binding globulin and hence total plasma cortisol. In practice, therefore, circadian rhythm is not a widely used screening test.

Urinary free cortisol excretion

For many years the diagnosis of Cushing's syndrome was based on the measurement of urinary metabolites of cortisol (24-h urinary 17-hydroxy-corticosteroid or 17-oxogenic steroid excretion, depending on the method used). However, the sensitivity and specificity of these methods is poor and most investigators have replaced these assays with the much more sensitive measurement of urinary free cortisol excretion. Urinary free cortisol is an integrated measure of plasma free cortisol. As cortisol secretion increases, the binding capacity of cortisol-binding globulin is exceeded and results in a disproportionate rise in urinary free cortisol. This is a useful screening test, but even so, it is accepted that urinary free cortisol may be normal in up to 8 to 15 per cent of patients with Cushing's syndrome.

Measurement of the cortisol–creatinine ratio on the first urine specimen passed on waking obviates the need for a timed collection and has been used by some as a sensitive screening test, particularly if cyclical Cushing's syndrome is suspected. Urine aliquots are stable when left at room temperature for up to 7 days and can then be sent by post to the local endocrine laboratory.

Low-dose/overnight dexamethasone suppression tests

In normal subjects, administration of a supraphysiological dose of glucocorticoid results in suppression of ACTH and hence of cortisol secretion. In Cushing's syndrome of whatever cause there is a failure of this suppression when low doses of the synthetic glucocorticoid dexamethasone are given.

The overnight test is often used as an outpatient screening test. Various doses of dexamethasone have been used, usually given at midnight. A normal response is a plasma cortisol of less than 50 nmol/l between 08.00 and 09.00 h the following morning. A dose of 1.5 or 2 mg gives a 30 per cent false-positive rate, whereas after 1 mg this is reduced to 12.5 per cent with a false-negative rate of less than 2 per cent. Thus, the outpatient overnight test has high sensitivity but low specificity, and further investigation is often required.

In the 48-h test, plasma cortisol is measured at 09.00 h on day 0 and 48 h later following dexamethasone given in a dose of 0.5 mg every 6 h for 48 h. This test is reported as having a 97 to 100 per cent true-positive rate and a false-positive of less than 1 per cent.

Certain drugs (phenytoin, rifampicin) may increase the metabolic clearance rate of dexamethasone thereby giving false-positive results.

Insulin tolerance test

Patients with severe depression may show many of the biochemical features of Cushing's syndrome (loss of circadian rhythm of plasma cortisol, increased urinary free cortisol, failure of cortisol suppression with low-dose dexamethasone). Patients with Cushing's syndrome are also frequently depressed. It is thus important in a depressed patient to take particular care in distinguishing the two conditions. In normal subjects and patients with severe endogenous depression, insulin-induced hypoglycaemia results in a rise in ACTH and cortisol levels, a response which does not usually occur in Cushing's syndrome.

Differential diagnostic tests

Once the biochemical diagnosis has been made, a series of investigations is required to determine the cause of the Cushing's syndrome.

Plasma ACTH at 09.00h

This will differentiate ACTH-dependent from ACTH-independent causes. ACTH is either within the normal reference range (50 per cent of cases) or elevated in patients with Cushing's disease. ACTH levels in the ectopic ACTH syndrome are high but overlap values seen in Cushing's disease in 30 per cent of cases and cannot therefore be used to differentiate these two conditions (Fig. 4). The measurement of ACTH precursors (pro-ACTH, POMC) is not routinely available but may be more useful in detecting an ectopic source of ACTH.

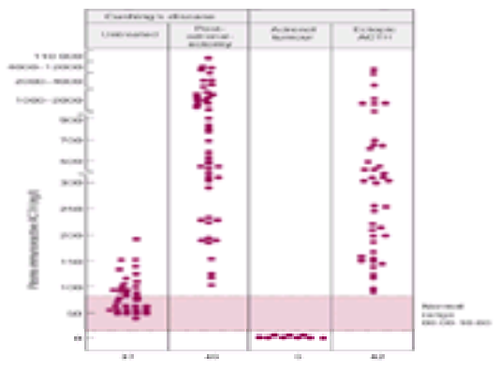

Fig. 4 Immunoreactive N-terminal ACTH levels in plasma samples taken between 08.00 and 10.00 h in normal subjects (hatched area), and patients with Cushing's disease either untreated or postadrenalectomy, patients with adrenal tumours, and in the ectopic ACTH syndrome (by courtesy of Professor Lesley Rees).

In patients with adrenal tumours, plasma ACTH is invariably undetectable. This can also occur with degradation of ACTH; consequently, non-haemolysed blood samples should be taken on ice and immediately separated.

