In general, monosodium urate monohydrate is the most inflammatory, followed by calcium pyrophosphate dihydrate, then apatite and the less common crystals. In general, smaller particle size, marked surface irregularity, and high negative surface charge correlate with inflammatory potential. Some surface effects result from direct crystal contact but others are mediated via adsorbed protein, particularly immunoglobulin. Although adsorbed IgG may enhance inflammation, most other protein binding is inhibitory.

Less is known of chronic crystal-induced tissue damage. Postulated effects include persistent synovial inflammation, altered cell metabolism, and deleterious mechanical effects from large deposits. Evidence for activation of inflammatory mediators in chronic crystal-associated synovitis is lacking, although a chronic 'granulomatous' reaction often occurs around large accretions. The physicochemical effects of hard highly charged crystals embedded within cartilage, or occurring as wear particles at the surface, are largely unknown.

Gout (see also Chapter 11.4)

Monosodium urate monohydrate crystals are undoubted causal agents in gout, usually depositing in previously normal tissues and eliciting acute inflammation and eventual tissue damage. Their effective removal halts progression and results in 'cure'. In these respects gout is a true 'crystal deposition disease'.

The incidence of gout varies in populations from 0.2 to 0.35 per 1000, with an overall prevalence of 2.0 to 2.6 per 1000. Prevalence rises with age and increasing serum urate concentration. There is strong predominance in men (about 10:1), particularly under 65 years of age. Untreated gout evolves slowly through four clinical phases: asymptomatic hyperuricaemia, acute gout, intercritical gout, and chronic tophaceous gout.

Asymptomatic hyperuricaemia

Monosodium urate monohydrate crystals preferentially deposit in peripheral connective tissues in and around synovial joints, favouring lower rather than upper limbs. Deposits occur first in articular cartilage, most commonly the first metatarsophalangeal and small joints of the feet. Deposits later develop in synovium, capsule, and periarticular soft tissues, with progressive involvement of more proximal sites. Monosodium urate monohydrate crystals probably take months if not years to grow *in vivo* to detectable size, implying a long asymptomatic phase. Absence of inflammation during this period may relate to low crystal yield, positioning within hypovascular tissues, or inhibitory protein coating. Around 95 per cent of hyperuricaemic subjects remain asymptomatic throughout life, although how many have occult monosodium urate monohydrate deposits is unknown. Of those who develop gout, one in five will have suffered renal colic due to uric acid urolithiasis, sometimes more than a decade earlier. The first presentation of gout is usually acute synovitis, although an insidious onset of chronic arthropathy or nodular deposits ('tophi') occasionally occurs without preceding attacks.

Acute attacks

The classical attack

In almost all initial episodes a single peripheral joint is involved. This is the first metatarsophalangeal joint ('podagra') in 50 per cent of first attacks and 70 per cent of all attacks. Other common sites are the knee, ankle, midtarsal joints, small hand joints, wrist, and elbow. The axial skeleton and large central joints are rarely involved and never as the first site.

Attacks often wake the patient in the early morning with localized irritation and aching. Within a few hours the joint and surrounding tissues are swollen, hot, red, shiny, and extremely painful. The patient cannot bear even bedclothes to touch the joint and it is often described as 'the worst pain ever experienced'. Inflammation is maximal within 24 h and is often associated with pyrexia and malaise. Examination reveals florid synovitis and swelling, extreme tenderness, and overlying erythema. If left untreated, the attack resolves spontaneously over 5 to 15 days, often with pruritus and desquamation of overlying skin.

Although many attacks occur spontaneously, certain situations encourage shedding of preformed monosodium urate monohydrate crystals and triggering of acute attacks. Suggested mechanisms include mechanical loosening (local trauma), partial dissolution and reduction of crystal size (initiation of hypouricaemic treatment), and local increase in cytokines which encourage inflammatory responses to crystals and facilitate crystal escape via alterations in cartilage matrix (intercurrent illness, surgery). Although some triggers (alcohol, dietary excess, diuretics) increase local urate levels, acute crystallization is considered unlikely.

Atypical attacks

Acute attacks may manifest as tenosynovitis, bursitis, or cellulitis. Many patients describe mild episodes of discomfort without swelling lasting a day or so. Ten per cent of all typical attacks involve more than one joint. Sometimes acute gout, by triggering the acute response, provokes migratory attacks in other joints over subsequent days ('cluster attacks'). Polyarticular attacks are rare, usually occurring after a long history of recurrent attacks: marked systemic upset, fever, and confusion may dominate the clinical picture.

Intercritical periods

These are asymptomatic intervals between attacks. Some patients never have a second attack, in others the next episode occurs after many years; in most, however, a second attack occurs within 1 year. Subsequently the frequency of attacks and number of sites involved gradually increase with time. Later attacks are more often pauciarticular or polyarticular and more severe. Eventually, recurrent attacks and continuing monosodium urate monohydrate deposition cause joint damage and chronic pain. The interval between the first attack and development of chronic symptoms is variable, but averages about 10 years. The principal determinant is the serum uric acid—the higher it is, the earlier and more extensive the development of joint damage and tophaceous deposits.

Chronic tophaceous gout

Large crystal deposits ('tophi') produce irregular firm nodules, principally around extensor surfaces of fingers, hands, the ulnar surface of the forearms, olecranon bursae, Achilles tendons, first metatarsophalangeal joints, and the cartilaginous helix of the ear. Marked asymmetry, both locally and between sides, is particularly characteristic (Fig. 3). Monosodium urate monohydrate crystals beneath the skin may give a 'chalky' appearance (Fig. 4). If untreated, tophi can enlarge into gross knobbly swellings that may ulcerate, discharging material which is white and gritty and causes local inflammation (erythema, pus) even in the absence of secondary infection. If extensive, tophi may rarely involve the eyelids, tongue, larynx, or heart (causing conduction defects and valvular dysfunction).

Fig. 3 Chronic tophaceous gout affecting the hands. Note the eccentric nature of the tophi and the asymmetry between sides.

Fig. 4 Diuretic-induced gout in an elderly women, showing tophaceous deposition on pre-existing nodal osteoarthritis; the white monosodium urate monohydrate crystals are clearly visible beneath the skin.

Joints most commonly involved with signs of damage (restricted movement, crepitus, deformity) and varying degrees of synovitis are the first metatarsophalangeal joints, midfoot, small finger joints, and wrists. As with tophi, joint involvement is usually asymmetrical. Occasionally gross destruction may occur in feet and hands, and less commonly other sites. Acute attacks may become less of a feature as chronic symptoms become established. If untreated, the combination of extensive joint destruction and large tophi may cause grotesque deformities, particularly of hands and feet. Ankylosis is a rare late event. Although axial involvement is rare even in late stages, gouty involvement of hips, shoulders, spine and sacroiliac joints, and spinal cord compression by tophi, are all reported.

Classification

Traditional classification into primary or secondary gout depends on defining predisposing factors for hyperuricaemia. Most gout is primary, strongly predominating in men, with initial onset between 30 and 60 years of age (Table 2). Presentation is with acute attacks, and untreated disease progresses to chronic tophaceous gout. Such patients often give a family history of gout and are 'undersecretors' of uric acid.

Secondary gout usually results from chronic diuretic therapy and presents in older subjects (over 65 years). This increasingly common form affects women and men and is often associated with osteoarthritis. Upper and lower limb joints are affected equally. Acute attacks are less prominent and presentation is often with painful, sometimes discharging, tophaceous deposits in Heberden's and Bouchard's nodes (Fig. 4).

Associations

Hyperuricaemia

Mechanisms resulting in decreased excretion or increased production of uric acid are fully discussed in Section 11.4. Though hyperuricaemia and gout are strongly linked, they are not synonymous. Most hyperuricaemic subjects never develop gout, emphasizing the importance of local tissue factors in crystal nucleation/growth, and gouty patients may not be hyperuricaemic at presentation. Associations also differ: for example, impaired glucose tolerance, ischaemic heart disease, and hypertension are common in men with gout but do not associate with hyperuricaemia *per se*. The majority (75–90 per cent) of patients with primary gout are 'undersecretors' of uric acid, having inherited an isolated renal lesion that reduces fractional urate clearance; fewer than 10 per cent are 'overproducers' of uric acid. The cause usually remains unclear, although a very few have an inherited purine enzyme defect (see Chapter 11.4). Some patients are both undersecretors and overproducers.

Clinical associations differ according to gender. In men important associations are obesity, excessive alcohol intake, type IV hyperlipoproteinaemia, impaired glucose tolerance, and ischaemic heart disease (Table 3). Obesity and lifestyle, rather than hereditary factors, appear to be central factors linking these 'associations of plenty'. Excessive beer drinking, with its high calorie and alcohol intake, is a common form of alcohol abuse associated with gout. The nineteenth century association with port is partly explained by addition of lead to sweeten the port: lead inhibits uric acid excretion and also promotes nucleation of monosodium urate monohydrate, predisposing to 'the gout, the colic and the palsy' (all features of lead poisoning). However, 'saturnine' gout still occurs in individuals who drink alcohol distilled or stored in lead-contaminated containers ('moonshine'). Alcohol is a less common association in women, usually occurring in young to middle-aged, thin, spirit drinkers. In women the main associations are diuretic therapy, chronic renal impairment, and pre-existing osteoarthritis. Other drugs may predispose to gout, such as aspirin in low doses and cyclosporin.

A strong negative association exists between gout and rheumatoid arthritis. This remains unexplained, but probably reflects impaired nucleation/growth of monosodium urate monohydrate crystals rather than masking of monosodium urate monohydrate crystal-induced inflammation (for example, by crystal coating with rheumatoid factors).

Renal disease

Urolithiasis (see also Chapter 20.13)

Uric acid stones account for 5 to 10 per cent of all stones in the United Kingdom and United States, and up to 40 per cent in Israel. A history of renal colic is seen in 10 to 25 per cent of patients with gout, the important aetiological factors being low urinary pH, low urinary volume, and high urinary uric acid concentration. In particular, high urinary concentrations occur in overproducers of uric acid, if renal urate clearance is increased (uricosuric drugs, defects in tubular reabsorption), and

in situations of dehydration with lowering of urinary pH (diarrhoea, ileostomy). Gouty subjects also have an increased incidence of calcium-containing stones, particularly calcium oxalate, with no detectable uric acid nidus.

Acute uric acid nephropathy describes rapid precipitation of uric acid crystals in renal collecting ducts with secondary acute obstructive renal failure. This event correlates with the amount of uric acid excreted rather than the level of hyperuricaemia. Strongly acid urine, which reduces uric acid solubility, potentiates the problem. The condition is most likely in ill, dehydrated patients with lymphoma or malignancy subjected to aggressive chemotherapy without adequate prophylactic treatment with allopurinol. It also occurs in gouty patients with markedly accelerated purine synthesis, for example following excessive exercise or after epileptic seizures. The condition is largely avoidable by appropriate hydration, urine alkalinization, and allopurinol prophylaxis.

Chronic urate nephropathy (see also Section 20.10)

Widespread monosodium urate monohydrate deposition in the interstitium of the medulla and pyramids results in crystal-induced inflammation with surrounding giant-cell reaction and fibrosis, affecting in particular the tubular epithelium of the loop of Henle and juxtaposed interstitial tissues. Subsequent changes include glomerular hyalinization and hypertrophy of the intima and media of arterioles. Hypertensive damage, tubular obstruction, and secondary pyelonephritis may all complicate this picture. Albuminuria and inability to concentrate the urine maximally are early clinical manifestations. Progressive renal disease is an important complication of untreated chronic tophaceous gout, end stage renal failure occurring in up to 25 per cent of cases.

In advanced renal disease of any cause, calcium oxalate or phosphate crystals may deposit in renal parenchyma but are predominantly cortical in location (compare the medullary site of monosodium urate monohydrate).

The association between parenchymal disease and less severe gout remains controversial, being confounded in males by frequent accompanying obesity, hypertension, and drug therapy. The minor progression of renal insufficiency that occurs in most gouty patients, however, is probably largely age-related and life expectancy is not reduced.

Investigations and diagnosis

The history and signs of classical acute or chronic tophaceous gout are highly characteristic, and with a raised serum uric acid a strong presumptive diagnosis is readily made. However, definitive confirmation requires demonstration of monosodium urate monohydrate crystals by compensated polarized light microscopy of fluid from a gouty joint, bursa, or tophus. Synovial fluid in acute attacks is typically turbid with diminished viscosity and greatly elevated cell count (more than 90 per cent neutrophils). Chronic gouty fluid is more variable, but occasionally appears white due to the high crystal load. Only a few drops collected directly on to a slide are required for crystal identification (Chapter 18.3). Monosodium urate monohydrate crystals are seen readily as strongly birefringent (negative sign), needle-shaped crystals, 5 to 20 μm in length, within cells or occurring freely in fluid. In tophaceous material they occur as dense, tightly packed sheets. During intercritical periods, aspiration of an asymptomatic first metatarsophalangeal joint or knee often permits confirmation of the diagnosis by revealing monosodium urate monohydrate crystals.

Hyperuricaemia is confirmed if two or more fasting serum uric acid levels exceed the normal range for the patient's age and sex. Uric acid levels may be lowered during an acute attack of gout and should be remeasured during an intercritical period. In primary gout in a young patient, determination of undersecretion or overproduction of uric acid is best undertaken by measuring total urinary excretion on a low-purine diet, but a quick guide is given by the uric acid/creatinine ratio estimated on a single urine sample (normally less than 0.5). In young overproducers, a purine enzyme defect becomes more likely and should be sought (Chapter 11.4). Assessment of renal function (creatinine, urea, electrolytes, urine testing) should always be undertaken (Table 3). Measurement of fasting lipoprotein concentrations should be made in all patients with primary gout. An intercritical full blood count and measurement of erythrocyte sedimentation rate/viscosity should detect any underlying myeloproliferative disease. During acute attacks a marked acute phase response (high erythrocyte sedimentation rate, neutrophil leucocytosis, thrombocytosis, elevated C-reactive protein) is usual; modest elevations of erythrocyte sedimentation rate also accompany chronic gout.

Radiographs supplement the clinical assessment of structural damage but can also aid diagnosis. In early disease they are usually normal. During acute gout, non-specific soft tissue swelling (rarely juxta-articular osteopenia) may be evident. After repeated attacks, and in chronic disease, joint space narrowing, sclerosis, cysts, and osteophytes (that is, the changes of osteoarthritis) become more frequent in feet and hands. Gouty 'erosions' are a less common but more specific abnormality, occurring as para-articular 'punched-out' bone defects with well-demarcated sclerotic margins, overhanging hooks of bone, and retained bone density (Fig. 5). They are typically asymmetric, eccentric lesions positioned away from the 'bare area' of the joint, contrasting with more symmetrical, ill-defined marginal erosions (with osteopenia) of rheumatoid arthritis. Tophi appear as eccentric soft tissue swellings, occasionally with patchy calcification due to epitaxial growth of apatite. In late disease, severe destructive change with osteopenia may occur and distinction from rheumatoid arthritis or other conditions becomes more difficult.

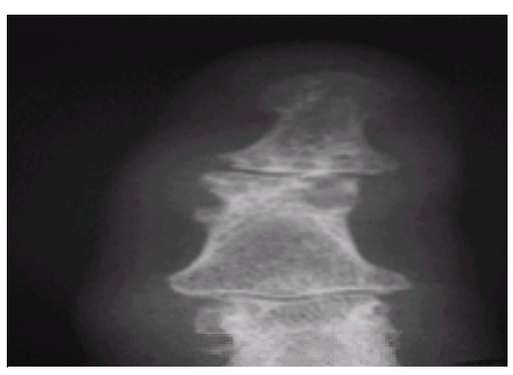

Fig. 5 Characteristic radiographic changes of established gout in a finger: joint space loss and cystic change at the distal interphalangeal joint, 'pressure erosions' with overhanging bony 'hooks' at both interphalangeal joints, and eccentric soft tissue swelling at the proximal joint.

Differential diagnosis

Acute attacks

Sepsis and other crystal-associated synovitis are the main considerations. Gout and sepsis may coexist, as may monosodium urate monohydrate and calcium pyrophosphate dihydrate deposition (particularly in elderly subjects). Examination of aspirated fluid for both crystals and sepsis (Gram stain, culture) is the only sure way of obtaining the correct diagnosis. A wider search for sepsis may be indicated (for example blood and urine cultures), particularly in those who are ill. With less classic attacks, other conditions that may be considered include psoriatic and acute Reiter's arthropathy, acute sarcoid arthropathy, traumatic arthritis, palindromic rheumatism, and exacerbation of osteoarthritis.

Chronic tophaceous gout

Other causes of arthritis and periarticular swellings/nodules that require differentiation are rheumatoid arthritis, generalized nodal osteoarthritis, xanthomatosis with arthropathy, and multicentric reticulohistiocytosis. Gout is usually less symmetrical in distribution than these conditions and, except for xanthomatosis, acute attacks are not a feature. Nodal osteoarthritis, of course, may coexist with gout. Aspiration (joint fluid, nodules) and plain radiographs readily facilitate correct diagnosis.

Treatment

Acute gout

The treatment aim is pain relief by reducing inflammation and intra-articular hypertension. Alteration of uric acid levels is avoided until the attack has resolved, since

initiation of hypouricaemic drugs may prolong the attack.

Rapid symptom relief may be obtained with a quick-acting non-steroidal anti-inflammatory drug (**NSAID**), given in full dosage. Although indomethacin has a long tradition in this context, it is preferably avoided in the elderly due to its frequent renal, gut, and nervous system side-effects.

Oral colchicine is rapidly effective within a few hours (1 mg immediately, followed by 0.5 mg every 6 h until symptoms abate). Unfortunately, at the doses necessary, diarrhoea, nausea, and abdominal cramps are common, causing the patient 'to run before he can walk'. Colchicine, however, is a useful alternative if NSAIDs are contraindicated. Intravenous colchicine, however, is particularly toxic and should never be used. Although previously used as a 'diagnostic test' the efficacy of colchicine is not specific to gout: it also ameliorates other crystal-associated syndromes.

Joint aspiration often provides immediate relief by reducing intra-articular hypertension. Intra-articular steroid is useful for large joints such as the knee, or when NSAIDs or colchicine are contraindicated or unsuccessful. In difficult cases, joint lavage may terminate an attack, and for troublesome polyarticular attacks there is support for the use of parenteral steroid.

Long-term management

Once any acute attack has resolved, long-term strategies need consideration. Gout is potentially curable. Treatment may involve:

1. considering and eliminating modifiable factors that cause hyperuricaemia; and
2. utilizing hypouricaemic drugs.

Management of gout may require alteration in lifestyle and chronic medication: patient compliance and motivation, which depend on appropriate education and counselling, are essential for success.

Modification of provoking factors

In early primary gout, gradual weight loss, reduction in alcohol consumption, and avoidance of toxins (low-dose aspirin, lead) may alone be sufficient. Similarly, in diuretic-induced gout, stopping the diuretic (plus substitution of alternative therapies) may prove possible and be all that is required.

Hypouricaemic drug therapy

Indications for drug therapy are:

1. recurrent, troublesome acute attacks;
2. presence of tophi;
3. bone or cartilage damage;
4. coexistent renal disease, uric acid urolithiasis;
5. very high uric acid levels (particularly with overproduction and hyperexcretion).

The logical approach would be allopurinol for overproducers and uricosurics for undersecretors. In practice, however, allopurinol is the usual drug of choice, permitting flexible tailoring of dose to reduce urate levels below the solubility limit. Allopurinol inhibits xanthine oxidase and often also depresses *de novo* purine synthesis. The starting dose is 100 to 300 mg daily, which is then adjusted within the range 100 to 900 mg daily according to the serum uric acid level (initially checked monthly). In patients with renal insufficiency, particularly the elderly, excretion of the active metabolite oxypurinol is delayed: the starting dose should therefore be 100 mg daily and adjustments made cautiously.

The uricosurics probenecid (0.5–1.0 g twice a day) and sulphinpyrazone (100 mg three or four times daily), which prevent proximal tubular reabsorption of urate, are rarely used. Benzbromarone, a newer uricosuric, is now increasingly used in parts of Europe. Uricosurics are alternatives to allopurinol in patients with normal renal function but are contraindicated in those with renal impairment, urolithiasis, or gross overproduction of uric acid. The therapeutic aim of hypouricaemic therapy is to maintain the serum uric acid well within the normal range (preferably the lower half). Treatment should be lifelong.

Acute attacks may be provoked during the first few months of hypouricaemic treatment. Prophylactic colchicine (0.5 mg twice a day) or a standard dose of NSAID given for the first 2 to 3 months of treatment largely avoids 'breakthrough' attacks. With any uricosuric, high fluid intake and urine alkalinization in the early weeks of treatment are recommended to avoid deposition of uric acid within the kidney.

Serious side-effects are unusual with any hypouricaemic drugs. Rare problems include toxic epidermal necrolysis, interstitial nephritis and vasculitis (allopurinol), nephrotic syndrome (probenecid), and hepatitis and marrow suppression (both drugs). Important interactions with allopurinol occur with coumarin anticoagulants (due to hepatic microsomal enzyme inhibition) and purine analogues (such as azathioprine) which are inactivated by xanthine oxidase. Associated hypertension should be treated, but preferably not with diuretics which elevate serum urate and may provoke acute attacks.

Pyrophosphate arthropathy

Deposition of calcium pyrophosphate dihydrate crystals ($Ca_2P_2O_7.2H_2O$) in articular cartilage is a common age-related phenomenon. Calcium pyrophosphate dihydrate crystals preferentially deposit within fibrocartilage and are the most common cause of cartilage calcification (chondrocalcinosis).

Calcium pyrophosphate dihydrate deposition may occur in otherwise normal cartilage or associate with structural change and clinical arthropathy—'pyrophosphate arthropathy'. A causal role for calcium pyrophosphate dihydrate crystals in acute inflammation is accepted, but their role in chronic arthropathy is unclear. The strong association/overlap with osteoarthritis has led some to consider pyrophosphate arthropathy not as a crystal deposition disease but as a 'subset' of osteoarthritis, with calcium pyrophosphate dihydrate a 'process' marker associating with a hypertrophic articular response.

Radiographic chondrocalcinosis is rare under 50 years of age, but its prevalence rises from 10 to 15 per cent in those aged 65 to 75, to 30 to 60 per cent in those over 85, showing female preponderance (relative risk 1.33) and association with osteoarthritis (relative risk 1.52 at the knee). No epidemiological data exist for pyrophosphate arthropathy, but in patient series the mean age of presentation is around 65 to 75 with female preponderance (about 2:1 to 3:1), particularly in older patients.

Clinical features

Common presentations are acute synovitis, chronic arthritis, or as an incidental finding. Other presentations are rare.

Acute synovitis ('pseudogout')

This is the most common cause of acute monoarthritis in the elderly. Attacks may occur as isolated events or be superimposed upon a background of chronic symptomatic arthropathy. Most attacks occur spontaneously, but provoking factors include intercurrent illness, surgery, and local trauma. Although any joint may be involved, the knee is by far the most common site, followed by the wrist, shoulder, and ankle. Concurrent attacks in several joints are uncommon (fewer than 10 per cent of cases) and polyarticular attacks rare.

The typical attack develops rapidly with severe pain, stiffness, and swelling, becoming maximal within 6 to 24 h of onset. Examination reveals a very tender joint with signs of florid synovitis (increased warmth, tense effusion, restricted movement with stress pain) and often overlying erythema. Fever is common and elderly patients may appear unwell or mildly confused. Attacks are self-limiting, usually resolving within 1 to 3 weeks.

Chronic pyrophosphate arthropathy

This common condition affects mainly elderly women and targets the same large and medium-sized joints as pseudogout. Knees are the usual and most severely affected joint. Presentation is with chronic pain, stiffness, and functional impairment (plus superimposed acute attacks). Symptoms usually relate to just a few joints, although examination often reveals more widespread abnormalities. Affected joints show signs of osteoarthritis (crepitus, bony swelling, restricted movement) with varying degrees of synovitis (often most marked at the knee, radiocarpal, or glenohumeral joint). Knees typically show abnormality of two or three compartments; valgus or varus deformity may occur.

Although symptoms and signs are those of osteoarthritis, chronic pyrophosphate arthropathy may often be distinguished from uncomplicated osteoarthritis by:

1. the joint distribution: in osteoarthritis wrist, glenohumeral, ankle, elbow, and midtarsal involvement are uncommon;
2. the often marked inflammatory component; and
3. superimposition of acute attacks.

The outcome for chronic pyrophosphate arthropathy is generally good, most patients running a relatively benign course, particularly with respect to small and medium-sized joints. If progression occurs, it is usually slow and related to knees, hips, or shoulders. Occasionally severe, rapidly progressive, destructive arthropathy develops at these sites. This is virtually confined to very elderly women and is associated with severe pain, recurrent haemarthrosis (shoulder, knee), and occasional joint leakage.

Incidental finding

As with osteoarthritis, clinical or radiographic evidence of pyrophosphate arthropathy and chondrocalcinosis are not uncommon incidental findings in the elderly, and may confound the cause of regional pain if a through history and examination are not undertaken.

Uncommon presentations

Acute tendinitis (triceps, Achilles), tenosynovitis (hand flexors, extensors), and bursitis (olecranon, infrapatellar, retrocalcaneal) occur uncommonly, usually in patients with widespread calcium pyrophosphate dihydrate crystals. Median and ulnar nerve compression at the wrist may accompany flexor tenosynovitis. Rare tophaceous deposits of calcium pyrophosphate dihydrate usually present as solitary lesions in areas of chondroid metaplasia.

Classification and associations

Calcium pyrophosphate dihydrate deposition is traditionally classified as:

1. hereditary;
2. associated with metabolic disease; or
3. sporadic/idiopathic (by far the commonest, associated with osteoarthritis).

Familial predisposition

This is reported from many countries and different ethnic groups. Two clinical phenotypes occur: early onset (third to fourth decade) florid polyarticular chondrocalcinosis with variable severity of accompanying arthropathy; and late onset (sixth to seventh decade) oligoarticular chondrocalcinosis (mainly knee) with arthritis resembling sporadic disease. The pattern of inheritance varies, although autosomal dominance is usual. Studies on several families have suggested the short arm of chromosome 5 as a potential site for a candidate gene. The mechanism of familial predisposition remains unclear and may differ between families. A primary cartilage abnormality that promotes calcium pyrophosphate dihydrate crystal nucleation and growth (Swedish and Japanese families), and a generalized abnormality of pyrophosphate metabolism resulting in a local increase in cartilage levels (French and American kindreds) have both been reported.

Metabolic disease associations

Inorganic pyrophosphate is a byproduct of many biosynthetic reactions, with a turnover of several kilograms per day. Much extracellular inorganic pyrophosphate derives from ATP via the action of NTP pyrophosphatase, and is rapidly converted to orthophosphate by pyrophosphatases (particularly alkaline phosphatase) (Fig. 6). A number of metabolic diseases associate with deposition of calcium pyrophosphate dihydrate (Table 4), their association being rationalized through putative effects on metabolism of inorganic pyrophosphate. Suggested mechanisms include:

1. Reduced breakdown of inorganic pyrophosphate by alkaline phosphatase, due to (i) reduced levels, (ii) inhibitory ions (calcium, iron, copper), or (iii) impaired complexing with magnesium.
2. Enhanced nucleation by iron or copper.
3. Increased calcium concentration.
4. Increased production of pyrophosphate through stimulation of adenylate cyclase by parathyroid hormone.

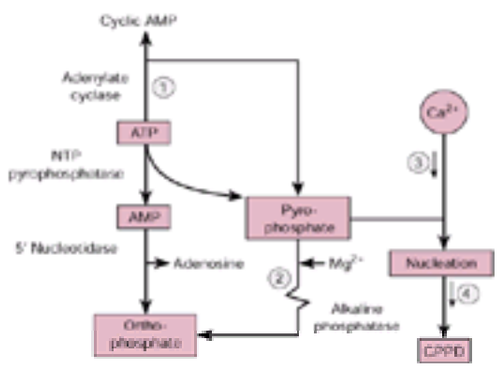

Fig. 6 Simplified scheme of extracellular pyrophosphate metabolism, showing putative sites of interaction by metabolic diseases. Hyperparathyroidism, 1, 2, 3; haemochromatosis, 2, 4; hypophosphatasia, 2; Wilson's disease, 2, 4; and hypomagnesaemia, 2. CPPD, calcium pyrophosphate dihydrate; NTP, nucleotide triphosphate

Osteoarthritis and joint insult

Several observations support a relationship between osteoarthntis and deposition of calcium pyrophosphate dihydrate, the latter often following rather than preceding joint damage. However, a negative association exists between deposition of calcium pyrophosphate dihydrate and rheumatoid arthritis, with atypical radiographic features in coexistent disease (retained bone density; marked osteophyte, cyst, and bone remodelling) suggesting that the primary association of calcium pyrophosphate dihydrate is with hypertrophic tissue response/osteoarthritis and not joint damage *per se*. The explanation for this association is unknown. Levels of inorganic pyrophosphate in the synovial fluid are increased in pyrophosphate arthropathy and osteoarthritis and are low in rheumatoid arthritis, but the order of change is unlikely to influence formation of calcium pyrophosphate dihydrate significantly. These crystals form in pericellular sites and associate with lipid, proteoglycan depletion, and adjacent hypertrophic chondrocytes containing lipid granules. It is therefore possible that reduction of inhibitors (such as proteoglycan)

and increase in promotors (such as lipid) may combine to copromote calcium pyrophosphate dihydrate formation in metabolically active osteoarthritic tissue.

Investigations and diagnosis

Critical investigations are synovial fluid analysis and plain radiographs. In pseudogout aspirated fluid is often turbid or bloodstained with an elevated cell count (more than 90 per cent neutrophils). Compensated polarized microscopy reveals calcium pyrophosphate dihydrate crystals as weakly birefringent (positive sign) rhomboids or rods, about 2 to 10 μm long. Calcium pyrophosphate dihydrate crystals are less readily identified and often less numerous than those of monosodium urate monohydrate; examination of a spun deposit may increase detection.

Radiographic aspects relate both to calcification and arthropathy. Chondrocalcinosis signifies extensive deposition and is not always evident: it mainly affects fibrocartilage (particularly knee menisci, wrist triangular cartilage, symphysis pubis), and less commonly hyaline cartilage (Fig. 7). Although occasionally monoarticular, it usually affects several sites. Calcification of capsule, synovium, and tendons is less common. Chondrocalcinosis and calcification may increase or decrease with time, diminishing chondrocalcinosis often accompanying crystal 'shedding' or cartilage loss.

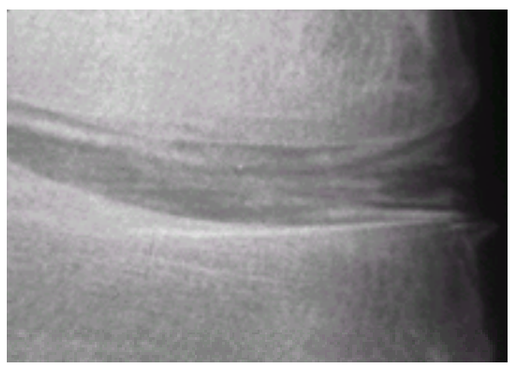

Fig. 7 Radiographic chondrocalcinosis of the knee, affecting meniscal fibrocartilage (central, triangular) and hyaline cartilage (linear, parallel to bone).

Changes of arthropathy are those of osteoarthritis: cartilage loss, sclerosis, cysts, and osteophyte. However, characteristics which suggest pyrophosphate include:

1. distribution between and within joints that is atypical of osteoarthritis (for example glenohumeral disease; isolated or predominant patellofemoral or radiocarpal involvement);
2. prominence of osteophytes and cysts; and
3. prominent osteochondral bodies.

Such combined features may present a distinctive 'hypertrophic' appearance even in the absence of chondrocalcinosis (Fig. 8). In destructive arthropathy, marked cartilage and bone attrition with fragmentation and loose osseous bodies may resemble a Charcot joint.

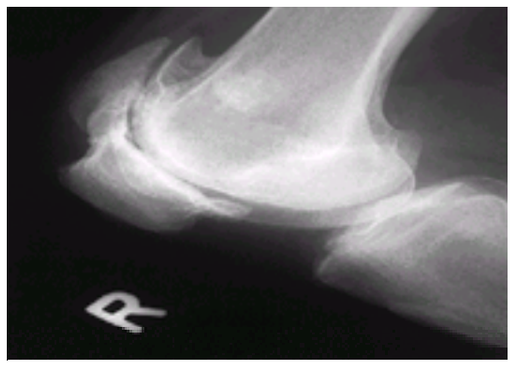

Fig. 8 Lateral knee radiograph showing predominant patellofemoral involvement by 'hypertrophic' osteoarthritis characteristic of pyrophosphate arthropathy.

Metabolic predisposition is rare and routine screening of all patients is unrewarding. Nevertheless, arthritis associated with calcium pyrophosphate dihydrate crystals may be the presenting feature of metabolic disease, and a search is warranted in the following circumstances:

1. early onset arthritis (under 55 years)
2. florid polyarticular chondrocalcinosis; or
3. presence of additional clinical or radiographic clues.

A reasonable screen would include serum calcium, alkaline phosphatase, magnesium, ferritin, and liver function.

Differential diagnosis

The principal differential diagnosis for pseudogout is sepsis or gout, both of which may coexist with calcium pyrophosphate dihydrate deposition. Gram stain and culture of joint fluid should be undertaken even when calcium pyrophosphate dihydrate (and monosodium urate monohydrate) crystals are identified. Marked bloodstaining may lead to consideration of other causes of haemarthrosis, especially a bleeding disorder or subchondral fracture.

Chronic pyrophosphate arthropathy is usually readily distinguished from rheumatoid arthritis by the synovial fluid and radiographic findings, the infrequency of severe systemic upset, absence of extra-articular features, and an acute phase response which is only modest. Proximal stiffness due to glenohumeral involvement may suggest polymyalgia rheumatica, although clinical examination and near normal erythrocyte sedimentation rate should exclude the diagnosis. Destructive pyrophosphate arthropathy may simulate a neuropathic joint, although such joints are severely symptomatic and neurological abnormality is absent.

Treatment

Pseudogout

Since pseudogout usually affects only one or a few joints in elderly patients, local therapy is preferred. Aspiration alone often relieves symptoms, but may be combined with intra-articular steroid in florid cases. Simple analgesics and NSAIDs give additional benefit but should be used cautiously in the elderly. Joint lavage is reserved for troublesome steroid-resistant cases. Colchicine is effective but rarely warranted. Triggering illness (for example chest infection) will require appropriate treatment. Rapid mobilization should be instituted once the synovitis is settling.

Chronic pyrophosphate arthropathy

Unlike gout there is no specific therapy, and treatment of any underlying metabolic disease does not influence outcome. Aims are to reduce symptoms and maintain or

improve function. This may include education of the patient in appropriate use of the affected joints, reduction in obesity, improvement of muscle strength, use of a stick or other walking aid, and surgery for severe disease. Chronic synovitis may be improved by intermittent steroid injection or intra-articular radiocolloid (yttrium-90). As with pseudogout, symptomatic drugs are to be used with caution in older patients; simple analgesics are generally preferable to NSAIDs.

Other crystal-related disorders

Apatite-associated syndromes

Hydroxyapatite is the principal bone mineral. Apatites or basic calcium phosphates (partially carbonate-substituted hydroxyapatite, octacalcium phosphate, rarely tricalcium phosphate) are also the usual mineral to deposit in extraskeletal tissues (for example tuberculous lesions, arteries).

The [calcium × phosphate] product must be kept high to maintain skeletal integrity. Specific cellular mechanisms activate calcification where appropriate (for example matrix vesicles in growing cartilage), whilst other mechanisms (such as pyrophosphate and aggregated proteoglycan) inhibit calcification elsewhere. In general, abnormal calcification results from:

1. elevation of the [calcium × phosphate] product, causing widespread 'metastatic' calcification, or
2. alteration in the balance between inhibitory and promoting tissue factors, resulting in local 'dystrophic' calcification.

In rheumatic diseases abnormal deposition of basic calcium phosphates may occur in:

1. periarticular tissues (particularly tendon);
2. hyaline cartilage, in association with osteoarthritis; or
3. subcutaneous tissues and muscle, principally in connective tissue diseases.

Apatite crystals are too small (5–500 nm) to be seen by light microscopy. Particles may aggregate, however, to form spherulites visible with the light microscope. Confirmation of basic calcium phosphates requires sophisticated analytical techniques and most clinical diagnoses are presumptive, based on radiographic calcification or non-specific staining of joint fluid or histological material.

Acute calcific periarthritis

Apatite deposition in the supraspinatus tendon (Fig. 9) is a relatively common incidental finding (about 7 per cent of adults). It occasionally results in severe acute inflammation of the subacromial bursa, periarticular tissues, or joint itself. Periarticular sites around the greater hip trochanter, the foot, or the hand are less commonly affected.

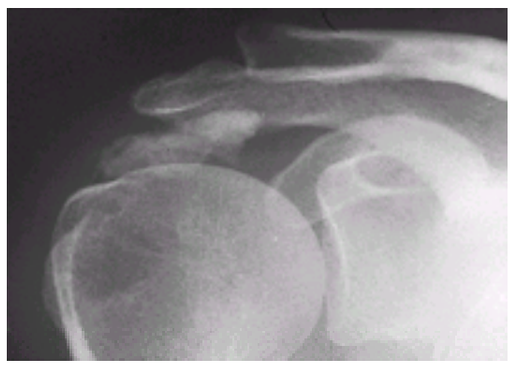

Fig. 9 Shoulder radiograph showing florid supraspinatus tendon calcification (calcific periarthritis).

Acute episodes may follow local trauma or occur spontaneously. Within a few hours pain and tenderness are often extreme and the area appears swollen, hot, and red. Modest systemic upset and fever are common. Sepsis is usually considered first, but the diagnosis is made following demonstration of radiographic calcification. If the lesion is aspirated, thick white fluid containing many apatite aggregates may be obtained. The condition usually resolves spontaneously over 1 to 3 weeks, often accompanied by radiographic dispersal of modestly sized calcifications (crystal 'shedding'). NSAIDs ameliorate symptoms and the attack can be abbreviated by aspiration and injection of steroid. Large deposits may require surgical removal. Calcific periarthritis rarely results from metabolic abnormality (renal failure, hyperparathyroidism, hypophosphatasia) and measurements of serum calcium, alkaline phosphatase, and creatinine are usually normal. Rare families are predisposed to calcific periarthritis at multiple sites with no evidence of altered calcium phosphate product.

Osteoarthritis and apatite-associated destructive arthritis

Modest amounts of basic calcium phosphates are commonly found in synovial fluid from osteoarthritic joints, in isolation or with calcium pyrophosphate dihydrate ('mixed crystal deposition'). Whether apatite plays any part in inflammatory exacerbations or associates with severity or progression of osteoarthritis remains uncertain.

The uncommon condition 'apatite-associated destructive arthritis' is often considered a 'subset' of osteoarthritis. It is virtually confined to elderly women and affects the hip, shoulder ('Milwaukee shoulder'), or knee. It has the general appearance of severe large joint osteoarthritis but is particularly characterized by:

1. rapid progression, often leading to severe pain and disability within a few months of onset;
2. development of marked instability;
3. large, cool effusions;
4. an atrophic radiographic appearance with marked cartilage and bone attrition and little osteophyte or bone remodelling.

Aspirated fluid has normal viscosity and a low cell count but contains large amounts of apatite aggregates, seen readily on light microscopy following non-specific calcium staining (alizarin red, acidic pH). The differential diagnosis may include sepsis (excluded by synovial fluid culture), late avascular necrosis, or neuropathic joint. The pathogenesis of this condition remains unclear. Although apatite particles could contribute to tissue damage by stimulating release of collagenase and other proteolytic enzymes from synovial cells, it is most likely that the apatite is non-contributory and principally reflects the severity of subchondral bone attrition. The outcome is poor and inevitably requires surgical intervention.

Other apatite syndromes

Deposition of tophaceous periarticular apatite may occur in patients with chronic renal failure managed by dialysis. Apatite has also been incriminated in the occasional erosive interphalangeal arthropathy seen in such patients.

Other crystals

Cholesterol

Cholesterol crystals may induce acute synovitis, acute tenosynovitis, and chronic xanthomatous tendinitis in hypercholesterolaemic subjects. Cholesterol and other lipid crystals may also occur as a non-specific finding in chronic synovitis, most commonly due to rheumatoid arthritis. In this situation the lipid probably derives from

cellular debris and its pathogenic significance is uncertain.

Oxalate

Oxalate crystals have been incriminated in acute and chronic articular and periarticular syndromes occurring in association with either primary familial oxalosis (types I and II) or secondary oxalosis (Chapter 11.10). Chronic renal failure managed with dialysis is the commonest cause of secondary oxalosis, particularly if ascorbic acid supplementation has been given. Acute symmetrical interphalangeal and metacarpophalangeal arthritis, with or without tenosynovitis, and digital calcific deposits are the usual manifestation. Large joint involvement, chondrocalcinosis, and tophaceous periarticular masses are less common. Calcium oxalate crystals may also cause life-threatening organ involvement, with peripheral vascular insufficiency and digital necrosis, cardiomyopathy, peripheral neuropathy, and aplastic anaemia. There is no effective treatment.

Extrinsic crystals

These are a rare cause of locomotor problems. Acute flares following intra-articular injection of corticosteroids are uncommon but may represent iatrogenic crystal-induced inflammation. Penetrating injuries involving plant thorns and sea-urchin spines may cause acute and chronic inflammatory synovitis, periostitis, or periarticular lesions which only resolve following surgical removal of the crystalline material.

18.10.1 Autoimmune rheumatic disorders and vasculitis

I. P. Giles and D. A. Isenberg

Definition and epidemiology

The autoimmune rheumatic diseases are a heterogeneous group of disorders characterized by clinical involvement of the joints, connective tissues, muscles, internal organs, Raynaud's phenomenon, and cutaneous manifestations. Hence the autoimmune rheumatic diseases include a broad clinical spectrum of disease, including systemic lupus erythematosus, rheumatoid arthritis, Sjögren's syndrome, scleroderma, dermatomyositis, polymyositis, antiphospholipid syndrome, and the vasculitides. This latter group of diseases all share inflammation and necrosis of blood vessels as cardinal features, and may be divided into primary (e.g. giant cell arteritis, Wegener's granulomatosis, polyarteritis nodosa, etc.), occurring in the absence of a recognized precipitating cause, or secondary to established disease (e.g. systemic lupus erythematosus or rheumatoid arthritis) or infection (e.g. hepatitis B, C, or HIV) (see Table 1). On the whole these diseases have a predilection for young women and share defects in immune regulation leading to the production of autoantibodies, activation of the complement system, and generation and deposition of immune complex.

Some autoimmune rheumatic diseases are rare, for example systemic sclerosis; others are common, rheumatoid arthritis affecting approximately 1 per cent of the population (see Table 2). Taken as a whole, however, these autoimmune disorders affect as many as 1 in 20 people. Some are severely debilitating or life-threatening illnesses, others produce minor symptoms that require little, if any, medical intervention.