Diagnosis is a problem in those patients whose plasma ACTH levels are low normal or intermittently detectable. This may occur in macronodular hyperplasia. The danger is that in some patients the asymmetry of the nodular hyperplasia may lead to a diagnosis of adrenal adenoma, the plasma ACTH is ignored, and an inappropriate adrenalectomy is performed. Conversely, in some patients with this syndrome an autonomous adrenal tumour develops and, despite detectable ACTH, unilateral adrenalectomy is required.

Plasma potassium (see also Chapter 20.2.2)

Hypokalaemic alkalosis is present in more than 95 per cent of patients with the ectopic ACTH syndrome, but is present in fewer than 10 per cent of patients with Cushing's disease. The aetiology of this is now becoming clearer. Patients with the ectopic syndrome usually have higher cortisol secretion rates that saturate the renal protective 11b-hydroxysteroid dehydrogenase type 2 enzyme resulting in cortisol-induced, mineralocorticoid hypertension (see apparent mineralocorticoid excess syndrome, below). In addition, these patients have higher levels of the ACTH-dependent mineralocorticoid, deoxycorticosterone.

High-dose dexamethasone suppression test

The rationale for this test is that in Cushing's disease there is negative feedback control of ACTH but it is set at a higher level than normal. Thus in this disease cortisol levels are not suppressed with a low dose of dexamethasone but are with a high dose. The original test introduced by Liddle was based on giving dexamethasone at a dose of 2 mg every 6 h for 48 h and measuring urinary 17-oxogenic steroids. Suppression was defined as a greater than 50 per cent fall in 24-h urinary 17-oxogenic steroids. In the modern test, plasma cortisol is measured at 0 and after 48 h or, less commonly, 8 mg of dexamethasone is given orally at 23.00 h and plasma cortisol taken at 08.00 h on the same day (basal sample) and at 08.00 h on the following morning. In both these tests greater than 50 per cent suppression of plasma cortisol in comparison with the basal sample has been used to define a positive response. In Cushing's disease about 90 per cent of patients have a positive 48-h test in comparison with 10 per cent with the ectopic ACTH syndrome. With overnight high-dose testing, 89 per cent sensitivity and 100 per cent specificity has been reported for Cushing's disease. A further variation on this test is the 5-h infusion of dexamethasone (1 mg/h).

Metyrapone test

Metyrapone is an 11b-hydroxylase inhibitor which blocks the conversion of 11-deoxycortisol to cortisol and deoxycorticosterone to corticosterone (Fig. 1). This lowers plasma cortisol and, via negative feedback control, increases plasma ACTH. This in turn stimulates an increase in the secretion of adrenal steroids proximal to the block. Given in doses of 750 mg every 4 h for 24 h, patients with Cushing's disease exhibit an exaggerated rise in plasma ACTH with 11-deoxycortisol levels at 24 h exceeding 1000 nmol/l. In most patients with the ectopic ACTH syndrome there is little or no response, but occasional patients (possibly those producing both ACTH and CRF) have an 11-deoxycortisol response which may be similar to that in Cushing's disease.

The metyrapone test was originally used to distinguish patients with Cushing's disease from those with a primary adrenal cause. However, these can be more reliably distinguished by measuring plasma ACTH and CT scanning of the adrenals. As indicated, the test does not reliably distinguish between Cushing's disease and the ectopic ACTH syndrome and the value of this test has been questioned. It should be reserved for patients when the results of other tests are equivocal.

Corticotrophin-releasing factor (CRF) test

CRF is a 41 amino acid peptide, identified by Vale in 1981 from ovine hypothalami. The ovine sequence differs by seven amino acid residues from that of the human, but despite this, stimulates the release of ACTH in humans. The test involves the intravenous injection of either ovine or human CRF in a dose of 1 µg/kg body weight or a single dose of 100 µg. The test can be performed in the morning or afternoon, and after basal sampling, blood samples for ACTH and cortisol are taken every 15 min for 1 to 2 h after administering CRF.

In normal subjects, CRF produces a rise in ACTH and cortisol, and this response is exaggerated in Cushing's disease. It is typically absent in the ectopic ACTH syndrome and in patients with adrenal tumours. In distinguishing pituitary-dependent Cushing's from the ectopic ACTH syndrome the response of ACTH to CRF has a specificity of 90 per cent, and with cortisol as the end-point, 95 per cent. Using an ACTH increase of 100 per cent over basal or a cortisol rise of 50 per cent as an end-point, this positive response eliminates a possible diagnosis of the ectopic ACTH syndrome.

As with the other tests, patients with macronodular hyperplasia may present a problem in diagnosis and show no response to CRF. The test is valuable in distinguishing patients who are obese and depressed from those with Cushing's disease; in the former the CRF response is either normal or reduced.

Inferior petrosal sinus sampling/selective venous catheterization

To distinguish Cushing's disease from the ectopic ACTH syndrome it may be necessary to identify the source of ACTH secretion. As blood from each half of the pituitary drains into the ipsilateral inferior petrosal sinus, catheterization of both sinuses with simultaneous sampling of venous blood can distinguish a pituitary from an ectopic source and aid in the lateralization of a pituitary microadenoma (Fig. 5). In patients with the ectopic ACTH syndrome, there is usually no ACTH gradient between the inferior petrosal sinus samples and simultaneously drawn peripheral venous levels. In Cushing's disease the ipsilateral:contralateral ACTH ratio is usually greater than 1.4. However, because of the problem of intermittent ACTH secretion, it is useful to make measurements before and at intervals (for example, 2, 5, and 15 min) after intravenous injection of 100 µg of synthetic ovine CRF. Using this approach, patients with Cushing's disease and bilateral inferior petrosal sinus ratios of less than 1.4 can be readily distinguished from those with the ectopic syndrome. The precise ratio that distinguishes Cushing's disease from the ectopic syndrome has been debated. Some authors use 2 rather than 1.4.

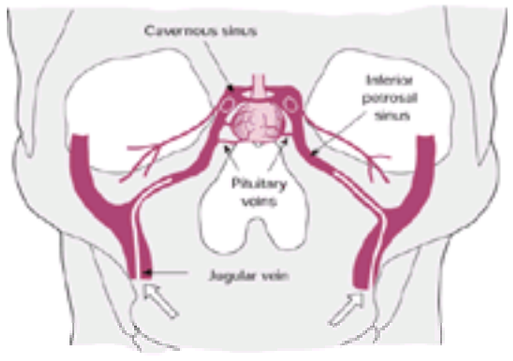

Fig. 5 Positions of bilateral catheters in inferior petrosal sinus sampling.

It is clear that inferior petrosal sinus sampling is a useful technique for making the differential diagnosis in ACTH-dependent Cushing's syndrome. However, it should be reserved for those cases where the differential diagnosis is still in doubt after high-dose dexamethasone and peripheral CRF testing. Inferior petrosal sinus catheterization may also be of value to the surgeon who is planning to explore the pituitary in a patient with Cushing's disease in whom imaging techniques have failed to demonstrate a microadenoma.

Rarely, selective catheterization of vascular beds may be required to identify the source of ectopic ACTH secretion, for example from a small pulmonary carcinoid or thymic tumour.

Tumour markers

Many tumours responsible for the ectopic ACTH syndrome also produce peptide hormones other than ACTH or its precursors.

Imaging

MRI/CT scanning of pituitary and adrenals

There is no doubt that high-resolution, thin-section, contrast-enhanced imaging using either CT or MRI has revolutionized the investigation of Cushing's syndrome. However, it is essential that the results of any imaging technique must always be interpreted in the light of the biochemical results if mistakes are to be avoided. In imaging the adrenals, asymmetrical nodular hyperplasia may lead to a false diagnosis of adrenal adenoma (Fig. 6). Owing to the presence of 'pituitary incidentalomas', pituitary MRI/CT scanning may produce false-positive results, particularly for lesions of less than 5 mm in diameter.

Fig. 6 CT scan of adrenals in patient with asymmetrical nodular hyperplasia. The macronodule on the left was initially thought to be an adrenal tumour. The biochemistry indicating ACTH-dependent Cushing's syndrome was ignored and a unilateral adrenalectomy performed without cure of the hypercortisolism. Further investigation confirmed Cushing's disease and a selective pituitary microadenomectomy resulted in cure.

Pituitary MRI is the investigation of choice if the biochemical tests suggest Cushing's disease, with a sensitivity of 70 per cent and specificity of 87 per cent (Fig. 7 and Fig. 8). About 90 per cent of ACTH-secreting pituitary tumours are microadenomas (that is, less than 10 mm in diameter). The classic features of a pituitary microadenoma are a hypodense lesion after contrast, associated with deviation of the pituitary stalk and a convex upper surface of the pituitary gland (Fig. 7). With such small tumours it is not surprising that the sensitivity of CT scanning is relatively low (20 to 60 per cent) with a similar specificity.