The clinical spectrum

Each of the autoimmune rheumatic diseases is a distinct entity and can be clearly defined clinically, serologically, and in terms of treatment and prognosis. However, many patients with these diseases have non-specific features of malaise, fever, and arthralgia, and there is also much overlap in terms of multisystem involvement, as shown in Table 3. Organ-specific features, for example lung fibrosis, pericarditis, and less frequently glomerulonephritis, can all occur in several of the autoimmune rheumatic diseases and the presence of such a feature is not pathognomonic of an individual disease.

The clinical features of each patient must be considered together with the laboratory investigations, which should include an autoantibody profile. A preliminary 'autoimmune screen' includes a rheumatoid factor and antinuclear antibody test as a bare minimum, the results of which then guide the need for further autoantibody testing. Immunologically rheumatoid factor (especially if the titre is greater than 1 in 320) remains the most important guide to establishing the diagnosis of rheumatoid arthritis, although the American College of Rheumatology classification criteria for rheumatoid arthritis may still be fulfilled in the absence of rheumatoid factor. The antibody is of no value, however, in the monitoring of the disease.

The presence and pattern of staining of antinuclear antibody is a very useful guide to the presence of disease, as shown in Table 4. In the case of the vasculitides the antineutrophil cytoplasmic antibody (**ANCA**) fulfils this role. An important proviso to the antinuclear antibody test is that it is present in a low titre (up to 1 in 80) in about 1 to 2 per cent of the normal population, and more frequently (up to 10 per cent) in healthy people over the age of 75 years. Hence, its presence alone at low titres does not in itself justify the diagnosis of an autoimmune rheumatic disease: the whole clinical picture must be considered. Further confusion may arise because some autoantibodies may be found in more than one disease, such as anti-U1RNP (in systemic lupus erythematosus and undifferentiated autoimmune rheumatic disease), whilst others may be found in other diseases 'beyond' the autoimmune rheumatic diseases, such as perinuclear staining ANCA (p-ANCA) which is well recognized in patients with inflammatory bowel disease, some chronic infections, and malignancies.

Immunopathogenesis

Autoimmune rheumatic disorders

The precise aetiologies of the autoimmune rheumatic diseases remain unknown, but are undoubtedly complex. Inciting agents, such as infection, are involved, as are genetic susceptibility, hormonal factors, and both cellular and immune dysregulation.

Common to all of the autoimmune rheumatic diseases is the phenomenon of production of autoantibodies by activated B cells. Many of the pathogenic autoantibodies are of the IgG class and have undergone somatic mutation in their hypervariable regions leading to a gradual increase in specificity and binding affinity of an antibody produced by a particular clone of cells. This latter finding is particularly true of anti-dsDNA antibodies in systemic lupus erythematosus and antiphospholipid antibodies in the antiphospholipid syndrome.

The origins of autoantibody production remain an enigma. Mechanisms that have been invoked include antigen-driven T helper cell responses, failure of efficient clearance of nuclear antigens which become surface expressed following cellular apoptosis, and epitope spreading. These might act alone, in combination with each other, or together with other factors. Each has been proposed to lead to increased B-cell activation. Impaired tolerance appears to be the central defect and once this has occurred abnormal immunoregulation leads to persistence of the inappropriate self-directed immune response.

Cellular mechanisms also play a role in the development of autoimmunity in the autoimmune rheumatic diseases: T-cell dysfunction, impaired macrophage and natural killer cell cytotoxicity, decreased clearance of immune complexes by the mononuclear phagocytic system, increase in the number of activated B cells, cytokine dysregulation, and upregulation of adhesion molecules have all been reported.

Genetic factors are important, especially in the case of systemic lupus erythematosus, where there is a higher rate of concordance in monozygotic twins (25 per cent) than dizygotic (3 per cent). The best described of the genetic contributions to autoimmune rheumatic disease is the increased risk associated with particular HLA class II molecules. The HLA DR4 (the Dw4 and Dw14 subtypes, notably the DRb1*0404 allele) and HLA DR1 (Dw1) are particularly associated with rheumatoid arthritis. These subtypes share a similarity of the amino acid sequence in the third hypervariable region of the DRb1 chain, the shared epitope that has been proposed as the underlying unit of susceptibility to rheumatoid arthritis. There are, however, conflicting data proposing that this epitope is better related to the severity of disease. In systemic lupus erythematosus, among Caucasians, the haplotype A1 B8 DR3 is associated with an approximately tenfold increase in risk, although the primary link may be with the complement C4 null allele with which there is linkage disequilibrium.

HLA associations are not only seen with autoimmune rheumatic disease, but also with certain autoantibodies. Anti-Ro and La are strongly correlated with HLA DR3 and DQ, an association that is stronger than that seen with the disease in which these autoantibodies are most frequently encountered (systemic lupus erythematosus and Sjögren's syndrome).

Vasculitides

HLA class I and class II associations are seen throughout the primary vasculitides, whilst infectious agents and circulating immune complexes are pathogenic in the secondary vasculitides. In the primary vasculitides a pathogenic role has been proposed for antiendothelial cell antibodies and sensitized T cells, but undoubtedly the most important role is that of ANCA. Immunofluoresence studies have localized the antigen to the cytoplasm of granulocytes in the azurophilic granules, and two patterns of staining are seen: cytoplasmic ANCA (c-ANCA), of which 90 per cent of sera recognize proteinase 3; and perinuclear staining ANCA (p-ANCA) which is directed against myeloperoxidase in 70 per cent of p-ANCA vasculitis patients. A positive c-ANCA is strongly associated with Wegener's granulomatosis, although 10

per cent of these patients may be p-ANCA positive, whilst antimyeloperoxidase antibodies occur in necrotizing glomerulonephritis (65 per cent), Churg–Strauss syndrome (60 per cent), and microscopic polyangiitis (45 per cent).

Clinical features

As mentioned previously, the presentation of an autoimmune rheumatic disease may be diffuse and non-specific, with fatigue and arthralgia frequently the major features. In this instance, systemic review should enquire for the presence of alopecia, mouth ulcers, Raynaud's phenomenon, rash, sicca symptoms, and lymphadenopathy. The presence of these would lend an autoimmune flavour to the illness, but not necessarily help to make a precise diagnosis. The history should also seek a possible trigger such as a preceding infection, drugs (for example hydralazine, isoniazid, procainamide in drug-induced lupus), or environmental exposure to chemicals, as may be seen in scleroderma-like illnesses. A family history must pay particular attention to the presence not only of other autoimmune rheumatic diseases but also other autoimmune diseases such as diabetes, pernicious anaemia, and thyroid disease, which are often found in association with the autoimmune rheumatic diseases.

The protean clinical manifestations mean that an autoimmune rheumatic disease may present not only to a rheumatologist but to many other specialists, including those in nephrology, dermatology, and less commonly neurology, cardiology, haematology, or even obstetrics, in the case of recurrent miscarriages in the antiphospholipid syndrome.

In many cases it is not possible to make a precise diagnosis on the first encounter with a patient. In those with mild disease, symptomatic relief can be obtained with a non-steroidal anti-inflammatory drug, whilst the results of baseline investigations and an 'immunological screen' of antinuclear antibody and rheumatoid factor are awaited. It is worth noting, however, that there is increasing emphasis on trying to make the diagnosis of rheumatoid arthritis promptly, so that a disease-modifying drug can be used as early as possible, rather than waiting for the development of erosive, destructive joint disease.

Since the autoimmune rheumatic diseases are systemic disorders, it is always important to search for evidence of involvement of any of the major organ systems. Baseline investigations must therefore include urinalysis, a full blood count, simple blood tests of renal and liver function, measurement of serum inflammatory markers, an ECG, and a chest radiograph. The simple bedside test of urinalysis is particularly important: the finding of proteinuria and haematuria immediately identifies those who require further, often urgent, renal investigation and whose prognosis may be chiefly determined by the extent of renal involvement.

Damage to major organ systems can be part of the presenting illness in a patient with an autoimmune rheumatic disease, but may also occur in a previously diagnosed patient with 'stable' disease. Myocardial infarction can occur as the result of a vasculitic illness, or accelerated atherosclerosis in systemic lupus erythematosus. Pericarditis can lead to tamponade (for example in systemic lupus erythematosus or rheumatoid arthritis), whilst myocarditis may induce complex arrhythmias or even heart failure (for example in systemic lupus erythematosus or polymyositis). Seizures or a disturbed level of consciousness can occur due to cerebral infarction or meningoencephalitis (for example in systemic lupus erythematosus, antiphospholipid syndrome, Wegener's granulomatosis). Rapidly progressive glomerulonephritis (systemic lupus erythematosus, Wegener's granulomatosis, microscopic polyangiitis) may be associated with pulmonary haemorrhage, whilst hypertension requires urgent treatment in scleroderma renal crisis. Pneumonitis or myositis due to systemic lupus erythematosus may be life threatening if not recognized and treated appropriately with adequate immunosuppression. Venous or arterial thromboses are likely to complicate the antiphospholipid syndrome, which in its primary form may be catastrophic and characterized by widespread microvascular disease with adult respiratory distress syndrome, profound thrombocytopenia, and acute renal failure.

Physicians treating patients with autoimmune rheumatic diseases need to be constantly aware of the possibility of organ involvement: prompt diagnosis and treatment being necessary to prevent irreversible end organ damage. The immunosuppressive therapy used will be similar, regardless of the particular diagnosis.

Precise identification of an autoimmune rheumatic disease is reliant upon clinical and laboratory features, of which the presence of antinuclear antibody (and its pattern of staining), antibodies to extractable nuclear antigens, disease-specific antibodies, or ANCA are crucial. There are many instances where the disease may not be precisely labelled, and up to 20 per cent of patients have features of several autoimmune rheumatic diseases, most commonly systemic lupus erythematosus/scleroderma and systemic lupus erythematosus/rheumatoid arthritis, or those who would be considered to have an undifferentiated autoimmune rheumatic disease. In the case of these latter diseases, treatment is guided according to disease features and the pattern of organ/system involvement.

18.10.2 Systemic lupus erythematosus and related disorders

Anisur Rahman and David Isenberg

Introduction

Systemic lupus erythematosus is an autoimmune rheumatic disorder that can present with symptoms in almost any organ or system of the body. Classification criteria have been published by the American College of Rheumatology which should universally be used to make the diagnosis. These are shown in Table 1 and demonstrate the wide variety of clinical and serological features that are associated with this condition. They provide a useful guide to the clinical features that should place the suspicion of systemic lupus erythematosus in the mind of a clinician. It is important not to be too dogmatic in searching for 'pathognomonic' features of the disease. For example, although the characteristic butterfly rash over the face is perhaps the best known sign of systemic lupus erythematosus, many patients will never develop such a rash.

Aetiology

The aetiology is multifactorial, incorporating genetic, hormonal, and environmental elements. The best established genetic link is with the presence of null alleles of genes encoding early components of the complement cascade (C1q, C2, and C4). Over 90 per cent of patients homozygous for C1q deficiency and 75 per cent of those with C4 deficiency develop a lupus-like disease (similar clinical features but a relative paucity of antibodies). Major histocompatibility complex genes, particularly HLA A1, B8, and DR3, have also been associated with the presence of lupus in family studies, although part of this association may be due to linkage disequilibrium with the C4 and C2 genes also present in that region of chromosome 6.

Hormones are likely to play a role in pathogenesis, since systemic lupus erythematosus is far commoner in women than men (see below). There is a relatively high incidence of the condition in Klinefelter's syndrome (males with the XXY karyotype) and this is associated with abnormalities in oestrogen metabolism.

Viruses may be important in triggering the autoimmune dysfunction that leads to the production of pathogenic autoantibodies in systemic lupus erythematosus. Reactivation of BK polyomavirus infection, in particular, has been associated with the presence of antibodies to double-stranded DNA (anti-dsDNA) in Norwegian studies. This association has not yet been confirmed in large populations.

Certain drugs induce a form of systemic lupus erythematosus which is generally characterized by the presence of antihistone rather than anti-dsDNA antibodies, a milder course of disease, and total remission when the causative drug is withdrawn. The most common drugs involved are isoniazid, procainamide, hydralazine, minocycline, penicillamine, and anticonvulsants.

Epidemiology

The incidence of systemic lupus erythematosus in the United Kingdom is about four cases per 100 000 people per year. The prevalence varies between the sexes and between different ethnic groups. Systemic lupus erythematosus occurs between 10 and 20 times more frequently in women than in men and is commoner in some ethnic groups. A recent study in Birmingham, United Kingdom gave the prevalence of systemic lupus erythematosus in women as 206 per 100 000 in Afro-Caribbeans, 91 per 100 000 in Asians, and 36 per 100 000 in Caucasians. These gender and racial differences are broadly consistent with those reported from studies in the United States and the Caribbean, although the reported prevalence of systemic lupus erythematosus in Africa is much lower.

Mortality from systemic lupus erythematosus has fallen significantly over the last half century. Whereas systemic lupus erythematosus was reported to have a 50 per cent 5-year survival in the 1950s, 10-year survival rates rose to between 80 and 90 per cent by the 1970s. Since then, survival rates have improved a little, but deaths from renal failure have become less common, whilst those from infection have increased. The latter are generally associated with immunosuppressive therapy, highlighting the need for better and more accurately targeted methods of treating the underlying immunological abnormalities in this disease.

Pathogenesis and immune dysfunction

No single abnormality of the immune system can be considered to be the sole cause of systemic lupus erythematosus. The pathogenesis of the disease depends on the interplay of a number of different factors, the relative importance of which may differ from one patient to another. These include autoantibodies, T lymphocytes, cytokines, the complement system, and apoptosis. Research to unravel this complex system of interrelated factors has been carried out by studying properties of cells and tissue components derived from patients with systemic lupus erythematosus and by studying mouse models of the condition.

B lymphocytes and autoantibodies

Autoantibodies are those which bind to antigens present within the tissues of the body itself. A wide variety of different autoantibodies have been described in systemic lupus erythematosus. Those most frequently reported are listed in Table 2.

Antibodies to double-stranded DNA (anti-dsDNA) have been cited widely as possible causative agents in systemic lupus erythematosus, particularly in lupus glomerulonephritis. Raised titres of anti-dsDNA antibodies are found in 50 to 70 per cent of patients with systemic lupus erythematosus but hardly ever in healthy

people or those with other diseases. Levels of these antibodies rise and fall with disease activity in systemic lupus erythematosus, and deposits of anti-dsDNA occur in the glomeruli of patients with lupus nephritis. In experimental murine models of systemic lupus erythematosus, monoclonal anti-dsDNA antibodies can also be shown to deposit in the glomeruli with associated proteinuria.

The titre of anti-dsDNA antibodies present in the bloodstream of patients with systemic lupus erythematosus can be a useful indicator of disease activity. It is increasingly clear, however, that not all anti-dsDNA antibodies are equally likely to be associated with tissue damage. Antibodies of IgG isotype, which show specific, high-affinity binding to dsDNA generally show the closest association with disease activity in patients and the greatest ability to cause renal damage in experimental models.

Why are such antibodies produced in patients with systemic lupus erythematosus? Studies of monoclonal anti-dsDNA antibodies derived from patients or mice indicate that those which show the isotype and binding properties described above often show sequence characteristics suggestive of antigen-driven somatic mutation. This is the process whereby mutations accumulate in the expressed immunoglobulin gene sequences of a B lymphocyte under the influence of a particular antigen. The mutations are accumulated non-randomly, such that the end result is an increase in specificity and affinity of binding. This process is dependent on help from T lymphocytes and on the presence of an appropriate antigen. Naked mammalian DNA, however, is a poor immunogen in experimental animals, and the concentration of free DNA in the bloodstream is low even in patients with systemic lupus erythematosus. It is therefore believed that the antigen which stimulates production of high-affinity anti-dsDNA antibodies is probably a complex of DNA and protein. Nucleosomes derived from cell apoptosis may be the most important antigens involved, although a role for viral DNA binding proteins has also been suggested.

How do the autoantibodies exert their pathogenic effects? Deposition of IgG and complement in inflamed tissues such as kidney and skin is a consistent feature of active systemic lupus erythematosus. The pathogenic potential of autoantibodies in systemic lupus erythematosus (particularly IgG anti-dsDNA) may therefore rest upon their ability to deposit in these tissues and to activate complement. However, the role of complement activation has recently been called into question by work showing that knockout mice deficient in both the classical and alternative pathways of the complement cascade still develop a form of glomerulonephritis similar to that seen in systemic lupus erythematosus, but since these mice do not typically produce anti-dsDNA antibodies they may not be an appropriate model of most patients with systemic lupus erythematosus.

Why are anti-dsDNA antibodies deposited in target tissues? Much of the work designed to answer this question has concentrated on autoantibodies in lupus nephritis. Originally, it was felt that DNA–anti-DNA immune complexes would form in the bloodstream and accumulate in glomeruli as the blood was filtered there. It has not been possible to demonstrate large quantities of such complexes in the blood of patients with systemic lupus erythematosus, though their clearance may well be abnormal due to complement deficiency. Anti-dsDNA antibodies may be targeted to the kidney due to cross-reaction with cell surface proteins there, or may deposit due to an interaction with histones and heparan sulphate. According to this latter model, anti-dsDNA antibodies bind to DNA in nucleosomes, and the positively charged histones in these nucleosomes bind to negatively charged heparan sulphate in the renal basement membrane.

Antiphospholipid antibodies

Between 20 and 30 per cent of patients with systemic lupus erythematosus possess serum antiphospholipid antibodies. The origin of these antibodies may be similar to that of anti-dsDNA antibodies since monoclonal antiphospholipid antibodies from patients with systemic lupus erythematosus also show antigen-driven accumulations of somatic mutations. The antigen in this case may be phosphatidylserine on the outer surfaces of blebs derived from apoptotic cells.

The pathological effects of antiphospholipid antibodies are not due to deposition and complement activation but to promotion of thrombus formation. This leads to arterial and venous thromboses that may be particularly harmful in the cerebral and renal circulation. The mechanism by which thrombosis is altered is not fully understood, but it has become clear that antiphospholipid antibodies found in systemic lupus erythematosus and the primary antiphospholipid antibody syndrome recognize a complex of negatively charged phospholipid with the plasma protein b2-glycoprotein 1. Antiphospholipid antibodies found in infectious diseases such as syphilis bind to phospholipids in the absence of this cofactor, and are not associated with increased thrombosis or adverse clinical effects.

T lymphocytes

Since the process of antigen-driven selection of mutations in B lymphocytes is dependent on help from helper T lymphocytes, it would be reasonable to suppose that antigen-specific T cells might also contribute to the pathogenesis of the disease. The isolation of T-cell clones reactive with DNA and/or DNA binding proteins such as histones has been demonstrated from both patients with systemic lupus erythematosus and murine models of the disease. The clones frequently show specificity for histone epitopes that are cryptic (i.e. not exposed) in normal chromatin. These results reinforce the idea that the antigenic stimulus for production of pathogenic T cells and autoantibodies in systemic lupus erythematosus may be a DNA/histone complex rather than DNA alone.

Patients with systemic lupus erythematosus have decreased levels of the subset of T cells carrying the CD4 and CD45Ro surface markers. This population may be involved in stimulation of suppressor T lymphocytes, so that suppression in these patients is insufficient to prevent the production and survival of autoreactive B-lymphocyte and helper T-lymphocyte clones.

Apoptosis and complement

MRL *lpr/lpr* mice are deficient in apoptosis because they lack the Fas protein which plays a major role in promoting this process. These mice develop a disease very similar to systemic lupus erythematosus with death resulting from glomerulonephritis. One possible reason for this might be the failure of the immune system to delete by apoptosis autoreactive clones of T or B lymphocytes which are then able to cause autoimmune disease. By contrast, humans with the equivalent genetic lesion to MRL *lpr/lpr* mice do not develop systemic lupus erythematosus, and other strains of mice show an accumulation of apoptotic debris within nephritic kidneys which resemble those of systemic lupus erythematosus. A simple deficiency in apoptosis is therefore unlikely to be the underlying mechanism in systemic lupus erythematosus.

Apoptosis leads to the production of surface blebs of cellular material. These blebs include a number of the antigens to which autoantibodies develop in systemic lupus erythematosus, notably DNA and associated nuclear proteins and negatively charged phospholipids. A deficiency in the clearance of products of apoptosis has been demonstrated which might allow the production of a wide spectrum of autoantibodies, as found in systemic lupus erythematosus. Removal of immune complexes containing such potentially antigenic material may be compromised in patients with systemic lupus erythematosus. Monocytes derived from such patients show reduced phagocytosis of cell debris *in vitro*. This process may be complement dependent. Humans with homozygous C2 deficiency process immune complexes very differently from normal controls. Administration of fresh frozen plasma to these patients as a source of complement is successful in ameliorating the symptoms of systemic lupus erythematosus and in normalizing (albeit transiently) the processing of immune complexes.

C1q knockout mice develop a form of glomerulonephritis similar to that seen in systemic lupus erythematosus, and their kidneys are characterized by accumulations of apoptotic debris. Similarly, as noted earlier, humans homozygous for C1q deficiency develop a form of systemic lupus erythematosus with the frequent occurrence of nephritis.

The role of cytokines

Cytokines enhance the ability of cells to interact and are therefore critically important in abnormalities in both T- and B-cell functions seen in patients with lupus. Table 3 summarizes the major differences between the different subsets of T helper (T_H) cells in terms of their cytokine profiles and functions. The balance between cytokines from the T_{H1} and T_{H2} cells is essential in determining the outcome of the immune response. Lupus might be expected to be a disease in which T_{H2} cells predominate, resulting in excessive help for B cells and overproduction of antibodies. In support of this notion, increased levels of IL-10 have been found in patients with lupus. This cytokine suppresses T_{H1} cells and thus impairs cell-mediated immunity, a characteristic feature of the disease. Both macrophage and natural killer cell-mediated cytotoxicity are frequently impaired in patients with lupus. g-interferon-induced enhancement of both types of cytotoxicity is also impaired, despite normal levels of g-interferon production by lupus T_{H1} cells.

Accessory cells in lupus seem to produce insufficient amounts of IL-1 to provide the necessary activation signals for T cells. Both CD4+ and CD8+ T cells have been described as producing either normal or decreased amounts of IL-2 in response to exogenous antigens. Such a reduction is likely to have a profound effect on T-cell

responses.

Clinical features of systemic lupus erythematosus

Systemic lupus erythematosus is a chronic condition in which a low level of baseline activity is punctuated by flares of higher activity. The overall severity of the disease in a particular patient depends on the nature and frequency of these flares.

The diverse clinical features of systemic lupus erythematosus mean that the disease may present to any of a number of different specialists, including rheumatologists, dermatologists, nephrologists, and general physicians. It is important to be aware of systemic lupus erythematosus as a possible diagnosis in any patient, especially a woman aged between 15 and 50, in whom a number of different organs are inflamed either simultaneously or sequentially. The frequency of occurrence of symptoms in various organs is shown in Table 4.

According to the diagnostic guidelines published by the American College of Rheumatology (Table 1) systemic lupus erythematosus may be diagnosed where a patient meets at least four of the 11 criteria specified (though not necessarily at a single time). In everyday practice, however, these requirements may be too stringent, and systemic lupus erythematosus is often diagnosed on the basis of typical clinical findings in one organ or tissue combined with the presence of appropriate autoantibodies.

Constitutional symptoms

Patients with systemic lupus erythematosus find fatigue to be the most troublesome feature of the disease. Excessive tiredness is both very common and difficult to treat. Hypothyroidism coexists in 5 to 10 per cent of patients with systemic lupus erythematosus and so thyroid function tests should be performed in the fatigued patient. There is an ongoing debate as to whether fibromyalgia is a significant comorbid condition.

Weight loss and low-grade fever may both be indicative of disease activity. Lymphadenopathy is also recognized. The nodes may be markedly enlarged but show no diagnostic features on biopsy, which may nevertheless be necessary to exclude other conditions such as lymphoma.

Musculoskeletal involvement

Arthralgia is the commonest symptom in systemic lupus erythematosus, occurring in 90 per cent of patients. This may be severe but is rarely associated with frank synovitis. Effusions may occur but the fluid shows no diagnostic features.

Erosive arthritis is uncommon, though up to 5 per cent of patients may have an overlap syndrome with features of rheumatoid arthritis as well as systemic lupus erythematosus. These patients tend to have both serum rheumatoid factor and erosions.

When progressive deformity of the hands does occur in systemic lupus erythematosus, it is usually due to an aggressive tenosynovitis and tendon dysfunction rather than to joint damage. This leads to reversible subluxation of the joints, often known as Jaccoud's arthropathy (Fig. 1 and Plate 1).

Fig. 1 Deforming Jaccoud's arthropathy. (See also Plate 1.)

Development of hip pain in patients who have been treated with corticosteroids should raise the suspicion of avascular necrosis of the femoral head, which may be diagnosed on plain radiograph or, in earlier stages, by magnetic resonance imaging. Corticosteroids also promote osteoporosis, which can be diagnosed in the presymptomatic phase by bone density scanning, but which may present with the acute pain of a vertebral fracture.

Myalgia is common and a true myositis may occur in 5 per cent of cases. Corticosteroid-induced proximal myopathy may also be a problem where these drugs have been used for long periods.

Cutaneous and mucosal involvement

Photosensitivity is very common, particularly in white female patients. Patients should be advised to avoid strong sunlight and to wear protective clothing and/or a high-factor sunblock.

The butterfly rash over the malar area of the face occurs in up to one-third of patients (Fig. 2 and Plate 2). A number of other forms of cutaneous involvement can occur, although these are less specific for systemic lupus erythematosus. These include maculopapular rash, discoid lesions, alopecia, and nailfold infarcts. Scarring alopecia may be particularly distressing and difficult to treat (Fig. 3 and Plate 3).

Fig. 2 Malar 'butterfly' rash. (See also Plate 2.)

Fig. 3 Severe scarring alopecia. (See also Plate 3.)

A variant of systemic lupus erythematosus in which cutaneous manifestations dominate is known as subacute cutaneous lupus. This condition is often associated with anti-Ro antibodies and may be exacerbated by smoking cigarettes.

Antiphospholipid antibodies are associated with a non-raised lattice-like rash concentrated particularly over the thighs and arms. This rash is termed livedo reticularis (Fig. 4 and Plate 4).

Fig. 4 Livedo reticularis. (See also Plate 4.)

Painless oral ulcers are common enough to be recognized as one of the diagnostic criteria for systemic lupus erythematosus. However, they are rarely troublesome for the patient. Approximately 20 per cent of patients develop secondary Sjögren's syndrome. The dry eyes and mouth in this condition may respond to artificial tears and saliva.

Renal involvement

Glomerulonephritis is the most serious and potentially lethal manifestation of systemic lupus erythematosus. Its presence may be detected by the finding of haematuria and/or proteinuria on routine stick testing of the urine. It may present as the nephrotic syndrome, or less commonly as a florid nephritis with haematuria, proteinuria, hypertension, and acute renal failure with red cell casts in the urine. The diagnosis and management of glomerulonephritis in systemic lupus erythematosus are more fully discussed in Chapter 20.10.4.

It is important to be aware of the possibility of glomerulonephritis in any patient with systemic lupus erythematosus (Fig. 5 and Plate 5). Measurement of blood pressure and analysis of urine should be carried out at each consultation. Early diagnosis and treatment are invaluable in avoiding deterioration of renal function to the extent that dialysis or renal transplantation become necessary.

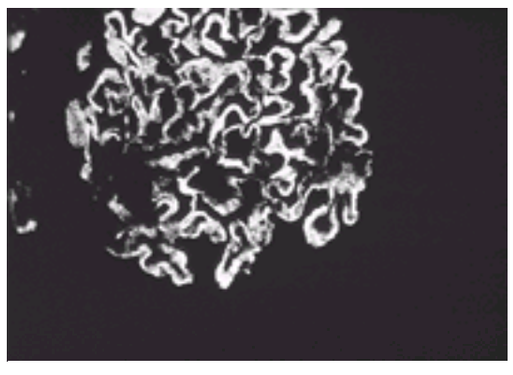

Fig. 5 Immunofluorescence microscopy showing deposition of IgG in the glomerulus of a patient with lupus nephritis. (See also Plate 5.)

Patients with antiphospholipid antibody syndrome may develop a different type of renal lesion characterized by thrombi in small renal vessels rather than by glomerulonephritis. These patients develop hypertension and impairment of renal excretory function, detected as a fall in creatinine clearance, rather than proteinuria and are best managed by anticoagulation rather than immunosuppression.

Respiratory involvement

The commonest form of respiratory involvement in systemic lupus erythematosus is pleuritis, manifesting either as pleuritic chest pain or breathlessness caused by pleural effusion. The lung parenchyma is more rarely involved, but fibrosis can occur.

A patient with systemic lupus erythematosus may present with shortness of breath or chest pain for a number of reasons. Pulmonary emboli must be suspected in those with antiphospholipid antibodies. Infections are common in immunosuppressed patients and rib fractures may occur, particularly in those rendered osteoporotic by treatment with corticosteroids.

The shrinking lung syndrome is characterized by reduced lung volumes and poor respiratory reserve in the face of a normal appearance of the lung parenchyma on computed tomography scanning. It is believed to arise from basal atelectasis in association with diaphragmatic dysfunction.

Cardiovascular involvement

The commonest cardiac manifestation of systemic lupus erythematosus is pericarditis, which occurs in approximately 15 per cent of patients. This generally presents

with chest pain or an asymptomatic friction rub. Pericardial effusions may occur but are rarely large enough to cause haemodynamic compromise.

Myocarditis and endocarditis are less common, though post-mortem and echocardiographic studies suggest that both may occur without symptoms in a significant proportion of patients with systemic lupus erythematosus. For example, the classic endocarditis described by Libman and Sacks is characterized by small vegetations that often do not cause murmurs or cardiac compromise, but which have been identified in up to 50 per cent of patients with systemic lupus erythematosus at autopsy.

It is increasingly recognized that atherosclerosis and the attendant deficiencies of cerebral and cardiac circulation are commoner in patients with systemic lupus erythematosus than in the general population. This may be partially due to the use of corticosteroids, which raise serum cholesterol and can promote hypertension. Patients possessing antiphospholipid antibodies are also at a higher risk of stroke or arterial thrombosis.

Raynaud's phenomenon occurs in about one-third of patients with systemic lupus erythematosus, though it is not usually as severe as that seen in systemic sclerosis. Vasculitis presents with a skin rash or ulcers that may be very difficult to heal, but rarely affects the internal organs.

Gastrointestinal involvement

Like pleuritis, peritonitis may occur in patients with systemic lupus erythematosus and must be considered in the event of abdominal pain.

Involvement of the liver and pancreas is recognized but uncommon. The term 'lupoid hepatitis' was previously used for a form of autoimmune hepatitis characterized by the presence of autoantibodies. These patients, however, do not generally have any form of systemic lupus erythematosus and the term is misleading. Minor enlargements of the liver and/or spleen occur in 10 to 25 per cent of cases but these are usually asymptomatic and require no treatment.

H4>Neuropsychiatric involvement

Systemic lupus erythematosus can affect the central nervous system in many ways, so that the true incidence of this type of involvement is difficult to quantify. Symptoms such as poor memory, change of personality, and depression or anxiety occur in many patients. It is difficult, however, to be sure whether these are caused by cerebral systemic lupus erythematosus or represent a reaction to the diagnosis and treatment of the disease.

More florid presentations such as psychotic episodes and convulsions are well recognized. By contrast to the milder symptoms noted above, these manifestations generally call for immunosuppression.

Migraine occurs in up to 40 per cent of patients with systemic lupus erythematosus, particularly in the presence of antiphospholipid antibodies. Peripheral neuropathy can occur, and is usually sensory rather than motor. Cranial nerve palsies are less common, as is transverse myelitis (another feature linked to antiphospholipid antibodies).

Ocular involvement can include episcleritis, conjunctivitis, and the presence of cytoid bodies (white patches on the retina). Patients treated with high-dose steroids may develop cataracts.

Haematological involvement

A normochromic normocytic anaemia is frequently seen in systemic lupus erythematosus, particularly during periods of high disease activity. Microcytic iron-deficiency anaemia may be present due to blood loss from gastritis and ulcers in patients treated with non-steroidal anti-inflammatory drugs. Anaemia may also result from chronic renal failure in lupus nephritis.

A positive Coombs' test, signifying the presence of antibodies to red blood cells, is present in 10 to 15 per cent of patients with systemic lupus erythematosus but does not always indicate haemolytic anaemia.

The presence of lymphopenia (less than 1.5×10^9 per litre) is a common feature, occurring in up to 80 per cent of patients. Neutropenia may occur secondary to the use of cytotoxic drugs such as azathioprine or cyclophosphamide.

Three different types of thrombocytopenia occur in systemic lupus erythematosus. The mildest form is characterized by stable platelet levels of between 50 and 100×10^9 per litre, is rarely symptomatic, and usually requires no treatment. Other patients develop an acute autoimmune thrombocytopenia with levels dropping rapidly below 10×10^9 per litre, but rising when treated with oral steroids. A third group of patients present with thrombocytopenia alone, are treated with steroids, intravenous immunoglobulins, or splenectomy and some years later develop full-blown systemic lupus erythematosus. Thrombocytopenia is also one of the cardinal features of the antiphospholipid antibody syndrome and may be severe enough to necessitate splenectomy in that condition.

Other complicating disorders

Approximately 30 per cent of lupus patients have another autoimmune condition. Sjögren's syndrome is the commonest of these, being present in some 15 to 20 per cent of patients with systemic lupus erythematosus. In the past 15 years it has been recognized that clinical features of the antiphospholipid antibody syndrome, notably venous and arterial thromboses, recurrent miscarriages, thrombocytopenia, and livedo reticularis, may complicate 10 to 15 per cent of patients with systemic lupus erythematosus. When these features, together with the presence of antiphospholipid antibodies (usually cardiolipin, anti-b2-glycoprotein 1 or the lupus anticoagulant) occur in the presence of other more classical lupus features, the condition is known as secondary antiphospholipid syndrome, but they can occur on their own, in which case the patient is said to have primary antiphospholipid syndrome as described elsewhere. Autoimmune thyroid disease (hyper- or hypothyroidism) occurs in 5 to 10 per cent of the patients, and rather less frequently, rheumatoid arthritis, myasthenia gravis, coeliac disease, diabetes, and pernicious anaemia may be found.

Investigations and pathology

Autoantibodies

The most commonly requested test to screen for systemic lupus erythematosus is the antinuclear antibody assay. A positive antinuclear antibody simply indicates that the patient's blood contains antibodies which will bind to the nuclei of a sample of cells used in the test. The test is a sensitive one since over 95 per cent of patients with systemic lupus erythematosus are antinuclear antibody positive. Although a small group of patients do seem to have persistently antinuclear antibody negative systemic lupus erythematosus, the absence of antinuclear antibody in a patient with suspected lupus raises serious doubt about the diagnosis.

The specificity of the antinuclear antibody test for systemic lupus erythematosus is not high. The titre of antibody represents the highest dilution of the patient's serum at which the test is still positive. Low-titre antinuclear antibody (1 in 10) is of little significance and may occur in healthy people. Higher titres (1 in 160 or more) are more worrying and are found in most patients with systemic lupus erythematosus and in a few patients with other autoimmune conditions including rheumatoid arthritis, systemic sclerosis, and Sjögren's syndrome. However, some people with high-titre antinuclear antibody may be followed in rheumatology clinics for years without developing a frank autoimmune disease.

The finding of a positive antinuclear antibody in a patient with symptoms suggestive of systemic lupus erythematosus should lead to a series of other autoantibody tests. These are listed in Table 2 together with the identity of the target antigen and the approximate prevalence of the antibodies.

Anti-dsDNA antibody levels are particularly useful. This test is virtually specific for systemic lupus erythematosus (as is the anti-Sm antibody), especially if the immunoglobulins are of the IgG isotype. The anti-dsDNA result is usually quantified and this value is a measure of the activity of the disease. Indeed, in one study, trial patients were treated with high-dose corticosteroids on the basis of anti-dsDNA levels alone. In comparison with a control group treated only when symptoms or signs also suggested disease activity, the trial group had less disease activity overall and fewer flares. However, frequent large doses of corticosteroids resulted in significant side-effects and a number of subjects dropped out of this arm of the trial. The current evidence therefore suggests that anti-dsDNA should be used only as

an adjunct to the clinical impression of disease activity when deciding on a treatment regimen.

Anti-Ro and anti-La antibodies are linked to concurrent Sjögren's syndrome. Mothers who have these antibodies have a higher incidence of neonatal lupus (see below) and should be advised about this before embarking upon a pregnancy. Anti-Ro antibodies are also associated with photosensitivity.

There are no good antibody markers for the presence of disease of the central nervous system. Antibodies to ribosomal protein P were previously thought to have some value in the diagnosis of central nervous system lupus, but this has not been borne out by later results and the test is not available routinely in most laboratories.

Antiphospholipid antibodies can be recognized by one of two assays. The enzyme-linked immunosorbent assay for binding to cardiolipin distinguishes IgM and IgG isotypes. This is helpful because the level of IgG antiphospholipid antibodies is a better predictor of clinical sequelae than that of IgM. Antiphospholipid antibodies can also be diagnosed by testing the clotting properties of the blood *in vitro* in the Russell's viper venom test. An abnormal result in this assay is reported as showing the presence of a lupus anticoagulant. It is quite possible for the anticardiolipin test to be positive while the lupus anticoagulant assay is negative or vice versa. If either is positive, the patient may be at risk of manifestations of the antiphospholipid antibody syndrome. Antibodies to the phospholipid cofactor, known as b2-glycoprotein 1, are now becoming available commercially, offering a third way of detecting antiphospholipid antibodies.

Coombs' test and assays for antithyroid antibodies are often requested in patients with systemic lupus erythematosus, particularly those with coexisting anaemia or hypothyroidism.

Measures of disease activity and end-organ damage

Blood and urine tests

The three most reliable measures of highly active disease are high erythrocyte sedimentation rate, depletion of complement, and high anti-dsDNA levels. The erythrocyte sedimentation rate increases much more than the level of C-reactive protein in active systemic lupus erythematosus. The combination of high erythrocyte sedimentation rate and normal C-reactive protein in a patient with a multisystem disorder should raise the suspicion of systemic lupus erythematosus, leading to appropriate autoantibody tests as described above. The C-reactive protein may, however, be raised in the presence of infection, serositis, or arthritis.

Complement components C3 and C4 are the most commonly measured, and both tend to fall in active systemic lupus erythematosus. A persistently very low level of either C3 or C4 (or a high level of their degradation products C3d or C4d), regardless of immunosuppressive therapy, may signify the presence of a homozygous complement deficiency disorder. Though such disorders are very rare, it is important to diagnose them because they respond better to infusions of fresh frozen plasma than to immunosuppression.

It is important to measure creatinine and electrolyte values regularly and to check the urine for proteinuria and/or haematuria. These measures ensure that renal involvement is diagnosed early. It must be remembered that substantial deterioration in renal function may occur before serum creatinine rises beyond the normal range. It is therefore prudent to note even relatively small rises in creatinine if these are persistent. Renal function may be measured more accurately by creatinine clearance using a 24-h collection of urine or by measuring the clearance of a radio-isotope to obtain the glomerular filtration rate. Persistent proteinuria on bedside testing can be investigated further by measuring the total protein in a 24-h urine sample or the albumin to creatinine ratio in a spot sample.

Liver function tests are not usually abnormal in systemic lupus erythematosus (abnormal in less than 10 per cent of patients), but a baseline value should be measured, particularly in cases where potentially hepatotoxic drugs such as azathioprine may be used. Thyroid function abnormalities, particularly hypothyroidism, are well recognized to coexist with systemic lupus erythematosus.

A full blood count should be measured regularly. Falling haemoglobin, white cell count, and platelet counts may all occur (see under haematological involvement above). Anaemia in the presence of a positive Coombs' test may indicate haemolysis which can be confirmed by requesting a blood film and serum haptoglobins.

Infections occur commonly in patients with systemic lupus erythematosus, particularly in those on high-dose immunosuppressants. Infection may not always be accompanied by high fever or leucocytosis, although C-reactive protein is usually raised. It is wise to carry out blood and urine cultures whenever even mild pyrexia is accompanied by a deterioration in health.

Imaging

Plain radiographs are rarely useful in systemic lupus erythematosus. There is no characteristic appearance in the joints and chest radiographs are unlikely to show abnormalities except in the presence of infection or effusion.

Requests for more specialized imaging studies should be directed by the clinical findings. For example, the presence of dyspnoea and abnormal respiratory function tests often necessitates a computed tomography scan of the thorax, which is the investigation of choice for diagnosis of pulmonary fibrosis. Echocardiography is useful if pericardial effusion, myocarditis, or endocarditis are suspected clinically. Bone density scanning is becoming increasingly important, since patients with systemic lupus erythematosus are often at risk of osteoporosis due to use of corticosteroids and reduced capacity for physical exercise during young adult life.

Histopathology

The two tissues most often subjected to biopsy in systemic lupus erythematosus are the skin and kidneys.

Skin biopsies are chiefly carried out to facilitate the diagnosis of an atypical rash. If systemic lupus erythematosus is suspected, it is important to take a sample of apparently normal skin as well as skin from the rash. Both should show deposition of IgG and complement at the dermoepidermal junction (Fig. 6 and Plate 6).

Fig. 6 Immunofluorescence microscopy showing deposition of IgG at the dermoepidermal junction in the skin of a patient with systemic lupus erythematosus (sometimes called the lupus band test). (See also Plate 6.)

There are two main indications for renal biopsy in the patient who has, or might have, systemic lupus erythematosus. Firstly, to establish the diagnosis when this is not certain, for example in a patient with poorly characterized multisystem disease with renal involvement. Secondly, to help determine prognosis and decide upon treatment in the patient known to have systemic lupus erythematosus, but with deterioration in renal function, for example development of nephrotic syndrome and/or declining renal excretory function. The activity of glomerular inflammation is graded on a scale of I to V according to World Health Organization criteria. The biopsy can also be used to grade the degree of chronicity of glomerular disease, i.e. how much irreversible damage such as fibrosis and atrophy has occurred. The activity

and chronicity scores can both be used to determine appropriate treatment and the risk of a progressive decline in renal function, although the predictive value of such data remains controversial. The subject of renal pathology in systemic lupus erythematosus is considered further in Chapter 20.10.4.

Treatment and prognosis

Systemic lupus erythematosus is a disease that still has the potential to kill young people. In many cases, however, the condition runs a fairly indolent course in which an initial flare is followed by many years of low-grade activity. General measures of value in the treatment of systemic lupus erythematosus are shown in Table 5.

In the pharmacological management of a patient with systemic lupus erythematosus, the clinician will typically seek to answer four questions:

1. Can the patient be managed without immunosuppression?
2. If immunosuppression is needed, how should it best be started?
3. If immunosuppression is being used, is the current level of immunosuppression inadequate or excessive? How should it be increased or reduced?
4. Is the patient suffering side-effects from the drugs?

Is immunosuppression required?