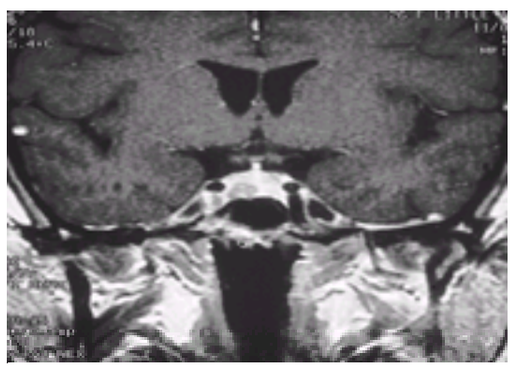

Fig. 7 MRI scan of pituitary demonstrating the typical appearance of a pituitary microadenoma. A hypodense lesion is seen in the left side of the gland with deviation of the pituitary stalk away from the lesion. Following a biochemical diagnosis of Cushing's disease, this patient was cured following trans-sphenoidal hypophysectomy.

Fig. 8 MRI scan of the pituitary gland demonstrating a large macroadenoma in a patient with Cushing's disease. In contrast to smaller tumours, these tumours are

invariably invasive and recur following surgery.

By contrast, for adrenal imaging, CT scanning rather than MRI is the investigation of choice offering better spatial resolution (Fig. 9). Once again, it is stressed that 'adrenal incidentalomas' are present in up to 5 per cent of normal subjects, and thus adrenal imaging should not be performed unless biochemical investigation suggests a primary adrenal cause. Adrenal carcinomas are large and often associated with metastatic spread at presentation (Fig. 10).

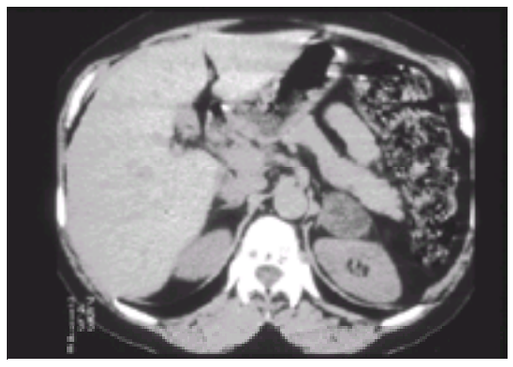

Fig. 9 Typical solitary left-sided adrenal adenoma on adrenal CT scanning.

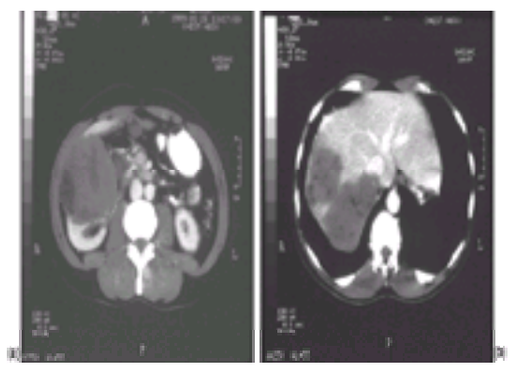

Fig. 10 CT scan of a patient with rapidly progressing Cushing's syndrome due to a right-sided adrenal carcinoma. An irregular right adrenal mass is shown (a) with a large liver metastasis (b).

In patients with 'occult' ectopic ACTH syndrome, high-definition MRI/CT scanning with images every 0.5 cm may be required to detect small ACTH-secreting carcinoid tumours.

Adrenal scintigraphy

This is of value in certain patients with primary adrenal pathology. The most commonly used agent is ^{131}I-6b-iodomethyl-19-norcholesterol. This is a marker of adrenocortical cholesterol uptake. In patients with adrenal adenomas the isotope is taken up by the adenoma but not by the contralateral suppressed adrenal. Adrenal scintigraphy is useful in patients with suspected adrenocortical macronodular hyperplasia, in which CT scanning may be misleading by suggesting unilateral pathology, whereas with isotope scanning the bilateral adrenal involvement is identified (Fig. 11).

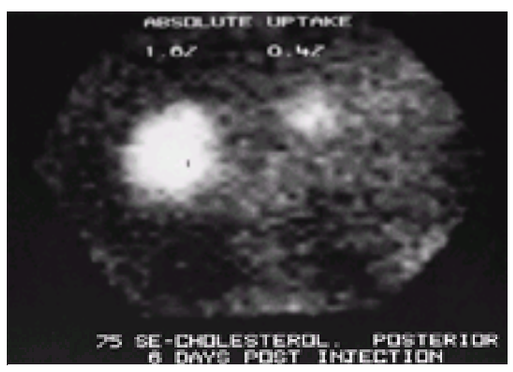

Fig. 11 Adrenal scintigraphy in a patient with Cushing's syndrome and macronodular hyperplasia. Note asymmetrical uptake in the adrenals, with 1.6 per cent uptake on the left and 0.4 per cent on the right.