Patients whose disease activity is confined to arthralgia, tiredness, and/or mild rash do not usually have greatly raised erythrocyte sedimentation rate or anti-dsDNA antibodies or reduced complement. These patients can often be treated symptomatically, for example with agents such as paracetamol and diclofenac to control joint pain.

Where such symptoms are more severe, the antimalarial agent hydroxychloroquine at a starting dose of 400 mg per day may be useful. This drug has less potential for retinal toxicity than the closely related chloroquine and is therefore preferred in systemic lupus erythematosus. It is often possible to reduce the dose to 200 mg per day after 3 months and gradually withdraw the drug thereafter. Regular blood tests are not required to monitor the effects of hydroxychloroquine, but there is a very small risk of retinopathy such that review by an ophthalmologist every 6 to 12 months is considered advisable in many units.

Where the main symptoms in a patient with systemic lupus erythematosus are those of the antiphospholipid antibody syndrome immunosuppression is rarely useful. Aspirin at a dose of 150 to 300 mg daily is recommended for those with mild symptoms of the disease or who have other risk factors for thrombosis. Patients who have suffered recurrent thromboses or cerebral infarcts and who have serum antiphospholipid antibodies should usually be treated with lifelong anticoagulation. This is a major commitment for a young patient and raises particular problems in pregnancy (discussed below).

Some patients require a low maintenance dose of oral steroids to control their symptoms even though laboratory indices do not indicate high activity of disease. A dose of 5 to 7.5 mg daily is typically used in such cases. Topical steroids may be useful where lupus activity is confined to the skin.

Is the current level of immunosuppression inadequate or excessive?

Corticosteroids and cytotoxic agents are used to treat flares of disease. A mild flare of arthralgia, myalgia, and general fatigue may be alleviated by a single intramuscular dose of a corticosteroid preparation such as prednisolone acetate (usually 50 to 125 mg are given).

More severe flares of arthritis, pleuritis, or pericarditis require oral prednisolone at a dose of 20 to 40 mg daily. This usually leads to a rapid improvement in symptoms and the dose of prednisolone can be reduced by 5 mg every 1 to 2 weeks until it reaches 5 mg per day. It may not be possible to withdraw the drug completely for several months.

Alternatively, a shorter course of corticosteroids can be given intravenously. A typical course would consist of 750 mg to 1 g of methylprednisolone given over 3 to 4 h on each of three successive days. This requires admission to hospital, making it less convenient than oral therapy, and it is generally reserved for those patients who are not responding to oral prednisolone or cannot tolerate that drug in high doses.

Autoimmune haemolytic anaemia requires higher doses (60–80 mg/day) of oral prednisolone, with the dose reduced in 5 to 10 mg increments according to the clinical response. Azathioprine may be required as a steroid-sparing agent and is used at a dose of 2.5 to 3 mg/kg/day.

Renal flares of systemic lupus erythematosus require the most aggressive treatment, generally involving both corticosteroids and cyclophosphamide. A number of regimes have been used and a debate continues as to which is optimal. One of the most common regimes is that recommended by the United States National Institutes of Health, in which the patient is given oral prednisolone at a dose of between 30 and 80 mg/day depending on the severity of the disease. Intravenous boluses of 750 mg to 1 g cyclophosphamide are given at monthly intervals for 6 months, then every 3 months for 2 years. Cyclophosphamide pulses should be accompanied by adequate intravenous hydration and the use of mesna (mercaptoethane sulphonate) to reduce bladder toxicity. It has been suggested that the use of intravenous pulse therapy is preferable to treatment with oral cyclophosphamide on the grounds of improved compliance and less gonadal dysfunction. The latter claim has not been proved beyond doubt and some groups use oral cyclophosphamide (2–4 mg/kg/day) or oral azathioprine (2–3 mg/kg/day) per day as an alternative to intravenous pulses.

In renal systemic lupus erythematosus it is critically important to control the patient's blood pressure. ACE inhibitors, alpha-adrenergic antagonists such as doxazosin, and calcium channel blockers such as nifedipine are the agents most commonly used.

The treatment of central nervous system lupus varies depending on the manifestation of cerebral dysfunction. Mild cases may respond to relatively small doses of oral steroids (up to 30 mg per day). More florid manifestations such as convulsions or major psychosis require treatment with appropriate anticonvulsants or antipsychotic drugs, higher-dose oral steroids (60–80 mg per day), and sometimes azathioprine or intravenous pulses of cyclophosphamide in similar doses to those used in renal systemic lupus erythematosus.

Is the patient suffering side-effects from the drugs?

The side-effects of corticosteroids are well known. The most common early problems are weight gain, hirsutism, easy bruising, and insomnia. It is difficult to prevent them, except by using the lowest dose of steroid that is effective and reducing it as rapidly as possible whilst maintaining control of the disease.

Longer-term sequelae of corticosteroid use include increased susceptibility to infection, osteoporosis, avascular necrosis, and diabetes mellitus. The most rapid loss of bone in steroid-induced osteoporosis occurs within the first year of treatment, though doses of 7.5 mg/day or less of prednisolone are thought to have little effect on bone. At higher doses, it may be advisable to carry out a bone density scan and to give either calcium and vitamin D tablets or a bisphosphonate (either etidronate or alendronate are commonly used) as prophylaxis.

Cyclophosphamide causes alopecia, nausea, bladder toxicity, and gonadal dysfunction that may lead to infertility. The problem of infertility becomes more likely with increasing age. Women over 30 given cyclophosphamide are at particular risk. Again, the best way to prevent such problems is to use as small a cumulative dose of the drug as is feasible. Bone marrow suppression may occur. During a programme of cyclophosphamide pulses, the white blood cell count falls to a nadir 10 days after each pulse and should be measured at that time to decide whether the next pulse can be given safely. Nausea and vomiting during pulses may be so severe that antiemetics such as metoclopramide or granisetron are necessary.

Azathioprine also causes bone marrow suppression and can cause abnormalities of liver enzymes which resolve once the drug is withdrawn.

Systemic lupus erythematosus in pregnancy

Systemic lupus erythematosus itself does not usually reduce the ability to conceive, although as described the drugs used to treat it, notably cyclophosphamide, may induce infertility due to gonadal failure. There is an increased risk of spontaneous abortion, particularly in the presence of high-titre antiphospholipid antibodies. Pregnant mothers with a high antiphospholipid antibody level and a history of previous miscarriage should be considered for anticoagulation until the birth of the baby.

Since warfarin is potentially teratogenic, heparin may be used from the second trimester until parturition.

Mothers often ask whether their children are likely to inherit systemic lupus erythematosus. Inheritance of the adult form of the disease is very rare (approximately 1 per cent of all cases), though a transient illness termed neonatal lupus can occur. The characteristics of this condition are rash, hepatitis, anaemia, and thrombocytopenia which usually resolve by 8 months after birth, and inflammation of the cardiac conducting tissues which may lead to heart block in the fetus. The cardiac problem may be diagnosed by ultrasound scans of the fetal heart between 16 and 24 weeks' gestation. Treatment of the mother with 4 mg oral dexamethasone per day may prevent progression from incomplete to complete fetal heart block. If complete heart block occurs, the neonate may require a cardiac pacemaker. Interestingly, children born with neonatal lupus sometimes develop heart block later in life. In one reported case this problem occurred at the age of 35.

The presence of maternal anti-Ro and anti-La antibodies predicts a higher risk of neonatal lupus. Where both are present the risk is approximately 5 per cent. It is believed that the antibodies cross the placenta and bind to some component of the fetal cardiac tissue (laminin is a particular 'suspect'). The mechanism whereby this leads to heart block is mysterious, especially as the mother's heart is never affected.

Although overall the risk of a flare during pregnancy is probably no greater than at other times, systemic lupus erythematosus may exacerbate during the pregnancy. Corticosteroids may be used in moderate doses without affecting the fetus, but higher doses (over 30 mg) given for long periods can potentially cause fetal adrenal suppression. If lupus activity is such that these doses are required, the risk to the fetus of not treating the disease adequately should outweigh any risk from the drug.

Cyclophosphamide, methotrexate, and azathioprine are contraindicated in pregnancy, although there have been many successful pregnancies in transplant patients taking azathioprine without obvious increased risk of adverse effect. Use of hydroxychloroquine is not recommended by the manufacturers, though there is little evidence that it has adverse effects.

It may be difficult to distinguish pre-eclampsia from a flare of renal lupus. Both can cause hypertension and proteinuria. In pre-eclampsia, unlike systemic lupus erythematosus, there are rarely urinary casts and levels of anti-dsDNA and complement are normal. These tests are therefore useful in making the diagnosis.

For further discussion of autoimmune rheumatic disorders in pregnancy see Chapter 13.14.

Occupational and psychological aspects of systemic lupus erythematosus

Systemic lupus erythematosus typically presents in young people, especially women. The onset of a chronic, essentially incurable condition at a time of life when the patient is otherwise healthy and has many plans and responsibilities is an unexpected and unwelcome burden. Many concerns arise, in particular the outlook for fertility and the ability to care for children are major worries. In those cases where the use of high-dose corticosteroids and immunosuppressive agents are essential, detailed explanations of the benefits and risks of these treatments in both the short and long term are necessary. Although a 10-year survival rate of 90 per cent may appear reassuring, it is probably less so to a 25-year-old who recognizes a 10 per cent chance of dying by the age of 35.

In making the diagnosis of systemic lupus erythematosus, therefore, the doctor must consider the effect of this condition on the overall life of the patient as well as his or her individual organs. A sympathetic understanding of the anxieties associated with the diagnosis is vital.

Controversial areas and future prospects

It is clear that we do not yet possess a cure for systemic lupus erythematosus or even a method of controlling the disease without the risk of major side-effects. The main sources of controversy concern attempts to develop new forms of treatment and to establish indices of disease activity that can be used to measure the effects of these treatments.

Plasma exchange and intravenous immunoglobulin therapy have been tried in systemic lupus erythematosus, particularly in renal crises. Overall, the results do not suggest that either form of treatment should be used routinely. New drugs such as tacrolimus and mycophenolate mofetil have been administered to small numbers of patients. Some encouraging results have been reported, but it is too early to decide on the place of these agents in the management of the disease.

There are now many different murine models of systemic lupus erythematosus. These differ in their clinical and serological characteristics and each represents at best a partial approximation to the human disease. This is important because it is now possible to administer agents such as monoclonal anticytokine antibodies to these mice and to assess the effect on the disease process. In deciding which of these agents might be effective in humans it is important to know how far one can extrapolate from the results in mice.

If new drugs or monoclonal antibodies are to be used in human systemic lupus erythematosus, it is necessary, given that mortality is now (thankfully) a rare end point, to have a recognized index by which to judge the response to treatment. Such an index must include a disease activity index, a damage index, a patient health perception index, a record of toxicity, and cost. Several global score disease activity indices, for example the systemic lupus erythematosus disease activity index, SLAM (systemic lupus activity measure), and ECLAM (European Community lupus activity measure) have been developed and provide a 'rough and ready' guide to activity. A more sophisticated approach based on the 'physician's intention to treat principle', has been derived by the British Isles Lupus Activity Group, providing an 'at a glance' review of activity in eight different organs or systems. These indices have all been compared favourably in both paper and real patient exercises. By contrast, a single damage index (the SLICC/ACR damage index) has been developed by a group of investigators and records a wide variety of potential permanent changes (for example avascular necrosis, myocardial infarction) that can occur in patients with lupus as part of the development of the disease. These principally clinical features have to be present for at least 6 months before they count. The medical outcome survey, short form 36 (SF-36), provides a useful health perception index for patients with lupus. Although not designed specifically for this condition, it has been widely used in a number of ongoing drug trials.

It is likely that the treatment of systemic lupus erythematosus in 10 years' time will be different from that given now. Basic science research is starting to identify the various strands of immune dysfunction at the core of this disease. At the same time, drug development is providing agents that are capable of selectively targeting single cell types or cytokines within the immune system. At least some of these agents are likely to be relevant to the dysfunctional mechanisms in systemic lupus erythematosus. In addition, clinicians are becoming more aware that conditions such as atherosclerosis and osteoporosis are common in patients with systemic lupus erythematosus. By increasing efforts to detect and control these associated conditions, as well as seeking to attack the underlying autoimmune disease, it should be possible to improve the lives of patients with systemic lupus erythematosus, even if a cure for the disease remains a distant prospect.

18.10.3 Systemic sclerosis

Carol M. Black and Christopher P. Denton

Introduction

The scleroderma-spectrum of disorders includes a number of diseases with similar clinical and pathological features, and which have Raynaud's phenomenon or skin sclerosis in common. They are clinically important because the systemic forms have the highest case-related mortality of any of the rheumatic diseases, and because of the particular difficulties encountered in their management. In the United Kingdom there are approximately 300 new cases of systemic sclerosis per year and the population prevalence has been estimated to be 100 per million. Both these figures are significantly lower than estimates of disease frequency in the United States. Recent epidemiological survival analyses of patients with systemic sclerosis suggest a reduction in mortality compared with earlier studies, but this may partly be accounted for by the greater awareness of the milder forms of the disease. The disease most often develops in the fifth decade of life, and affects women approximately four times as often as men, with this ratio increasing during the childbearing years.

Those disorders included within the scleroderma spectrum are described in Table 1. The term 'prescleroderma' can be applied to the subgroup of patients with autoimmune Raynaud's phenomenon who manifest an abnormal microcirculation and scleroderma-hallmark autoantibodies (anticentromere antibodies, antitopoisomerase, or anti-RNA polymerase I).

Clinical features of localized scleroderma conditions are summarized in Table 2. The importance of distinguishing between these conditions and their subsets lies in the different clinical features, natural history, and patterns of visceral involvement that are characteristic of each subgroup.

There have been important developments in understanding the pathogenesis, clinical diversity, and management of the scleroderma-spectrum disorders over the last few years. This progress has occurred in parallel with improvements in the management of many of the organ-based complications of the condition.

Clinical features

Although thorough baseline and longitudinal investigation of patients with scleroderma-spectrum disorders is central to their management, the diagnosis of scleroderma is essentially clinical. A number of other causes of skin sclerosis or poor peripheral circulation must be considered in the differential diagnosis (summarized in Table 3). Marked differences between the major subsets of systemic sclerosis in the pattern and time-course of clinical features allow most patients to be characterized into the appropriate subset.

Patients with diffuse, cutaneous systemic sclerosis typically present over 1 to 3 years with widespread changes in skin texture, puffy oedematous extremities, generalized pruritis, and profound constitutional and inflammatory symptoms. Vasospastic symptoms are not usually prominent during the early stages, although within 18 months of their onset most patients will describe definite Raynaud's phenomenon. By contrast, the cutaneous and vasospastic symptoms of limited cutaneous systemic sclerosis are very different. The onset of skin changes is more gradual, often preceded by several years of Raynaud's phenomenon, often becoming progressively more severe, with skin sclerosis limited to the face, neck, and hands distal to the wrists. The main differences between the subsets of systemic sclerosis are summarized in Table 4.

Raynaud's phenomenon

Raynaud's phenomenon is characterized by pallor, cyanosis, suffusion, and/or pain of the fingers in response to cold or stress. The same process can also affect the toes, ears, nose, or jaw. It is present in up to 15 per cent of otherwise healthy individuals. About 1 per cent of those showing the phenomenon develop a connective tissue disease. Other conditions associated with Raynaud's phenomenon include cervical rib, vibration white finger, hypothyroidism, and uraemia. Cold-induced peripheral vasospasm is present in the majority of patients with systemic sclerosis, although generally not in those with localized forms of scleroderma.

It is important to distinguish between the primary and secondary forms of Raynaud's phenomenon. This is most reliably achieved by combining nailfold capillaroscopic assessment with autoantibody testing. Primary Raynaud's phenomenon cases are often familial, typically with onset in the late teens or early adulthood, have normal or only minimally disrupted capillaroscopic architecture, and negative antinuclear antibody tests. Those who present with isolated Raynaud's phenomenon but later develop a connective tissue disease invariably have abnormal autoimmune serology and nailfold capillary studies before they develop associated clinical features. Patients who demonstrate antibodies, including hallmark specificities for lupus or systemic sclerosis, may be designated as having autoimmune Raynaud's phenomenon.

Limited cutaneous systemic sclerosis

This was formerly termed '**CREST**' (calcinosis circumscripta, Raynaud's, (o)esophagus, sclerodactyly, and telangiectasia) and is the most common form of systemic sclerosis, accounting for over 60 per cent of cases. Patients are usually women, between 30- and 50-years old, with longstanding Raynaud's phenomenon.

Early in the disease there is non-pitting oedema of the fingers (sausage-shaped fingers), which, after several weeks or months, is gradually replaced by thickened and shiny skin. This is not usually so closely adherent to underlying structures that mobility is severely impaired, which is in sharp contrast to the findings in those with diffuse disease. Skin involvement does not spread proximally on to the trunk, but the face should be examined carefully for thin, tightly pursed lips, with furrowing and puckering of the surrounding skin, and microstomia. The most striking cutaneous finding is digital and facial telangiectasia caused by dilated capillary loops and venules (Fig. 1). Other evidence of structural vascular change is to be seen in the fingertips, where small areas of ischaemic necrosis or ulceration are common, often leaving pitting scars and pulp atrophy. Loss of the tufts of the terminal phalanges, confirmed on radiography, is also presumed to be due to ischaemia. Patients with limited cutaneous disease often develop intracutaneous and subcutaneous calcification. These deposits frequently occur in the fingers, particularly the digital pads, and in periarticular tissues such as the prepatellar area and olecranon bursa. The calcinotic masses vary in size and are often complicated by ulceration of the overlying skin, extrusion of calcific material, and secondary bacterial infection. Patients may complain of dyspepsia from reflux oesophagitis: this and other visceral

complications are discussed in detail below.

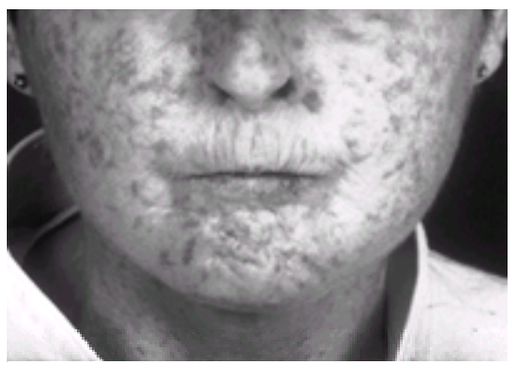

Fig. 1 This patient shows the typical facial features of limited cutaneous systemic sclerosis—microstomia, furrowing, and puckering of the skin around the mouth, beaking of the nose, and telangiectasia on the lips and face.

Diffuse cutaneous systemic sclerosis

By contrast to limited cutaneous systemic sclerosis, the onset of diffuse disease is often abrupt. It may present with widespread, symmetrical, sometimes itchy, painful swelling of the fingers, arms, feet, legs, and face. Rapid weight loss and constitutional symptoms of fatigue or weakness are frequent. If a patient with early disease presents with headache, blurring of vision, and significant hypertension, then this is a medical emergency, portending hypertensive renal crisis and requiring immediate action (see below).

The clinical findings in diffuse scleroderma depend on the stage of the disease. At onset, examination of the skin will usually reveal cold, painful, swollen hands, with swelling and stiffness already extending to the arms, feet, lower legs, face, and trunk. This oedematous phase is usually replaced within a few months by one of induration, when the skin becomes tight, shiny, and bound to underlying structures. Pigmentary changes (hyperpigmentation or hypopigmentation) accompany skin thickening in many patients. Skin involvement in diffuse scleroderma is quite different from that in the limited form of the disease, and can be mapped semiquantitatively by measuring the degree and extent of cutaneous thickening at multiple sites, from which is derived a skin score. In diffuse scleroderma this score increases rapidly at first, often peaking after 1 to 3 years, and is accompanied by impaired mobility of tendons, joints, and muscles that is clinically all too apparent. Contractures and stretching of the skin over bony points often lead to painful ulcers that are slow to heal, particularly over the proximal interphalangeal joints, elbows, and ankle malleoli.

In its earliest stages, diffuse scleroderma can be confused with an acute inflammatory arthropathy, particularly if Raynaud's phenomenon is absent. The oedematous puffy skin is often accompanied by symmetrically stiff, painful joints (hands, feet, knees, ankles, and wrists), but the classic synovitis of rheumatoid arthritis is usually absent. The clinical sign of tendon friction rubs should carefully be sought in this group of patients: these have a distinctive leathery crepitus and can be elicited during joint movement over elbows, knees, fingers, wrists, and ankles. They frequently antedate a rapid increase in cutaneous involvement, or the onset of visceral disease. Signs of carpal tunnel syndrome may be present, due to flexor tenosynovitis at the wrist.

Mild muscle disease is common and can be detected on examination, but is not usually accompanied by an increase in plasma creatine kinase or inflammatory changes on muscle biopsy. It is generally non-progressive. The few patients with florid changes of polymyositis are usually classified as having an overlap syndrome. As with limited disease, evidence of structural vascular damage—sometimes extensive—may be found in the nailfold capillaries and the digital pads.

Scleroderma sine scleroderma

These patients constitute less than 2 per cent of those with systemic sclerosis, but they are the most difficult group to recognize. They may or may not have Raynaud's phenomenon, but by definition they never have the skin changes of scleroderma: common presenting problems include oesophagitis, malabsorption, pseudo-obstruction, renal failure, cardiac arrhythmias, and interstitial lung disease.

Overlap syndromes

There are patients whose disease is not easy to define, having features overlapping with those of other connective tissue diseases. A variety of terms such as 'mixed connective tissue disease', 'undifferentiated connective tissue syndrome', and 'overlap syndromes' have emerged to describe such patients.

Whether or not mixed connective tissue disease is a true entity is controversial. Sharp and colleagues used the term in the 1970s to describe patients with some features of polymyositis, lupus, and scleroderma who ran a benign course with no pulmonary, cerebral, or renal involvement, and no vasculitis. They supposedly responded well to low-dose steroids, and could be identified by the presence of a high-titre antibody with specificity for a nuclear U1 ribonucleoprotein (**RNP**) antigen. However, the clinical features, laboratory tests, and the response to therapy have all proven not to be specific, and these patients do not fulfil the definition of and diagnostic criteria for a single disease. Neither can they be sensibly described as having an 'overlap syndrome', assuming that this definition means the coexistence of two separate diseases. Nevertheless, over time, many do develop major internal organ involvement and evolve into a defined connective tissue disease.

Ribonucleoprotein antibodies can be found in patients with scleroderma or systemic lupus erythematosus. The typical patient with the overlap syndrome presents with Raynaud's phenomenon, puffy hands, arthralgia, myositis, abnormal oesophageal motility, and lymphadenopathy. Over a period of a few years, the skin may become thickened, telangiectasia and calcinosis may appear, signs and symptoms of interstitial lung disease emerge, and the patient has developed scleroderma. Another patient with similar initial findings may develop alopecia, photosensitivity, mouth ulcers, renal disease, antibodies to double-stranded DNA and has developed systemic lupus erythematosus. Other patients may develop a prominent destructive arthropathy reminiscent of rheumatoid disease.

Autoimmune serology in systemic sclerosis

The majority of patients with scleroderma carry a hallmark autoantibody, and almost all have antinuclear reactivity, often with an antinucleolar pattern on Hep2 cells. Thus either anticentromere, and antitopoisomerase or anti-RNA polymerase III (generally also with anti-RNA polymerase I) are present in most patients and are generally (although not always) mutually exclusive reactivities. Rarer specificities include U3-RNP, PM-Scl, and anti-Th. Each serologically defined group shows somewhat different clinical features, which is of some value in risk stratification for management. There are also well-established class II MHC associations with the various autoantibodies, although some differences in association occur in different racial groups. The reactivities and reported clinical associations of the autoantibodies associated with scleroderma are summarized in Table 5.

Studies using an immunoblotting technique, which is more sensitive than immunofluorescence, have demonstrated that the anticentromere antibody (the antigen actually resides in the kinetochore region of the chromosome) is predictive for the development of limited cutaneous disease (sensitivity 60 per cent, specificity 98 per cent) and Scl-70 (an antibody known to recognize the nuclear enzyme DNA topoisomerase I) for the diffuse subset (sensitivity 38 per cent, specificity 100 per cent). Other serum autoantibodies, notably those to nucleolar antigens, are also relatively specific for scleroderma, and the proportion of patients having one or more antibody is over 80 per cent of the total. Some of these antibodies have been shown to have correlations with class II MHC haplotypes.

Less specific serological abnormalities are also found in scleroderma and include hypergammaglobulinaemia, the presence of immune complexes, low concentrations of complement components, and a weakly positive rheumatoid factor. Antibodies to SSA/Ro and SSB/La are found in 50 per cent of patients with scleroderma who also have Sjögren's syndrome, and are nearly always found in those with glandular lymphocyte infiltration rather than fibrosis.

Organ-based complications of systemic sclerosis

Despite the usefulness of an accurate subset classification of patients with systemic sclerosis, management requires that an organ-based approach be taken once the subset has been assigned. This ensures that important complications, which occur with different frequencies in the different subsets, are not missed. The overall prevalence of the different complications is summarized in Table 4.

Vascular manifestations

Raynaud's phenomenon

Episodic acral vasospasm, precipitated by cold or emotional stress (Raynaud's phenomenon), is almost universally present in patients with systemic sclerosis, although its prominence varies considerably between cases. The pathogenetic mechanism is uncertain, but probably represents an imbalance between vasoconstrictor and vasodilator mechanisms in small blood vessels, or an exaggerated release of vasoconstrictor mediators in response to physiological levels of stimulation by cold or emotion.

Raynaud's phenomenon is common in otherwise healthy individuals, with some series estimating its prevalence to be up to 15 per cent in women, with a much lower frequency in men. It may precede the onset of systemic sclerosis, especially the limited cutaneous subset, by many years, whereas in diffuse cutaneous systemic sclerosis it generally first becomes manifest around the time of the onset of other features of the disorder, or afterwards. Patients who have Raynaud's phenomenon in association with one of the hallmark autoantibodies of systemic sclerosis, such as anticentromere or antitopoisomerase-1, will often develop other features of systemic sclerosis, typically within 3 to 5 years, and so may represent a prescleroderma state—but they can also develop features of other autoimmune rheumatic disorders. Current approaches to the management of patients with Raynaud's phenomenon are summarized in Table 6.

Macrovascular disease

There have been several reports that macrovascular disease is increased in patients with systemic sclerosis. This is plausible, given the number of common aetiopathogenic mechanisms between the processes of atherosclerosis and systemic sclerosis, including endothelial-cell perturbation, activation and damage, and subsequent fibroproliferation. Large-vessel disease has important implications for the organ-based complications of systemic sclerosis such as renal disease, peripheral ischaemia, and bowel involvement. Some non-invasive studies have suggested the presence of flow abnormalities in large vessels in the cerebral and renal circulations in systemic sclerosis. Extrapolating from the results of studies investigating cardiac and pulmonary blood flow variations attributable to vasomotor instability, it is certainly possible that episodic vasospasm is not restricted to the extremities in this disease.

Skin manifestations

Scleroderma means 'hard skin' and is the hallmark of the scleroderma-spectrum disorders. The skin lesions of scleroderma differ between diffuse and limited cutaneous subsets, not only by their extent and distribution, but also by the greater tendency for there to be induration and oedema of affected tissues in diffuse cutaneous systemic sclerosis. This may reflect a local release of cytokines or altered endothelial permeability in the diffuse form. The inflammatory phase evolves into established fibrosis, sometimes leading to sheets of thickened skin or a hide-bound texture. The skin sclerosis score (skin-score) is a validated method for assessing the extent of skin involvement, and has been shown to predict survival and to correlate with some other disease features, for example a rapidly increasing skin-score is associated with an increased occurrence of scleroderma renal crisis.

Another common vascular manifestation of scleroderma is the development of local dilated loops of small blood vessels in the skin, termed 'telangiectasias'. These are often distressing for patients and may also cause problems from haemorrhage if they are at sites prone to trauma. Haemorrhage from mucosal telangiectasias is increasingly recognized as a clinical problem that may require local therapy if recurrent: gastrointestinal haemorrhage and epistaxis have both been reported. Men with facial telangiectasia may experience difficulties when shaving. Cosmetic camouflage techniques can be very effective in masking facial telangiectasia, and appropriate advice should be offered to all who might benefit. Recently the pulsed dye laser has also been used with some success.

Pulmonary disease

The most frequent cause of death related to systemic sclerosis is pulmonary disease, which can take the form of interstitial fibrosis or pulmonary vascular disease. These two processes can coexist in patients with secondary pulmonary hypertension, a subgroup that should probably be considered separately from those with isolated pulmonary hypertension.

There has recently been substantial progress in the assessment of pulmonary disease in those patients with systemic sclerosis. This has refined diagnosis and classification, will almost certainly result in different treatment strategies for particular subsets of patients, and illustrates a general theme that the subsetting of organ-based complications is becoming as important as the correct classification of major disease subsets. The investigation and treatment of the pulmonary manifestations of systemic sclerosis are summarized in Table 7.

Fibrosing alveolitis

The initial events in the development of lung disease in patients with systemic sclerosis appear to involve alveolar inflammation and subsequent epithelial and endothelial perturbation. Although all patients should be screened for this complication, it appears to affect only around 25 per cent of those with limited cutaneous disease and up to 40 per cent of those with the diffuse cutaneous form. It is strongly predicted by the presence of antitopoisomerase-1 autoantibodies and also by the *HLA-Dr52a* genotype. Increased frequency also occurs in patients with anti-RNA polymerase III antibodies, but the presence of anticentromere antibodies (**ACA**) is associated with a reduced risk. These tests are therefore of clinical value in planning the frequency and intensity of lung screening tests.

Technical developments have made the early detection of interstitial lung disease possible. Chest radiography is not sufficiently sensitive. Serial lung function tests including CO diffusing capacity are probably the most sensitive screening tool. A significant reduction from predicted values at baseline with a restrictive pattern, or a worsening of serial tests, warrants further testing with a high-resolution, thin-section (3 mm), computed tomography (**CT**) scan of the lungs and bronchoalveolar lavage. The combined use of these techniques and diethylenetriaminepentaacetic acid (**DTPA**) scans can provide much earlier diagnosis and/or indices of progression.

The earliest detectable abnormality on CT is usually a narrow, often ill-defined, subpleural crescent of increased attenuation in the posterior segment of the lower lobe. Other early CT changes include an amorphous ground-glass pattern of parenchymal opacification, or a more reticular appearance (Fig. 2). The relative extent of each pattern is important because there is good correlation between these appearances and histological findings at open-lung biopsy; an inflammatory biopsy equating to an amorphous pattern and fibrosis to a reticular one. Such information may reduce the need for an invasive biopsy.

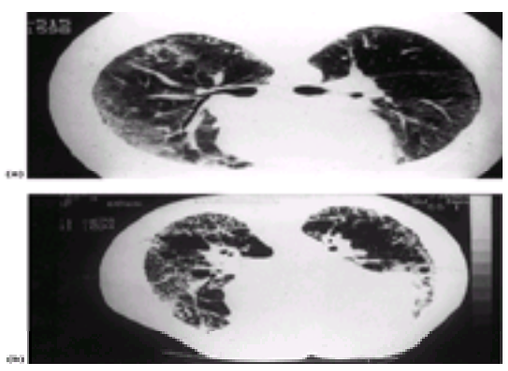

Fig. 2 (a) Thin-section CT scan image illustrating the ground-glass appearance of early pulmonary involvement posteriorly. A chest radiograph taken at the same time was normal. (b) Thin-section CT scan image illustrating extensive honeycomb shadowing and cystic air spaces involving both lower lobes. Chest radiographic appearances at the same time were of advanced interstitial lung disease (bibasilar reticulonodular shadowing). (Both images with grateful acknowledgement to Drs A.

Wells, R. du Bois, and B. Strickland, Departments of Respiratory Medicine and Radiology, Royal Brompton National Heart and Lung Hospitals.)

Bronchoalveolar lavage often identifies patients with alveolitis before the onset of symptoms or abnormalities on chest radiography or in pulmonary function tests. DTPA scans, particularly serial studies, may become useful predictors of progression or improvement: a persistently abnormal DTPA scan is associated with a higher rate of decline in pulmonary function tests subsequently, whereas a reversion to normal clearance is associated with sustained improvement in pulmonary function.

These tests have obvious value for assessing the progress of the disease and are critically important in evaluating new treatments. Lung biopsy is still the 'gold standard' for establishing the diagnosis of fibrosing alveolitis, although it is required less often than previously. However, it is now recognized that histological and CT scan appearances allow further classification of systemic sclerosis-associated fibrosing alveolitis into 'usual-pattern' (**UIP**) or 'non-specific interstitial pneumonia' (**NSIP**). These have different prognoses and probably require different treatment approaches. In general, the outcome for patients with systemic sclerosis-associated fibrosing alveolitis is better than that for cryptogenic fibrosing alveolitis of equivalent extent. Most patients with active alveolitis receive immunomodulatory therapy and many studies have suggested that this is effective. However, formal prospective controlled trials are still needed to confirm this and to refine therapeutic regimens. The management of interstitial lung disease can be further complicated by the development of secondary pulmonary hypertension.

Pulmonary vascular disease

Pulmonary vascular disease is of substantial clinical importance in patients with scleroderma. The overall prevalence is estimated at between 10 and 20 per cent. This is higher than was previously reported, reflecting the use of non-invasive methods of detection, such as echocardiography with Doppler estimation of the peak pulmonary arterial systolic pressure (from the velocity of retrograde flow into the right atrium in the presence of tricuspid regurgitation).

Isolated pulmonary hypertension (**PHT**) in scleroderma, occurring without other pulmonary pathology, is characteristic of limited cutaneous systemic sclerosis, especially in the classical CREST form of this subset with florid cutaneous telangiectasias. Some cases of isolated PHT have been seen in the diffuse form of the disease, associated with antibodies to U3-RNP, but pulmonary hypertension in this condition usually occurs in the context of established pulmonary fibrosis and constitutes secondary PHT.

There are considerable similarities between the histological features of isolated PHT in scleroderma and primary pulmonary hypertension. There is evidence of subintimal cell proliferation, endothelial hyperplasia, and the obliteration of small intrapulmonary vessels. It has been suggested that initial proliferative changes lead to the characteristic plexiform pathology of rapidly progressive pulmonary hypertension, with remodelling leading to the concentric obliterative lesions that predominate at necropsy in patients succumbing to severe systemic sclerosis-associated PHT.

Survival analysis suggests that patients with systemic sclerosis-associated PHT may have a better prognosis that those with primary pulmonary hypertension, especially if they have a mild to moderate elevation in pulmonary arterial pressure. Although patients with this condition are being identified more frequently than previously, and probably earlier, treatment remains difficult. The prognosis for those with systemic sclerosis and PHT is still to be fully defined, and haemodynamic predictors of outcome are being sought. Treatment, up to and including continuous ambulatory prostacyclin infusion or heart–lung transplantation, is probably appropriate for the most severe cases.

Cardiac involvement

Autopsy studies have identified at least three patterns of myocardial involvement in systemic sclerosis, when up to 50 per cent of patients show features of myocardial fibrosis. Other histological patterns of cardiac disease include contraction-band necrosis and, less frequently, inflammatory cardiomyopathy, the latter probably occurring most often in those with an inflammatory skeletal myopathy.

Non-invasive imaging techniques such as magnetic resonance imaging (**MRI**) or spiral CT scanning may allow myocardial fibrosis to be detected. Indirect clues of cardiac involvement may be deduced from ECG or echocardiographic studies. The investigation and management of the cardiac manifestations of systemic sclerosis are summarized in Table 8.

Pericarditis is well recognized as a complication of systemic sclerosis. It is seen particularly in the context of severe diffuse cutaneous disease and seems to be most frequently encountered in patients with established or imminent scleroderma renal crisis. Echocardiographic studies often reveal small haemodynamically insignificant effusions in patients with scleroderma: around 17 per cent of those with diffuse cutaneous and 4 per cent of those with limited cutaneous disease. Therapeutic pericardiocentesis is only occasionally required, but pericardial effusion is associated with active progressive diffuse cutaneous disease.

Electrophysiological cardiac abnormalities are commonly seen in patients with scleroderma. Conduction defects are frequent, especially Q–Tc prolongation on 12-lead ECG. Later, conduction tissue fibrosis may lead to varying degrees of heart block, including first- or second-degree block or complete heart block necessitating pacemaker implantation. Bundle-branch blocks may reflect abnormalities in the conducting tissues or be complications of ventricular strain. Thus right bundle-branch block may be seen in association with PHT, and left bundle-branch block may occur when there is left ventricular strain from hypertension or cardiac muscle disease. Paroxysmal arrhythmias are much more difficult to detect than conduction abnormalities, and in those with occult cardiac disease are probably an important cause of unexplained death in patients with systemic sclerosis.

Renal disease

Several patterns of renal pathology are recognized in patients with scleroderma: all involve vascular abnormalities. The most clearly defined is the scleroderma renal crisis, which describes the occurrence of acute renal failure in a patient with scleroderma, usually associated with accelerated hypertension (further compounding the renal pathology), and in whom no other cause for nephropathy is present. Scleroderma renal crisis was almost always fatal prior to the routine use of angiotensin-converting enzyme (**ACE**) inhibitors and the improvement in outcome over the last 20 years represents a considerable therapeutic triumph. However, in addition to scleroderma renal crisis, many patients demonstrate less severe renal complications, probably associated with reduced renal blood flow and the consequent reduction in glomerular filtration rate. The mechanism of this slowly progressive form of chronic renal disease is unclear. A small number of patients develop significant glomerulonephritis.

Acute renal crisis

This generally occurs in patients with diffuse cutaneous systemic sclerosis within 5 years of disease onset. It is often associated with rapidly advancing skin disease and the presence of tendon friction rubs. Patients often carry the antitopoisomerase-1 or anti-RNA polymerase-III autoantibody, and presence of the latter should prompt extra vigilance in monitoring for renal involvement, particularly in those with limited cutaneous disease who otherwise very rarely develop scleroderma renal crisis. The overall incidence of scleroderma renal crisis varies between different systemic sclerosis subsets and disease stages: in high-risk patients it may be as great as 20 per cent, but overall is probably less than 10 per cent.

The following diagnostic criteria for scleroderma renal crisis have been proposed: abrupt onset of arterial hypertension greater than 160/90 mmHg; hypertensive retinopathy of at least grade III severity; rapid deterioration of renal function; and elevated plasma renin activity. Other typical features include hypertensive encephalopathy and the presence of a microangiopathic haemolytic blood film: the presence of fragmented erythrocytes on a blood film is a simple and inexpensive method of identifying early scleroderma renal crisis.

Symptoms of scleroderma renal crisis usually present abruptly and the condition should be regarded as a life-threatening medical emergency requiring prompt intervention. The pulse rate is increased and patients develop headaches, visual phenomena, and convulsions due to accelerated hypertension. Symptoms and signs of left ventricular failure may follow rapidly. Oliguria or anuria lead to a rising serum creatinine level, and death from renal failure can occur within a short time in untreated patients. Proteinuria is almost universal, and although this may be present long before the renal crisis develops, it often increases with the crisis, though not to nephrotic levels. Microscopic haematuria and granular or red cell urinary casts are typically present.

Although renal crisis usually occurs in patients with established systemic sclerosis, it can occasionally be the presenting feature of the disease. For this reason the

hands and face of any patient presenting with unexplained severe or accelerated hypertension should be examined for clues that might suggest an underlying connective tissue disorder such as systemic sclerosis. Clinical suspicions should be followed up with appropriate investigations, particularly autoimmune serology and nailfold capillaroscopy.

Hypertension should be treated using ACE inhibitors. It has been suggested that quinapril may be preferable to other agents. Historically, most patients have received either captopril or enalapril together with calcium-channel blockers, aimed at reducing both diastolic and systolic pressure by 10 to 15 mmHg per day until baseline levels of diastolic pressure at 80 to 90 mmHg are achieved. Sublingual nifedipine or subcutaneous hydralazine can be used if the patient is vomiting. Intravenous prostacyclin, which may directly benefit the microvascular lesion, is often administered from diagnosis.

It is generally useful to perform a renal biopsy when hypertension has been adequately controlled. This provides prognostic information, allows histological confirmation of the diagnosis, and permits exclusion of other causes for abrupt-onset renal failure such as glomerulonephritis. Histological examination usually shows fibrinoid necrosis; mucoid or fibromucoid proliferative intimal lesions (when extensive, termed 'onion-skinning') in renal arteries, particularly the arcuate and interlobular vessels; glomerular thrombi; and ultimately glomerulosclerosis. The extent of the glomerular lesion can sometimes be useful in predicting the likely degree of ultimate functional recovery. Occasionally a similar pattern of renal dysfunction occurs without hypertension (normotensive renal crisis), suggesting that the pathological features are not simply the end-organ consequences of raised arterial pressure.

Renal function should be monitored closely with daily measurement of serum creatinine. Regular full blood counts, clotting screens, and fibrin-degradation product estimations are important to detect and monitor microangiopathic haemolytic anaemia, which often reflects activity of the disease process. Short-term haemodialysis should be given if necessary, and peritoneal dialysis often works well if long-term renal replacement therapy is needed. It has been observed that skin sclerosis and other features of systemic sclerosis can improve after a renal crisis, particularly if the patient is undergoing maintenance dialysis. The basis for this is uncertain: it may result from the removal or inactivation of circulating mediators, or simply reflect the natural history of the disease. Considerable recovery in renal function often occurs after an acute crisis, sometimes allowing dialysis to be discontinued, and improvement can continue for up to 2 years. Decisions regarding renal transplantation should not be made before this time.

Chronic nephropathy

Patients who survive scleroderma renal crisis may develop similar but less florid proliferative changes in the interlobular and arcuate arteries. Even those who have never had a renal crisis may show reduplication of elastic fibres, sclerosed glomeruli, tubular atrophy, and interstitial fibrosis, presumably reflecting the chronic changes of scleroderma.

Glomerulonephritis

There are a small number of case reports of glomerulonephritis occurring in systemic sclerosis, including a progressive crescentic glomerulonephritis in association with positive antimyeloperoxidase autoantibodies. More commonly, biopsy reveals coincident pathologies such as drug-induced injury or overlap syndromes with features of other connective tissue disorders such as systemic lupus erythematosus.

Gastrointestinal complications

The majority of patients with systemic sclerosis exhibit at least one gastrointestinal manifestation. Most frequent is oesophageal dysmotility and associated reflux oesophagitis. These symptoms often respond dramatically to treatment with proton-pump inhibitors. Involvement can also occur at other sites: these are described in Table 9, together with current management approaches for each complication.

Gastric involvement typically leads to slow gastric emptying and symptoms of postprandial fullness. This, together with sicca symptoms and difficulty swallowing, encourages poor nutritional intake and is a significant contributor to the weight loss observed in patients with this disease. The earliest feature of small bowel involvement is also dysmotility, leading to increased intestinal transit time, which together with a propensity to form wide-mouthed jejunal diverticulae leads to stagnation of the luminal contents and small intestinal bacterial overgrowth. This may in turn lead to bloating, flatulence, malabsorption, and chronic diarrhoea. Endstage involvement of the small bowel leads to profound malabsorption and malnutrition and is a significant cause of miserable scleroderma-associated death. Large-bowel manifestations include constipation and anorectal incontinence. Alternating constipation and diarrhoea is common and complicates management, which is generally empirical.

Musculoskeletal complications

Musculoskeletal features are almost universal in established systemic sclerosis, although often relatively well tolerated. Most patients with diffuse disease experience muscle weakness, although prominent myositis is unusual. Flexion contractures of the interphalangeal joints are common and can be very debilitating. Surgical intervention can be valuable but should focus on functional rather than cosmetic gain. Arthralgia and stiffness are the most frequent symptoms. Frank arthritis is uncommon and points towards an overlap syndrome. Other musculoskeletal manifestations include carpal tunnel syndrome, tendonitis (with friction rubs—most often in diffuse cutaneous disease), and the consequences of contractures—especially affecting the hands, but also more proximal joints in diffuse disease.

Other organ involvement

Neurological involvement is uncommon, but in the late stages of limited cutaneous disease a small but significant proportion of patients develop unilateral or bilateral trigeminal neuralgia. Impotence is a problem for men, usually occurring 1 to 2 years after disease onset, thought to have an neurovascular cause, and is refractory to treatment. Dryness of the mucous membranes is common, leading to dyspareunia. Hypothyroidism occurs in as many as 50 per cent of patients with systemic sclerosis and is frequently missed. Some patients have antithyroid antibodies, but lymphocytic infiltration in the gland is uncommon, fibrosis being the more typical finding.

Disease course

Since the clinical course of particular subsets of systemic sclerosis can to a great extent be predicted, appropriate classification within the scleroderma-spectrum is valuable in planning disease management.

Patients with limited disease have an 'early phase' that lasts about 10 years, when the picture is usually dominated by vascular problems such as Raynaud's phenomenon, pitting scars, digital ulcers, and telangiectasias. Later there may be worsening of the vascular disease, both cutaneously and in the pulmonary circulation. Pulmonary interstitial disease, usually more indolent than that seen in the diffuse form, can also occur as a late complication. Gut involvement may worsen with time, and oesophageal strictures, malabsorption, pseudo-obstruction, and anal incontinence are all possible late and troublesome events in this subset.

During the early phase of diffuse disease (the first 5 years), the patient is fatigued and loses weight. Hypertensive renal crisis is a real risk, and rapid progression of pulmonary and cardiac disease may occur. Arthritis, myositis, and tendon involvement can be most marked at this time. After 5 years, considered to be the late stage of diffuse disease, the constitutional symptoms settle down, the skin and musculoskeletal problems have usually reached a plateau, and there is progression of existing visceral disease but a reduced risk of new organ involvement. These differences in the pattern and natural history influence evaluation and therapy.

Pathogenesis

Systemic sclerosis involves immunological, vascular, and connective tissue abnormalities. Models of pathogenesis focus upon the importance of an initiating stimulus in a susceptible individual and subsequent amplification of pathogenic processes, leading to one of the different subsets of the disease. There is a complex interplay between a number of factors: some of the mechanisms implicated in pathogenesis of systemic sclerosis are indicated in Table 10.

Current models suggest that initiating events eventually lead to the establishment of a fibrogenic population of interstitial fibroblasts that produce increased amounts of extracellular matrix. Disruption of normal tissue architecture and secondary mechanisms such as ischaemia produce the pathological and clinical features. Determination of the discrete patterns of organ involvement within and between disease subsets is not understood, although associations with class II MHC

haplotypes and with particular autoantibodies suggest that genetic or immunological mechanisms may be important. Despite the extreme rarity of familial scleroderma, it seems likely that there is a substantial, if complex, genetic component to the pathogenesis of systemic sclerosis, which is likely to involve both severity and susceptibility loci. Twin data have failed to confirm a substantial inherited component, but some studies—for example, of the Choctaw Native American tribe—have shown a very high incidence of diffuse systemic sclerosis in some populations. A number of candidate genes, including *Fbn-1* (Fibrillin-1), are currently under investigation.

Survival

There have been a number of studies of survival in the past 50 years, and the 5-year cumulative survival rate ranges from 34 to 73 per cent. Even prolonged survival does not protect against an increased mortality risk, which continues for at least 15 years. Factors that adversely affect outcome are increasing age, being male, extent of skin involvement, and heart, lung, and renal disease. Most recent studies point to a substantial improvement in survival over the last 20 years: this is likely to be attributable to the treatment of renal crisis—previously almost invariably fatal—and perhaps to better detection and treatment of other major complications.

Management of systemic sclerosis

There have been significant recent advances in the management of patients with scleroderma, mainly related to improved treatment of organ-based complications and to the appreciation that successful management depends upon accurate diagnosis, subsetting, staging within subset, and screening for specific complications. Many advances have occurred in parallel with the improved treatment of other medical conditions such as hypertension and gastro-oesophageal reflux disease.

One of the most improved areas of clinical understanding of the scleroderma-spectrum of disorders has been the concept of risk stratification. This enables precious resources to be appropriately focused, so that patients at highest risk of particular complications are thoroughly investigated. Subsetting and staging within subsets is the starting point. Associations with particular autoantibodies are helpful, as summarized in Table 5. Additional predictive power is provided by genetic markers, and this is likely to increase considerably over the next few years. In particular, functionally relevant single nucleotide polymorphisms, such as those in cytokine or growth-factor receptors, or other polymorphic markers, including immunogenetic ones, are likely to increase predictive power.

Unfortunately there has been relatively little progress in developing disease-modifying therapies for the most aggressive subset of patients, those with diffuse cutaneous systemic sclerosis, which is probably, in part, a reflection of our relatively limited understanding of the pathogenesis of systemic sclerosis. Effective therapies are likely to be directed against key processes or mediators, and may be different depending upon the subset and stage of disease. In general, it is believed that immunomodulatory strategies are most appropriate in the earlier stages of diffuse disease (1 to 3 years from onset), whereas antifibrotic approaches may be more appropriate in established cases. An induction–maintenance approach has been used in some centres. Current approaches to disease-modifying treatment are summarized in Table 11. Although curative treatments are lacking, scleroderma-spectrum disorders, and especially systemic sclerosis, should be considered treatable. Strategies are now available to treat all the diverse manifestations, and an algorithm summarizing current approaches is shown in Fig. 3.

Fig. 3 Overview of the management of organ-based complications of systemic sclerosis.

18.10.4 Polymyalgia rheumatica and giant-cell arteritis

Alastair G. Mowat

Polymyalgia rheumatica and giant-cell arteritis are common debilitating conditions that may represent opposite ends of a disease spectrum, but since they appear to present with different clinical symptoms and signs and demand different treatment it is best to describe them separately.

Polymyalgia rheumatica

Polymyalgia rheumatica occurs predominantly in patients over the age of 60 years. There is marked pain and stiffness in the shoulder and pelvic girdles associated with variable systemic symptoms and elevated C-reactive protein and erythrocyte sedimentation rate. While an incidence of some 50 per 100 000 of the population aged 50 years and over has been accepted for hospital referrals on both sides of the Atlantic, careful study of defined elderly populations has shown an incidence of 1.5 per cent which exceeds that of any other inflammatory rheumatic disease in the elderly.

Disease characteristics

Although the most common age group involved is that between 60 and 70 years, a third of patients are under 60 years old. Initial symptoms are seldom seen before 45 years or after 80 years. The male to female ratio is 1:2. The onset is often dramatic, with some patients giving the precise date of their first symptoms, and in most cases it is fully developed within a month. Pain and stiffness are usually localized to muscles, although tenderness is not as severe as in myositis. There may be additional tenderness involving periarticular structures. The onset is most common in the shoulder girdle, spreading to involve both shoulders, the pelvic girdle, and proximal muscles with striking symmetry. Involvement of distal muscles is unusual. Immobility is most severe on waking; a characteristic complaint is a need to roll out of bed, often with the aid of a spouse. Such morning stiffness may persist for hours. Most patients look unwell and complain of general malaise, fatigue, and depression. Anorexia and weight loss can be striking, often suggesting neoplasia, while night sweats and fever are frequent and are occasionally the presenting feature.

The spectrum of musculoskeletal features is broader than is often recognized; the prominent proximal myalgia overshadowing asymmetric peripheral synovitis, particularly of the knee and wrist, while in others there are periarticular features and tenosynovitis. The latter may be the principal cause of carpal tunnel syndrome, found in 10 per cent of cases. Peripheral joint features occur in up to 50 per cent of patients. Radiographs show age-related degenerative change but distinctive erosions may occur in some central joints, for example the sternoclavicular, and provide a basis for the pattern of referred pain. Arthroscopic and isotopic studies and recently magnetic resonance imaging have all supported the existence and importance of a wide pattern of synovitis.

Laboratory findings

An acute phase response (raised erythrocyte sedimentation rate, C-reactive protein) is typical. The elevation in erythrocyte sedimentation rate, often to more than 100 mm/h should not be overinterpreted since polymyalgia rheumatica accounts for only 2 per cent of such high values. Although a normal erythrocyte sedimentation rate may occur in 10 per cent of patients and be associated with the same disease course, 40 mm/h has good diagnostic value. A mild hypochromic normocytic anaemia is common. Rheumatoid factor shows a low incidence of positivity consistent with the patient's age. Serum values of liver enzymes, alkaline phosphatase, and g-glutamyl transferase are elevated in most patients, and can be correlated with the erythrocyte sedimentation rate and disease severity. Liver biopsy shows only a mild cellular infiltrate and minor changes in the bile canaliculi.

Despite the prominent muscle symptoms, electromyographic studies and serum muscle enzyme values are normal while changes on muscle biopsy, including recent studies of mitochondrial function are non-specific. While several studies have shown changes in the absolute number and percentage of activated CD8 T cells and interleukin receptors these have not provided diagnostic or therapeutic correlation.

Differential diagnosis

Polymyalgia rheumatica remains a clinical diagnosis. It is critical that a careful history is taken and a full examination carried out. This sometimes to leads to claimed disease association, for example connective tissue disease, malignancy, and thyroid disease, but statistically this has not been substantiated. Several diagnostic criteria have been validated over the years but the first remains practical: the seven best discriminatory features are shown in Table 1 of which three or more criteria are required.

Differential diagnosis includes a wide range of conditions (Table 2). Infection may be viral or bacterial, with miliary tuberculosis and infective endocarditis causing confusion. Bone diseases may be difficult to separate as they are common in this elderly group and alkaline phosphatase is raised in polymyalgia rheumatica. This is also the case with neoplastic disease, which may be associated with myalgia even in the absence of secondary spread to bone. Primary muscle disease can be distinguished by electromyography, biopsy, and enzyme values, but joint disease, particularly osteoarthritis, rheumatoid arthritis, and other connective tissue diseases, all of which may start with a polymyalgic pattern lasting for some months in older patients, cause confusion, although appropriate serological tests should help.

Aetiology and pathogenesis

No distinctive pathophysiological mechanisms have been found. Polymyalgia rheumatica may include several different conditions. The distinctive arteritis may occur in up to 15 per cent of cases on biopsy in North American series but much less frequently in Europe, perhaps reflecting case selection. However, newer techniques such as positron emission tomography again suggest that arteritis may be under-recognized. A prodromal malaise and a possible summer/winter peak incidence has promoted a generally unrewarding search for infective causes, although there may be an arteritic subset associated with parainfluenza virus type 1. The evidence for a central arthritis affecting clavicular, shoulder, and sacroiliac joints comes from a study which reproduced the usual pain patterns by injecting hypertonic saline into these joints. In those with proven arteritis, which need not be confined to the temporal and other central vessels but can be found in larger arteries all over the body, a similar pattern of referred pain can be implicated. An immune destruction of the internal elastic lamina is supported by finding circulating immune complexes, together with immunoglobulins, complement deposition, and mononuclear cell infiltrate adjacent to the lamina (Fig. 1).

Fig. 1 Photomicrograph of a temporal artery biopsy showing giant cells, mononuclear infiltrate, and disruption of the internal elastic lamina.

Although polymyalgia rheumatica is found worldwide, it is more common in Caucasians, particularly those of Scandinavian extraction. The infrequency of the disease in spouses argues against environmental factors, while familial aggregation and an association with HLA DR4 suggests both genetic and immunological mechanisms, possibly similar to seronegative rheumatoid arthritis. Both polymyalgia rheumatica and giant-cell arteritis are negatively associated with pregnancy, suggesting a vascular protection by the hyperoestrogenic state. No benefit from hormone replacement therapy is documented.

Treatment

A decade ago, the average delay to diagnosis and treatment was 6 months. Now, greater awareness and the fear of the link with giant-cell arteritis and possible blindness has led to overdiagnosis and overtreatment, and the commonness of middle-aged muscle ache has been forgotten. It is a myth that a prompt or dramatic response to corticosteroids confirm a diagnosis; many of the listed differential diagnoses show a similar response. Nevertheless corticosteroids are the drugs of choice.

As the average duration of symptoms is 2 to 3 years, with some persisting for 7 or more years, side-effects of corticosteroids are commonly recorded. Fluid retention, weight gain, diabetes, or osteoporosis are shown by 35 to 75 per cent of patients with polymyalgia rheumatica. Many clinicians now advocate starting therapy appropriate to the patient's age and wishes, to prevent osteoporosis at the outset of corticosteroid therapy. Higher initial erythrocyte sedimentation rates tend to be associated with a longer duration of disease and a greater risk of osteoporosis. Suggested corticosteroid regimes for the first 2 months are shown in Table 3. An intramuscular schedule of 120 mg methylprednisolone every 3 weeks, reducing by 20 mg every 12 weeks appears to be associated with fewer side-effects.

The gradual reduction of corticosteroid treatment over 2 years minimizes the risk of relapse; most clinical problems and associated diagnostic doubts appear to be caused by fluctuating corticosteroid dose. Erythrocyte sedimentation rate and C-reactive protein do not show a sufficiently reliable responce to help in adjusting dosage or in predicting relapse. A few patients can be managed on non-steroidal anti-inflammatory drugs, but the value of poorer and slower symptom control and the risk from different side-effects is debatable. Azathioprine 50 mg twice daily or methotrexate 10 mg per week may be helpful in steroid sparing although the evidence from clinical trials is not striking.

Relationship of polymyalgia rheumatica to giant-cell arteritis

William Bruce, a physician practising in Strathpeffer Spa, Scotland, described polymyalgia rheumatica in 1888 using the term senile rheumatic gout, and Jonathan Hutchison described giant-cell arteritis in 1890. The current names were applied much later. For more than 20 years a common cause has been suggested, emphasized by the term polymyalgia arteritica, and based upon the similar clinical and laboratory features. This has led some to search hard for arterial biopsy evidence lest the patient suffer visual features of giant-cell arteritis. Because the arteritis may be patchy and hence missed, attempts have been made to increase the sensitivity of selection of the biopsy site—angiography, sonography, isotope studies, MRI—without success. However, prospective studies emphasize the difference between the conditions, even if part of a spectrum, and the lack of need for biopsy studies in clear polymyalgia rheumatica. In giant-cell arteritis biopsy proof underpins the need for higher and sustained steroid therapy.

Giant-cell arteritis

Giant-cell (cranial, senile, or temporal) arteritis, which is rare before the age of 50 years, chiefly affects those between 65 and 75 years with a male to female ratio of 1:2. An annual incidence of biopsy-proven disease amongst those aged 50 years or more of 18 per 100 000 (25 per 100 000 for women and 10 per 100 000 for men) has been recorded in the United States and Scandinavia, with the rate for women appearing to rise.

Disease characteristics

The features of giant-cell arteritis are protean, but typical ones are shown in Table 4. The diagnosis depends upon clinical suspicion in less typical cases. As with polymyalgia rheumatica, the onset may be dramatic and the condition always becomes fully developed over a few weeks, although the delay in diagnosis may be months. The malaise, fever, and anaemia are similar to those in polymyalgia rheumatica; the differences are in the vascular symptoms. The majority have temporal features with headache, scalp sensitivity, and tender thickened arteries; the classical nodular red streaks are unusual. Overwhelming generalized headache and the feared complication of irreversible loss of vision are more readily recognized. The clinical features listed emphasize developing arteritis. A wide range of cranial manifestations reflects the involvement of larger arteries with an internal elastic lamina in the face, neck, and brain base but not in the cerebral vessels. They include headache, scalp tenderness, skin necrosis, jaw claudication while talking or chewing, tongue pain and claudication, and face and neck pain with nerve damage. The visual manifestations, which include blurred vision, amaurosis fugax, transient and permanent blindness, diplopia, and visual hallucinations, are due to ischaemic changes in the ciliary arteries causing optic neuritis or infarction, with a smaller number of cases being due to thrombosis of the central retinal artery. Fifteen per cent have evidence of arteritis elsewhere, with intermittent claudication, peripheral neuropathy, widespread vessel tenderness with bruits, myocardial ischaemia and damage, and occasionally an aortic syndrome with valve disease. Stroke due to vascular disease in the brainstem is uncommon, accounting for only 1 to 2 per cent of such cases. In contradistinction to other vasculitides, renal involvement is rare.

Laboratory features

These are the same as in polymyalgia rheumatica. Temporal artery biopsy is the definitive diagnostic test. A 2 cm segment of a tender artery will provide positive histology in 70 per cent of cases. The rate may be enhanced by taking longer segments or by the biopsy of other tender scalp vessels. While biopsy confirmation of the diagnosis is important, it should not be a reason for withholding steroids, since characteristic pathological features persist for at least 2 weeks after treatment has begun, and some argue that scar change never clears.

Differential diagnosis

Since the diagnosis of giant-cell arteritis depends upon a positive biopsy, the differential diagnosis does not include other causes of headache, neck pain, anaemia, and weight loss. The vasculitis of rheumatoid arthritis or systemic lupus erythematosus affects arterioles and is associated with other disease features, particularly arthritis and characteristic immunological tests. Polyarteritis affects small arteries with cutaneous, abdominal, and renal rather than cranial features and the histology is distinctive. Although cranial and central nervous system features occur in Wegener's granulomatosis, involvement usually includes characteristic lesions of the respiratory tract. Takayasu's arteritis, in which the pathological lesions mimic those of giant-cell arteritis, is confined to the aortic arch and its major branches and occurs chiefly in young oriental women.

Treatment

Corticosteroids are mandatory; immunosuppressive therapy has no direct effect and the modest steroid sparing rarely warrants the additional hazard. While doses of prednisolone up to 100 mg per day are often advocated, careful sequential studies indicate that lower doses are quite satisfactory (Table 3). Ophthalmologists, who

are likely to see patients with established visual effects or threatening features in the second eye, may use higher doses or methylprednisolone infusions. Dosage reduction must be gradual and should be judged solely on clinical features as acute phase responses are no guide. Most should have achieved a maintenance dose of 10 mg per day after 1 year. Subsequently the known persistence of disease in a significant proportion for 4 years or more and the possible recurrence of symptoms, including blindness, even a year after corticosteroid withdrawal argues for very gradual reduction of dosage. Unfortunately, there are no predictors of these risks. Accordingly, the hazards of therapy are even greater than in polymyalgia rheumatica and require preventive treatment for osteoporosis. Despite all the problems, giant-cell arteritis does not reduce life expectancy.

18.10.5 Behçet's disease

T. Lehner

Introduction

Behçet's disease is a recurrent, multifocal disorder that persists over many years. It was first described by Hippocrates in ancient Greece and later by Behçet, a Turkish dermatologist. Initial description of the disease comprised oral and genital ulcers and uveitis, but later a number of other clinical features were added, notably skin, joint, neurological, and vascular manifestations. This creates considerable difficulty in diagnosis and a multidisciplinary approach is often required.

An international study group has proposed a set of diagnostic criteria based on data from 914 patients with the disease from 12 centres and seven countries, requiring the presence of recurrent oral ulcers and any two of the following: genital ulcers, defined eye lesions, defined skin lesions, or a positive skin pathergy test. These criteria (Table 1) show better discrimination in sensitivity, specificity, and relative value than the previous criteria. A large number of important clinical manifestations of Behçet's disease have not been included (Table 2) because their lower frequency does not contribute to the accuracy of diagnosis. The same group has proposed that the term 'Behçet's syndrome' be replaced by 'Behçet's disease'.

Epidemiology

A striking feature of the disease is the relatively high prevalence in Japan (1 in 10 000), where in 1977 there were an estimated 11 000 patients. The prevalence is also high in countries bordering the Mediterranean: Italy, Greece, Turkey, Israel, Egypt, Lebanon, Syria, Jordan, Saudi Arabia, as well as Algeria, Tunisia, and Morocco. An epidemiological study in the United Kingdom has shown a prevalence of 1 in 170 000, which compares with 1 in 800 000 in a study in the United States.

Although the disease may develop at any age, onset is most commonly in the third decade. However, it can start in childhood with orogenital ulcers, followed by the other manifestations years or decades later. Male predominance is found in most reported series, but this may vary from 2:1 in Japan to 9:1 in the Middle East. Increased familial prevalence of the syndrome has frequently been recorded.

Aetiology

The cause of Behçet's disease is unknown but an immunogenetic basis has been established. HLA B51 is significantly associated with the disease. As with other HLA disease associations, there are at least two interpretations of these findings:

1. The HLA antigen might function as a specific receptor for viruses (or other pathogens).
2. The antigenic determinants of some pathogens might mimic the HLA antigens.

Recently, the *MIC*A6 allele (*MIC* is the major histocompatability complex class I chain-related gene, thought to be a cell stress response gene), which is in linkage disequilibrium with HLA B51, has been shown to be significantly associated with Behçet's disease.

A viral aetiology for Behçet's disease has often been claimed, but attempts to isolate viruses from patients have failed. Indirect evidence supporting a viral aetiology includes the following. Herpes simplex virus failed to replicate in inactivated cultures of mononuclear cells from patients with Behçet's disease, the interference with viral growth being interpreted as consistent with a viral aetiology of the disease. A more direct approach, using herpes simplex virus DNA probes for complementary DNA obtained from mononuclear cells of patients with Behçet's disease, showed a significant increase in hybridization, suggesting that at least part of the herpes simplex virus genome is transcribed in the circulating mononuclear cells of these patients. However, the role of the virus in the immunopathogenesis has not been elucidated; it may induce some defect in immunoregulation or invoke an autoimmune response.

A variety of streptococci (*Streptococcus sanguis*, *S. pyogenes*, *S. faecalis*, and *S. salivarius*) have been implicated in the aetiology of Behçet's disease, one hypothesis being that heat-shock protein might be a common and perhaps causative agent. Indeed, a significant increase in serum IgA antibodies to the mycobacterial 65 kDa heat-shock protein has been found in patients with Behçet's disease. Earlier reports of autoimmune responses to oral epithelial antigens have been reinvestigated, and a 65 kDa band has been identified with anti-65 kDa heat-shock protein antibodies and mucosal homogenates, as well as streptococci. This evidence, that the 65 kDa heat-shock protein might be involved in the disease is consistent with the finding of a significant increase in circulating T cells with the g† T-cell receptor. Furthermore, four peptides derived from the sequence of the mycobacterial 65 kDa heat-shock protein and the corresponding four homologous human heat-shock protein peptides specifically stimulate T cells from patients with Behçet's disease. The potential pathogenicity of some of these peptides has now been established in rats that developed anterior uveitis when the peptides were injected with adjuvant by the subcutaneous route or given orally. Overall, the evidence is growing that Behçet's disease may be closely associated with heat-shock protein peptides of microbial and crossreactive human origin.

Immunopathology

An early lymphomonocytic infiltration is usually found at the onset of ulceration in the lamina propria, the adjacent epithelium, and around small blood vessels. The latter may show endothelial cell proliferation and some obliteration of the lumen. Although the early stages are suggestive of the type IV cell-mediated immune reaction, this is followed by polymorphonuclear infiltration and fibrinoid necrosis in the blood vessels, consistent with a type III Arthus reaction. The keratinocytes of oral epithelial cells adjacent to an ulcer express HLA class II antigen.

Cell-mediated immune responses can be induced *in vitro* by homogenates of oral mucosa; these elicit lymphoproliferative responses, inhibition of leucocyte migration, and cytotoxicity. The proportion of CD4 cells may be decreased, but that of CD8 cells remains within the normal range.

Circulating immune complexes have been detected in 40 to 60 per cent of patients with Behçet's disease and are associated with disease activity. Although the concentrations of serum C3 and C4 are normal, careful sequential studies have revealed that C3, C4, and C2 are significantly reduced before an attack of uveitis, suggesting consumption of complement by the classical pathway. Electron microscopical examination of centrifuged pellets of serum reveal the presence of small membrane fragments, some of which show complement-dependent holes, suggesting that the soluble immune complex may generate C5b–9 complexes that may bind to the surface of cells and result in lysis.

Acute-phase proteins are increased in Behçet's disease, especially serum C-reactive protein and C9, which is a good marker of disease activity. An increased serum chemotactic activity is found with polymorphonuclear leucocytes and this might be due to IgG complexes releasing chemotactic factors. Serum IgA is often increased in Behçet's disease, but IgG and IgM are variable.

Unlike most autoimmune diseases, nuclear, thyroid, and gastric autoantibodies are not found in greater proportion in Behçet's disease than in the normal population. Rheumatoid factor is also negative, even in patients with joint involvement.

Clinical features

Many patients appear to be generally well and complain only of the localized lesions. However, others present with acute exacerbation of malaise, fever, dysphagia, and loss of weight. Other manifestations are listed in Table 2.

Recurrent oral ulcers

Oral ulcers are the presenting feature in most but not all patients with Behçet's disease. The ulcers can be of the minor or major aphthous or herpetiform type. However, since these ulcers are common in the general population and usually give rise only to local discomfort, they may be missed in the patient's history. Minor aphthous ulcers are found in 67 per cent of the neurological and 76 per cent of the ocular types of Behçet's disease, whereas the more severe major aphthous ulcers are found in 40 and 64 per cent, respectively, of the mucocutaneous and arthritic types. Herpetiform ulcers are found mostly in the mucocutaneous type (45 per cent). An essential feature in relation to the diagnosis of Behçet's disease is that the ulcers recur frequently, at intervals of weeks or months, but this varies from one patient to another. The long-cherished view that oral ulcers in Behçet's disease are rather severe and associated with scarring is no longer tenable. The clinical manifestations can be readily recognized and differentiated from those of similar disorders. The pharynx can also be the site of aphthous ulcers that tend to be rather large, shallow, and covered with a fibrinopurulent exudate (Fig. 1).

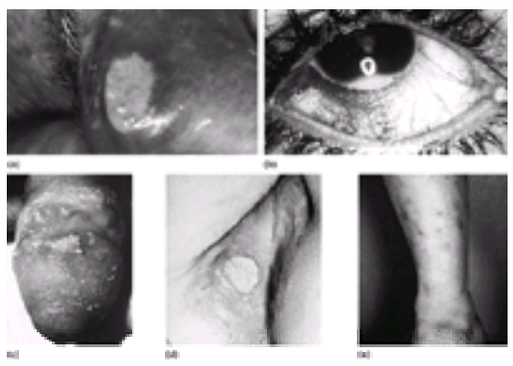

Fig. 1 Behçet's disease: (a) oral ulcer, (b) hypopyon in the eye, (c) ulceration of the head of the penis, (d) vulval ulcers, (e) multiple erythema nodosum lesions of the leg.

Genital ulcers

These are found in most, but not all, patients and can be of the three types described for oral ulcers. They affect women more commonly than men, and scars may follow healing in either sex. Females develop recurrent ulcers of their labia or vagina and they suffer from dysuria and dyspareunia. Males develop recurrent ulcers on the penis or scrotum, again with dysuria and pain on sexual intercourse; occasionally they may develop epididymo-orchitis.

Skin lesions

These vary, but diffuse pustular lesions on the face and (particularly) the back are most common. Erythema nodosum may affect the limbs or other parts of the body. Occasionally, erythema multiforme is found. Both men and women may develop perianal ulcers and, curiously, these may present in the young, well before genital ulcers have appeared.

Ocular lesions

These are the most serious developments in Behçet's disease. Relapsing uveitis, with or without hypopyon, iridocyclitis, retinal vascular lesions, and optic atrophy are common findings. Other manifestations are relapsing conjunctivitis, keratitis, and choroiditis. Gross retinal vascular changes affect both arteries and veins, and fluorescein angiography is particularly helpful in such cases. Both eyes tend to be involved: within 2 years of onset of symptoms in one eye, 90 per cent have involvement of the other eye. There is a painless, bilateral decrease in visual activity, and about 25 per cent of patients with ocular lesions become blind.

Neurological features

These are found in 10 to 25 per cent of patients with Behçet's disease. Patients most commonly develop a transient or persistent brainstem syndrome, resembling a minor stroke, but focal cerebral or spinal cord dysfunction can also occur. Others may present with meningomyelitis or meningoencephalitis, and some with organic confusional syndromes. Multiple sclerosis-like features have also been described. The cerebrospinal fluid sometimes shows pleocytosis, and raised protein and IgG concentrations but more often is normal. Computed tomography scanning does not often reveal abnormalities but the electroencephalogram can show slowing of basic rhythm. Magnetic resonance imaging is the most sensitive and reliable examination, since most patients with neurological involvement may manifest:

1. atrophy of the cerebral cortex, cerebellum, or brainstem;
2. the sinuses may be enlarged;
3. high-intensity focal lesions are found in the brainstem, basal ganglia, or the midbrain;
4. demyelinating processes may be found in the pons and medulla.

Magnetic resonance imaging can help to differentiate Behçet's disease from multiple sclerosis and other neurological diseases, as well as being useful in assessing the response to treatment.

The prognosis of Behçet's disease with neurological features used to be poor, with mortality of about 40 per cent being recorded in the literature before 1970. However, the prognosis has since been improved with reduced mortality, although whether this can be attributed to steroid and/or cytotoxic agents remains uncertain.

Arthritis or arthralgia

In about half of patients with Behçet's disease the joints are affected, typically at irregular intervals and usually more than one joint. The knees, ankles, and elbows are most commonly involved; less frequently the joints of the hands, feet, shoulders, and hips. Effusions, especially in the knees, cause considerable disability. Radiography of the joints does not usually demonstrate erosive or destructive changes, but a number of exceptions have now been recorded with erosive change in the hips, wrists, and elbows. The test for rheumatoid factor is negative.

Vascular lesions

Recurrent thrombophlebitis of leg veins is a significant feature of Behçet's disease. This has been ascribed to decreased plasma fibrinolytic activity. Less frequently,

thrombosis of the superior or inferior vena cava may develop. Arterial aneurysms have also been reported.

Gastrointestinal manifestations

These are ill-defined. The Japanese literature records diarrhoea, distension, nausea, and anorexia in more than half of patients. The ileocaecal region is the most common part of the gut to be affected. However, a British series failed to identify consistent gastrointestinal manifestations, although various transient symptoms were noted in 13 of 70 patients; two of these had rectal ulcers and one each an anal ulcer, a small intestinal ulcer, and perianal fistula. It should be noted that patients with inflammatory bowel disease are excluded from the diagnosis of Behçet's disease by the Mayo Clinic, although they may fulfil current criteria for that diagnosis.

Renal involvement

This has not been established in Behçet's disease. A small number of patients have been reported with Behçet's disease and amyloidosis affecting the kidneys, and a few also with glomerulonephritis. It is doubtful if these renal changes can be considered as primary manifestations of the disease, and they may well be coincidental. Asymptomatic proteinuria and haematuria without evidence either of amyloidosis or nephritis have also been reported in a small number of patients. In a prospective British study, two out of 38 patients with Behçet's disease showed evidence of renal disease: one of these, with biopsy-proven focal proliferative glomerulonephritis, has had no clinical symptoms, and in a 5-year follow-up period the glomerular filtration rate remained normal.

Pulmonary manifestations

These have been reported occasionally, usually with haemoptysis. In some of these patients, pulmonary tuberculosis has been suspected.

Diagnosis

A set of diagnostic criteria is presented in the Introduction (Table 1) that requires recurrent oral ulcers and any two of the following: genital, eye or skin lesions, or a positive pathergy test. However, it is recognized that the wide spectrum of clinical manifestations may not fit the above criteria and the terms incomplete and complete Behçet's disease are often used. The spectrum of the disorder can be divided into four types:

1. Mucocutaneous disease—involving oral and genital ulcers, with or without skin manifestations.
2. Arthritic type—when joint involvement is combined with some or all of the mucocutaneous manifestations.
3. Neurological type—involving the central nervous system and some or all of the features in (1) and (2).
4. Ocular type—affecting the eyes with some or all the features described in (1), (2), and (3).

Thrombosis of blood vessels can be found in any of the types of Behçet's disease, as can some of the other clinical features.

HLA B51 is significantly associated with, but not diagnostic of, the disease. The pathergy test, whereby a sterile subcutaneous puncture (without injection of any material) elicits a pustular reaction within 24 to 48 h, has been used as a diagnostic test in the Middle Eastern countries and in Japan. The presence of immune complexes is consistent with Behçet's disease and so are the raised levels of acute-phase-reacting proteins; C9 is particularly useful in monitoring the course of the disorder.

Patients with rheumatoid arthritis, osteoarthritis, or Reiter's syndrome are excluded from the diagnosis of Behçet's disease, as are patients with a firm diagnosis of ulcerative colitis or Crohn's disease. Stevens–Johnson syndrome may mimic Behçet's disease, but the recurrences are less frequent and tend to be seasonal, the ulcers are large and shallow, the lips are often covered with haemorrhagic crusts, and the skin may show typical lesions of erythema multiforme. Sarcoidosis and viral retinitis should be excluded.

Treatment

The management of patients with Behçet's disease can be difficult, as it requires close liaison between different specialties. Whenever possible, topical treatment of local lesions should be attempted before embarking on systemic anti-inflammatory or immunosuppressive therapy.

Oral and genital ulcers often respond to topical application of steroids or tetracycline or both. Uveitis is initially treated with mydriatic agents and local steroids. However, at some stage systemic prednisolone is usually administered, with a starting dose of 30 to 60 mg/day, which is rapidly brought down to a minimum effective maintenance dose of about 10 mg. There is usually a prompt response, although a small core of patients are resistant to steroid therapy. Azathioprine is often used with prednisolone (2–3 mg/kg body weight daily) and, quite apart from its steroid-sparing function, it may have additional beneficial effects. Colchicine has been advocated by Japanese and Turkish physicians, especially for the treatment of the mucocutaneous type of the disease, with a recommended dose of 0.5 mg twice a day. The rationale is that this drug inhibits the motility of polymorphonuclear leucocytes that is increased in Behçet's disease. There is a general consensus that cyclosporin (2.5–5 mg/kg body weight) should be used in patients with unresponsive uveitis, and is helpful in most patients, though its effect may gradually decline. However, cyclosporin is contraindicated in patients with neurological manifestations, because it may cause or enhance these features. Chlorambucil has also been applied successfully in the treatment of uveitis, but side-effects have limited its application. Recently, interferon-a has been found to be effective in the treatment of ocular manifestations of Behçet's disease. Thalidomide appears to be surprisingly effective in the treatment of orogenital ulcers and pustular lesions, but its teratogenic effect prevents its use in those who are or could become pregnant. Anticoagulant treatment is indicated in deep vein thrombosis.

18.10.6 Sjögren's syndrome

Patrick J. W. Venables

Introduction

Sjögren's syndrome is characterized by inflammation and destruction of exocrine glands. The salivary and lachrymal glands are principally involved, giving rise to dry eyes and mouth. It was originally described by Sjögren in 1933 as the triad of dry eyes, dry mouth, and rheumatoid arthritis. It is now classified as primary Sjögren's syndrome where the disease exists on its own, and secondary Sjögren's syndrome where it is associated with other diseases. Well-recognized secondary associations are rheumatoid arthritis, systemic lupus erythematosus, scleroderma, polymyositis, and primary biliary cirrhosis. The recent descriptions of a Sjögren's syndrome-like illness in patients infected with HTLV-I, HIV-1, and hepatitis C virus infection have drawn attention to the importance of considering these viruses in differential diagnosis, as well intensifying the search for a virus underlying idiopathic disease.

Aetiology and pathology

The aetiology of Sjögren's syndrome is unknown but is often considered to be an interaction between constitutional and environmental factors leading to autoimmunity. Primary Sjögren's syndrome is strongly associated with HLA DR3, and the linked genes *B8*, *DQ2*, and the *C4A* null gene. Aetiological candidates for triggering autoimmunity in Sjögren's syndrome are viruses that infect the salivary gland. Sialotropic herpesviruses including Epstein–Barr virus, cytomegalovirus, and human herpesvirus-6 have been examined with conflicting reports of abnormal responses to infection. Using DNA hybridization techniques, Epstein–Barr virus has been detected in the parotid gland and in labial biopsies, but it remains controversial whether the virus is simply persistent in the glands or whether it is triggering inflammation in Sjögren's syndrome. Retroviruses have also attracted interest recently as they infect and persist in cells of the immune system such as T cells and macrophages, and infect salivary gland epithelium. In spite of increasing circumstantial evidence for their involvement in Sjögren's syndrome, the demonstration of a pathogenic role remains elusive.

The cardinal pathological features of Sjögren's syndrome are inflammation and destruction of salivary gland tissue. The inflammatory infiltrates consist of focal aggregates of lymphocytes, mainly CD4-positive T cells, localized around ducts and acini. Scattered interstitial plasma cells are commonly found, although these are not disease specific and are also found in glands from healthy individuals. The destructive changes are predominantly duct dilation, acinal atrophy, and interstitial fibrosis. These latter findings have also been described in biopsies from people without Sjögren's syndrome, particularly in the elderly, and cannot be regarded as diagnostically specific.

The most striking feature of the systemic autoimmune response in Sjögren's syndrome is the marked activation of B cells which can lead to immunoglobulin levels of over three times the upper limit of the normal range. Rheumatoid factors of all isotypes are observed in blood in about 70 per cent of patients and their detection can lead to some patients with Sjögren's syndrome being misdiagnosed as having rheumatoid arthritis. The typical autoantibodies are those against the cellular ribonucleoprotein antigens Ro and La, named after the patients in whom the antibodies were originally described. Anti-Ro antibodies are more frequently detectable (50–90 per cent of cases) than anti-La antibodies (30–50 per cent of cases), but the latter are more diagnostically specific for primary Sjögren's syndrome. More recently two further potential autoantigens have been described: fodrin, which is a cellular protein involved in apoptosis, and the muscarinic acetylcholine receptor, which is important in mediating parasympathetic stimulation of exocrine glands. An astonishing degree of diagnostic sensitivity and specificity has been claimed for serum antibodies to both antigens in Sjögren's syndrome, but these findings have yet to be confirmed by independent laboratories and must be interpreted with caution.

Clinical features

Sjögren's syndrome is nine times more common in women than men and can develop at any age from 15 to 65. Patients rarely complain of dry eyes, but rather a gritty sensation, soreness, photosensitivity, or intolerance of contact lenses. In early disease excessive watering or deposits of dried mucus in the corner of the eye and recurrent attacks of conjunctivitis may occur. The dry mouth is often manifest as the 'cream cracker' sign, inability to swallow dry food without fluid, or waking up in the night to take sips of water. About half of the patients complain of intermittent parotid swelling, sometimes misdiagnosed as recurrent mumps. When the swelling is excessively painful it is often due to secondary bacterial infection. On examination, xerostomia can be detected as a diminished salivary pool, a dried fissured tongue, often complicated by angular stomatitis, and chronic oral candidiasis. The eyes may be reddened and roughened due to shallow erosions in the conjunctivae. Occasionally the front of the eye is eroded to reveal strands of underlying collagen leading to the appearance of filamentary keratitis.

Other exocrine glands may be affected. Dry nasal passages and upper airways may lead to recurrent bouts of sinusitis, a dry cough, and, possibly, a higher than expected frequency of chest infections. Dry skin and dry hair are symptoms frequently elicited on direct questioning. About 30 per cent of women with Sjögren's syndrome have diminished vaginal secretions and may present with dyspaerunia. Involvement of the gastrointestinal tract leads to reflux oesophagitis or gastritis due to lack of protective mucus secretion, and some patients complain of constipation, which may be attributed to defective mucus in the colon and rectum. Rarely, pancreatic failure leading to malabsorption syndromes may occur.

Recent studies have highlighted yet another complication, namely interstitial cystitis. It has been suggested that this is due to an autoimmune immune response to the muscarinic acetylcholine receptor that is extensively expressed in the bladder wall. There is no doubt about the clinical association, although the serological link awaits confirmation.

There is a higher than expected frequency of thyroid autoimmunity in those with Sjögren's syndrome: whether this is part of the same pathological process is debatable, but it is important to check thyroid function from time to time in patients with this condition.

Systemic manifestations

True Sjögren's syndrome is a systemic disease. Two-thirds of patients complain of fatigue, which, according to a recent epidemiological study, is the single most important cause of disability. Occasionally weight loss and fever mimicking an occult malignancy may be the presenting symptoms, particularly in the elderly. Other features include an arthritis that resembles the Jaccoud-like arthritis of systemic lupus erythematosus (Fig. 1). Raynaud's phenomenon occurs in about 50 per cent of patients, though a true vasculitis is less common. Waldenström's benign hypergammaglobulinaemic purpura affecting the lower legs is found in patients with very high IgG levels. Patients with Sjögren's syndrome may also present with polymyalgia rheumatica or, much less frequently, polymyositis. Pleurisy occurs in about 40 per cent of patients and a high prevalence of abnormalities of pulmonary function has been described, although these are rarely clinically significant. A wide range of neurological diseases has been described: peripheral neuropathies are relatively common, particularly mononeuritis multiplex mediated by vasculitis, and a condition resembling multiple sclerosis has been reported. Interstitial nephritis leading to renal tubular acidosis or nephrogenic diabetes insipidus occurs in about 30 per cent of patients: these are usually subclinical but may lead to hypokalaemia causing muscular weakness or, occasionally, nephrocalcinosis. Lymphoma, almost always of B-cell lineage, is a characteristic but unusual feature. This occurs in about 5 per cent of patients referred to specialist centres and is particularly likely in patients with high levels of immunoglobulins, autoantibodies, and cryoglobulins. As the lymphoma develops, the immunoglobulin levels often fall and the autoantibodies become negative. Women of childbearing age are at increased risk of giving birth to babies with congenital heart block. Although rare, about 1 in 20 000 births, this complication is of great immunopathogenic interest as it is thought to be mediated by transplacental transfer of anti-Ro and anti-La antibodies.

Fig. 1 Hands of a patient with long-standing primary Sjögren's syndrome showing correctable swan-necking deformities similar to the Jaccoud-like arthritis seen in systemic lupus erythematosus.

In secondary Sjögren's syndrome the sicca symptoms are less severe than in primary disease. In rheumatoid arthritis with Sjögren's syndrome the patient tends to have more frequent extra-articular disease manifested as digital infarcts and subcutaneous ulcers. In systemic lupus erythematosus, those with Sjögren's syndrome have a lower frequency of renal disease and a relatively good prognosis.