Prognosis of untreated Cushing's syndrome

Studies carried out prior to the introduction of effective therapy suggested that 50 per cent of patients with untreated Cushing's syndrome died within 5 years. Even with modern management, an increased prevalence of cardiovascular risk factors persists for many years after an apparent 'cure'. Close follow-up of all patients is recommended.

Treatment of Cushing's syndrome

Adrenal causes

Adrenal adenomas should be removed by unilateral adrenalectomy, with 100 per cent cure rate. With the increasing experience of laparascopic adrenalectomy in most tertiary centres, this has now become the surgical treatment of choice for unilateral tumours, reducing surgical morbidity and postoperative hospital stay compared with traditional open approaches. After surgery it may take many months or even years for the suppressed adrenal to recover. It is wise therefore to give slightly suboptimal replacement therapy with dexamethasone at a dose of 0.5 mg in the morning, with intermittent measurement of the 08.00 h level of plasma cortisol prior to taking dexamethasone. When the morning plasma cortisol is above 180 nmol/l, dexamethasone can be stopped. A subsequent insulin tolerance test may then demonstrate whether the response to stress is normal.

Adrenal carcinomas have a very poor prognosis and most patients are dead within 2 years. It is usual practice to try to remove the primary tumour, even though metastases may be present, so as to enhance the response to the adrenolytic agent *o*,*p*'-DDD (Mitotane, see below). Radiotherapy to the tumour bed and to some

metastases, such as those in the spine, may be of limited value.

Pituitary-dependent Cushing's disease

The treatment of Cushing's disease has been improved by trans-sphenoidal surgery conducted by an experienced surgeon. Before the selective removal of a pituitary microadenoma the treatment of choice was bilateral adrenalectomy. This had an appreciable mortality even in the best centres (about 4 per cent) as well as morbidity. The main risk was the subsequent development of Nelson's syndrome (postadrenalectomy hyperpigmentation with locally aggressive pituitary tumour) (Fig. 12 and Plate 1). To avoid this, pituitary irradiation was often carried out following bilateral adrenalectomy. These patients required lifelong replacement therapy with hydrocortisone and fludrocortisone. Nowadays bilateral adrenalectomy is reserved for the occasional patient with Cushing's disease in whom no pituitary tumour can be found, or when pituitary surgery has failed, or where the condition has recurred.

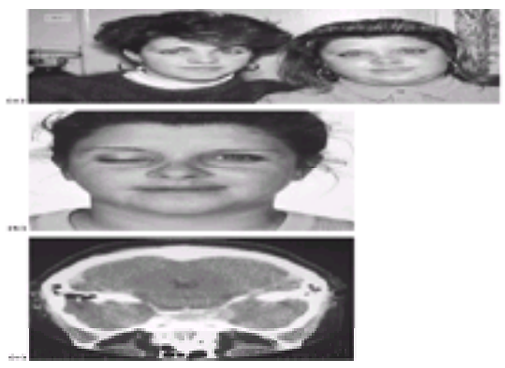

Fig. 12 A young woman with Cushing's disease, photographed initially alongside her identical twin sister (a). In this case treatment with bilateral adrenalectomy was undertaken and several years later the patient re-presents with Nelson's syndrome and a right III cranial nerve palsy due to cavernous sinus infiltration from a locally invasive corticotrophinoma. (See also Plate 1.)

After selective removal of a microadenoma, the surrounding corticotrophs are normally suppressed (Fig. 13). In these cases plasma cortisol concentrations are also suppressed postoperatively and glucocorticoid replacement therapy is required. Using the dexamethasone regime described above after removal of an adrenal adenoma, there is usually (but not invariably) gradual recovery of the hypothalamic–pituitary–adrenal axis (Fig. 14). A non-suppressed plasma cortisol postoperatively suggests that the patient is not 'cured', even though cortisol secretion may have fallen to normal or subnormal values. Close follow-up of such individuals is required.

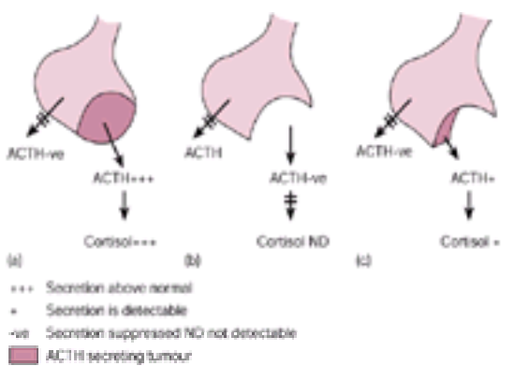

Fig. 13 Selective removal of a microadenoma and its effect on the hypothalamic–pituitary–adrenal axis. Because the surrounding normal pituitary corticotrophs are suppressed in a patient with an ACTH-secreting pituitary adenoma, successful removal of the tumour results in ACTH and hence adrenocortical deficiency with an undetectable (less than 50 nmol/l) level of plasma cortisol. A plasma cortisol of more than 50 nmol/l postoperatively implies that the patient is not cured. (Figure by courtesy of Dr Peter Trainer.)

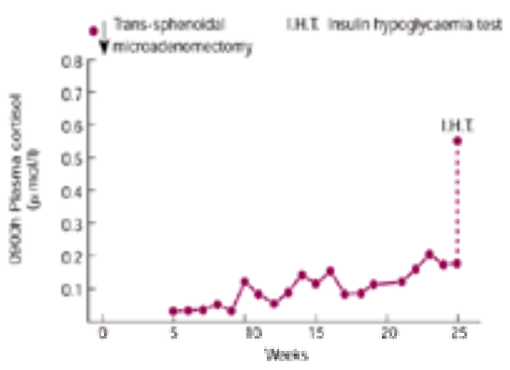

Fig. 14 Gradual recovery of function of the hypothalamic–pituitary–adrenal axis after removal of a pituitary ACTH-secreting microadenoma. The insulin hypoglycaemia test eventually demonstrated the return of a normal stress response.

In the past, pituitary irradiation was often used in the treatment of Cushing's disease. However, the improvements in pituitary surgery have resulted in far fewer patients being so treated. In children pituitary irradiation appears to be effective. Radiotherapy is not recommended as a primary treatment but is reserved for patients not responding to pituitary microsurgery or when bilateral adrenalectomy has been performed, or in those with established Nelson's syndrome.

Ectopic ACTH syndrome

Treatment of the ectopic ACTH syndrome depends on the cause. If the tumour can be found and has not spread, then its removal can lead to cure (for example bronchial carcinoid or thymoma). However, the prognosis for small-cell lung cancer associated with the ectopic ACTH syndrome is poor. The cortisol excess and associated hypokalaemic alkalosis and diabetes mellitus can be ameliorated by medical therapy (see below). Treatment of the small-cell tumour itself will also, at least initially, produce improvement (see Chapter 17.13). Sometimes, if the ectopic source of ACTH cannot be found, it may be necessary to perform bilateral adrenalectomy and then follow the patient carefully (sometimes for several years) to find the primary tumour.

Medical treatment of Cushing's syndrome

Several drugs have been used in the treatment of Cushing's syndrome. Their site of action is shown in Fig. 15. Most commonly, metyrapone has been given, often to lower cortisol concentrations prior to definitive therapy, or while awaiting benefit from pituitary irradiation. The daily dose has to be determined by measuring either plasma or urinary free cortisol. The aim should be to achieve a mean plasma cortisol of about 300 nmol/l during the day or a normal urinary free cortisol. The drug is usually given in doses ranging from 250 mg twice daily to 1.5 g every 6 h. Nausea may be produced and can be alleviated (if not due to adrenal insufficiency) by

giving the drug with milk.

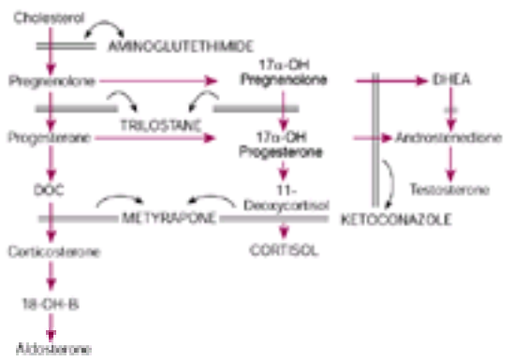

Fig. 15 Medical treatment of Cushing's syndrome: site of action of various drugs.

Aminoglutethimide is a more toxic drug which in high dose blocks initial steps in the biosynthetic pathway and thus affects the secretion of steroids other than cortisol. In doses of 1.5 to 3 g daily (start with 250 mg every 8 h) it commonly produces nausea, marked lethargy, and a skin rash.

Trilostane, a 3b-hydroxysteroid dehydrogenase inhibitor, is ineffective in Cushing's disease, since the block in steroidogenesis is overcome by the rise in ACTH. However, it can be effective in patients with adrenal adenomas.