Diagnosis

Keratoconjunctivitis sicca can be detected by Schirmer's test, tear break-up time, and Rose Bengal staining and xerostomia by a reduced parotid salivary flow rate and by reduced uptake and clearance on isotope scans. It is important to remember that both salivary and lachrymal function decline with age and may be impaired in conditions other than Sjögren's syndrome. One cause of diagnostic confusion arises from treatment with drugs with anticholinergic side-effects, the most frequent being the tricyclic antidepressants.

Biopsy and histology of the labial glands from behind the lower lip provides the most definitive diagnostic test. The area is anaesthetized with lidocaine (lignocaine) containing adrenaline and an incision 1.5 cm long allows access to five to ten glands 2 to 4 mm in diameter that are removed by simple blunt dissection. A diagnosis of Sjögren's syndrome depends on finding foci of periductular infiltrates of at least 50 lymphocytes and/or plasma cells at a density of more than one focus/4 mm^2 (Fig. 2).

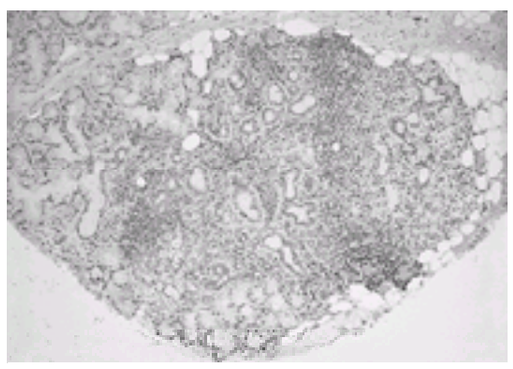

Fig. 2 Biopsy showing a lobule of minor salivary gland from a patient with Sjögren's syndrome. There is a focal inflammatory infiltrate surrounding blood vessels and ducts with the acini being relatively spared.

The majority of patients have a raised erythrocyte sedimentation rate and a mild normocytic anaemia with leucopenia in about 50 per cent of cases. One of the most remarkable features of primary Sjögren's syndrome is a high level of IgG, which can be up to 50 g/litre. Complement levels are usually normal, although C4 levels can sometimes be reduced because of the link between Sjögren's syndrome and the *C4A* null gene. Anti-La antibodies, although of relatively low sensitivity, are of great diagnostic help when present.

Rheumatoid factors, as measured by routine assays, occur in all forms of Sjögren's syndrome and their detection in primary disease is a common reason for misdiagnosing such patients as having rheumatoid arthritis. Similarly, antinuclear antibodies can occur. Both rheumatoid factors and antinuclear antibodies, although not diagnostically specific, can help in distinguishing Sjögren's syndrome from non-autoimmune causes of sicca symptoms. Primary Sjögren's syndrome can be mimicked very closely by infection with HTLV-I, HIV-1, and hepatitis C virus. All three diseases cause dry eyes and mouth, swelling of salivary glands, and biopsy changes very similar to that of primary Sjögren's syndrome. All are associated with hypergammaglobulinaemia, a raised erythrocyte sedimentation rate, and autoantibodies, although anti-Ro and anti-La are unusual. The only way to differentiate them with certainty is by specific serological testing. The Sjögren's-like syndrome associated with HIV infection has been termed diffuse infiltrative lymphocytosis syndrome and occurs in approximately 5 per cent of HIV-positive individuals. Chronic fatigue syndrome is frequently mistaken for Sjögren's syndrome and vice versa (less frequently); a salivary gland biopsy usually clarifies the situation.

Diagnostic criteria

Diagnostic criteria are essential for the standardization of any research involving patient groups, particularly with a disease, or group of diseases, as heterogeneous as Sjögren's syndrome. Currently used criteria depend on the demonstration of keratoconjunctivitis sicca, xerostomia, and a positive labial gland biopsy. The 'European' criteria based on the results of a multicentre European study are probably the most thoroughly evaluated and the simplest to apply. They are based on a short questionnaire (Table 1) about ocular and oral symptoms. Other essential criteria are ocular signs (by Schirmer's test or Rose Bengal staining), lymphocytic infiltrates on lip biopsy, salivary gland involvement (scintigraphy, sialography, or decreased salivary flow rate), and demonstration of serum autoantibodies (rheumatoid factors, antinuclear antibodies, and/or Ro or La antibodies).

Treatment

Most treatment in Sjögren's syndrome is topical and symptomatic. Simple measures can help preserve the integrity of the cornea as well as the gums and teeth and are worth pursuing with enthusiasm rather than with the negative attitude that some patients find in their physicians. Tear substitutes, such as hypromellose eye drops, are the mainstay of treatment for dry eyes, and it is generally worth trying several different types before settling on the most suitable preparation. Where thick mucus strands are a particular problem topical acetylcysteine may help. Eye ointments, particularly at night, can help lubricate sticky eyes. Bacterial infection should be treated immediately with chloramphenicol ointment or drops. Some benefit can be achieved by preventing evaporation of tears by fitting side panels to spectacles. Temporary or permanent occlusion of the canaliculi or, rarely, tarsorraphy may help to retain tears within the conjunctival sac.

The dry mouth may be treated with saliva substitutes that are now available as convenient sprays. Pilocarpine tablets have shown promising results in recent controlled trials but patients often seem to stop taking them after a few weeks or months because of cholinergic side-effects such as palpitations, sweating, and abdominal cramps. Candidal infections are extremely common in Sjögren's syndrome and are often missed. They are best treated with prolonged courses of anticandidal drugs such as fluconozole 50 mg daily for ten days. Attention to dental hygiene may help to prevent the premature caries that is a common problem in Sjögren's syndrome.

Attempts to treat the underlying disease with steroids or cytotoxic drugs are generally thought ill-advised unless there are systemic complications. Fever, weight loss,

parotid swelling, and interstitial cystitis often respond well to a low dose of steroids. Serious systemic complications such as polymyositis, mononeuritis multiplex, or fibrosing alveolitis are treated with steroids and cytotoxic drugs as in other connective tissue diseases. The arthritis of primary Sjögren's syndrome may be treated with anti-inflammatory drugs, although it also responds to hydroxychloroquine. There is no convincing evidence that methotrexate has a role in Sjögren's syndrome. It is generally agreed that other second-line agents for rheumatoid arthritis such as gold or sulphasalazine are associated with a high frequency of side-effects and this is one of the most important reasons for distinguishing between the arthritis of primary Sjögren's syndrome and rheumatoid arthritis.

There is accumulating evidence that hydroxychloroquine may have a beneficial disease-modifying effect in Sjögren's syndrome. Certainly the drug helps with arthralgia, lowers the erythrocyte sedimentation rate and immunoglobulin levels, and may also prevent bouts of purpura. More importantly there is anecdotal evidence that it may help with fatigue. Properly controlled clinical trials are needed to address this point, but it could be that hydroxychloroquine will emerge as the first disease-modifying drug which can be used in patients with uncomplicated disease.

18.10.7 Polymyositis and dermatomyositis

John H. Stone and David B. Hellmann

Introduction

Polymyositis and dermatomyositis are the two major types of inflammatory muscle disease. Despite numerous shared features, immunopathological evidence now confirms that they are separate disorders. Polymyositis and dermatomyositis are considered to be autoimmune diseases because of their inflammatory nature and the frequent occurrence of autoantibodies (both antinuclear antibodies and myositis-specific antibodies), but the precise causes of these disorders remain unknown. Both are associated with proximal muscle weakness, and both may affect organs other than skeletal muscle, such as the lungs and heart. In adults, dermatomyositis is so frequently a paraneoplastic disorder that its diagnosis should prompt a search for an underlying malignancy.

Clinical features

Classification and epidemiology

The traditional classification of polymyositis and dermatomyositis distinguishes between five subgroups of patients:

1. primary idiopathic polymyositis;
2. primary idiopathic dermatomyositis;
3. either disorder occurring in association with a malignancy;
4. childhood dermatomyositis (or, more rarely, polymyositis); and
5. overlap syndromes, in which polymyositis or dermatomyositis occur along with features of other systemic autoimmune conditions.

This chapter focuses on primary idiopathic polymyositis and dermatomyositis, referring to the other subgroups when appropriate. The principal features of polymyositis and dermatomyositis are displayed in Table 1.

In general, polymyositis and dermatomyositis may afflict individuals of any age and either gender, but female cases outnumber males by a 2:1 ratio. Cases associated with malignancy are clustered among older patients with dermatomyositis, and seldom if ever occur among children.

Polymyositis

Polymyositis is characterized by symmetrical proximal muscle weakness that develops slowly, usually over weeks to months. Routine tasks that require proximal muscle strength, for example rising from a chair or climbing stairs, become increasingly challenging for the patient. In addition to weakness of the extremities, skeletal muscles at many sites, including the upper one-third of the oesophagus, the muscles of neck flexion, the intercostal muscles, and the diaphragm, are also susceptible to muscular inflammation. Dysphagia and nasopharyngeal regurgitation of food may result from oesophageal involvement. Patients with severe neck flexor weakness secondary to polymyositis may be unable to lift their heads from the pillow. Hypercapnoeic respiratory failure sometimes results from weakness of the chest wall muscles and diaphragm. By contrast, polymyositis usually spares the muscles that mediate facial expression and extraocular movements, even in patients with profound weakness elsewhere. Similarly, handgrip strength and the ability to perform fine motor tasks usually remain preserved until advanced stages of the disease.

Prominent muscle pain and tenderness are atypical, and rarely constitute the chief complaint. Deep tendon reflexes and muscle bulk are preserved except in severe, advanced disease. Fasciculations, a manifestation of denervation rather than myopathic injury, are absent in polymyositis. Similarly, sensory function remains normal even as muscle weakness progresses. Endomysial inflammation leads to the release of muscle enzymes into the blood. Thus, polymyositis is characterized by striking elevations of serum creatine kinase, aldolase, aspartate aminotransferase, alanine aminotransferase, and lactate dehydrogenase.

Dermatomyositis

The pattern of muscle involvement in dermatomyositis is clinically indistinguishable from that of polymyositis. In addition to inflammatory muscle disease, however, dermatomyositis has an array of characteristic cutaneous manifestations. Gottron's sign, an erythematous, scaly eruption confined to skin overlying the knuckles, is pathognomonic of this disease (Fig. 1 and Plate 1). Identical lesions known as Gottron's papules also occur over the extensor surfaces of many other joints, particularly the elbows and knees. The heliotrope rash consists of a lilac discoloration of skin over the eyelids, often accompanied by eyelid oedema (Fig. 2 and Plate 2). Cutaneous erythema may involve several sites in dermatomyositis, including the upper back and shoulders (the 'shawl sign'), the upper chest (in a 'V' distribution), and the face and hands. 'Mechanic's hands' (see below) often occur in association with certain types of myositis-specific antibodies.

Fig. 1 Gottron's sign. Roughened, violaceous papules over the dorsal surfaces of several metacarpophalangeal and proximal interphalangeal joints. Note also the erythema at the bases of the fingernail, caused by capillary loop dilatation. (See also Plate 1.)

Fig. 2 Heliotrope rash. An erythematous (often lilac-coloured) rash over the eyelids in a patient with dermatomyositis (reproduced from Mousari HC, Wigley FM (2000). *Journal of Rheumatology* **27**,1542-5 with permission). (See also Plate 2.)

Patients with dermatomyositis may mimic systemic lupus erythematosus in demonstrating photosensitivity and malar rash. Skin biopsies in these two diseases share the histopathological features of 'interface dermatitis', i.e. immune complex deposition at the dermal–epidermal junction. Acral regions are also affected by characteristic features. Both periungual erythema and capillary loop dilatation underscore the vascular nature of this disorder. Sometimes the classic skin features are apparent for months before muscle weakness becomes evident, in which case the condition is termed amyopathic dermatomyositis (or 'dermatomyositis sine myositis').

Extramuscular features

Lung

Weakness of the intercostal muscles and diaphragm occasionally leads to ventilatory failure in polymyositis or dermatomyositis. More commonly, however, patients suffer pulmonary involvement in the form of interstitial lung disease, a complication that occurs in up to 30 per cent of cases. The pattern of pulmonary involvement in the inflammatory myopathies is typical of that which occurs in connective tissue disorders, namely interstitial fibrosis, predominantly at the lung bases. High-resolution computed tomography is very sensitive for detecting this type of pulmonary change, which in the early stages corresponds to an inflammatory alveolitis. The severity of interstitial lung disease in polymyositis and dermatomyositis ranges from asymptomatic radiological findings to a refractory process indistinguishable from idiopathic pulmonary fibrosis. Lung involvement is often, but not always, associated with antisynthetase antibodies (see below). Restrictive findings on pulmonary function testing are the rule. Another common pulmonary complication of the inflammatory myopathies is aspiration pneumonia, caused by weakness of the hypopharynx and upper oesophagus.

Cardiac

Cardiac involvement in polymyositis or dermatomyositis is usually subclinical, and its prevalence is not known with certainty. When measured, creatine kinase-MB isoenzyme levels are frequently elevated in the absence of overt cardiac symptoms. Electrocardiograms usually demonstrate non-specific ST-T wave changes. Even so, the occurrence of clinically evident myocarditis in these diseases may lead to cardiac failure or intractable, life-threatening arrythmias.

Gastrointestinal

Involvement of the gastrointestinal tract beyond the pharynx and oesophagus is particularly common in juvenile dermatomyositis (the childhood form). This complication is mediated by vasculitis, and may result in intestinal haemorrhage or perforation.

Malignancy

A significant proportion of adults with polymyositis or dermatomyositis have underlying malignancies, usually carcinomas. The association with malignancy is stronger for adults with dermatomyositis, who die from cancer significantly more often than age-matched controls. The weaker association of polymyositis with malignancy may be attributable to ascertainment bias resulting from more frequent visits to the doctor and cancer surveillance.

Many types of malignancy have been reported in association with dermatomyositis, including lung, oesophageal, breast, colon, and ovarian tumours. Among women with dermatomyositis, the risk of ovarian cancer may be 20 times greater than that of the general population. Most patients diagnosed with primary polymyositis or dermatomyositis (children excepted) should undergo some surveillance for a disease-associated malignancy. This screening should be based upon careful histories, physical examinations, and the performance of a limited number of routine tests (for example chest radiography), in addition to age-appropriate cancer screening such as mammography and flexible sigmoidoscopy. Costly, undirected 'fishing expeditions' rarely benefit the patient.

Differential diagnosis

Polymyositis and dermatomyositis must be distinguished from numerous disorders that cause subacute weakness. These are shown in Table 2.

Pathology

Polymyositis is characterized by an endomysial infiltrate containing large numbers of CD8+ T cells, combined with foci of cytotoxic T cells and macrophages. The inflammatory infiltrate surrounds and invades non-necrotic muscle fibres. In polymyositis, both uninvolved and involved fibres express increased amounts of HLA class I antigen (normal muscle fibres, by contrast, express neither class I nor class II antigens). Thus, the pathological findings in polymyositis suggest an HLA class I-restricted immune response mediated by cytotoxic T cells. Polymyositis must be distinguished from inclusion body myositis, a more indolent form of inflammatory myopathy associated with asymmetric and distal motor weakness. Inclusion body myositis has distinctive pathological findings: 'rimmed vacuoles' distributed around the myocyte's edge, basophilic 'inclusion bodies' within these vacuoles, and filamentous inclusions within the cytoplasm. Cases of 'refractory polymyositis' are often misdiagnoses of inclusion body myositis.

Muscle biopsies from patients with dermatomyositis contain increased numbers of CD4+ T cells and B lymphocytes. The inflammatory infiltrate in dermatomyositis is localized to perivascular regions. Capillary obliteration, fibrin thrombi, and endothelial cell damage are all hallmarks of dermatomyositis. Evidence of the membrane attack complex, comprising complement components C5 to C9, is present early in dermatomyositis, consistent with the humorally mediated destruction of muscle-associated microvasculature. Focal capillary depletion is one of the earliest pathological changes. In addition to its vascular orientation, the inflammatory infiltrate in dermatomyositis centres on the interfascicular septae and around, rather than within, muscle fascicles. Even in the absence of inflammation, perifascicular atrophy is diagnostic of dermatomyositis.

Myositis-specific antibodies

Approximately 30 per cent of patients with polymyositis/dermatomyositis have myositis-specific antibodies, immune globulins directed against a variety of nuclear or cytoplasmic antigens. Three major types of myositis-specific antibodies have been identified: the antisynthetases; antisignal recognition particle antibodies (**anti-SRP**); and anti-Mi-2 antibodies. Individual patients generally develop only one type of myositis-specific antibody. The antisynthetase antibodies are directed against aminoacyl-tRNA synthetase enzymes, which catalyse the attachment of specific amino acids to their cognate tRNAs. In the case of Jo-1 (the most common type of myositis-specific antibody), the antibody is formed against antihistidyl-tRNA synthetase. Anti-Jo-1 antibodies inhibit the function of their target antigens *in vitro*. In addition to anti-Jo-1 antibodies, antibodies to several other aminoacyl-tRNA synthetase enzymes have been described, including anti-OJ, anti-PL-12, and anti-KJ.

Patients with antisynthetase antibodies often manifest a unique disease phenotype known as 'the antisynthetase syndrome'. This syndrome occurs in 30 per cent of

patients with either polymyositis or dermatomyositis. It is characterized by relatively acute disease onset, the presence of constitutional symptoms (for example fever), interstitial lung disease, Raynaud's phenomenon, arthritis, and 'mechanic's hands'. 'Mechanic's hands' consist of roughened, cracked skin on the lateral and palmar surfaces of the fingers and hands, with irregular, dirty-appearing lines, resembling the hands of a manual labourer. The presence of antisynthetase antibodies in a patient denotes a disease phenotype that usually responds to corticosteroid treatment but which is likely to persist. Thus, patients with antisynthetase antibodies may be candidates for early use of immunosuppressive agents in addition to corticosteroids.

Anti-SRP antibodies occur exclusively in polymyositis. They react with the signal recognition particle, a complex of RNA and protein involved in translocating newly synthesized proteins into the endoplasmic reticulum. Anti-SRP antibodies, which occur in approximately 5 per cent of all adult patients with polymyositis, are associated with muscle inflammation of acute onset, severe degree, and refractoriness to therapy.

Finally, anti-Mi-2 antibodies almost always occur in patients with dermatomyositis, often in patients whose cutaneous involvement is prominent. The target of Mi-2 is a complex of nuclear proteins whose function remains unknown. In comparison with patients with antisynthetases and anti-SRP antibodies, those with antibodies to Mi-2 usually have better treatment outcomes.

Diagnosis and treatment

The unequivocal presence of Gottron's sign in association with proximal muscle weakness and elevation of muscle enzymes obviates the need for muscle biopsy because it is pathognomonic. In virtually all other cases of possible polymyositis or dermatomyositis, however, confirmation of the diagnosis by muscle biopsy is essential. Other studies, such electromyography, nerve conduction studies, and magnetic resonance imaging, are adjuncts to diagnosis but do not supplant tissue biopsy.

Corticosteroids, usually beginning with 1 mg/kg/day of prednisone, remain the cornerstone of all initial treatment regimens for polymyositis and dermatomyositis. Decline of the creatine kinase level within 2 weeks of starting treatment may portend a good outcome, but improvement in muscle strength frequently lags and is sometimes not evident for up to 3 months. Patients should be treated with 1 mg/kg/day of prednisone until the creatine kinase is normal (or nearly so), and then undergo a slow taper that does not exceed 10 mg/month. Once the steroid taper has begun, creatine kinase levels are useful in gauging disease activity, but mild creatine kinase elevations do not justify escalations in treatment, particularly if the patient's muscle strength continues to improve. Conversely, once treatment has begun, low creatine kinase levels do not guarantee inactive muscle disease. Dermatomyositis is particularly notorious for the finding of low or normal creatine kinase levels despite active muscle inflammation. Steroid myopathy is a common complication of treatment, and may be difficult to distinguish from active disease.

Many patients with polymyositis or dermatomyositis require additional immunosuppressive agents during their course.

Methotrexate (up to 25 mg/week) or azathioprine (2 mg/kg/day) are the initial second-line agents of choice. Cyclophosphamide may be preferred for patients who have severe interstitial lung disease at presentation or for the rare patient presenting with overt features of necrotizing vasculitis. Intravenous immune globulin is useful in refractory cases of dermatomyositis, but its expense precludes its use in all patients as an initial therapy. Finally, in addition to pharmacological treatments, physical therapy and rehabilitative medicine play important roles in patient recovery.

Prognosis

Prompter diagnoses, a broader range of therapies, and improved general medical care have improved the 5-year survival rate of patients with polymyositis or dermatomyositis to greater than 80 per cent. However, morbidity from both the diseases themselves and their treatments is high, and few patients emerge from treatment cured and unscathed. Several variables may contribute to worse outcomes or suboptimal therapeutic responses, including delay in diagnosis, the presence of severe myositis, dysphagia, pulmonary or cardiac involvement, the diagnosis of inclusion body myositis, association with malignancy, and the presence of certain myositis-specific antibodies.

18.10.8 Kawasaki syndrome

Tomisaku Kawasaki

Introduction

Kawasaki disease, first described by Kawasaki in 1967, is an acute febrile, multisystem vasculitic illness of unknown aetiology most commonly affecting children younger than 5 years of age. Originally, the prognosis was believed to be favourable. However, as more studies were carried out, the mortality rate was found to be about 0.3 to 0.5 per cent, but this has subsequently declined to around 0.05 to 0.1 per cent. Autopsy findings revealed exceptional pathological features such as coronary artery aneurysms with thrombosis in many cases. However, since the disease cannot be differentiated histopathologically from infantile periarteritis nodosa (infantile polyarteritis), previously the subject of a few reports in the American and European literature, it is still unclear whether Kawasaki disease is a new entity or a condition that had previously been overlooked. This problem will remain unsolved until the pathogenesis of both diseases is determined.

Although in most cases Kawasaki disease is self-limiting, approximately 25 per cent of untreated patients manifest coronary artery changes such as dilatation and/or aneurysms on echocardiogram. Since 1984, treatment with high-dose intravenous immunoglobulin (**IVIG**) has been used to produce a rapid resolution of the fever and other inflammatory manifestations of Kawasaki disease, in addition to reducing the frequency and severity of coronary artery abnormalities.

Since more than 30 years has elapsed from the first description of Kawasaki disease, some of the earlier patients are now adults. The coronary artery features of the condition may be an important cause of ischaemic heart disease in young adults. Physicians should therefore ask patients with ischaemic heart disease, particularly those under 40 years of age, whether they have a history of childhood Kawasaki disease.

Clinical manifestations

Kawasaki disease is a clear-cut clinical entity that can be diagnosed after the recognition and analysis of six main symptoms (Table 1). The clinical features can be classified into two categories: principal and subsidiary. At least five of the six main features are required for diagnosis. However, patients with four features can also be diagnosed as having the condition, provided that coronary aneurysms are identified by echocardiography or coronary angiography.

Principal features

Fever of unknown aetiology lasting 5 days or more

In general, the onset of Kawasaki disease is with abrupt high fever but without prodromal symptoms such as coughing, sneezing, or rhinorrhoea. Cervical lymphadenopathy is sometimes felt, particularly if the patient complains of neck pain, and this can precede the fever by a day. Usually the fever is remittent or continuous, ranging from 38 °C to 40 °C, for 1 to 2 weeks. High fever lasting more than 2 weeks is seen in 14 to 20 per cent of untreated cases, but it rarely lasts for more than 30 days. The longer the high fever continues, the greater the possibility of coronary artery aneurysm. Nothing apart from IVIG appears to reduce the fever, which resolves significantly faster when IVIG is administered with aspirin, as compared to therapy with aspirin alone. However, in about 10 per cent of cases, IVIG is not effective in reducing fever.

Bilateral congestion of ocular conjunctiva

Conjunctival infection develops 2 to 4 days after the onset of fever. Each capillary vessel is dilated. There is no purulent discharge, so the term 'conjunctivitis' is inappropriate. In most cases redness of the eyes is obvious, but in some cases it can only be seen upon very close examination. Pseudomembrane formation, iris adhesion, or visual disturbance has not been reported. Anterior uveitis can be observed in 66 per cent of cases upon careful slit-lamp examination early in the course of the disease.

Changes of lips and oral cavity

Dryness, redness, and fissuring of the lips occur 3 to 5 days after the onset of fever. The membranes of the oral cavity and pharyngeal mucosa are diffusely red. There is no vesicle, aphtha, or pseudomembrane formation. Frequently there is prominence of the tongue papillae, referred to as a strawberry tongue and similar to that seen in scarlet fever (Fig. 1 and Plate 1).

Fig. 1 Typical appearance of a patient with Kawasaki disease, note the red eyes and red lips (picture of a 5-year-old boy, taken on the fourth day of illness). (See also Plate 1).

Acute non-purulent swelling of cervical lymph nodes

From the day before the onset of fever, or together with fever, there is swelling of the cervical lymph nodes. The patient complains of pain and often suffers a wry neck. In some cases the swelling occurs several days after the onset of fever. The nodes range from 1.5 to 5 cm in size and form a firm, non-fluctuant mass. Sometimes there is bilateral swelling leading to a misdiagnosis of mumps.

Polymorphous exanthema

From the first to the fifth day after the onset of fever, a polymorphic rash appears on the trunk or extremities. It is variously morbiliform, scarlatiniform, urticariform, or

erythema multiform-like. In each case the rash is a different combination of these forms. They are not accompanied by vesicles or crusts, but sometimes there are small aseptic pustules on the knees, buttocks, or other sites. The eruptions usually disappear in less than a week.

Changes in the extremities

Approximately 2 to 5 days after the onset of the disease, when the rash on the trunk has appeared, there is reddening of the palms and soles. Simultaneously, there is an indurative oedema in the hands and feet. From 10 to 15 days after the onset of the illness, desquamation begins from the tips of the fingers and membranous desquamation spreads over the palm up to the wrist. From 45 to 60 days after onset, transverse furrows frequently appear in the nails of both the fingers and toes.

Subsidiary clinical manifestations and complications

Cardiovascular complications

Cardiovascular manifestations can be remarkable in the acute phase of Kawasaki disease and are the leading cause of long-term morbidity and mortality. In this phase, the pericardium, myocardium, endocardium, and coronary arteries may all be involved. Clinically recognizable myocarditis is common, with tachycardia, gallop rhythm, and signs of cardiac failure.

The electrocardiogram is abnormal in one-third of patients, showing low-voltage, ST-segment depression, and T-wave flattening or inversion. Coronary arterial abnormalities develop in approximately 25 per cent of untreated patients (Fig. 2). Aneurysms have been detected within 7 days of illness, but more commonly they occur between 10 days and 3 weeks after the onset of symptoms. The appearance of aneurysms more than 4 weeks after the onset of illness is uncommon. Patients with giant aneurysms (internal diameter of at least 8 mm) have the worst prognosis and are at the greatest risk of developing coronary thrombosis, stenosis, or myocardial infarction. Angiography is sometimes used for diagnosis, particularly in patients with suspected or definite echocardiographic changes or ischaemia. Because of considerable normal variations in the coronary arteries in childhood, only an experienced paediatric cardiologist can properly interpret the angiograms.

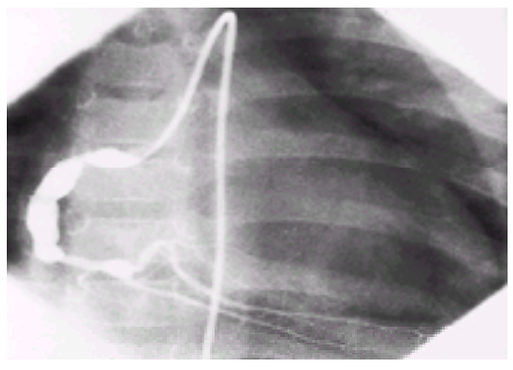

Fig. 2 Right coronary artery aneurysms, seen 1 month after the onset of Kawasaki disease in a boy aged 5 years and 7 months. (By courtesy of Dr T Sonobe of the Japanese Red Cross Medical Center, Tokyo.)

Myocardial infarction is the principal cause of death in patients with Kawasaki disease. It may occur within a year; even later in patients who have giant aneurysms. Children with giant aneurysms more likely have other arterial involvement including that of the renal, brachial, and iliac arteries. Valvular involvement, primarily mitral regurgitation, has been described in about 1 per cent of children with Kawasaki disease.

Gastrointestinal tract

Diarrhoea occurs in approximately 35 per cent of patients. Patients with gall bladder involvement (acute acalculous distension: 'hydrops') often suffer severe abdominal pain, especially in the upper right quadrant. Mild jaundice occurs in approximately 5 per cent of cases. The total serum bilirubin level is almost always lower than 10 mg/dl. In the acute phase, serum transaminase levels are often increased. Serum glutamate-oxaloacetate transaminase (**GOT**) and glutamate-pyruvate transaminase (**GPT**) levels increase from 60 to 200 IU, while the lactate dehydrogenase (**LDH**) level increases from 600 to 900 IU. Paralytic ileus has been reported.

Blood

In almost all cases there is leucocytosis with a shift to the left, an increased erythrocyte sedimentation rate (**ESR**), elevated C-reactive protein, and an increased a2-globulin level. The platelet count increases from the second week and may reach 1000 to 1500 × 10^{9} per litre. Hypoalbuminaemia and slight anaemia are common.

Urinary tract

Albuminuria is frequently seen in the acute phase, with aseptic microscopic pyuria. These findings disappear in the convalescent phase.

Respiratory system

Preceding or concurrent respiratory symptoms such as cough and rhinorrhoea are occasionally seen. Abnormal infiltrates on the chest radiograph are occasionally observed.

Joints

Arthritis or arthralgia can occur in the initial phase of the illness and are usually polyarticular, involving the knees, ankles, and hands. A pauciarticular arthritis involving the knees, ankles, or hips commonly appears during the second or third week of illness. These symptoms disappear within 30 days after their onset in most cases.

Nervous system

Infants with Kawasaki disease are often more irritable than infants with other febrile illnesses. Signs and symptoms suggestive of aseptic meningitis may be present in some patients, and this is found in 20 to 50 per cent of those with Kawasaki disease who undergo lumbar puncture. Other neurological complications such as facial palsy, hemiplegia, and encephalopathy have been reported.

Other systems

Auditory abnormalities, testicular swelling, and peripheral gangrene have also been reported.

Pathological findings

Kawasaki disease is an acute inflammatory disease with systemic angiitis which is distinguishable from classic periarteritis nodosa of the Kussmaul–Maier type. Coronary aneurysms are usually present at autopsy. The angiitis is characterized by acute inflammation with or without mild fibrinoid necrosis. Middle- or large-sized arteries (such as the main coronary, iliac, axillary, or renal arteries and aorta) are commonly involved. The course of the angiitis can be classified into four stages

according to the duration of the illness:

- *Stage 1* (1–2 weeks from onset) shows perivasculitis and vasculitis of the microvessels, small arteries, and veins. There is inflammation of the intima, externa, and perivascular areas in medium- and large-sized arteries. Oedema and infiltration with leucocytes and lymphocytes are also present.
- *Stage 2* (2–4 weeks from onset) shows less inflammation in the vessels than in Stage 1. This stage is characterized by panvasculitis of the main coronary arteries and aneurysm with thrombus in the stems. Myocarditis, coagulation necrosis of heart muscle, lesions of the conduction system, pericarditis and endocarditis with valvulitis are also present.
- *Stage 3* (4–7 weeks from onset) shows subsidence of inflammation in the vessels. Granulation may occur in the medium-sized arteries.
- *Stage 4* (more than 7 weeks from onset) reveals scar formation and intimal thickening with aneurysms, thrombus, and stenosis in the medium-sized arteries.

Other lesions include myocarditis, pericarditis, and inflammation of almost all organs. All these lesions are frequently seen in Stage 1 and 2, but rarely in Stage 4. Ischaemic heart disease usually occurs in Stages 2 to 4. The major cause of death in Stage 1 is myocarditis, including inflammation of conduction systems. In Stage 2 and 3, the causes are ischaemic heart disease, rupture of an aneurysm (rare), and myocarditis. In Stage 4, there may be ischaemic heart disease, and, in rare cases, heart failure due to mitral insufficiency.

Epidemiology

The first nationwide survey was conducted in 1970 by the Japanese Kawasaki disease Research Committee. Since then 15 nationwide surveys have been carried out at 2-year intervals up to December 1998. A total of 153 803 cases (89 272 males and 64 531 females M:F ratio of 1.38:1) has been reported, including 426 (0.28 per cent) deaths. The number of cases reported has been steadily increasing since 1971. There were outbreaks in 1979, 1982, and 1986, when a high incidence of the disease was reported in the early or late spring throughout Japan. A shift of the epidemic wave from warm to cool geographical areas was observed in 1979, but not in 1982 and 1986.

Since 1974, a number of cases have been reported from outside of Japan. Kawasaki disease is now known to have a worldwide distribution, having been observed in all continents and in all ethnic groups. It currently ranks as the leading cause of acquired heart disease in the paediatric population of the United States and Japan.

Aetiology

It is not proven, but the clinical and epidemiological features of Kawasaki disease strongly suggest that it is caused by an infectious agent; one to which the great majority of people become immunized in early life by subclinical infection. The spacing between waves of the disease is determined by the build-up of a new group of susceptible individuals.

The rarity of the illness in the first few months of life and in older children and adults, the low incidence of disease in siblings, and the absence of person-to-person transmission, are all compatible with infection by a ubiquitous agent, to which virtually all adults are immune and from which very young children are protected by passive maternal antibody. The majority of infected individuals probably experience an asymptomatic infection, whilst a select few develop the recognizable clinical features of Kawasaki disease.

Treatment and management

Therapy with the combination of intravenous immunoglobulin (IVIG) and aspirin during the acute phase of Kawasaki disease produces a more marked anti-inflammatory effect and reduction in coronary artery abnormalities than does aspirin alone. It is recommended that patients with acute disease be treated with a single 2 g/kg infusion of IVIG and aspirin (30–50 mg/kg per day) within the first 10 days from onset, and that the aspirin dose be reduced to 3–5 mg/kg per day given as a single daily dose after defervescence. Aspirin is discontinued if no coronary abnormalities have been detected by echocardiography by 6 to 8 weeks after the onset of illness, but continued if coronary artery abnormalities are present. Aspirin should be discontinued if the patient develops an illness suspected to be varicella or influenza, this is to reduce the risk of Reye's syndrome, when the use of an alternative antiplatelet agent should be considered.

Approximately 10 per cent of patients with Kawasaki disease are resistant to IVIG therapy. These patients are at greatest risk for the development of coronary artery aneurysms and long-term sequelae of the disease. As in other vasculitides, blood vessel damage appears to result from an aberrant immune response leading to endothelial cell injury and vessel wall damage. Steroids such as methylprednisolone are the treatment of choice in other forms of vasculitis, yet they have been considered to be unsafe in patients with Kawasaki disease. However, it has been reported that at least some patients with severe disease, resistant to IVIG therapy, may be safely treated with intravenous pulse-steroid therapy and benefit from this treatment.

The management of patients with severe obstructive coronary artery disease, who may develop symptomatic ischaemic heart disease, is an important issue. Patients must be immediately admitted to hospital when myocardial infarction occurs. Management strategies employed are those well defined in the context of atheromatous coronary artery disease. Massive thrombus formation can be visualized by serial echocardiographic studies and is a clear indication for anticoagulation. Recurrence of infarction, which is associated with high mortality, occurs in approximately 20 per cent of patients, and emphasizes the need for the careful management of children with myocardial infarction, even if this is silent.

Patients with cardiac complications or sequelae, such as ventricular dysfunction, heart failure, severe arrhythmias, or postinfarction angina, are managed by conventional medical and/or surgical techniques. As a prelude to surgical treatment, detailed coronary angiography is essential, and viability of the myocardium should be evaluated by thallium scintigraphy. Long-term results and prognosis after surgery remain uncertain. Heart transplantation of patients with Kawasaki disease has been performed in 15 cases.

18.11 Miscellaneous conditions presenting to the rheumatologist

D. O'Gradaigh and B. Hazleman

Musculoskeletal symptoms can occur in a wide range of diseases, or as a paraneoplastic manifestation or drug side-effect. Careful assessment of the history, physical signs, and investigation results are required to identify significant underlying conditions that may first present to the rheumatologist. A number of uncommon conditions can present with non-specific musculoskeletal manifestations and are also discussed in this chapter.

Adult Still's disease

In 1971, Bywaters described a series of 14 adults with an illness very similar to the systemic onset-type of juvenile idiopathic arthritis described by Still in 1897. Adult-onset Still's disease is found worldwide with an incidence of 1-3 per million, most commonly in the age range 16 to 35 years and affecting males and females equally in most populations. There is no consistent HLA association.

Features common to both childhood and adult-onset forms are the high, spiking pyrexia, arthralgia or arthritis, and a characteristic rash. The fever typically appears in the evening, and a patient with pyrexia of unknown origin should always be assessed at least once at the end of the day. Spikes in excess of 39°C are typical (and required in diagnostic criteria), though a return to a normal temperature does not occur in 20 per cent. Arthralgia is almost universal and may intensify during the febrile episodes. Distal interphalangeal joint involvement, seen in one in five patients, is useful to distinguish from other inflammatory arthropathies. The classical 'Still's rash' is a maculopapular, salmon-pink rash on the trunk, thighs, and arms or axillae that appears during the temperature spike (termed 'evanescent'). The rash may also appear on the face, palms and soles, and at sites of skin trauma (Koebner phenomenon) in a third of adults. A (culture-negative) severe sore throat is relatively common in adults (though not a feature of the juvenile form).

Other common manifestations are hepatosplenomegaly with or without generalized lymphadenopathy, and polyserositis, of which pericarditis (in a third) and pleuritis are the most common. Rare features include sicca symptoms (dry eyes, mouth), myocarditis, restrictive lung disease, liver or renal failure, panophthalmitis or inflammatory orbital pseudotumour, epilepsy, intravascular coagulopathy or haemophagocytic syndrome, and amyloidosis.

Diagnosis is primarily clinical, it being important to remember that the classical features may only emerge over a period of time, and the possibility of Still's disease may need to be reconsidered as symptoms progress. The differential diagnosis is wide, and while diagnostic criteria have been proposed they have poor sensitivity and specificity until infection (particularly infectious mononucleosis), neoplasia (lymphomas), and connective tissue diseases (such as polyarteritis nodasa and systemic rheumatoid vasculitis) have been excluded.

There are no specific laboratory features, but typical findings include elevated ESR and CRP, thrombocytosis, neutrophil leucocytosis (total leucocytes in excess of 15×10^9/l) and a normochromic normocytic anaemia. Elevated liver enzymes can be found, and may rise further during non-steroidal anti-inflammatory treatment. Both rheumatoid factor and antinuclear antibodies are negative in most cases. A highly elevated (>5 times upper limit) serum ferritin is a useful marker to discriminate from other arthropathies, but is not sufficiently specific to exclude the differentials (especially neoplasia) mentioned above.

Indomethacin (or another non-steroidal anti-inflammatory agent) has largely replaced high-dose (100 mg/kg/day) salicylate as the first line treatment for fever and systemic features. If these agents fail individually, they may be given together, but adequate prophylaxis against peptic ulceration is essential. Corticosteroid is required in two-thirds of cases, and should be initiated without delay in cases of myocarditis, pericardial tamponade, or other severe organ involvement. Doses of prednisolone in the range 0.5–1 mg/kg/day are usually given, and should be continued for 2 to 3 months after remission before gradually tapering the dose.

The role of disease modifying antirheumatic drugs or cytotoxic agents is not established. In refractory cases with systemic features, or as steroid-sparing therapy, methotrexate is particularly useful. Salazopyrin, azothioprine, and intravenous immunoglobulin have also been used. Intramuscular gold is appropriate when arthritis dominates. Most recently, the antitumour necrosis factor-a therapies have been used with some success.

Prognosis is variable. A chronic progressive arthritis is predicted by early arthritis (rather than arthralgia), particularly of the hip and shoulder, and occurs in 30 to 50 per cent of cases, with ankylosis of the carpus and tarsus and involvement of the cervical spine and hips. Equal proportions of the remainder experience either a self-limiting course (lasting up to 1 year), or a polycyclic, relapsing, and remitting course. The rash, fever, and serositis are typically less severe in subsequent relapses, and complete remissions up to 10 years after first presentation have been recorded.

Acne arthralgia

Patients may complain of myalgia, arthralgia, or swelling, typically involving the large joints. Most patients are male adolescents with aggressive acne. *Propionibacterium acnes* has been isolated from joint aspirates; however, effusions are typically sterile and the arthritis is believed to be reactive rather than septic. Hydradenitis suppurativa, producing large abscesses in the axilla and groin, is also associated with a reactive type of large-joint oligoarthropathy. In both conditions, symptoms usually improve with treatment of the skin lesion. A seronegative spondyloarthropathy syndrome of acne, palmoplantar pustulosis, hyperostosis (especially

of the clavicles or sternum), and (sterile) osteomyelitis (**SAPHO**) is associated with enthesitis and an inflammatory polyarthritis that often includes the sacroiliac joints.

Neutrophilic dermatoses

The neutrophilic dermatoses include pyoderma gangrenosum and Sweet's syndrome (acute febrile neutrophilic dermatosis). Erythema nodosum is now considered part of this spectrum.

Pyoderma gangrenosum is a reactive neutrophilic dermatosis associated with ulcerative colitis, rheumatoid arthritis, and monoclonal gammopathies or other haematological malignancies, which produces painful ulcerative skin lesions (Fig. 1 and Plate 1). Approximately 30 per cent of patients describe arthralgia or a seronegative, progressive, erosive polyarthritis. Treatment usually requires corticosteroid therapy in addition to that for the underlying disorder.

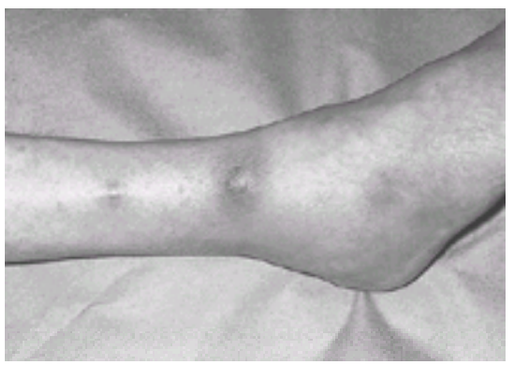

Fig. 1 Pyoderma gangrenosum. (See also Plate 1.)

Sweet's syndrome presents with tender red or purple raised nodules associated with fever and generalized myalgia and/or arthralgia. Joint effusions may occur, and aspirates reveal high neutrophil counts. Sterile osteomyelitic foci have rarely been described. Skin biopsy is diagnostic. Symptoms typically resolve over 2 to 3 months, requiring symptomatic treatment with a non-steroidal anti-inflammatory drug (**NSAID**) or intra-articular steroid. An association with acute myeloid (particularly premyelocytic) leukaemia is noted in about 15 per cent of cases, and recombinant granulocyte colony-stimulating factor (**rG-CSF**) has also been implicated in a number of cases.