Ketoconazole is an imidazole which has been widely used as an antifungal agent; it produces abnormal liver function tests signifying hepatitis in about 14 per cent of patients. Ketoconazole blocks a variety of steroidogenic cytochrome P450-dependent enzymes and thus lowers plasma cortisol levels. For effective control of Cushing's syndrome, 400 to 800 mg of ketoconazole daily have been required.

o,*p*'-DDD, or Mitotane, is an adrenolytic drug which is taken up by both normal and malignant adrenal tissue causing adrenal atrophy and necrosis. Because of its toxicity, Mitotane has been used mainly in the management of adrenal carcinoma. Doses of up to 8 g/day are required to control glucocorticoid excess, though evidence that it causes tumour shrinkage or improves long-term survival is scant. The drug will also produce mineralocorticoid deficiency and both glucocorticoid and mineralocorticoid replacement therapy may be required. Side-effects are common and include fatigue, skin rashes, and gastrointestinal disturbance.

Glucocorticoid deficiency—primary and secondary hypoadrenalism

Primary hypoadrenalism refers to glucocorticoid deficiency occurring in the setting of adrenal disease, whilst secondary hypoadrenalism arises because of deficiency of ACTH, the major trophic hormone controlling cortisol secretion. The principal distinction between these two conditions is that mineralocorticoid deficiency invariably accompanies primary hypoadrenalism but this does not occur in secondary hypoadrenalism because only ACTH is deficient; the renin–angiotensin–aldosterone axis is intact.

Primary hypoadrenalism

Congenital adrenal hyperplasia

Various inherited enzyme defects in the synthesis of adrenocortical hormones have been identified and this group of conditions is addressed in Chapter 12.7.2.

Addison's disease

Thomas Addison described this condition in his classic monograph published in 1855. Addison worked with Bateman, a dermatologist who produced one of the first classifications of skin disease. It seems likely that this stimulated Addison's interest in the skin pigmentation which is so characteristic of this disease.

Aetiology

This is a rare condition with an estimated incidence in the developed world of 0.8 cases per 100 000 population. The causes of Addison's disease are listed in Table 6.

Worldwide, infectious diseases are the most common cause of primary adrenal insufficiency. Leading causes include tuberculosis, fungal infections (histoplasmosis, crytococcus), and cytomegalovirus. Adrenal failure may occur in the acquired immunodeficiency syndrome. In tuberculous Addison's disease, the adrenals are initially enlarged with extensive epithelioid granulomas and caseation. Calcification eventually ensues in most cases (Fig. 16). Both the cortex and the medulla are affected.

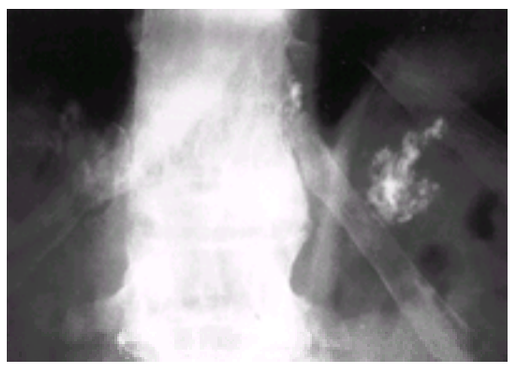

Fig. 16 Plain radiograph of the abdomen showing adrenal calcification in a patient with tuberculous Addison's disease.

In the Western world, autoimmune adrenalitis accounts for over 70 per cent of all cases of Addison's disease. Pathologically, the adrenal glands are atrophic with loss of most of the cortical cells, but the medulla is usually intact. Adrenal autoantibodies can be detected in up to 75 per cent of newly diagnosed cases and have recently been characterized. The major autoantigen is the adrenal enzyme, 21-hydroxylase, but antibodies directed against cholesterol side-chain cleavage and 17a-hydroxylase may rarely be detected. Fifty per cent of patients with Addison's disease have an associated autoimmune disease and these 'polyglandular autoimmune syndromes' have been classified into two distinct variants. Type I is inherited as an autosomal recessive condition and comprises Addison's disease, chronic mucocutaneous candidiasis, and hypoparathyroidism. The condition is rare and usually presents in childhood with either candidiasis or hypoparathyroidism. Other autoimmune conditions such as pernicious anaemia, thyroid disease, chronic active hepatitis, and gondal failure may occur but are rare. Autoantibodies to 21-hydroxylase are not normally present.

Type II polyglandular autoimmune syndrome is more common and may comprise Addison's disease, autoimmune thyroid disease, diabetes mellitus, and hypogonadism. The condition has an inherited basis with linkage to the HLA major histocompatibility complex, notably HLA DR3 and DR4. Autoantibodies to

21-hydroxylase are usually present and are predictive for the development of adrenal destruction.