Erythema nodosum presents with discrete nodules on the extensor aspect of the lower leg and less commonly on the upper limbs (Fig. 2 and Plate 2). Joint manifestations (arthralgia in two-thirds) occur in 75 per cent of cases. Arthritis with synovial thickening and joint effusions usually affects the knee and ankle symmetrically. The small joints of the hands, wrists, elbows, and shoulders are less commonly affected. Various underlying conditions, infections, and drugs are associated with erythema nodosum. Whilst their recognition is important, the arthritis is usually self-limiting, responding as it does to treatment with NSAIDs, although corticosteroids are occasionally required, and resolving without sequelae.

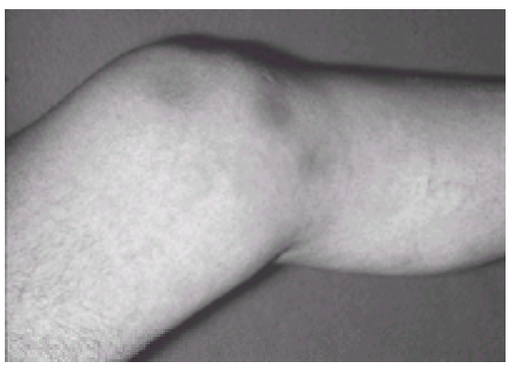

Fig. 2 Erythema nodosum. (See also Plate 2.)

Panniculitis

Also called lupus erythematosus profundus, this is an unusual variation of cutaneous lupus characterized by recurrent inflammation of subcutaneous tissue leading to fibrosis. Asymptomatic, firm, sharply defined subcutaneous nodules or plaques appear on the proximal upper and lower limbs, buttocks, face, and scalp. Histology reveals a non-specific lobular panniculitis with necrobiosis of adipose tissue and fibrotic deposits. Some one in eight patients have systemic lupus erythematosus (**SLE**) at presentation, particularly generalized arthralgia and fatigue. A further 10 to 15 per cent will develop SLE up to 10 years later. Skin and joint features are treated with hydroxychloroquine, though a steroid and dapsone are occasionally required for more florid panniculitis.

Multicentric reticulohistiocytosis

This is a rare systemic disease of unknown aetiology, with infiltration of lipid-laden histiocytes and multinucleate giant cells into various organs. Skin nodules and a rapidly progressive deforming arthritis are the most frequently recognized features. Light copper or red–brown nodules appear on the face and hands, but can appear anywhere, and may number from a few to several hundred. The disease affects middle-aged women who typically present with an insidious onset of polyarthritis in the interphalangeal joints. The spine and other joints may be involved. There is no satisfactory treatment. Underlying malignancy is reported in 20 to 30 per cent of cases.

Sarcoidosis

One-third of patients with sarcoid will have musculoskeletal features, of which an acute symmetrical polyarthritis is the most common. Lofgren's syndrome associates this pattern of arthritis with erythema nodosum and bilateral hilar lymphadenopathy. The ankles and feet are the most commonly affected, followed by the hands, wrists, and elbows. Symptoms develop rapidly and usually respond well to NSAIDs, although corticosteroids are occasionally necessary. Remission without joint destruction occurs after 2 to 4 months. A chronic arthropathy is uncommon, occurring mostly in those with multiorgan involvement and those requiring steroid treatment during the acute phase. Dactylitis, joint space narrowing, and osseous involvement are then the most common features, with superimposed episodes of acute arthritis. Radiographic findings appear late, and include acro-osteolysis, cystic lesions, or a reticulated coarse trabecular pattern in the phalanges. Corticosteroid in doses of 30 to 60 mg are the mainstay of treatment at this stage, but is frequently disappointing, with recurrence of symptoms on cessation of therapy.

Amyloidosis

Musculoskeletal features occur in three main settings. Dialysis-related amyloidosis is due to the accumulation of b $_2$-microglobulin. Synovitis usually involves large joints such as the hip and shoulder. Magnetic resonance imaging (**MRI**) may show characteristic features, and joint fluid aspiration may identify amyloid deposits, particularly using the more sensitive combination of Congo Red staining and immunocytochemistry. Symptomatic treatment with an NSAID is usually sufficient, considerations of the effect of NSAIDs on renal function only being relevant in those dialysis patients with substantial urine output, but the condition can be disabling and refractory. Significant improvement often follows transplantation. Cystic (lytic) bone lesions are typically painless, and present difficulties in the differential

diagnosis. They may be complicated by pathological fracture. Soft tissue amyloid deposits usually present with entrapment neuropathies such as carpal tunnel syndrome.

In primary (AL) amyloidosis, a symmetrical polyarthritis with synovitis and morning stiffness involves large and small joints. Radiographic changes include osteoporosis and, less commonly, joint erosions. Diagnostic confusion can arise, as frequently the erythrocyte sedimentation rate is not significantly elevated. The synovitis is often described as 'pasty', and flexion contractures occur relatively early. The early appearance of carpal tunnel syndrome should also raise the suspicion of underlying amyloidosis. In addition to treatment addressing the underlying paraproteinaemia, joint symptoms may require therapy with a corticosteroid.

Familial amyloidosis and secondary (AA) amyloid due to persistent inflammation are not usually associated with rheumatological symptoms. Exceptions include the Muckle–Wells syndrome of urticaria, deafness, arthritis, and amyloid nephropathy.

Familial Mediterranean fever (FMF)

This is an autosomal recessive disorder appearing in people of Armenian, Arab, and Sephardic Jewish descent. A number of genetic defects have been localized to the *marenostrin* or *pyrin* genes on chromosome 16p. The function of this protein is not known, but the *M694V* mutation is particularly associated with joint involvement. Presenting in childhood with episodes of fever and abdominal pain, synovitis occurs in 75 per cent of cases. Monoarticular involvement of a knee or ankle, or symmetrical involvement of these joints, are the most common of the six patterns of joint involvement described. A symmetrical polyarthritis indistinguishable from juvenile idiopathic arthritis often causes diagnostic confusion, particularly as fever and abdominal pain are not uncommon in this condition. The pattern tends to be similar in subsequent episodes, and despite frequent florid synovitis, residual damage rarely occurs. Episodes typically last for less than 1 week, though more protracted attacks may persist for months. Treatment with colchicine has almost eliminated amyloidosis as a complication of this condition and it also reduces the frequency of symptom relapse. However, it is ineffective once an episode has started, and an NSAID and rest are then the most effective measures. Interferon-a has been used to good effect in resistant cases.

Another two periodic fever syndromes—hyperimmunoglobulin D syndrome (**HIDS**) and familial Hibernian fever (also called autosomal dominant recurrent fever)—occur in The Netherlands and Northern France, and in a few Irish and Scottish families, respectively. To date, neither has been associated with the joint symptoms of FMF. Frequent mouth ulcers resembling Behçet's syndrome appear during attacks of HIDS. However, the markedly elevated levels of IgD and IgA in the latter are diagnostic. The place of colchicine is not yet established in the treatment of these disorders.

Haematological disorders

Leukaemia, lymphoma, and uncommon lymphoproliferative disorders

Between 13 and 60 per cent of patients with acute leukaemia will develop arthralgia or less commonly a frank arthritis. Monoarthritis, symmetrical polyarthritis, and a large joint oligoarthropathy are described. Diagnostic clues include a disproportionate amount of pain, fever, and weight loss, though in children the latter may be mistaken for Still's disease. Arthralgia is an uncommon feature of lymphomas; however, 7 to 25 per cent of patients with non-Hodgkin's lymphoma experience polyarthralgia, secondary gout, or hypertrophic pulmonary osteoarthropathy (see below) during the course of their disease.

Large granular lymphocyte syndrome is a monoclonal expansion of T cells associated with a variety of conditions including rheumatoid arthritis (in one-third of cases). Both neutropenia and splenomegaly can occur, mimicking Felty's syndrome. Some consider it to be indistinguishable in every respect, including its management.

Human T-cell lymphotrophic virus-1 (**HTLV-1**) is associated with the development of leukaemia or lymphoma, and may independently produce a symmetrical polyarthritis closely resembling rheumatoid arthritis.

Haemophilia

Prophylactic, factor replacement between 2 and 18 years of age is cost-effective in preventing disabling joint complications. Without this, acute haemarthroses begin from around 5 years of age, causing recurring episodes of very painful and tender joint swelling, particularly in the hinge joints such as the knee, ankle, and elbow (presumably because these joints are less tolerant of angular or rotational strain). Pain is increased by the additional irritant effect of blood on the synovium. Ultrasonography is useful in the differentiation of haemarthrosis from soft tissue or subperiosteal haemorrhage. Repeated episodes, without appropriate treatment, result in persistent synovitis and joint contracture. Early coagulation factor replacement, ice, joint immobilization, and elevation all reduce further bleeding. Joint aspiration may also be required (after adequate factor replacement). Rehabilitation is required to prevent contraction. Synovectomy by an intra-articular injection of radioactive isotope is a useful treatment in cases of chronic synovitis, but joint replacement continues to be needed where disabling secondary degenerative arthritis has occurred. Acute haemarthrosis due to disseminated intravascular coagulation should be similarly managed.

Cryoglobulinaemia

Cryoglobulins are immune complexes that precipitate spontaneously at low temperatures. Type I (25 per cent) comprises a monoclonal immunoglobulin and is associated with lymphoproliferative disorders including myeloma and Waldenström's macroglobulinaemia. Type II (25 per cent) complexes a monoclonal immunoglobulin, usually of IgM class, with a polyclonal anti-immunoglobulin typically of IgG type (that is, a rheumatoid factor). Previously called mixed essential cryoglobulinaemia, it is now recognized that over 90 per cent of these individuals have serological evidence of hepatitis C virus (HCV) infection. Type III accounts for 50 per cent of cases, and is a complex of two polyclonal immunoglobulins, usually occurring as a paraneoplastic phenomenon.

Precipitation of cryoglobulin leads to complement activation and vasculitis in small vessels. Complete vascular occlusion is less common. A classical triad of a palpable purpuric rash on the extremities, arthralgia, and muscle weakness is described. Joints are involved in 70 per cent of patients in a relapsing and remitting pattern, affecting, in order of frequency, the hands, knees, ankles, and elbows. Inflammatory arthritis is uncommon, and radiological changes do not occur. Other skin presentations include petechiae, urticaria, and acrocyanosis. Other organ involvement is frequently seen in addition to this triad, particularly glomerulonephritis.

Diagnosis requires meticulous attention to phlebotomy and laboratory techniques. A positive rheumatoid factor and raised ESR are supportive features, and urinalysis and microscopy, looking for an 'active sediment' (proteinuria, haematuria, and red cell casts), should always be carried out in patients presenting with purpura and arthralgia. A thorough search is required for underlying malignancy and for associated HCV infection.

Treatment is directed at any underlying cause. NSAIDs, corticosteroids, and steroid-sparing drugs, particularly azathioprine, are used to relieve arthralgia and to prevent the progression of purpura to ulceration. Neurological or renal involvement requires more aggressive therapy, for which cyclophosphamide (oral or intravenous pulses) or chlorambucil are used. Plasmapharesis is sometimes considered for those with rapidly progressive glomerulonephritis, but requires particular care to avoid blood cooling in the extracorporeal circuit.

POEMS

This is an uncommon disorder that may present to any specialty, depending on the dominant feature in the spectrum of **p**olyneuropathy, **o**rganomegaly, **e**ndocrinopathy, **M**-protein (i.e. a monoclonal paraproteinaemia), and **s**kin abnormalities. Skin changes may resemble scleroderma. Radiographs show single or multiple osteosclerotic lesions with unusual patterns of proliferative change, both of which are unexpected in myeloma. The diagnosis of POEMS should therefore be considered in those presenting with osteosclerotic lesions accompanied by paraproteinaemia, particularly when associated with peripheral neuropathy. Treatment must be directed at the principal presenting features—bone lesions are rarely symptomatic unless they result in bone swelling or fracture.

Hypogammaglobulinaemia

Primary hypogammaglobulinaemia is associated in 10 to 30 per cent of patients with a non-erosive polyarthritis resembling rheumatoid arthritis. Features include morning stiffness, pain, and tender swelling in the peripheral joints. Subcutaneous nodules may appear. However, rheumatoid factor is negative, histology reveals the absence of plasma cells, and permanent joint damage is rare. Synovitis may be transient or it may persist for many years, requiring symptomatic treatment. Intra-articular corticosteroid treatment is used, though these patients are somewhat more at risk of septic arthritis. In the absence of any intra-articular procedure, the

rate of septic arthritis is approximately 20 per cent over 20 years.

Sickle-cell disease (SCD)

Sickle-cell crises commonly include bone pain. The cause is believed to be intramedullary hypertension due to vascular occlusion resulting in bone ischaemia. Vasodilator drugs have been used with varied results. Avascular necrosis is less commonly associated with other haemoglobinopathies. Synovitis, frequently complicated by haemarthrosis, usually occurs during crises, and is due to synovial infarction. The effusion is non-inflammatory. Osteomyelitis may complicate avascular necrosis due to SCD, *Salmonella* spp. being particularly common. However, septic arthritis is unusual. Hyperuricaemia and gout occur in 40 per cent of adults with SCD, and is treated in the standard way. Less commonly, a hand-and-foot syndrome affects infants aged between 6 months and 2 years, dactylitis and periostitis producing symmetrical tender, diffuse swelling and stiffness lasting several weeks.

Gastroenterological and metabolic conditions

Hepatitis

The common viral hepatitides, hepatitis-A, -B, and -C viruses (**HAV**, **HBV**, and **HCV**, respectively) are associated with a serum-sickness during their prodromal phase. Early morning stiffness and mild arthralgia, or, less commonly, inflammatory arthritis, affect the small joints of the hands, and, in decreasing order of frequency, the knees, ankles, shoulders, wrists, and feet. The spine and hips are not usually affected. Symptoms typically resolve as hepatitis evolves. Less common features include a leucocytoclastic ('hypersensitivity') vasculitis in HAV and an association with polyarteritis nodosa in HBV. HCV is associated with cryoglobulinaemia (in 50 per cent) and with antiphospholipid antibodies and thrombosis.

Enteropathies

Coeliac disease may result in osteoporosis or osteomalacia with bone pain and pathological fracture. Arthritis is uncommon, but can precede overt bowel symptoms by up to 3 years. Symmetrical involvement with swelling and stiffness can affect the lumbar spine, hips, knees, and shoulders. Dermatitis herpetiformis is more common among those with joint involvement. The joint manifestations resolve on changing to a gluten-free diet, and do not reappear on rechallenge with gluten.

Whipple's disease presents with fever and abdominal pain. Acute or subacute migratory polyarthritis may precede bowel symptoms by years, and typically involves the ankles, knees, shoulders, and elbows. Lymphadenopathy is a prominent feature. Duodenal biopsy shows Periodic acid–Schiff (**PAS**) -staining macrophages, and the polymerase chain reaction (**PCR**) detects the causative organism *Tropheryma whippelii*. Its presence within cells implies a mechanism similar to reactive arthritis with a T_H2-dominant response and inability of the T_H1-cellular immune response to clear the microbe from macrophages, which therefore perpetuate the inflammatory reaction.

Surgical procedures that bypass a section of (proximal) small bowel are associated with so-called 'bypass' arthritis. This ranges from a mono- or oligoarthropathy to a diffuse polyarthritis involving large and small joints. Tenosynovitis of the wrist is a particularly common feature. Treatment is symptomatic, though sulfasalazine is occasionally used as a disease-modifying therapy.

Haemochromatosis

An autosomal recessive inherited disorder of iron transportation and storage, this condition may present up to 10 years before the underlying condition is recognized, usually in men between 50 and 60 years of age, with a painful inflammatory synovitis principally affecting the second and third metacarpophalangeal joints. About 80 per cent of those with genetically identified haemochromatosis will develop arthritis at some point. Acute exacerbations may occur due to calcium pyrophosphate dihydrate deposition, particularly in the knee and wrist. The reason for this is unclear, though iron is known to inhibit the clearance of pyrophosphate from the synovial lining layer. Crystals may be identified on polarized light-microscopy of a joint aspirate. Their presence is implied by radiographic evidence of chondrocalcinosis. Radiographs of the hands may also show cyst formation in the affected joints, with erosive changes and characteristically hook-shaped osteophytes. Treatment is symptomatic, intra-articular corticosteroid therapy being of value during acute episodes. Arthritis persists in the majority of cases, and can be relentlessly progressive, despite regular venesection.

Wilson's disease

A disorder of copper metabolism, this condition typically presents in childhood with neurological problems. Some two-thirds of patients with Wilson's disease will develop musculoskeletal manifestations, half of whom being symptomatic by 15 years of age. Features include arthritis (primary, attributed to copper deposition in synovium; or secondary, due to chondrocalcinosis), rhabdomyolysis, hypermobility (due to effects on collagen synthesis), and osteopenia. Radiographic appearances are generally non-specific, with joint space narrowing, sclerosis, and cyst formation. A fluffy periostitis at the greater trochanter and inferior aspect of the calcaneus, and corticated ossicles near affected joints (particularly the wrist) are characteristic but rare. Diagnosis requires measuring urinary 24-hour copper excretion: caeruloplasmin may be elevated as part of an acute-phase response and therefore is of no diagnostic value in presentations with acute arthritis. Penicillamine is the mainstay of treatment for this condition and alleviates joint symptoms.

Ochronosis

Deficiency of the enzyme homogentisic acid oxidase results in an accumulation of this organic acid. Though a congenital disorder, symptoms rarely appear until the fourth decade. The classical clinical features of pigmentation of the ear and sclera, and urine darkening on standing (giving the alternative name alkaptonuria) allow easy diagnosis. Deposition also occurs in the synovium and may appear in joint fluid aspirate. Pain and swelling affect the large joints, and the thoracolumbar spine is also affected producing pain and stiffness, but the lumbosacral spine is spared. Radiographs show chondrocalcinosis of the intervertebral discs with spondylosis that may progress to ankylosis. In the peripheral joints, radiographic changes of degeneration appear, though osteophytes are often less marked than in other degenerative arthritides. Erosion may occur. Recent treatment efforts are concentrated on early genetic diagnosis, dietary advice, and the possibility in the future of gene therapy.

Hyperlipidaemia

Articular symptoms can occur in a number of the hyperlipidaemias, particularly types II and IV. Joint manifestations typically precede diagnosis of the lipoprotein disorder. Xanthomas of tendons are a useful clue, but the clinical picture is otherwise non-specific. Morning stiffness, pain, and tenderness are noted, but overt joint inflammation is uncommon. A migratory polyarthritis is occasionally described in type II hyperlipoproteinaemia, but oligoarthritis and tendonitis are more common. Tendon xanthomas may result in periarticular bone cyst formation. In two-thirds of patients, symptoms resolve with treatment of the lipid disorder, the remainder requiring symptomatic therapy.

Musculoskeletal manifestations of HIV/AIDS

Rheumatological manifestations include serum-sickness at seroconversion, pyomyositis, and osteomyelitis (particularly in the setting of intravenous drug abuse) and a spectrum of presentations with acute arthropathy. Antiretroviral therapy, particularly zidovudine, may produce a polymyositis with ragged red fibres on muscle biopsy. Very rare manifestations include a vasculitis that appears to be directly induced by the virus, and hypertrophic osteoarthropathy (see below) secondary to *Pneumocystis carinii* pneumonia. Arthritis or arthralgia occur in 1 to 25 per cent of cases. Spondyloarthropathy with dactylitis and enthesitis is the most common. A severe, but self-limiting, large joint oligoarthritis has a predilection for the knees and ankles, resolving over 2 to 6 weeks and responding well to NSAIDs. A generalized articular syndrome is very short-lived though intensely painful, usually lasting only 24 h. Acute symmetrical polyarthritis is relatively uncommon, and septic arthritis is rare.

Reflex sympathetic dystrophy

This is one of a number of terms (including algodystrophy and Sudeck's atrophy) for a condition that has recently been renamed 'chronic regional pain syndrome' (**CRPS**). The dominant feature is pain, with allodynia (pain in response to an innocuous stimuli), hyperalgesia (increased pain perception), and hyperpathia (an

exaggerated delayed reaction). Pain usually involves a single limb or body region, typically distal to the site of some traumatic event, but a definite precipitant is recognized in only 50 per cent of patients. Marked joint stiffness and pain on movement cause considerable disability. CRPS may also follow myocardial infarction, stroke, pregnancy, or deep venous thrombosis. There is an association with HLA-DR2. Other cardinal features relate to excessive activity of the sympathetic nervous system, with localized swelling, sweating, and piloerection in the early stages, the skin often appearing stretched and shiny. Hyperaemia is believed to be responsible for osteopenia in the affected part.

Diagnosis is largely clinical, though diffuse osteopenia on plain radiography (comparing the symptomatic and normal limbs on the same film) and the absence of an acute-phase response are supportive. Bone scintigraphy offers the most reliable confirmation of the clinical impression. A three-phase scan is required, comparing the symptomatic and normal sides in the early blood phase (demonstrating hyperaemia in the affected part), the bone pool phase (increased bone turnover), and delayed phase. Physiotherapy is the key element of treatment and must be quite intensive initially. However, pain may limit patient co-operation. Sympathetic nerve blocks (stellate ganglion or lumbar sympathetic chain) with long-acting anaesthetic and/or guanethidine are specialized techniques that are often quite effective. Other pain-relieving modalities include corticosteroid injection to the involved joint, subcutaneous or intranasal calcitonin, intravenous pamidronate, and (oral) gabapentin.

Charcot's arthropathy

This is a disorder of joint destruction associated with neurological injury or damage. Diabetes mellitus, tabes dorsalis, and syringomyelia are the most commonly associated diseases. There are two leading pathogenesis theories. The more widely accepted neurotraumatic theory suggests that loss of sensation allows repeated subclinical trauma, culminating in a destructive arthropathy. The neurovascular theory is proposed to explain how the arthropathy can appear very early in the absence of use of the limb, and the observation, particularly in the tarsus of diabetic patients, that the arthropathy can be quite painful. Here, it is believed that damage to 'trophic centres' results in altered vascular supply and, hence, impaired bone and cartilage nutrition underlying the subsequent joint damage. Radiologically, a gross proliferative osteoarthrosis is most commonly seen, but significant resorption of bone can also feature, and stress fractures occur in up to one-third of patients. Painfree joints rarely require treatment; moreover, orthopaedic procedures are associated with a high failure rate. Management of painful neuropathic joints is very difficult. Orthoses help to prevent stressing of related soft-tissue structures, and a broad range of analgesics, including amitriptyline, should be considered.

Tietze's syndrome/chostochondritis

Both conditions are of unknown aetiology, though a viral trigger has been proposed in Tietze's syndrome (chondropathia tuberosa). A single chostochondral joint (usually the second or third) is involved in 80 per cent of patients. Coughing or deep breathing exacerbates paracentral chest pain. Tietze's syndrome is also associated with firm, tender lumps at the affected sites. Onset may be acute or more gradual, and the subsequent course is similarly variable, ranging from spontaneous remission to prolonged symptoms lasting for years. As these conditions typically affect middle-aged women, a visceral origin for the symptoms must not be overlooked. Local injection with lidocaine (lignocaine) or a corticosteroid may provide symptomatic relief when necessary.

Miscellaneous disorders of synovium, bone, cartilage, and calcification

Synovium

Pigmented villonodular synovitis (PVNS)

This is a benign synovial hyperplasia of unknown aetiology, possibly reactive or neoplastic. To date, three types of PVNS have been described. Giant-cell tumour of the tendon sheath occurs most commonly in extensor tendons of the hand; although painless, large nodules may restrict movement. Treatment is by surgical excision, which allows histological confirmation of the diagnosis. Recurrence is rare. Isolated nodular and true diffuse PVNS are intra-articular lesions occurring most commonly in the knee of adult males aged between 20 and 50 years. Pain, swelling, and a gradual reduction in the range of movement can continue for some years before the diagnosis is made. Aspiration of erosanguinous fluid in the absence of trauma should raise the suspicion. Intra-articular steroid administration gives effective but short-lived relief, and surgical excision is the treatment of choice as it also allows a definitive diagnosis. In the event of a recurrence (uncommon except in the diffuse form), radioisotope synovectomy or radiotherapy may be used. In late stages, haemosiderin deposition and chronic inflammation can lead to destructive changes requiring arthroplasty.

Synovial (osteo-)chondromatosis (Reichel syndrome)

A benign synovial proliferation, this is probably caused by reactive metaplasia secondary to osteoarthrosis, osteochondrosis, or other joint pathology. Most patients are men in their third to fifth decade. Typically monoarticular, usually in the knee, symptoms include joint swelling, locking, and giving way, suggestive of intra-articular loose bodies. Multiple (up to 200) calcified periarticular bodies of hyaline cartilage, 1 mm to 3 cm in size but usually uniform, fill the joint. Surgery is required to remove loose bodies. Rarely, malignant transformation to chondrosarcoma may occur.

Synovial haemangioma

A synovial haemangioma is a benign lesion comprising vascular and non-vascular tissue in an asymptomatic and well-localized intra-articular mass, most commonly in the knee (60 per cent) and elbow (30 per cent). Surgical excision is curative.

Lipomas are most commonly found in the thenar and hypothenar eminences producing compressive symptoms. They may calcify or undergo fibrosis and infarction. Lipoma arborescens occurs particularly in the suprapatellar bursa, producing painless swelling. MRI changes are diagnostic and surgery is curative.

Some two-thirds of 'synovial sarcomas' arise in the thigh. The tissue of origin is mesenchymal, with differentiation to synovium. Prognosis is poor despite surgical excision and radiotherapy.

Bone and cartilage

Bone cysts may be symptomatic or arise as incidental findings, thereby causing diagnostic difficulty. Cysts may be aneurysmal (primary or secondary) or simple (also called unicameral) and can appear in children or adults. Simple cysts are rarely symptomatic or complicated by fracture, and management is expectant. Aneurysmal bone cysts are rare (1 per million), non-neoplastic expansile lesions occurring principally in the metaphysis of long bones (50 per cent), the posterior part of vertebrae (30 per cent), or in the flat bones, particularly the pelvis. Most present with pain, swelling, or pathological fracture at a mean of 13 years of age. Radiological features that suggest the diagnosis include an eccentric location of a cyst containing fluid-fluid levels and trabeculae which remain distinct within it. Management has evolved from the mainstay of curettage with bone grafting or implanting autologous marrow (rich in osteoblasts) to intralesional corticosteroid injection. However, recurrence rates are high (20 to 50 per cent) and other options include embolization and radiotherapy. Secondary aneurysmal cysts complicate giant-cell tumours, chondroblastomas, and osteosarcomas, or they may develop from simple unicameral cysts.

Diffuse idiopathic skeletal hyperostosis (DISH; Forestier's disease)

Presenting in middle age, and more commonly in men (2:1, male:female ratio), this condition of unknown aetiology affects about 10 per cent of men aged 65 years or over, and up to 58 per cent of men with gout. Usually a radiographic diagnosis, the criteria include the presence of new bone forming bridging osteophytes spanning at least four adjacent thoracic vertebrae in the absence of degenerative disc disease or sacroileitis. (The cortex is preserved, unlike the erosive process seen in the Romanus lesion of ankylosing spondylitis.) New bone formation can occur at any site, though entheseal sites are especially common. Phalangeal tufting, and an increase in the cortical thickness of the tubular bones of the hand and in the size of sesamoid bones are recognized. Symptoms include restriction in range of movement, diffuse limb pain, and symptoms of nerve entrapment or myelopathy. Canal stenosis can occur in the lumbar spine. Fracture through bridging osteophytes may also produce pain. Hyperinsulinaemia is frequently associated and related features such as hypertension, type II diabetes, obesity, and hyperlipidaemia are more commonly seen in this group. There is no medical treatment of proven value for established DISH. In the early stages, physical therapy may preserve the range of movement, and weight reduction is of value, both directly and in reducing hyperinsulinaemia. If oral hypoglycaemic agents are required, those that increase serum insulin levels should be avoided. Efforts to reduce heterotopic bone formation at sites of joint replacement have included radiotherapy and perioperative NSAIDs with

mixed results. Corticosteroid, given into joints or at entheseal sites may also offer symptomatic relief.

Myositis ossificans (MO)

Calcification of muscle complicates an intramuscular haematoma following direct impact, occurring in 17 to 20 per cent of such injuries. The anterior thigh and upper arm are the most common sites. Predictive signs at onset include local swelling, tenderness, and (particularly) reduced range of stretch in the involved muscle. A sympathetic knee effusion is described in up to half of those with MO in the thigh. Diagnosis may be confirmed radiologically after 3 weeks. Magnetic resonance imaging will detect a haematoma very early, but to date has not identified specific features predictive of MO. Therefore, the classic 'rest, ice, compression, elevation' is appropriate in the acute setting, with NSAIDs where pain and swelling are particularly marked. Physical training should not resume until a full range of passive stretching is restored. Surgical debridement of ectopic calcification should only be undertaken if it interferes with limb function, and then only where bone is matured, as assessed by bone scintigraphy.

Fibrodysplasia (myositis) ossificans progressiva, by contrast, is a rare inherited disorder. It is characterized by abnormally short halluces and ectopic calcification of striated muscle leading to disability as the neck, shoulders, spine, hips, and knees become progressively and relentlessly fixed. Additional variable features include fusion of the lateral masses in the lumbar spine, broad femoral necks, and widened metaphyses, as well as episodes of myositis, principally in the neck and upper paraspinal areas, preceding ossification. Histological misdiagnoses include sarcoma or rhabdomyosarcoma and juvenile fibromatosis. The disease appears to be due to a spontaneous genetic mutation in most cases, and prognosis is extremely variable. It has been difficult to evaluate therapeutic options for this reason, and no single measure is clearly of benefit, though there are theoretical grounds for the use of corticosteroids during episodes of myositis, bisphosphonates, and surgical debridement.

Ectopic calcification in renal disease

This is one aspect of renal osteodystrophy, where painful calcification of soft tissue, particularly at sites of repeated trauma, occurs as a result of serum levels of calcium and phosphate exceeding their combined solubility. Careful monitoring of phosphate and calcium levels, particularly when vitamin D analogues are used, and early treatment of hyperparathyroidism are all important, because established calcification may be intractable. Reversal following renal transplantation has been noted.

Melorheostosis

This is a rare disorder of linear hyperostosis associated with fibrosis of the skin and soft tissue. Thickening of cortical bone appears in a linear fashion (akin to spilling wax on the side of a candle), usually involving one or several bones in the same (more commonly the lower) limb. Many cases are associated with skin changes in the dermatome corresponding to the origin (sclerotome) of the affected bone, resulting in joint contracture. Symptoms include joint pain, intermittent swelling, deformity, and nerve entrapment, usually presenting in the second decade of life. Surgical intervention is most successful.

Paraneoplastic presentations

Rheumatological presentations associated with malignancy include gout, poly- and dermatomyositis, necrotizing vasculitis and cryoglobulinaemia, systemic sclerosis, and the presentations of lymphoproliferative disorders mentioned above. There are two specific conditions: hypertrophic pulmonary osteoarthropathy (**HPOA**) and remitting seronegative symmetric synovitis with pitting (o)edema (**RS3PE**). A seronegative polyarthritis without oedema and otherwise indistinguishable from rheumatoid arthritis may also occur.

HPOA is almost always associated with finger clubbing. Patients complain of pain and stiffness of the wrist and ankles, or of a more diffuse polyarthritis. Radiologically, a proliferative periostitis is noted, particularly at the diaphysis of wrists, ankles, and, less commonly, of knees and elbows. Over 90 per cent of cases have an intrathoracic malignancy, though infections or inflammatory conditions in pulmonary, cardiovascular, or gastrointestinal systems are seen. Primary HPOA (pachydermoperiostitis) also occurs. The cause of the condition is unknown: it has been suggested that cytokines such as platelet-derived growth factor might reach the periphery through pulmonary shunts, thereby producing the clinical proliferative features, but, on the basis of this hypothesis, it is difficult to explain the observation that vagotomy can relieve symptoms and signs in some cases. The arthritis is typically coincident with the malignancy, and will resolve with treatment of the underlying disease. Radiotherapy (to the periostitis sites) and infusion of pamidronate have also been successful in the treatment of resistant cases.

RS3PE was first described in 1985. Mostly affecting older men (mean age 71 years), a symmetrical polyarthritis involves the metacarpophalangeal and interphalangeal joints, wrists, and, less commonly, the elbows and shoulders. Tendon sheath involvement is quite common, and diffuse pitting oedema on the dorsum of the hands is characteristic. This condition has diverse clinical associations, but malignancy is detected in only 10 per cent of cases. Resistance to corticosteroid treatment in this otherwise very responsive condition raises the possibility of malignancy, though in most cases the underlying disease is detected within weeks. In paraneoplastic presentations, symptoms mirror treatment and relapse of the tumour.

Drugs producing rheumatological presentations

Myalgia may occur on withdrawal of steroids, especially in those patients taking 10 mg prednisolone for at least 30 days. This is best managed by reintroducing the steroid with a more gradual reduction in dose (for example, 1-mg steps every few days or weeks, depending on severity). Arthralgia and even arthritis are described as rare adverse effects of steroid therapy. Muscle cramps or aching may also complicate therapy with digoxin, penicillamine, clofibrate, and, more recently, with the statins. Myositis and rhabdomyolysis are also recognized in patients prescribed this latter group of drugs. The oral contraceptive is associated with a syndrome of persisting arthralgia, myalgia, morning stiffness, and even synovitis. Myopathy complicates statin and corticosteroid therapy, and chloroquine may cause neuromyopathy, particularly affecting the lower limbs. Myasthenic weakness is an uncommon complication of penicillamine.

Hypersensitivity reaction is associated with penicillamine, sulphonamides, thiouracils, and allopurinol, to name but a few. Presentations vary, but typically include a small vessel vasculitis and generalized arthralgia or arthritis.

Drug-induced systemic lupus erythematosus is well recognized, though ten times less common than classical SLE. It is characterized by the presence of antihistone antibodies, in distinction to the anti-DNA antibodies of classical SLE. Positive antinuclear antigen (**ANA**) antibodies are considerably more common than any clinical evidence of lupus. Other important distinctions from idiopathic SLE include resolution on withdrawal of the drug—renal and CNS involvement being rare, and rash uncommon—older age of onset (50–60 years compared with a mean age of onset of 29 years in idiopathic SLE). Drug-induced SLE is uncommon among the Black population, though this group accounts for 30 per cent of idiopathic cases. The drugs associated with SLE include hydralazine and procainamide, with minocycline an important recent addition. Most rheumatologists believe that these agents can be used safely by patients with idiopathic SLE, but oestrogen-containing contraceptives are generally regarded as being contraindicated. If a patient develops SLE, any concurrent medication should be withdrawn and the patient observed for a period. However, corticosteroids may be required where there is severe involvement, particularly of the renal, CNS, or cardiorespiratory systems. Antibodies may persist after satisfactory clinical resolution and are not of themselves an indication for continued treatment.

Isoniazid and phenobarbital have been associated with a shoulder–hand syndrome (discussed above as reflex sympathetic dystrophy). The mechanism of this association is unclear, though alteration in serotonin metabolism has been implicated.

Quinolone antibiotics can cause a tendinopathy. This may lead to rupture, most commonly of the Achilles tendon in elderly patients who are also taking corticosteroids.

Retinoids have been associated in recent years with a hyperostosis otherwise indistinguishable from DISH discussed above.

This discussion of the associations between drugs and rheumatological presentations is far from complete, and the physician should always consider drug therapy as a potential cause of new symptoms or signs.

19.1 Disorders of the skeleton

R. Smith

Introduction

Bone is the only tissue, apart from teeth, that is mineralized to allow it to perform its normal function. The presence of mineral should not encourage the belief that bone is inert or that it is metabolically inactive. Many disorders affect the skeleton but only some can be considered here. Fractures, infections, and tumours that are more often dealt with by orthopaedic surgeons, are excluded from this chapter. The descriptions that follow may be divided into:

1. those disorders generally considered to be metabolic, such as osteoporosis, osteomalacia, Paget's disease of bone, and parathyroid bone disease;
2. those arising primarily from synthetic defects in the major components of the organic bone matrix and connective tissue, including osteogenesis imperfecta, the skeletal dysplasias, and Marfan's syndrome;
3. skeletal disorders that are clearly the result of enzyme defects, such as hypophosphatasia, homocystinuria, alkaptonuria, and the storage diseases;
4. those that appear to be intrinsic disorders of bone cells, such as osteopetrosis, fibrous dysplasia, and inherited ectopic ossification; and
5. various bone disorders that result from excessive minerals, vitamins, and metallic poisons.

To understand how these disorders arise and how to recognize them, a brief account of relevant aspects of bone physiology and clinical features is given here. More detail can be found in specialized texts (see Further reading list).

Physiology of bone

There is an increasing interest in the cells of bone, their control, activities, and communications, and in the non-collagen as well as the collagen components of the organic bone matrix. Advances in understanding of bone diseases such as osteoporosis, osteopetrosis, osteogenesis imperfecta, and Paget's disease reflect this. The causes of many rare skeletal disorders have been discovered (Table 1). Examples are Marfan's syndrome (mutations in the fibrillin gene); vitamin D-dependent rickets type II (mutations in the 1,25-dihydroxycholecalciferol receptor gene); pseudohypoparathyroidism and fibrous dysplasia (abnormalities in the G-protein signalling system); osteogenesis imperfecta (mutations in the type I collagen genes) and skeletal dysplasias (some with similar mutations in the type II collagen gene). Outstanding recent advances in bone physiology include the identification and elucidation of the functions of the parathyroid hormone-related peptide (**PTHrP**) and the bone morphogenetic proteins, known as **BMPs**. The discovery of the calcium-sensing receptor in the parathyroid and other tissues explains many rare disorders of mineral metabolism (Table 1). Further advances have been made in our understanding of the development of the osteoblast from the stromal-cell precursor and the ways in which the osteoblast controls osteoclast development and function (see below).

The mammalian skeleton serves two main functions, the demands of which often conflict. The first is to provide a rigid structure, the second is to act as an accessible mineral store. Both depend on the activities of specialized bone cells, controlled by genetic, mechanical, nutritional, and hormonal influences, and by a host of short-acting messengers produced by cells, collectively known as cytokines.

Structure

Bone tissue consists of cells and an extracellular mineralized matrix (35 per cent organic and 65 per cent inorganic). Some 90 per cent of the organic component is type I collagen. The remainder includes many non-collagen products of the osteoblast, such as osteocalcin, osteonectin, and proteoglycans. The mineral is present mainly as a complex mixture of calcium and phosphate in the form of hydroxyapatite.

Two anatomical types of bone may be defined, trabecular (cancellous) and cortical. The proportion of these differs from one bone to another; for example, vertebral bodies are predominantly trabecular, and the shafts of the long bones cortical. Such a distribution is related both to the functions of the bones and to the development of disorders of them, such as osteoporosis. Trabecular bone contains more metabolically active surfaces in a given volume than cortical bone. Cellular activities take place on the surfaces of trabecular bone and through resorbing channels (cutting cones) in cortical bone. The fine structure of bone is dealt with in anatomical texts.

Bone is often assumed to be inert because of its structural rigidity and persistence after death, and to be composed entirely of chalk because it contains 99 per cent of the body's calcium. These assumptions are superficially reasonable: neither is correct.

Bone cells

Conventional histological sections of bone demonstrate three types of bone cells which are clearly different (Fig. 1): osteoblasts, which may be plump and apparently active, or flat and apparently inactive—otherwise called bone-lining cells; multinuclear osteoclasts, which most often occupy areas of resorption; and osteocytes within their lacunae in the mineralized bone, apparently in contact with other osteocytes and bone cells through their extensions in the canaliculi. All these cells are in close contact with the bone marrow, which contains their precursors and brings them into close relationship with the immune system.

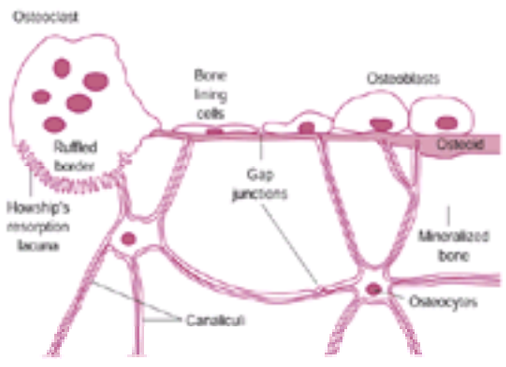

Fig. 1 A diagram showing the structure of bone and the relationship of the different cell types. (From the *Oxford textbook of rheumatology*, with permission.)

Bone cells are at the centre of an information system of astonishing complexity; and it is this complexity of bone that provides both the challenge and the fascination for those interested in its disorders. Histological techniques have been developed to study sequential cellular events in bone tissue; and the techniques of cell biology are used to study the origin and functions of different types of cells and the communications between them. All bone cells communicate with each other to control bone modelling during growth and remodelling throughout life. The constant processes of osteoclastic bone resorption and osteoblastic bone formation which achieve this are closely linked and take place in bone multicellular units (**BMUs**). The cellular cycle of such a unit begins with the activation of multinucleate osteoclasts from their macrophage-like mononuclear precursors, which produce resorption (Howship's) lacunae on the surface of trabecular bone, or cutting cones in cortical bone. These are identical processes; in cancellous (trabecular) bone the BMU may be looked upon as a sagittal section of a cortical BMU. Resorption is followed by a reversal phase, during which a cement line is deposited, and the formation by osteoblasts of new bone matrix which is subsequently mineralized. In the young adult, when the bone mass is constant and there may be several million resorbing sites in the skeleton at any one time, the amount of newly formed bone equals that resorbed. In childhood, more bone is formed than is resorbed; and in later years there is an imbalance between the two processes in favour of resorption, leading to osteoporosis.

The estimated time scale of the remodelling cycle is approximate. In the adult, the replacement of old bone with new occurs at an annual turnover rate of 25 per cent in cancellous bone, and 2 to 3 per cent in cortical bone. In the BMU resorption takes 1 to 2 weeks and new bone formation about 7 weeks. A complete BMU cycle, including reversal and mineralization, takes several months. The turnover of bone at a given site is determined by the frequency with which BMUs are activated and the rates of function of individual cells. Bone loss and gain depend on both factors; and the mechanism of bone loss is different in different disorders. Although the existence of the BMU system is widely accepted, it is far from understood. For instance, what factors lead to activation of the osteoclasts to initiate the resorbing cycle; how do cells talk to each other; and what links osteoblast and osteoclast activity?

It is clear that osteoblasts occupy a central position in bone physiology (Fig. 2). They are derived from the mesenchymal stromal-cell system within the bone marrow.

This system is multipotential and the stromal cells can give rise to osteoblasts, fibroblasts, chondrocytes, myocytes, and adipocytes. Under the influence of the differentiation factor identified as CBFA-1 (core-binding factor-a1) the stromal cells develop into osteoblasts. Osteoblasts respond to hormonal factors, both systemic and local (cytokines), and to mechanical stress. They synthesize the organic bone matrix, mainly collagen, and non-collagen proteins, and they control bone mineralization. Importantly, they also appear to direct the activity of other cell types, particularly the osteoclasts. In this respect they may also activate the bone-resorbing cycle. The osteoclast differentiation factor (**ODF**) has now been identified as osteoprotegerin ligand (**OPGL**, also known as **RANKL** and **TRANCE**), a soluble product of the osteoblast, which together with other factors controls the formation and activity of osteoclasts. It is possible that these many functions are divided between different osteoblasts. The bone-lining cells—resting osteoblasts—may not be as inactive as they appear, since they may provide a cellular barrier separating the so-called bone fluid from the general extracellular compartment. The separate existence of bone fluid has yet to be established.

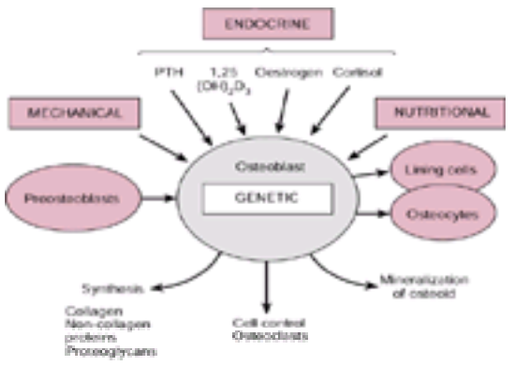

Fig. 2 To show the central position of the osteoblast in bone physiology. (From the *Oxford textbook of rheumatology*, with permission.)

Osteocytes, also derived from osteoblasts, occupy lacunae within the mineralized bone, and communicate with each other through gap junctions via their processes within the canaliculi. They probably have an important function in the detection of mechanical forces and the resultant response of bone.

Osteoclasts have a different origin from osteoblasts, since the former are multinucleated cells derived from the haemopoietic system. The osteoclasts resorb bone by attaching themselves to its surface via integrins and forming a seal to isolate their area of activity. Within this sealed zone they produce a very acid environment, with the aid of a proton pump linked to the enzyme carbonic anhydrase II, to enable digestion of whole bone by lysosomal enzymes. The absence of carbonic anhydrase II is linked to a rare form of osteopetrosis (see below). Osteoclasts have receptors to calcitonin which, when occupied, directly suppress their activity; the existence of any other hormone receptors is controversial. However, they are activated by prostaglandins. The osteoclastic resorptive effects of parathyroid hormone and of 1,25-dihydroxycholecalciferol are probably mediated through the osteoblast.

Bone formation

The factors that control bone formation are complex and not fully understood, but must work largely through the osteoblast. The stromal precursors of osteoblasts are found in the periosteum and the endosteal surfaces close to the bone marrow. The local remodelling stimulus for new bone formation appears to come from some product, or products, of bone resorption, which could, for instance, be a group of polypeptide growth factors or morphogenic proteins liberated from resorbed bone. Such substances are included in the category of cytokines. A cytokine may be defined as 'a peptide produced by a cell which acts as an autocrine, paracrine, or endocrine mediator'. This definition includes a large number of substances with effects on the metabolism of bone and cartilage. Such effects have largely been shown in experimental (and artificial) situations and their physiological role is unknown. Many cytokines have alternative names and multiple actions, featuring both synergism and antagonism. They include interleukins (1 and 6), tumour necrosis factor, g-interferon, platelet-derived growth factor, fibroblast growth factors, insulin-like growth factors, transforming growth factor-b, and bone morphogenic proteins.

Since bone cells contain, synthesize, and respond to many cytokines, they are part of a complex network. As an example, transforming growth factor-b (**TGF-b**) appears to belong to a family of multifunctional regulatory peptides, and bone is probably its most abundant source. Not only do osteoblasts synthesize TGF-b, but they also have high-affinity receptors for it, and are mitogenically stimulated by it. In addition, most of the bone morphogenic proteins belong to the TGF-b family.

Bone resorption

Osteoclasts are controlled by systemic and local hormones but there is no direct evidence that they are influenced by mechanical stress. Calcitonin directly inhibits the osteoclast, temporarily abolishes the active ruffled border, and suppresses the generation of new osteoclasts. Bone resorption is increased by parathyroid hormone and 1,25-dihydroxycholecalciferol. Since the osteoclast contains no receptors to either of these hormones it is proposed that their resorbing effect is mediated via the osteoblast. It is now realized that the interaction between osteoprotegerin (**OPG**) and its ligand (OPGL) is central to osteoblast/osteoclast interaction. The number and activity of the osteoclasts are also increased by a variety of cytokines produced by lymphocytes and monocytes (lymphokines and monokines, respectively), and by peptide growth factors such as epidermal growth factor. In myeloma the malignant plasma cells release interleukin-1 and -6 and tumour necrosis factor, all of which stimulate osteoclastic destruction of bone.

Bone mass (see also osteoporosis)

The development of the skeleton and its eventual size and density are influenced by important genetic factors modified by mechanical stress, nutrition, the systemic effects of endocrines, and by local factors produced by the bone cells themselves. These determine the balance between resorption and formation, and their relative contribution varies with age.

Recent work re-emphasizes the importance of the genetic contribution to bone mass. Apart from the difference in bone mass between races, this work has confirmed the hereditability of bone mass at all sites, which is greater in monozygotic than dizygotic twins. Clearly, mutations in the structural collagen genes will have a considerable effect on bone mass, as in osteogenesis imperfecta (see below). The contribution of vitamin D receptor-gene polymorphisms and genetic changes in the promoter region of type I collagen has been widely discussed (see osteoporosis).

The main function of the skeleton is mechanical and it has long been known that bone is laid down along its lines of stress. Although the way in which this occurs is obscure, experiments show that osteoblasts *in vitro* may respond to mechanical stress by an increase in levels of cyclic adenosine monophosphate (cAMP) and phosphonositol, partly mediated by prostaglandins. It also seems common sense that the size and density of the skeleton should be related to nutritional intake, particularly of calcium, protein, and energy. This has been difficult to prove, but recent co-twin studies in growing children have demonstrated a significantly greater density of bone (which may be temporary) in those taking calcium supplements, and that the starvation associated with anorexia nervosa reduces bone mineral content. This may also be due to oestrogen deficiency and emphasizes the important effect of reproductive hormones on the skeleton. The sex hormones, testosterone, and oestrogen, encourage new bone formation. It has recently been shown that oestrogen-deficient men have osteoporosis, and thus it is clear that the skeleton depends on a full complement of sex steroids for its integrity. Growth hormone is an important anabolic skeletal agent during the early years of life, partly through the local production of somatomedins (insulin-like growth factors). Several hormones that influence bone resorption may also have anabolic actions mediated by osteoblasts. One is parathyroid hormone, which under certain circumstances increases the proliferation of osteoblast precursors.

Collagen

Collagen is the principal extracellular protein in the body, more than half of which is contained within the skeleton, and is the main product of the osteoblast. There are many different molecular types, with different functions, each encoded by distinct genes (Table 2). Collagen in bone is type I. This heteropolymer is composed of two a-1 chains and one a-2 chain. The general structure of the a-1 chain is $(Gly–X–Y)_{338}$. The a-chains are synthesized as precursors within the osteoblasts and undergo a number of synthetic steps, including post-translational hydroxylation of proline and lysine residues; certain hydroxylysine residues are further modified into aldehydes and are also glycosylated (Fig. 3).

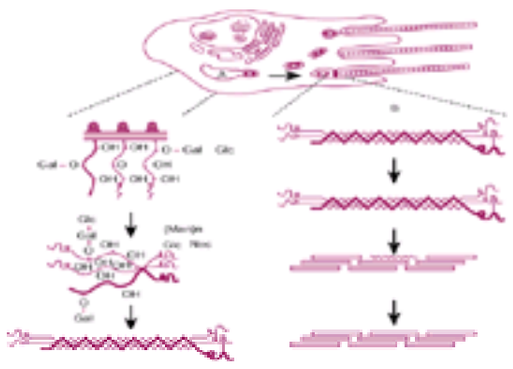

Fig. 3 The synthesis and assembly of collagen molecules. Within the fibroblast (A) the individual pro-a-chains are modified, assembled, and folded into the triple helix. In (B) these chains are exported, shortened, and self-assemble. (From the *Oxford textbook of Rheumatology*, with permission.)

After removal of their extensions, the triple-helical molecules form an exact structure with a quarter-stagger overlap that is subsequently crosslinked. The so-called 'hole zones' within this structure provide a template for early mineralization. Mutations in the collagen genes and defects in post-translational modification cause inherited disorders of connective tissue, of which osteogenesis imperfecta (type I collagen) and type IV Ehlers–Danlos syndrome (type III collagen) are examples (Table 1). Renal excretion of hydroxyproline peptides is an indicator of bone collagen turnover, and excretion of pyridinium compounds is a measure of bone resorption (see below).

Non-collagen proteins

Many such proteins may be extracted from bone, although their abundance differs according to the starting material and the methods used. They include osteocalcin (Gla protein), sialoproteins, various phosphoproteins, such as osteonectin and osteopontin, the bone morphogenetic proteins, and bone-specific proteoglycans.

The nature of non-collagen substances sequestered in bone matrix is complex and most are synthesized by the osteoblasts. Few, if any, are unique to bone, since they can be expressed transiently in other tissues—to date, no unambiguous function has been determined for any of these proteins. Osteonectin is the most abundant non-collagen protein produced by human osteoblasts. It binds strongly to calcium ions, hydroxyapatite, and native collagen, but is not limited to mineralizing tissue, being also found in human platelets. Although osteonectin mRNA is widely distributed in developing tissues, osteonectin is most abundant in bone. Two bone sialoproteins (**BSP**) are now recognized (BSP1 and BSP2). Their relative abundance varies with the species studied: for instance, BSP1 is a minor component of human bone, but a major contributor to total sialoprotein in rat bone. The protein contains an **RGD** (Arg–Gly–Asp) cell-attachment sequence and is therefore called osteopontin. The major human sialoprotein is BSP2.

There are two bone Gla-containing proteins: osteocalcin—bone Gla protein (**BGP**)—and matrix Gla protein (**MGP**). The term Gla refers to the g-carboxylated glutamic acid residues, formed by the vitamin K-modulated, post-translational carboxylation of peptide-bound glutamic acid. These proteins have some sequence homology but are products of different genes. MGP is also a cartilage protein and is found at an earlier developmental stage than BGP. The function of BGP is unknown. BGP biosynthesis is regulated by 1,25-dihydroxycholecalciferol (1,25(OH) $_2D_3$) (and no other hormone), which enhances its nuclear transcription and eventual secretion from bone cells. Plasma BGP has been linked to the rate of bone formation or, less specifically, bone turnover.

Proteoglycans are proteins with one or more attached glycosaminoglycan chains. They vary widely in form and function. Those of bone, which include decorin and biglycan, have been studied less extensively than those of cartilage, and differ from them in their small overall size and relatively larger amounts of protein. Such small proteoglycans are thought to interact with growing collagen fibrils in a precise manner and to regulate their growth, maturation, and interactions. Type IX collagen, closely associated with type II collagen, bridges the gap between the collagens and proteoglycans since it contains a chondroitin sulphate glycosaminoglycan chain.

It has been known for many years that demineralized bone matrix contains substances capable of inducing ectopic bone formation. Because they are present in such small amounts their extraction and isolation have presented great difficulties, but these bone morphogenic proteins have now been isolated and their genes localized and cloned. Interestingly, most belong to the TGF-b supergene family. Some evidence suggests their overexpression in fibrodysplasia ossificans progressiva (**FOP**).

Bone mineral and mineralization

Mineralization occurs on bone matrix collagen. The way in which it occurs has been long debated, but there is now good evidence that, in most mineralized tissues, calcifying vesicles derived from chondrocytes or osteoblasts provide a focus for mineralization. These vesicles are easily demonstrable in cartilage, but their function in the organized matrix of bone is controversial. The precipitation of calcium within these vesicles may be controlled by the action of a pyrophosphatase that locally destroys pyrophosphate, itself an inhibitor of mineralization. Alkaline phosphatase is one such pyrophosphatase which is readily demonstrable both in osteoblasts and in mineralizing vesicles. It is possible, for the purpose of clarity, to consider two types of mineralization: namely (1) homogeneous nucleation, which occurs in the lumen of the matrix vesicles, from amorphous calcium phosphate to form crystalline hydroxyapatite; and (2) heterogeneous nucleation, which is collagen-mediated and may partly rely on adsorbed non-collagen proteins as nucleators. After this first phase (mediated either by vesicles or collagen) there is a second phase of rapid spread of mineralization initially in the hole zones and later the overlap regions of the collagen matrix.

Calcium and phosphorus balance (see also Section 12)

Much has been written about calcium balance and the main hormones that control it. Phosphate balance is less well understood. The circulating level of plasma calcium is determined by the amount of calcium that is absorbed by the intestine, the amount that is excreted by the kidney, and the exchange of mineral with the skeleton. The relative importance of these exchanges differs during growth and in different disorders. Total plasma calcium concentration is closely maintained between 2.25 and 2.60 mmol/l, of which nearly half is in the ionized form (47 per cent ionized, 46 per cent protein bound, and the remainder complexed). The skeleton contains approximately 1 kg (25 000 mmol) of calcium. The main fluxes of calcium in the young adult are shown in Fig. 4.

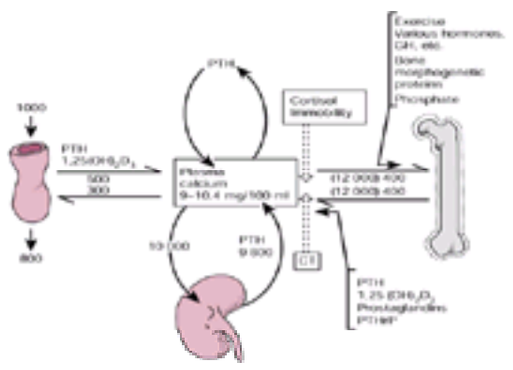

Fig. 4 Factors that control calcium balance. Units are in mg/day (to convert to mmol divide by 40) and refer to an adult. The figures in parentheses are an estimate of exchange through the cellular barrier of bone. CT, calcitonin; GH, growth hormone; PTH, parathyroid hormone; PTHrP, parathyroid hormone-related peptide. (From *Oxford textbook of rheumatology*, with permission.)

Parathyroid hormone (see also Chapter 12.6)

The gene for parathyroid hormone (PTH) is on chromosome 11. PTH is synthesized as a large precursor, in the way of proteins packaged for export, and its secretion is stimulated by a reduction in the plasma ionized-calcium concentration. Changes in plasma calcium are detected by a sensitive calcium-sensing receptor. Mutations in the gene for this receptor can cause hypocalcaemic and hypercalcaemic syndromes (Table 1). Increase in PTH secretion leads to an increase in calcium absorption through the gut, an increase in calcium reabsorption through the kidney, and an increase in bone resorption. Intestinal calcium absorption is mediated by 1,25-dihydroxycholecalciferol, and the 1a-hydroxylation of 25-hydroxy-cholecalciferol is stimulated by parathyroid hormone, so that the effect of parathyroid hormone in increasing intestinal calcium absorption is indirect. In contrast, the renal effect of parathyroid hormone on calcium reabsorption is direct. The cellular effects of parathyroid hormone on kidney and bone appear to involve two cellular systems, namely cAMP and phosphoinositol. Parathyroid hormone encourages osteoclastic bone resorption by its effects on the osteoblast (as previously described). Peripheral resistance to the effect of PTH due to inherited loss-of-function mutations in the G-protein signalling system occurs in pseudohypoparathyroidism (see below and Chapter 12.6).

Vitamin D

Vitamin D is synthesized either as vitamin D_3 (cholecalciferol) within the skin from its precursor 7-dehydrocholesterol under the influence of ultraviolet light (usually as sunlight), or taken in with food, either as vitamin D_3 or D_2 (ergocalciferol) (Fig. 5). It is transported to the liver by a binding protein where it undergoes 25-hydroxylation. 25-hydroxy-vitamin D is then hydroxylated in the 1a-position by the renal 1a-hydroxylase. 1,25(OH) $_2$D is the active metabolite of vitamin D and has widespread effects, the extent of which is only just being appreciated. These are mediated through a widely distributed vitamin D receptor which has DNA- and hormone-binding components. In addition to its classic effect on intestinal calcium transport, vitamin D is linked with the immune system and the growth and differentiation of a wide variety of cells. Measurement of the plasma 25-hydroxy-vitamin D concentration has proved to be a useful indicator of vitamin D status, and work on 1,25(OH) $_2$D and its receptors has illuminated the cause of the rarer forms of inherited rickets (see below). The kidney is the main source of 1,25(OH) $_2$D but it is now clear that this metabolite can be synthesized by macrophages in a variety of granulomas, providing an explanation for the hypercalcaemia of sarcoidosis, disseminated tuberculosis, and (occasionally) lymphomas.

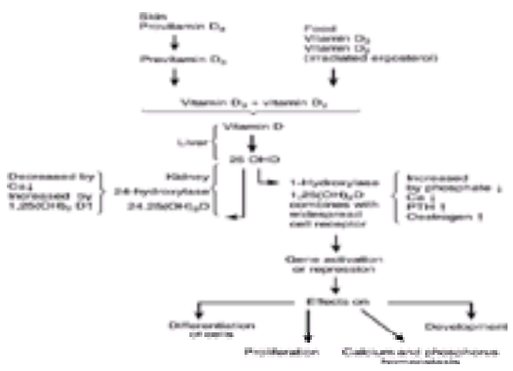

Fig. 5 The synthetic pathways and molecular and cellular effects of 1,25(OH) $_2$D. (From *Oxford textbook of rheumatology*, with permission.)

Calcitonin

The main effect of administered calcitonin is to reduce bone resorption by the direct and reversible suppression of osteoclasts and by inhibition of their production from precursors. The role of calcitonin is uncertain, although it is thought to protect the skeleton during physiological stresses such as growth and pregnancy. It is produced by alternative splicing of the primary gene transcript also responsible for the production of calcitonin gene-related peptide. Recent work has shown that its receptor is widely distributed.

Parathyroid hormone-related protein (PTHrP)

This hormone was discovered through studies on patients with non-metastatic hypercalcaemia of malignancy. PTHrP has close sequence homology to PTH at the amino-terminal end of the molecule and has very similar effects. Its gene is located on the short arm of chromosome 12, and is thought to have arisen by a duplication of chromosome 11, which carries the human *PTH* gene. It has been detected in a number of tumours, particularly of the lung. There is also evidence that it may have a role in fetal physiology, controlling the calcium gradient across the placenta to maintain the relatively higher concentrations in the fetal circulation. PTH and PTHrP have the same receptor. Mutations of this receptor can cause Jansen's metaphyseal dysplasia and it has become clear that PTHrP is involved in early development of the skeleton.

Other hormones

Apart from the recognized calciotrophic hormones, the skeleton is influenced by corticosteroids, the sex hormones, thyroxine, and growth hormone. The main effect of excess corticosteroids (either therapeutic or in Cushing's syndrome) is to suppress osteoblastic new bone formation, although there is also an element of secondary hyperparathyroidism. Androgens and oestrogens promote and maintain skeletal mass. Osteoblasts have receptors for oestrogens, although they are not abundant. Thyroxine increases bone turnover and increases resorption in excess of formation; thyrotoxicosis thus leads to bone loss. Excess growth hormone leads to gigantism and acromegaly (according to the age of onset) with enlargement of the bones. Absence of growth hormone will lead to proportional short stature; where there is general pituitary failure the reduction in gonadotrophins will also induce bone loss.

Biochemical measures of bone turnover

Knowledge of bone physiology allows one to interpret biochemical measures of bone turnover. These include plasma bone-derived alkaline phosphatase and osteocalcin (BGP), and the urinary total hydroxyproline and crosslinked collagen-derived peptides. The first two are produced by osteoblasts and indicate bone formation, the second two, bone resorption. Since formation and resorption are closely coupled, such measurements are usually closely related to each other and to overall bone turnover.

Total plasma alkaline phosphatase (largely derived from osteoblasts) provides a crude but readily accessible index of bone formation, being increased during periods of rapid growth and particularly when bone turnover is greatly increased, as in Paget's disease. Early measurements of serum BGP gave widely variable results and depended on the origin, sensitivity, and stability of the antibodies used. Total urinary hydroxyproline excretion is influenced by dietary collagen (gelatin) and reflects both resorption and new collagen synthesis. The recent development of methods for the measurement of urinary collagen-derived pyridinium crosslinks promises to give a reliable indication of bone resorption rate, unrelated to new collagen formation, and uninfluenced by diet. There are two forms of crosslinked peptide—pyridinoline and deoxypyridinoline, depending on whether they originate from oxidized hydroxylysine or lysine residues. Early assays were dependent on high-pressure liquid chromatography (**HPLC**) of urinary peptides after hydrolysis with acid. Simple and more direct immunoassays have now been developed.

Correct interpretation of collagen-derived fragments depends on knowledge of collagen's metabolic pathway (Fig. 3). Soon after export from the cell, the amino- and carboxy-propeptide extensions are cleaved from the mainly helical central part of the collagen chain. Measurement of these fragments in the plasma indicates the collagen formation rate. Once the collagen chains are crosslinked, measurement of different crosslinked fragments in the urine indicate (mainly bone) collagen resorption.

The diagnosis of bone disease

The diagnosis of bone disorders increasingly depends on investigation, with the result that important clinical points tend to be forgotten.

History

Deformity, pain, and fracture are common features. To these may be added proximal myopathy (in osteomalacia and rickets) and the symptoms of any underlying disease. The family history is always relevant.

Deformity

Deformity suggests previous skeletal disorder, especially if there is a disturbance of growth. Short stature and disproportion are more frequent than excessive height. In children, a knowledge of growth is essential; in the normal adult, height and span are approximately equal and the crown to pubis measurement is equal to the pubis to heel. Those with short stature can be divided into proportionate and disproportionate, of which the most frequent cause is short limbs. Proportionate short stature may occur in children who appear to be otherwise normal, whereas subjects with disproportionate short stature usually appear abnormal from birth. Some causes of short stature are given in Table 3. Skeletal chondrodysplasias are dealt with further below.

Kyphosis, with loss of trunk height, as in osteoporosis and osteomalacia, is the commonest acquired deformity of adult life. It is often noticed because clothes no longer fit. During childhood vertebral collapse will slow the growth rate. Other deformities are characteristic of the underlying disease; for instance, active childhood rickets produces knock knees, bowed legs, enlarged epiphyses, and bossing of the skull; Paget's disease produces thick limb bones and an enlarged skull vault; and severe osteogenesis imperfecta, very short limbs.

Bone pain and fracture

The cause of bone pain is not well understood. In osteomalacia it may be generalized and associated with tenderness on pressure. It may be due to excessive vascularity, with stretching of the periosteum; certainly it can be rapidly relieved by appropriate treatment, such as calcitonin for Paget's disease, or parathyroidectomy for parathyroid bone disease. Fractures of different sorts occur, examples being: the partial, multiple, and painful microfractures ('fissure' fractures) on the convexity of pagetic bone; the Looser's zones on medial borders of osteomalacic bones; and the multiple vertebral compression fractures of osteoporosis.

Myopathy

The cause of the proximal muscle weakness in osteomalacia and rickets remains unknown. The symptoms include a waddling gait, and inability to rise from a chair, to lift objects off high shelves, or to climb stairs. Limbs may be described as stiff rather than weak. Myopathy does not occur in subjects with inherited hypophosphataemia.

Underlying disease

It is necessary to be alert for the symptoms of the underlying disease, such as renal failure, steatorrhoea, or myeloma, and to enquire particularly about previous abdominal operations, including hysterectomy and oophorectomy.

Physical signs

It is important to see the patient out of bed so that an abnormal gait or stature is not missed. The appearance may give vital clues; for instance, the large vault of Paget's disease; the coarse features, large nose, big lower jaw, and widely spaced teeth of acromegaly; and the round face, simplicity, and cataracts of pseudohypoparathyroidism. Endocrine disorders affecting the skeleton, such as hypogonadism and hypopituitarism, are readily recognizable. Special facial features should receive attention; these include the eyes for such signs as corneal calcification, arcus juvenilis, and lens dislocation shown by the shimmering of the unsupported iris, iridodinesis. Further examples are corneal clouding (some mucopolysaccharidoses) and cystine crystals (cystinosis). In dentinogenesis imperfecta, often found with osteogenesis imperfecta, the teeth are abnormal in shape, tend to be transparent, and vary in colour from yellow to grey. Enamel defects occur in hypoparathyroidism, teeth are lost early in hypophosphatasia; and dental abscesses are common in hypophosphataemic rickets.

Hands and feet need particular attention. The fingers may be abnormally long and thin, as in Marfan's syndrome, or excessively short and mobile, as in pseudoachondroplasia; alternatively, they may be short, wide, and stiff in some mucopolysaccharidoses; or the hands may have short metacarpals, as in pseudohypoparathyroidism, or additional digits, as in the Ellis–van Creveld syndrome. The monophalangic big toe (and less often short thumbs) is characteristic of fibrodysplasia ossificans progressiva. Abnormal body proportions are common; the spine is relatively short after vertebral collapse. Scoliosis often dates from adolescence; occasionally it may be a clue to an inherited connective tissue disorder. A thoracolumbar gibbus is a particular (though not exclusive) feature of the mucopolysaccharidoses. Spinal deformity produces secondary changes; thus a young patient with severe osteoporosis will develop a prominent sternum with ribs that touch the iliac crest and a transverse crease across the front of the abdomen. Spontaneous tetany is a rare symptom, but there are two recognized bedside tests for latent tetany; of these Chvostek's sign is more convenient, but that of Trousseau more reliable. The first involves tapping the branches of the facial nerves as they spread out from within the parotid gland; a positive sign is twitching of the appropriate facial muscle. In the second the forearm is made ischaemic with a sphygmomanometer cuff for up to 3 min; if positive, carpal spasm will occur.

Investigations

Biochemistry

Many generalized disorders of the skeleton, such as postmenopausal osteoporosis, achondroplasia, osteogenesis imperfecta, and the epiphyseal dysplasias, have normal routine biochemical values; in others changes are diagnostic (Table 3). In normal persons the fasting plasma calcium concentration remains virtually constant through life, the plasma phosphate declines in adolescence to adult values and the plasma alkaline phosphatase level increases temporarily during rapid adolescent growth. Since total plasma calcium includes a protein-bound fraction, it is usual to relate it to the plasma albumin level and, if necessary, correct it to a plasma albumin of 4 g per 100 ml. Acceptable corrections include: corrected calcium (mg per 100 ml) = measured calcium – albumin (g per 100 ml) + 4; or for SI units: 0.02 mmol/l for every 1 g/l change of albumin from 40 g/l. The fasting plasma calcium is normal in osteoporosis and also in Paget's disease unless the patient is immobilized. It is increased in primary hyperparathyroidism, various neoplasms (including humoral hypercalcaemia of malignancy), in sarcoidosis, in vitamin-D overdosage, and in a number of other states, such as acromegaly and thyrotoxicosis (Table 4). It is often low in osteomalacia, but may be restored towards normal by secondary hyperparathyroidism, and is low in parathyroid insufficiency. Normal values are to be expected in inherited hypophosphataemia and in other forms of renal tubular rickets.

Since the main determinant of the fasting plasma phosphate concentration is its renal tubular reabsorption, hypophosphataemia occurs in primary hyperparathyroidism, in the humoral hypercalcaemia of malignancy, and it is also low in inherited hypophosphataemic rickets. Both oral aluminium hydroxide and prolonged intravenous nutrition also lower plasma phosphate levels. Hyperphosphataemia occurs in hypoparathyroidism, in renal glomerular failure, and in the rare, recessively inherited form of tumoral calcinosis.

Total plasma alkaline phosphatase and bone-derived alkaline phosphatase is normally increased in adolescence and in osteomalacia, particularly in the young, but it may be near-normal in renal tubular osteomalacia. Increases occur in primary hyperparathyroidism, but only where there is demonstrable bone disease. The highest values for plasma alkaline phosphatase are found in young patients with active Paget's disease, and in idiopathic hyperphosphatasia; and the lowest in hypophosphatasia.

Other plasma measurements, which have application in particular circumstances and in research, include: tartrate-resistant acid phosphatase (**TRAP**), a product of the osteoclast and therefore an indication of bone resorption; osteocalcin (bone Gla protein), a product of the osteoblast and therefore sometimes useful as an indicator of bone formation; and the N- and C-propeptide extensions of collagen, again an indicator of bone formation rate.

Glucose in the urine of a patient with inherited rickets suggests multiple renal tubular defects, and proteinuria is an important clue to myelomatosis.

The amount of calcium excreted in the urine is related both to the plasma levels and to the percentage of the filtered load reabsorbed through the renal tubules, itself altered by parathyroid hormone. Hypocalcaemia therefore causes hypocalciuria, particularly in osteomalacia and rickets; and hypercalcaemia leads to hypercalciuria, especially when this is due to rapid bone loss as in neoplastic disease of the skeleton, leukaemia, myeloma, and immobilization. Since parathyroid hormone increases the renal tubular reabsorption of calcium, the normal relationship between plasma and urine calcium is disturbed in parathyroid disease; however, most hypercalcaemic hyperparathyroid patients excrete more calcium than normal. Total hydroxyproline in the urine (after acid hydrolysis of the peptides) is a good indicator of bone breakdown and collagen turnover, provided the patient is ingesting a low-gelatin diet. The physiological changes in hydroxyproline excretion are striking, with a particularly sharp peak in adolescence coinciding with the maximum height velocity. The highest values are seen in active Paget's disease, where the excretion may be up to 50-fold the normal value. Hydroxyproline excretion correlates well with plasma alkaline phosphatase, and is therefore increased in some forms of osteomalacia and in hyperparathyroidism with bone disease. Since thyroxine increases collagen turnover, urinary hydroxyproline is also abnormally high in thyrotoxicosis and abnormally low in myxoedema (either primary or secondary).

Hydroxyproline excretion can be most usefully expressed as the amount in a 24-h urine sample in a patient on a gelatin-free diet, or in a fasting urine sample in relation to creatinine. However, hydroxyproline peptide excretion is related both to newly formed and mature collagen, and is not, therefore, a direct measure of bone resorption. The urinary excretion of pyridinium compounds (see above) from the lysyl- and hydroxylysyl-derived crosslinks of mature collagen is a direct measure of bone resorption, irrespective of dietary collagen.

Radiology

The diagnosis of bone disease often depends on the radiographic appearances, especially where there are no demonstrable biochemical changes. A particular example is in the differential diagnosis of perinatal lethal dwarfism. Conventional radiographs demonstrate well structural changes such as fractures, deformity, areas of resorption, and alteration in size, but are unreliable for the assessment of bone density. As radiographic techniques develop, increasing use is made of isotope bone scans, computed tomographic (**CT**), and magnetic resonance imaging (**MRI**) scans. Bisphosphonate-labelled scanning agents are selectively taken up in areas of increased vascularity or turnover. They are very useful in demonstrating the skeletal extent of Paget's disease of bone, the presence of bony metastases, the pathological fractures of osteoporosis, and Looser's zones in osteomalacia. An isotope scan is preferable to multiple radiographs to assess the distribution (but not the structure) of abnormal bone.

CT scanning can also be very useful in bone disease. Examples include the delineation of ectopic ossification, of spinal cord compression, and of bone tumours. Although magnetic resonance scanning (MRI) finds its most important application in soft-tissue pathology, it is also useful in giving an idea of the composition as well as the structure of bone.

Methods for measuring bone mass are considered under osteoporosis (see below).

Bone biopsy

Direct examination of bone is a valuable but under-used investigation. Bone can be taken by a transiliac trephine (using a local anaesthetic) and sections should be examined with and without decalcification. Ideally the bone should be labelled with tetracycline to allow an estimate of formation rates. In the various metabolic bone diseases the appearances are characteristic, with the: excess osteoid of osteomalacia; the disorganized mosaic pattern, excessive cellular activity, and fibrosis of Paget's disease; and osteitis fibrosa cystica in hyperparathyroid bone disease. In mild osteogenesis imperfecta there is typically an increase in the number of osteocytes, and, in the more severe form, a considerable increase in the amount of woven bone. A normal biopsy will exclude these diseases except where the pathological changes are patchy. Where possible, histological examination should now include transmission and scanning electron microscopy, and the report should include quantitative histomorphometry. More details are given in larger texts (see the Further reading list).

Further investigations

Measurement of the external calcium and phosphorus balance is a classic way of investigating generalized bone disease and the effects of treatment upon it, but it is also tedious. The use of isotopes to measure calcium absorption and apparent bone formation and resorption rates is less direct and also depends on a number of assumptions. This leaves a large number of measurements available for specific problems. Important examples (in the plasma) are intact PTH assays (to investigate hyper- and hypocalcaemia), PTHrP (mainly in research), 25-hydroxy-vitamin D, and 1,25-dihydroxy-vitamin D (for the investigation of rickets and osteomalacia). In inherited disorders, analysis of DNA extracted from whole blood and of collagen synthesized from fibroblast cultures derived from skin samples are used increasingly.

Diagnosis

The diagnosis of a skeletal disorder is not difficult where there are clear biochemical disturbances (Table 4), although, as in osteomalacia, the causes may be many. An exact diagnosis may be impossible when the standard biochemical results are normal, and this is particularly so in some of the rare heritable disorders. Guidance based on the age of the patient and frequency of the disorder is given in Table 5.

Osteomalacia and rickets

Osteomalacia results from a lack of vitamin D or a disturbance of its metabolism; in the growing skeleton it is referred to as rickets, and the terms are often used interchangeably. Very rarely, severe calcium deficiency can lead to rickets. Inherited hypophosphataemia and several other renal tubular disorders may also cause rickets without clear evidence of abnormal vitamin D metabolism. The causal mutations in inherited hypophosphataemia have now been identified.

The main histological feature of osteomalacia is defective mineralization of bone matrix (Fig. 6). Our present understanding of osteomalacia relies on advances in knowledge of vitamin D metabolism (Fig. 7). For clinical purposes two aspects of the physiology of vitamin D require emphasis. The first is the quantitative importance of vitamin D synthesis in the skin in comparison with that in the diet, and the second concerns the relative role of different vitamin D metabolites. The measurement of circulating concentrations of 25-hydroxy-vitamin D (**25(OH)D**) as an index of vitamin D status has identified those groups (Asian immigrants and the elderly) most at risk from vitamin D deficiency; importantly it has also shown the large amounts of vitamin D that can be synthesized in the human skin when exposed to ultraviolet light. The causes of osteomalacia can now be partly understood in terms of its metabolites, and the major importance of **1,25(OH)2D** (1,25-dihydroxy-vitamin D) is established. The effects of giving vitamin D can probably not be ascribed to the actions of $1,25(OH)_2D$ alone, and probably include other biologically active derivatives such as 25(OH)D and possibly 24,25-dihydroxy-vitamin D (**24,25(OH)2D**).

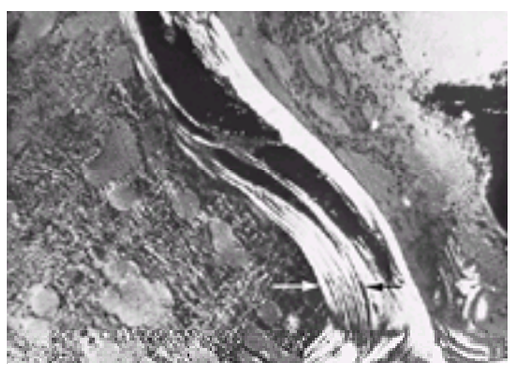

Fig. 6 Bone from a patient with osteomalacia. The birefringent osteoid is abnormally thick (up to 12 lamellae, arrows) and covers all bone surfaces. The bone preparation is undecalcified and viewed under polarized light (von Kossa stain; magnification 300 ×).

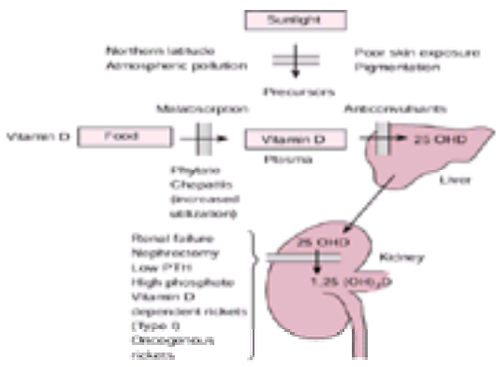

Fig. 7 The causes of rickets and osteomalacia related to the sources and metabolism of vitamin D (From *Oxford textbook of rheumatology*, with permission.)

Pathophysiology

The features of osteomalacia can be predicted largely from the known calciotropic effects of vitamin D. Examination of undecalcified bone shows wide osteoid seams with many birefringent lamellae of collagen (Fig. 6) covering more of the bone surface than normal, and absence of the 'calcification front'. The absence of this front is important since excessive osteoid may also be found in conditions other than osteomalacia, such as hypophosphatasia, Paget's disease of bone, and thyrotoxicosis, where the calcification front is normal; in these disorders the increase tends to be in the amount of bone surface covered rather than in the thickness of osteoid. Excess osteoid also occurs when bisphosphonates, such as etidronate, or aluminium accumulate in the skeleton. In rickets the main change is disorganization of the growth plate.

Since there is intestinal malabsorption of calcium in vitamin D deficiency, both the plasma and urine calcium levels are lower than normal; absorption of phosphorus is also defective, with resultant hypophosphataemia. As hypocalcaemia stimulates the secretion of parathyroid hormone, this will correct the low plasma calcium level and exaggerate hypophosphataemia. In osteomalacia, osteoblastic activity is increased and the plasma alkaline phosphatase is therefore also increased. There appears to be no difficulty in laying down bone matrix collagen, but it cannot be properly mineralized. One should recall that the effects of vitamin D are not confined to the skeleton, although they are clinically most obvious in this tissue—thus vitamin D has important effects on cellular differentiation and on the immune system.

Causes

There are many causes of osteomalacia (and rickets), some of which are very rare. They may conveniently be divided into three main groups: nutritional, malabsorptive, and renal (Table 6). Most can be understood in terms of vitamin D metabolism (see Fig. 7). In the elderly and immigrant populations the food intake of vitamin D is often deficient and the requirements may be increased; the absorption of vitamin D is poor in coeliac disease, after partial gastrectomy, intestinal resection or bypass, and in biliary disease. The intestinal absorption of calcium is reduced by phytate and chapatti ingestion, which may also increase vitamin D requirements (see below). Endogenous synthesis of vitamin D in the skin is reduced, especially in towns and city communities in the Northern hemisphere; it is further reduced by skin pigmentation. The 25-hydroxylation of calciferol may be impaired in some chronic liver diseases, and anticonvulsants may induce hepatic enzymes which degrade vitamin D. The 1a-hydroxylation of 25(OH)D is reduced or absent in renal failure, after nephrectomy, in hyperphosphataemia, parathyroid insufficiency, in type-I vitamin D-dependent rickets, and probably in some bone tumours. Many patients have more than one cause for their osteomalacia; in the elderly person vitamin D intake is poor, exposure to sunlight is limited, and renal glomerular failure progressive. Reduced exposure to sunlight is a frequent consequence of physical immobility and may contribute to osteomalacia in rheumatoid arthritis and other chronic diseases.

The effects of renal glomerular failure on the skeleton are complex (Chapter 20.8). Two main events occur: one is an increase in the plasma phosphate level, which leads to a fall in plasma calcium and to secondary hyperparathyroidism with excessive bone resorption; the other is the reduced formation of $1,25(OH)_2D$, with defective intestinal absorption of calcium and defective bone mineralization. The combination of these events rapidly produces severe deformity, especially in the growing skeleton. In patients receiving dialysis, renal osteodystrophy may be complicated by aluminium intoxication.

Clinical features

The main symptoms of osteomalacia are bone pain and tenderness, skeletal deformity, and proximal muscle weakness, often accompanied by the features of the underlying disorder and by those of hypocalcaemia. In severe osteomalacia all the bones are painful and tender, sometimes sufficiently so to disturb sleep. The tenderness can be particularly marked in the lower ribs and may also be accentuated over Looser's zones. Deformity is most often seen in rickets when the effects of vitamin D deficiency are superimposed on a growing skeleton. The linear growth rate is reduced, there is bowing of the long bones, enlargement of the costochondral junctions (rickety rosary), and bossing of the frontal and parietal bones. Later, osteomalacia may produce a triradiate pelvis, a gross kyphosis, and corresponding deformities of the chest.

Proximal muscle weakness is an important symptom. Its cause is unknown (although myoblasts require $1,25(OH)_2D$ *in vitro*, and the development of myofibrils in animals without the vitamin D receptor may be abnormal). It is more marked in some forms of osteomalacia than in others. Most commonly there is a waddling gait, a difficulty in getting up and down stairs, out of low chairs, and in and out of small cars. In the elderly, weakness may make walking impossible thereby suggesting paraplegia. In younger subjects even muscular dystrophy may be simulated.

Features of the underlying disorder include anaemia; tiredness and steatorrhoea in coeliac disease; pigmentation, thirst, and nocturia in renal failure. Occasionally hypocalcaemia may cause spontaneous tetany; in children the manifestations of carpopedal spasm, stridor, and fits are more dramatic than in the adult.

Examination of the patient with osteomalacia or rickets confirms the main symptoms. Measurement of the body proportions is useful. Thus patients with inherited hypophosphataemia and rickets have relatively short limbs, whereas those with late-onset osteomalacia will have a relatively short trunk. It is important to look for clues as to the cause of the osteomalacia, such as the scars of previous gastric or intestinal surgery.

Investigations

Biochemistry

Since there are many causes of osteomalacia, the detailed biochemical changes differ from one to another. In vitamin D deficiency or malabsorption there are low plasma calcium and phosphate, a low urine calcium, and an increase in the plasma alkaline phosphatase level. However, these may vary with the stage of the disease. Initially, hypocalcaemia may be the only abnormality. Later, with secondary hyperparathyroidism, the plasma calcium level returns towards normal, the plasma phosphate level falls, and the alkaline phosphatase level increases. In inherited hypophosphataemia (vitamin D-resistant rickets) plasma phosphate is low, but the plasma calcium is normal and the alkaline phosphatase may also be normal. Renal glomerular failure causes an increase in plasma phosphate, urea, and creatinine, and hypocalcaemia, and in the rare renal tubular syndromes there may be a marked systemic acidosis. In patients with osteomalacia the urine should always be examined for the presence of glucose and protein. If these are present, it is important to check for the aminoaciduria characteristic of renal tubular disorders.

The measurement of vitamin D metabolites is becoming routine, and a low plasma 25(OH)D level is a good indication of vitamin D deficiency. Estimation of plasma $1,25(OH)_2D$ is important to elucidate the very rare causes of rickets, and particularly to distinguish between type I (low $1,25(OH)_2D$) and type II (high $1,25(OH)_2D$) vitamin D-dependent rickets.