With the exception of tuberculosis and autoimmune adrenal failure, other causes of Addison's disease are rare (Table 6). Adrenal metastases (commonest primary lung, breast) are often found at postmortem examinations but adrenal insufficiency from these is uncommon. Necrosis of the adrenals due to intra-adrenal haemorrhage should be considered in any severely sick patient and this may be due to infection, trauma, or hypercoagulability. Intra-adrenal bleeding may be found in any cause of severe septicaemia, particularly in children. When this is due to meningococcus, the association with adrenal insufficiency is known as the Waterhouse–Friderichsen syndrome. Adrenal replacement leading to glandular failure may also occur with amyloidosis and haemochromatosis. Adrenal hypoplasia congenita is an X-linked disorder comprising congenital adrenal insufficiency and hypogonadotrophic hypogonadism. The condition is caused by mutations in the DAX-1 gene, a known member of the nuclear receptor family which is expressed in the adrenal cortex, gonads, and hypothalamus.

X-linked adrenoleucodystrophy is a cause of adrenal insufficiency in association with demyelination within the nervous system due to a failure of b-oxidation of fatty acids within peroxisomes. Increased accumulation of very long-chain fatty acids occurs in many tissues and serum assays can be used diagnostically. Only males have the fully expressed condition and carrier females are usually normal. Two forms are recognized. Adrenoleucodystrophy presents at 5 to 10 years of age with progression eventually to a blind, mute, and severely spastic tetraplegic state. Adrenal insufficiency is usually present but does not appear to correlate with the neurological deficit. X-linked adrenoleucodystrophy accounts for about 10 per cent of cases of adrenocortical failure in boys and men. Adrenomyeloneuropathy, by contrast, presents later in life with the gradual development of spastic paresis and peripheral neuropathy. As both the childhood and the adult condition result from the same mutant gene (recently mapped to chromosome Xq28), it has been suggested that there is an additional autosomal modifier gene. Monounsaturated fatty acids which block the synthesis of the saturated very long-chain fatty acids have been used for treatment. A combination of erucic acid and oleic acid (Lorenzo's oil) has led to normal levels of very long-chain fatty acids, but this has not altered the rate of neurological deterioration; bone marrow transplantation appears to be more effective if undertaken in the early stages of the disease.

Familial glucocorticoid deficiency is a rare, autosomal recessive cause of hypoadrenalism which usually presents in childhood. The renin–angiotensin–aldosterone axis is intact and children usually present either with neonatal hypoglycaemia or later with increasing pigmentation, often with enhanced growth velocity. Patients have glucocorticoid deficiency with very high plasma ACTH levels—this occurs because of mutations in the melanocortin-2 or ACTH receptor. A variant syndrome is called the triple A or Allgrove's syndrome and refers to the triad of adrenal insufficiency due to ACTH resistance, achalasia, and alachrima. Mutations have not been found in the ACTH receptor and the molecular basis for this inherited syndrome is unknown.

Secondary hypoadrenalism (ACTH deficiency)

This is a common clinical problem and is most often due to a sudden cessation of exogenous glucocorticoid therapy or a failure to give glucocorticoid cover for intercurrent stress in a patient who has been on long-term glucocorticoid therapy. Such therapy suppresses the hypothalamic–pituitary–adrenal axis, with consequent adrenal atrophy and this may last for months after stopping glucocorticoid treatment. Adrenal atrophy and subsequent deficiency should be anticipated in any subject who has taken more than the equivalent of 30 mg of oral hydrocortisone per day (approximately 7.5 mg/day of prednisolone or 0.75 mg/day of dexamethasone) for longer than 1 month. In addition to the magnitude of the dose of glucocorticoid, the timing of administration of the dose may affect the degree of adrenal suppression. Thus prednisolone in a dose of 5 mg given last thing at night and 2.5 mg in the morning will produce more marked suppression of the hypothalamic–pituitary–adrenal axis compared with 2.5 mg at night and 5 mg in the morning because the larger evening dose blocks the early morning surge of ACTH.

Other causes of secondary adrenal insufficiency are rare (Table 6) and reflect inadequate ACTH production from the anterior pituitary gland. In many of these, other pituitary hormones are deficient in addition to ACTH, so that the patient presents with partial or complete hypopituitarism. The clinical features of hypopituitarism make this a relatively easy diagnosis to make (see Chapter 12.4). However, if there is isolated ACTH deficiency, this diagnosis may be readily missed.

Clinical features of adrenal insufficiency