Radiology

The radiological appearances differ according to whether growth has ceased or not. In rickets the main abnormalities are at the ends of the long bones, where the width of the growth plate is increased, and the metaphysis is widened, cupped, and ragged (Fig. 8). Osteomalacia may show the deformities previously described, but the radiological hallmark of active osteomalacia is the Looser's zone (Fig. 9). This is a ribbon-like area of defective mineralization, which may be found in almost any bone but is seen particularly in the long bones, the pelvis, and the ribs, and also around the scapulas. Looser's zones may be bilateral and symmetrical; in bones such as the femur they occur on the medial border of the shaft or neck and are usually single, in contrast to the multiple fissure fractures on the lateral convexity of the bone in Paget's disease. In osteomalacia the vertebral bodies are often uniformly biconcave, to produce an appearance likened to a fish spine. Additionally, in renal glomerular osteodystrophy, the endplates may become relatively more dense than the rest of the vertebral body, to produce the so-called 'rugger jersey' spine. In the adult with inherited hypophosphataemia the bones may also become deformed, buttressed, and dense; in this disorder calcification of the tendons and ligaments at their insertions (enthesiopathy) and of the vertebral ligaments can produce an appearance similar to that of ankylosing spondylitis. Ossification of the ligamenta flava narrows the spinal canal and compresses the spinal cord and its roots. This is well shown on CT scans. In patients with osteomalacia and hypocalcaemia the radiological features of secondary hyperparathyroidism appear with subperiosteal bone resorption that affects the phalanges, the pubic symphysis, and the outer ends of the clavicles. In rickets, periostitis of the distal ends of the long bones, such as the radius and ulna, often occur.

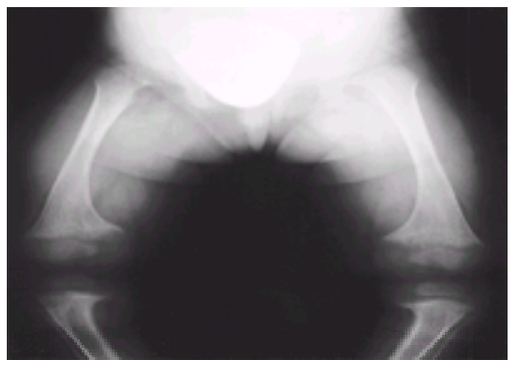

Fig. 8 The radiological appearance of rickets in a child with inherited hypophosphataemia. The growth plates are widened and the metaphyses cupped and ragged.

Fig. 9 To demonstrate the bilateral Looser's zones on the medial border of the femora in a woman with osteomalacia due to adult Fanconi's syndrome.

The most extreme effects of parathyroid overactivity are seen in the skeleton of the child with renal osteodystrophy, where the region of the growth plate and metaphyses may fracture (an appearance likened to a 'rotting stump'). A bone scintigram may be very useful in cases of osteomalacia, demonstrating multiple pathological fractures often not seen on the plain films. The appearance is similar to that of bony metastases.

Bone biopsy

The diagnosis of osteomalacia is often clear without examining the bone. Where doubt exists, a transiliac biopsy examined before and after decalcification will demonstrate the failure of mineralization and the wide osteoid seams. It is important to take all surgical opportunities to examine bone, particularly during operations on fractured femurs in the elderly.

Other investigations

Further investigation is not usually needed to diagnose osteomalacia, but may be necessary to identify its cause. Thus patients with vitamin D-deficient rickets and osteomalacia will have a low plasma 25(OH)D, but not all subjects with such low levels have osteomalacia. In the very rare condition of vitamin D-dependent rickets, measurement of circulating 1,25(OH)$_2$D will be necessary to distinguish the absence of 1a-hydroxylase from resistance to 1,25(OH)$_2$D. Further, CT scanning may help to identify the presence of a mesenchymal tumour causing hypophosphataemic osteomalacia.

Diagnosis

Osteomalacia is not difficult to diagnose once it is thought of. It should be distinguished from other forms of metabolic bone disease (Table 4), from other causes of proximal muscle weakness, and from other disorders causing bone pain. In patients with proximal muscle weakness, polymyalgia rheumatica, thyrotoxic myopathy, muscular dystrophy, neoplastic neuropathy, dermatomyositis, and polymyositis all need to be considered. Multiple myeloma and leukaemia may need to be excluded as causes of pain. Provided that the plasma calcium, phosphorus, and alkaline phosphatase levels are always measured in patients with these symptoms, those with osteomalacia should be easily identified. Patients with psychological illness may have an abnormal gait and complain of pain and weakness in their limbs, but in such patients the biochemistry will be normal. In practice, symptoms of pain and stiffness often first lead the patient with osteomalacia to a rheumatologist.

Treatment

Rickets and osteomalacia should respond rapidly to vitamin D (or to its metabolites) in an appropriate dose, and the response may be a useful way of confirming the diagnosis. Increased mobility with an increase in muscle strength may be the first clinical response, despite a temporary increase in bone pain. Biochemically, plasma phosphate and urine hydroxyproline levels are the first to increase. The alkaline phosphatase level may show a temporary rise and then fall slowly to normal levels. As the plasma calcium and 25(OH)D concentrations increase towards normal, the parathyroid hormone concentration falls.

The effective dose and the particular vitamin D preparation depends on the cause of the osteomalacia. That due to vitamin D deficiency will respond to microgram doses, but it is often useful to give considerably more than this, such as calciferol 1.25 mg daily for 1 to 2 weeks only. Where there is doubt about compliance, vitamin D may be injected intramuscularly in one large dose (up to 15 mg, 600 000 units). Lack of a response to microgram doses suggest that the osteomalacia is not due to simple vitamin D deficiency but, for instance, to malabsorption or renal failure. It is particularly in the last group that the 1a-hydroxylated metabolites of vitamin D are effective (see Chapter 20.8). Clearly, underlying disorders must be treated at the same time: for example, patients with coeliac disease will need a gluten-free diet.

Particular forms of osteomalacia and rickets

Nutritional osteomalacia

In the United Kingdom and other Northern European countries, so-called nutritional osteomalacia occurs particularly amongst the elderly and in Asian immigrants of all ages. In the elderly, the high incidence of osteomalacia is mainly due to their poor exposure to sunlight and to a low intake of vitamin D; and may be contributed to by the effects of drugs such as anticonvulsants and by increasing renal glomerular failure. Since the elderly are often housebound, they may develop osteomalacia despite a sunny climate. Certainly, the prevalence of osteomalacia in the elderly population is significant. The frequency of osteomalacia in patients with fractures of the femoral neck is also higher than previously suspected, but figures of up to 30 per cent, which continue to be reported (according to the histological definitions used), are probably overestimates. Osteomalacia should always be excluded in elderly people with bone disease, and particularly in those with femoral neck fractures. Where possible this should be done by histological examination of bone taken at operation or by biopsy. When this is not appropriate, a therapeutic trial with vitamin D is often useful. Since it is often difficult to define osteomalacia accurately in elderly people it is important to consider the use of such empirical treatment. In the geriatric population the mean concentration of 25(OH)D is much lower than in non-elderly patients; it shows the usual seasonal variation, with lowest values in the winter and early spring and highest in late summer.

Asian immigrants to the Northern hemisphere develop osteomalacia and rickets more often than the indigenous populations. There are probably several reasons for this. They tend to live in northern cities away from sunlight and, especially in women, do not expose their skin to the limited ultraviolet light. Where dermal synthesis of vitamin D is limited, dietary factors become more important, and it is particularly those on a meat-free diet containing chapattis who develop osteomalacia. The role of chapattis and the phytate they contain is not yet fully understood. Phytates bind to calcium so preventing its absorption, and it can be shown, at least experimentally, that reduced calcium absorption increases the vitamin D requirement by increasing its parathyroid-mediated breakdown. It has been suggested that such a mechanism of reduced calcium absorption may also contribute to the osteomalacia of malabsorptive syndromes, such as that following partial gastrectomy.

Pigmentation of the skin can be shown experimentally, using a standardized dose of ultraviolet light, to reduce vitamin D synthesis, but in practice this is of little significance. Since North European immigrants of Afro-Caribbean descent have a lower incidence of rickets than Asians in the same environment, it is clear that factors other than skin colour are important.

As in the elderly, 25(OH)D levels can be very low, especially in Asian immigrants. They increase in the summer, when there may be spontaneous healing of rickets. Important work in Glasgow has shown that Asian rickets can be prevented by fortifying food such as chapatti flour with vitamin D, although the incidence of osteomalacia in Asian adults remains unaffected. Other local lifestyle changes will also influence the diet of children.

Osteomalacia and malabsorption

Coeliac disease (gluten-sensitive enteropathy) (Chapter 14.9.3) is a relatively common cause of osteomalacia. It should be suspected at any age, and confirmed by the presence of circulating endomysial antibody and, if necessary, by a small intestinal biopsy showing an atrophic mucosa. Other causes of malabsorption vary in their frequency according to surgical practice. Thus it is well established that osteomalacia follows classic partial gastrectomy, but the actual incidence is debated and its cause is probably multifactorial. Postgastrectomy subjects tend to take little vitamin D in their diet and there is defective calcium absorption. Available evidence suggests that clinical osteomalacia is rare after vagotomy and pyloroplasty. Osteomalacia can also follow the removal of long segments of small intestine for conditions such as Crohn's disease, and complicates some intestinal bypass operations used for extreme obesity.

Osteomalacia and liver disease

Osteomalacia is uncommon in those with liver disease; in theory it may be due to a number of factors such as malabsorption of vitamin D and its defective 25-hydroxylation. Most research has concerned the osteomalacia of biliary cirrhosis, and osteomalacia in chronic liver disease appears to be a complication related to prolonged cholestasis.

Osteomalacia and renal disease

It is important to distinguish the osteomalacia and rickets of renal glomerular failure from that attributable to renal tubular disorders. Bone disease in renal glomerular failure (renal glomerular osteodystrophy) is dealt with elsewhere (see Chapter 20.8); this includes bone disease in the dialysed patient and the effects of aluminium. Renal glomerular osteodystrophy is a complex disease with excessive bone resorption, defective bone mineralization, and in some cases osteoporosis. Previously it was treated with large doses of native vitamin D; current therapy now includes 1a-hydroxy-cholecalciferol or 1,25(OH) $_2$D.

Many renal tubular disorders lead to osteomalacia (Chapter 20.8) (Table 7). Of these, the most common is inherited hypophosphataemia, so-called vitamin D-resistant rickets, which is normally inherited as an X-linked dominant characteristic; here, the main abnormality is hypophosphataemia due to a reduction in the maximum renal tubular reabsorption rate of phosphate. Some patients in a family will have hypophosphataemia alone, whereas others will have hypophosphataemia with accompanying bone disease. It is now known that inherited hypophosphataemia is caused by mutations in the *PEX* or *PHEX* gene, the cognate protein of which has the features of an endopeptidase. Endopeptidases degrade or activate peptide hormones. It is not yet known how the mutations produce the defect in phosphate homeostasis. Since the 1,25$(OH)_2$D levels are normal where the plasma phosphate is low, it is proposed that the sensitivity of the 1a-hydroxylase enzyme is reduced. Children with hypophosphataemic rickets or osteomalacia are unlike patients with other forms of rickets. They present with deformity but are otherwise well, without muscle weakness; however, growth is defective and their eventual height is usually less than 150 cm. Apart from hypophosphataemia there may be no other abnormality in the biochemical values routinely available, and the plasma alkaline phosphatase level can be normal for age. Radiographs show severe rickets, and later the bones are often dense with buttressing and exostoses. The enthesiopathy with ossification of the ligamenta flava can lead to para-plegia. Ligamentous calcification may also contribute to deafness. Finally, abnormal teeth in this disorder cause periapical translucencies and may lead to abscesses.

The treatment of inherited hypophosphataemia is controversial. For many years its mainstay was large doses of vitamin D; this posed a continuous danger of vitamin D poisoning and did not correct the eventual short stature. There is an improvement in growth rate when oral phosphate is given in addition to vitamin D, but the condition does not appear to respond to phosphate alone. More recently, it has been shown that combined oral phosphate and 1,25(OH) $_2$D produces healing of epiphyseal and trabecular bone and this is now the recommended treatment. This combination produces bone healing and increases eventual stature. However, it is still unusual for affected patients to have an eventual height of more than 1.5 m (5 ft). Accounts of the effects of medical treatment on deformity and height differ; the necessity for corrective osteotomy on the lower limbs is less than previously, but discussion with an orthopaedic surgeon is important.

It is also important that the parents should know the genetics of this condition. Because the defect in phosphate transport is inherited as a dominant on the X chromosome, an affected mother transmits the condition to 50 per cent of her children regardless of their gender. All the daughters of an affected father will have the disease, but none of his sons. In general, affected sons have a more severe disease while some affected daughters may be asymptomatic. Diagnosis can be made from birth, but this demands accurate knowledge of the normal plasma phosphate level at that age. Now that more is known about the exact gene location, prenatal diagnosis may be possible in future. Recently cloned human X-chromosome sequences that reveal restriction fragment length polymorphisms have been used in linkage studies of affected families to map the hypophosphataemic rickets gene. Flanking markers are potentially useful in the identification of mutant gene carriers and in presymptomatic diagnosis, but the distance between these markers and the hypophosphataemic gene is still large, at approximately 10 million base pairs. Hypophosphataemic animal models continue to help in furthering understanding of this disorder. A recently described murine *gy* mutation, in which hypophosphataemia is associated with gyratory activity, has no clear human equivalent. Rare human variants include an autosomal dominant form of hypophosphataemia.

Other renal tubular osteomalacic syndromes include hypophosphataemic osteomalacia presenting in adult life, which may be due to a tumour (see below), inherited and acquired forms of renal tubular acidosis, and rickets associated with multiple renal tubular defects and generalized aminoaciduria (Fanconi's syndrome). Renal tubular acidosis may be proximal or distal, with an inability to reabsorb bicarbonate or to acidify the urine. The osteomalacia may be cured by giving bicarbonate alone or with vitamin D. A persistent acidosis with resultant osteomalacia may also result from ureterosigmoid anastomosis. The commonest cause of Fanconi's syndrome in childhood is nephropathic cystinosis or cystine-storage disease, where there is a widespread deposition of cystine crystals throughout the tissues, and in which thirst, polyuria, dehydration, photophobia, and loss of weight begin at about the age of 1 year. The rickets will heal with the correction of the acidosis, and the administration of phosphate and 1a(OH)D; renal transplantation corrects the renal failure and prolongs survival, but does not prevent non-renal complications.

Other rare causes of renal tubular rickets and osteomalacia with generalized aminoaciduria are inherited, such as Wilson's disease and the X-linked oculocerebral

renal syndrome, or acquired, such as multiple myeloma, cadmium poisoning, and the toxic effects of ifosfamide used in the treatment of childhood malignant disease.

Anticonvulsant osteomalacia

In patients treated with anticonvulsants the incidence of rickets and osteomalacia is higher than normal. This has been attributed to the induction by the anticonvulsants of hepatic enzymes which metabolize vitamin D to biologically inactive derivatives. However, epileptic patients in institutions are often vitamin D-deficient because they are deprived of sunlight, and osteomalacia in such patients probably has several causes.

Tumour rickets

An unusual form of hypophosphataemic rickets or osteomalacia occurs in patients who have mesenchymal tumours, often of a particular histological type, namely sclerosing haemangioperiocytomas or non-ossifying fibromas. A tumour should be considered in any adult who develops hypophosphataemic osteomalacia, particularly with prominent myopathy. The disorder is improved by oral phosphate and cured by removal of the tumour. The way in which the tumour induces hypophosphataemia and subsequent osteomalacia is unknown, but current evidence suggests that it interferes with the renal 1a-hydroxylation of 25(OH)D, since the circulating levels of $1,25(OH)_2D$ are abnormally low but rapidly return to normal when the tumour is removed. Rarely, hypophosphataemic osteomalacia may become apparent in adults with neurofibromatosis and polyostotic fibrous dysplasia.

Osteogenic osteomalacia has also been described in cases of prostatic and small-cell carcinoma of the lung.

Vitamin D-dependent rickets

Patients with these very rare, recessively inherited forms of rickets show the features of severe rickets without vitamin D deficiency. There are at least two types of vitamin D-dependent rickets. In type I the activity of the renal 1a-hydroxylase is reduced so that the concentration of $1,25(OH)_2D$ is abnormally low. However, it can be increased by large doses of the native vitamin, which shows that the enzyme block is not complete. In type II there is an end-organ resistance to $1,25(OH)_2D$, which is present in high concentrations. In both forms there is severe rickets and myopathy from infancy; in type II, lifelong total alopecia is a striking feature. Vitamin D-dependent rickets type I responds to very large doses of vitamin D or physiological doses of $1,25(OH)_2D$. Type II may also respond to large doses of vitamin D or its metabolites, or to prolonged intravenous calcium, but some recorded cases suggest that recovery occurs spontaneously with age.

Recent work on type-II, vitamin D-dependent rickets (otherwise known as hereditary $1,25(OH)_2D$-resistant) shows that the $1,25(OH)_2D$-receptor defects, which are responsible for the end-organ resistance in this disease, are due to a variety of point mutations in the gene for the 1,25 receptor, either at its steroid- or DNA-binding domains.

Phosphate-deficiency rickets

If patients ingest large amounts of phosphate-binding drugs, such as aluminium hydroxide, a form of hypophosphataemic osteomalacia may develop. This differs clinically from inherited hypophosphataemic osteomalacia by the presence of severe muscle weakness. Other biochemical features include increased calcium absorption with hypercalcuria, associated with an increase above normal in the concentration of $1,25(OH)_2D$.

Paget's disease of bone

Paget's disease of bone, osteitis deformans, was described more than a century ago, but existed for many years before. It is the most common of the so-called metabolic bone diseases after osteoporosis. Its hallmark is excessive and disorganized resorption and formation of bone. Its cause is unknown, but recent studies on pagetic bone cells, particularly osteoclasts, have provided clues. The new generation of bisphosphonate drugs now provide effective treatment.

Pathophysiology

The natural history of Paget's disease is similar to that of a multicentric neoplasm or a slow virus disease that begins in young adult life. Electron microscopy shows virus-like inclusion bodies in the osteoclasts of patients with Paget's disease. Immunofluorescence studies suggest that these could represent the measles or respiratory syncytial virus. Another candidate has been the canine distemper virus, but the results of polymerase chain reaction amplification of reverse transcribed DNA from Paget's tissue to identify the putative virus remain controversial.

Histology shows multinucleate osteoclasts which appear to be resorbing bone, and busy osteoblasts which appear to be replacing it; these activities are closely linked. There is also excess fibrosis in the marrow. The bone matrix is laid down in all directions and partially loses its birefringence and strength. Mineralization may be defective, probably because of the excessive rate at which the organic bone matrix is laid down. The cement lines and the mosaic appearances of the bone result from the tidemarks of resorption followed by formation. Osteosarcoma which occurs in Paget's disease is presumably the result of the excessive and prolonged activity of the bone cells. Pagetic bone is large, vascular, and deformed. Its physical characteristics depend on the stage of the disorder and it may be hard or soft. In any event, it fractures more readily than normal.

Incidence

Paget's disease occurs in about 3 to 4 per cent of subjects over 40 years of age, is more common in men than in women and its frequency increases with age. It is not unknown in younger people. In Britain, about 750 000 people may have Paget's disease, of whom fewer than 5 per cent have symptoms. It appears to be a peculiarly Anglo-Saxon affliction, being very rare in countries such as Scandinavia and Japan. Within England, early radiological surveys in the 1970s showed that it occurs most often in Lancashire towns and in northern industrial regions (Table 8). It is also more frequent in recent British immigrants to Western Australia than in the Western Australian population, but less frequent than in those relatives who remained in Britain. Such studies do not distinguish between the effect of environment and heredity. In a disorder as common as Paget's disease many striking examples of 'familial' Paget's disease occur by chance. Recent studies suggest a reduction in the prevalence of Paget's disease.

Clinical features

Pain, deformity, fracture

In Paget's disease the bone itself may be painful, or pain may be due to arthritis of a nearby joint, to an associated fracture, or to the development of sarcoma. It has been suggested that there is a specific type of hip joint disorder associated with Paget's disease. Bone pain could be due to stretching of the periosteum, since this part of the bone (and the vessels within bone) contain nerves sensitive to pain. Clinically, the affected bones are enlarged, deformed, and warm. The enlargement is clearly seen in bones such as the tibia and the skull; in the former the bone is typically bowed forwards; the latter shows a characteristic enlargement of the vault that is said to look like a soft beret, or 'tam-o'-shanter', which appears to descend over the ears. Other long bones may become bent and a kyphosis may develop. Although any of the bones can be affected, including the maxilla and the phalanges, the most common sites for Paget's disease are the pelvis and the spine. Fracture may be the first symptom of undiagnosed Paget's disease, for instance at the junction of a resorbing front with normal bone (Fig. 10), or across a fissure fracture (see Fig. 11).

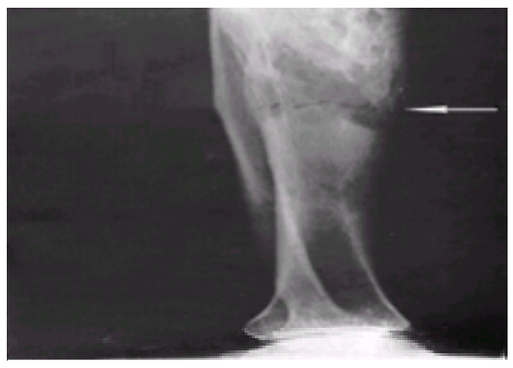

Fig. 10 A fracture in the region of a resorbing front in a pagetic bone (arrowed). Proximal to the area of bone resorption the cortex is thickened and the bone widened by disorganized formation of new bone.

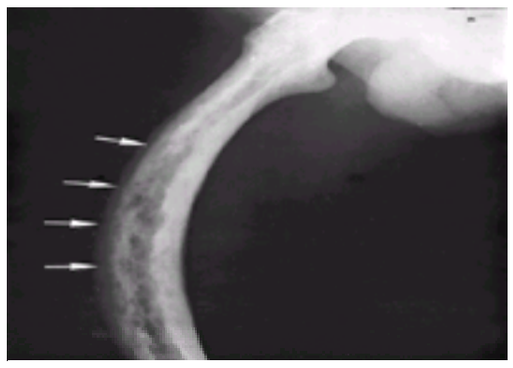

Fig. 11 Multiple microfractures ('fissure fractures' arrowed) on the convex surface of a pagetic femur.

Deafness and nerve compression

Deafness in Paget's disease is one of its most disabling symptoms and responds little to treatment. It has many causes, of which nerve compression is only one.

Most nerves can be compressed by enlarging pagetic bone. The spinal cord is particularly at risk, due to the combined effects of increased bone mass, vertebral collapse, and excessive vascularity. Paraplegia or cauda equina lesions may occur. Alterations in the shape of the skull may produce multiple cranial nerve palsies and brainstem lesions, with dysphagia, dysarthria, and ataxia. Basilar invagination with obstruction of cerebrospinal fluid drainage can lead to internal hydrocephalus, raised intracranial pressure, and confusion.

Heart failure

In severe Paget's disease, cardiac output may be increased by the excessive vascularity of the affected bones, but there is no convincing evidence of large arteriovenous shunts within the skeleton. The heart failure which results may be of the high-output variety, but this is excessively rare. Since heart failure and Paget's disease of bone are common in the elderly, their occurrence together is almost always coincidental.

Sarcoma

The incidence of sarcoma in Paget's disease has sometimes been overestimated in the past; it probably occurs in 1 per cent or less of those with symptoms. Paget's sarcoma often occurs in the humerus, although Paget's disease itself is most common in the pelvis and spine. Sarcoma should be considered in a patient known to have Paget's disease if pain has developed for the first time, or worsened, or if deformity has altered. Radiologically, the appearance of the pagetic bone alters, with evidence of bone destruction (Fig. 12); the tumours occur most often in the medulla. A recent review of 85 bone sarcomas associated with Paget's disease confirmed the humerus as a high-risk site. Rapidly worsening pain was the main symptom; lytic lesions were more common than sclerotic; periosteal reaction was uncommon; and radionuclide bisphosphonate scintigraphy usually showed areas of decreased uptake (contrasting with the underlying pagetic bone).

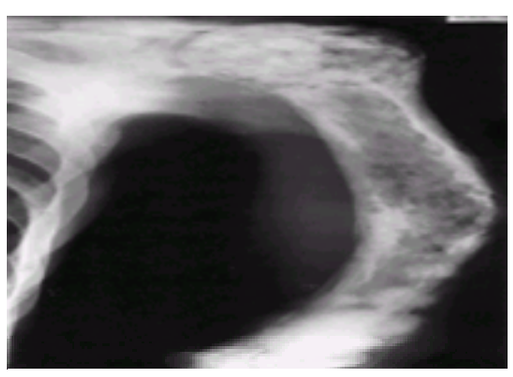

Fig. 12 A sarcoma in the upper end of the left humerus in a 70-year-old man with Paget's disease. The destructive lesion in the proximal humerus has been treated with radiotherapy; there are secondary deposits around the distal end of the bone.

Associated disorders

Paget's disease is said to be associated with other disorders such as osteoarthritis, gout, vascular calcification, and articular chondrocalcinosis. Since all these occur more often in the elderly the associations have little significance.

Investigations

Biochemistry

There is a marked increase in the level of plasma alkaline phosphatase, derived from the overactive osteoblasts, which is roughly related to the extent of clinical and radiological involvement with Paget's disease. In contrast, the acid phosphatase (derived partly from osteoclasts) level is only slightly increased. The rapid turnover of bone matrix collagen increases urinary hydroxyproline (and hydroxylysine), in proportion to the increase in alkaline phosphatase and also the urinary excretion of crosslinked collagen-derived peptides. Plasma calcium and phosphate levels are normal; hypercalcaemia suggests coexistent hyperparathyroidism, malignant disease, or immobility.

Radiology

The radiological appearances of Paget's disease are legion. The most characteristic is an increase in size of the affected bone. Resorption predominates early in the disease and in the young patient. A resorbing front may be seen in a long bone (as a flame-shaped area) (see Fig. 10) or in the skull (as 'osteoporosis circumscripta'). Excessive resorption is inevitably followed by disordered formation, and at this stage the bone becomes thick and deformed. In elderly subjects the affected bone may be very osteoporotic and liable to fracture. Multiple partial fractures (microfractures, fissure fractures) are common on the deformed convex surface of long bones (see Fig. 11), particularly the femur and tibia.

The use of bone-scintigraphic agents (such as $^{99}Tc^{m}$-labelled disodium etidronate (**EHDP**, [disodium] ethane-1-hydroxy-1,1-diphosphonate) has been particularly informative in Paget's disease. Affected bones take up the isotope avidly, which demonstrates both the extent of the bone lesions and the effects of treatment. In one study, 180 patients with Paget's disease underwent whole-body scintigraphy and 826 lesions were identified—one-third of the patients had only one lesion, and only 10 patients had no symptoms. The increase in plasma alkaline phosphatase and urinary total hydroxyproline was proportional to scintigraphic involvement, and patients with skull involvement had the highest values. Apart from the number of sites involved, any distinction between monostotic and polyostotic disease appeared to be artificial.

Diagnosis

The diagnosis of Paget's disease is usually obvious. Bone biopsy is useful to exclude other generalized bone diseases, such as osteomalacia, as well as to confirm Paget's disease. Paget's disease may initially be confused with osteomalacia because of the high plasma alkaline phosphatase level; rarely, an elevated plasma calcium should suggest additional hyperparathyroidism or malignant disease. In prostatic carcinoma with osteoblastic bone secondaries, the dense bones are not enlarged (as they are in Paget's disease) and the acid phosphatase level is considerably and disproportionately increased in relation to that of alkaline phosphatase. Of many other conditions with similar radiological appearance, fibrous dysplasia (see below), in which the alkaline phosphatase may also be slightly increased, may be difficult to distinguish; in the generalized form the unilateral bone lesions, pigmentation, and sexual precocity (in the female) are characteristic. Another very rare disorder usually mistaken for Paget's disease is fibrogenesis imperfecta ossium (see below), where the bone trabeculae are thickened without bony enlargement and there are multiple abnormal fractures.

Treatment

Many patients with Paget's disease require no treatment, but it may be required for symptoms, to suppress the activity of the disease, and to prevent its further progress. Indications include bone pain, nerve compression, and the suppression of vascularity before elective orthopaedic surgery. Since medical treatment is now so effective, these indications may be widened especially in young people.

Medical treatment

Patients with painful Paget's disease should first be treated with a simple analgesic. Where possible it should be determined whether the pain is directly due to the bone disease or to associated arthritis. Specific treatment aimed at the pagetic bone should be considered for those who have pain due to bone disease despite analgesia, or have the complications of deformity, nerve compression, deafness, or very rarely heart failure. This treatment should also be considered in the young person with Paget's disease to prevent further progression. There is no evidence that the rapid course of pagetic sarcoma is altered by any treatment. Of the many agents previously tried in Paget's disease, such as aspirin, fluoride, and corticosteroids, only three are currently in use, mithramycin, bisphosphonates, and calcitonin. Mithramycin is now rarely used. It is an antimitotic agent given intravenously which is hepatotoxic in high doses. It may rapidly abolish pain in Paget's disease, and rapidly reduce the plasma alkaline phosphatase level, but the effect is usually temporary. Mithramycin has been used on its own and in combination with bisphosphonates or calcitonin.

The bisphosphonates (once called diphosphonates) are a series of compounds with a P–C–P structure resistant to the naturally occurring phosphonates and pyrophosphatases. They are effective both orally and parenterally and reduce excessive bone turnover in Paget's disease. EHDP (Didronel®), one of the early bisphosphonates, also interferes with mineralization if given in high doses (20 mg/kg body weight); subsequent derivatives such as dichloromethylene diphosphonate (**Cl2 MDP**) and 3-amino-hydroxypropylidine-l,l-bisphosphonate (**APD**, pamidronate) do not appear to do this. According to their dose, the bisphosphonates may take up to 6 months to produce their effect on symptoms, histology, and biochemistry. The recommended dose for EHDP is 5 mg/kg per day for up to 6 months. It also has been used in combination with calcitonin, and together these agents suppress Paget's disease more effectively than when given alone. The biochemical effects of EHDP appear to last for a long time (possibly several years) after the drug is stopped. Many new bisphosphonates have now been developed based on side-chain substitutions in the basic P–C–P structure. The aminobisphosphonates are particularly effective. The new bisphosphonates are many times more potent than etidronate. They include pamidronate, tiludronate, alendronate, and risedronate. They may produce almost complete and permanent suppression of Paget's disease without significant side-effects. The dose regimes and expected responses are dealt with in larger reviews (see the Further reading list).

The calcitonins are less widely used for the treatment of Paget's disease, and salmon calcitonin is the most effective commercially available form. Various dose regimens are used, for which 100 IU given three times a week is average. Injected calcitonin may produce nausea and vomiting; if side-effects are troublesome, it is best given in the evening together with an antiemetic. Its main effects are seen during the first 3 months of treatment, and continued treatment is ineffective, especially when the alkaline phosphatase level has ceased to decline.

Antibodies to calcitonin do develop but are not necessarily related to calcitonin 'resistance'. Indications for the bisphosphonates and calcitonins are different. Calcitonin is preferred to treat bone pain, for osteolytic Paget's disease, and for preoperative treatment. Some evidence suggests that calcitonin may halt the progression of deafness. Spinal cord compression is also alleviated. Thus treatment of eight patients with paraparesis due to pagetic vertebrae with either calcitonin or bisphosphonate produced marked clinical improvement, at least comparable to the results of surgical decompression. Calcitonin can also be given preoperatively to reduce excessive bleeding when operations such as total hip replacement have to be performed on pagetic bone. Calcitonin can now be given by the nasal route, which is more acceptable to the patient but less effective.

Surgical treatment

Fractures through pagetic bone require the usual surgical treatment, although union may be delayed. Where fracture occurs through a deformed bone, this deformity should be corrected. In addition, elective osteotomy and intramedullary nailing may be considered for a severe long-bone deformity. Spinal cord compression not responding to medical treatment requires surgery. Rarely, hydrocephalus may require a ventriculojugular shunt. Whatever form of surgery is undertaken, it is important that the period of immobility is as short as possible, to avoid the development of hypercalciuria and hypercalcaemia.

Parathyroids and bone disease

Knowledge of the biochemistry of parathyroid hormone has expanded so rapidly that it now occupies a large and deserved part of any clinical description of parathyroid disorders (see Chapter 12.6). The close relationship between these endocrine glands and the skeleton becomes less obvious with increasing recognition of the many ways in which parathyroid disease presents. However, primary hyperparathyroidism was first identified because of its effects on bone, and only later was it realized that it might more often present with renal stones, with pancreatitis, and with the signs and symptoms of hypercalcaemia—or be a chance discovery as a result of multichannel biochemical analysis.

The subject is discussed further in Chapter 12.6.

Molecular advances

With the discovery of the calcium-sensing receptor (**CaR**) and extensive work on the cause of the multiple endocrine neoplasia syndromes our understanding of the rarer causes of abnormal plasma calcium levels has considerably increased. Thus missense mutations of the *CaR* gene cause both familial benign hypercalcaemia and neonatal hyperparathyroidism, whereas gain-of-function mutations in this receptor can cause familial hypoparathyroidism. Multiple endocrine neoplasia (**MEN**) syndromes have traditionally been divided into two types—type 1 with hyperparathyroidism, pituitary adenomas, insulin- and gastrin-secreting tumours of the pancreas, and gastric hyperacidity (Zollinger–Ellison syndrome); and type 2, also known as Sipple's syndrome, with hyperparathyroidism, medullary carcinoma of the

thyroid, and phaeochromocytoma. The molecular elucidation of these differences has identified subgroups. In MEN1 the principal genetic abnormality involves mutations in the *MEN1* gene together with loss of alleles on chromosome 11; in MEN2 (both A and B subgroups) there are mutations in the *RET* proto-oncogene on chromosome 10.

Hypercalcaemia

Of the known causes of hypercalcaemia in hospital inpatients, neoplasm is the most important (Table 9). It should always be considered and excluded clinically. The relative frequency of the causes of hypercalcaemia varies according to the population studied. In apparently healthy outpatients primary hyperparathyroidism is the most frequent cause. In those patients with primary hyperparathyroidism, with hypercalcaemia, hypophosphataemia, hyperphosphatasia, and radiological evidence of osteitis fibrosa, and without clinical evidence of neoplasm, little further investigation is needed. Since only a few patients with hyperparathyroidism have clinical bone disease, further differentiation from other causes of hypercalcaemia is usually necessary. In practice, this means the exclusion of neoplasm, sarcoidosis, thyrotoxicosis, vitamin D overdosage, treatment with thiazide diuretics, or the 'milk alkali' syndrome. The subject is addressed further in Chapter 20.8.

Secondary (and tertiary) hyperparathyroidism

Where hypocalcaemia is prolonged, as in renal glomerular failure or gluten-sensitive enteropathy, the parathyroid glands increase both their size and activity in an attempt to restore the plasma calcium level to normal. This increases bone resorption and is a particular feature of renal glomerular osteodystrophy. Occasionally hypercalcaemia develops and persists in such patients. It has been proposed that one of the hyperplastic parathyroid glands becomes autonomous and thus the label 'tertiary hyperparathyroidism' has been given. Hypercalcaemia may also occur after renal transplantation (see Chapter 20.8).

Hypoparathyroidism (see also Chapter 20.8)

Parathyroid insufficiency may occur after surgical removal of the parathyroids, in idiopathic hypoparathyroidism, and in a familial form of hypoparathyroidism which is often associated with manifestations of autoimmune disease, including moniliasis, malabsorption, thyroid and adrenal failure, and pernicious anaemia. In such patients the levels of immunoreactive parathyroid hormone (**PTH**) are undetectably low but the cAMP response to exogenous PTH is maintained. This distinguishes parathyroid insufficiency from pseudohypoparathyroidism, in which the biochemical features of hypoparathyroidism are associated with characteristic skeletal abnormalities (Albright's hereditary osteodystrophy). Pseudohypoparathyroidism is inherited as an autosomal dominant. In the most common form, the cAMP response to exogenous PTH is defective, and the circulating level of immunoreactive PTH is high. Variations of pseudohypoparathyroidism appear to exist, and disorders are described in which the cAMP response is present but there is still end-organ resistance, and also where the cAMP response is restored by giving vitamin D. Patients who have the skeletal manifestations of pseudohypoparathyroidism but with normal biochemistry may be found in families with pseudohypoparathyroidism, and to them the term 'pseudopseudohypoparathyroidism' is applied. Investigation has shown that the loss-of-function end-organ resistance is due to point mutations in the genes controlling one component of the G-protein signalling system.

So far as the skeleton is concerned, the most striking changes are found in pseudohypoparathyroidism. Clinical features include mental simplicity, short stature, round face, short neck, and abnormal metacarpals (or metatarsals), of which the most common change is shortness of the fourth and fifth. The bones may be excessively dense, and widespread ectopic calcification and ossification may also occur, in the basal ganglia and the subcutaneous tissues respectively. Treatment of the hypocalcaemia is the same as for idiopathic hypoparathyroidism, with 1a-hydroxycholecalciferol.

Osteogenesis imperfecta: the brittle bone syndrome

This disorder, which has emerged from the status of an obscure osteopathy to a metabolic bone disease, provides remarkable lessons concerning the effects of mutations in the collagen genes. The correlation between genotype and phenotype is by no means exact and leaves interesting problems.

Osteogenesis imperfecta is said to occur in about 1 in 20 000 births; since the milder forms may never be diagnosed, this could be an underestimate. It is a leading cause of lethal short-limbed dwarfism and crippling skeletal dysplasia. There is no convincing evidence of different racial frequency. Many patients with osteogenesis imperfecta do not fit easily into the Sillence classification (Table 10), and in some cases hypermobility and features of the Ehlers–Danlos syndrome (see below) are dominant.

Pathophysiology

Osteogenesis imperfecta involves those tissues that contain the main fibrillar collagen, type I. These include particularly bone and dentine, but also the sclerae, joints, tendons, heart valves, and skin. The pathology in bone varies with the type and severity of the disease, with age, previous fracture, and surgery. The skeletal effects of osteogenesis imperfecta are most severe in the lethal forms (type II) and at the region of the growth plate. There is faulty conversion of apparently normal mineralized cartilage to defective bone matrix. The collagen fibres are thin but show the normal striated pattern. The endoplasmic reticulum of the osteoblasts is dilated by retained mutant collagen. The bone structure is completely disorganized and structurally useless. In type III osteogenesis imperfecta, which is less severe, there are variable amounts of woven immature bone, with disorganized trabeculae and an apparent excess of osteocytes—as in other forms of the disorder. At the growth plate there are multiple islands of cartilage in the epiphyses and metaphyses. Accounts of the bone pathology in type IV are sparse. Defective mineralization is described in rare forms of osteogenesis imperfecta.

In mild, type I osteogenesis imperfecta there is a reduction in the amount of bone (and hence in measured bone mineral density) and defective bone formation at the cellular level, such that the osteoblasts each make approximately half as much bone collagen as normal. The result is an osteoporotic bone with an apparent excess of osteoblasts and osteocytes. This appearance of 'hyperosteocytosis' suggests (to some) an increase in bone turnover rate. The overall bone structure is otherwise normal, apart from occasional woven bone. In affected dentine, the odontoblasts produce short, branched dentinal tubules and fill in the dental pulp. In the ear, the auditory ossicles may be imperfect or fractured.

The reduction in collagen is repeated in non-skeletal tissues. Thus, the sclerae are thin (leading to their blueness since the pigmented coat of the choroid becomes visible), the tendons are gracile and weak, the thin heart valves may become incompetent, and the aortic root dilated.

Clinical features

Type I is the most frequent and least serious form, and accounts for 60 per cent of all patients with the disorder. Fractures can occur in the perinatal period or even be delayed until the early perimenopause. After the menopause the overall fracture rate has been recorded at seven times more than in the normal population, and the vertebral bone mineral content in adults with type I osteogenesis imperfecta has been found to be 70 per cent of normal.

Childhood fractures in type I osteogenesis imperfecta may be numerous but rarely lead to deformity unless treated inappropriately. Any type of fracture can occur; they become less frequent with age. Overall, fractures are more frequent in the lower limbs. Significant scoliosis is rare. The skull shows interesting changes; in addition to multiple wormian bones (Fig. 13) (which can occur in other disorders, such as pyknodysostosis, cleidocranial dysostosis, Menkes' syndrome, Prader–Willi syndrome, progeria, and, rarely, in normal subjects), the vault may overhang the base, leading to basilar impression requiring surgical correction.

Fig. 13 The innumerable centres of ossification in the occipital region, wormian bones, in an infant with severe (type III) osteogenesis imperfecta.

Clinical dentinogenesis imperfecta occurs in only some patients; the appearance varies widely and affects some teeth more than others; the teeth are discoloured and the enamel (which is normal) fractures easily from the dentine, leading to rapid erosion of both the first and second dentition. Blueness of the sclerae is a particularly important physical sign of osteogenesis imperfecta. The cause of the frequently early (juvenile) arcus is unknown: limited investigation excludes hypercholesterolaemia. The cardiac manifestations of osteogenesis imperfecta are also important, not only because of their effects but because tissue fragility makes surgery dangerous. Aortic incompetence, aortic root widening, and mitral valve prolapse all occur. Patients with osteogenesis imperfecta often show hypermobility of joints, with resultant flat feet, hyperextensible large joints, and dislocation.

Type II osteogenesis imperfecta is nearly always lethal, but the severity does differ: some children may be born dismembered, whereas others may (rarely) survive the perinatal period to later merge into the type III form. Not all infants with multiple fractures at birth succumb immediately. It is possible to give a prognosis from the extent of ossification of the skull, the shape of the long bones and ribs, and the number of fractures. In the most frequent form of lethal osteogenesis imperfecta (IIA) the infant is short with disproportionately short and deformed limbs, the skull is deformed and soft, the sclerae are often deep grey-blue. Whole-body radiographs, which distinguish osteogenesis imperfecta from other forms of lethal short-limbed dwarfism, show grossly defective mineralization of the skull, short broad limbs with multiple fractures, and broad ribs with innumerable fractures (Fig. 14). In type IIB, the ribs have some structure; in IIC, the long bones are narrow and beaded at the site of fractures and show some evidence of modelling. Perinatal death results from the mechanical uselessness of the skeleton, which leads to respiratory failure or intracranial haemorrhage.

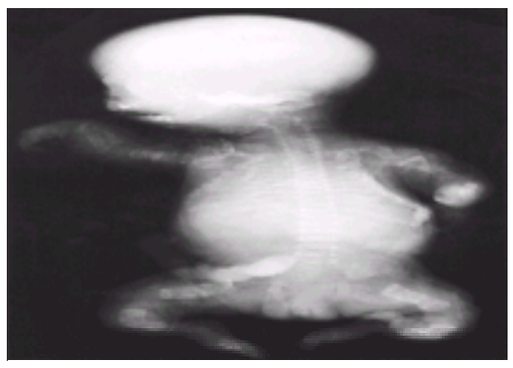

Fig. 14 Whole-body perinatal radiograph (babygram) of lethal (type II) osteogenesis imperfecta. The vault of the skull is not calcified, the ribs and long bones show multiple fractures. There was no family history.

Type III osteogenesis imperfecta causes most clinical difficulty, since the disability is severe and progressive. During the early years of life, progressive deformity affects the skull, the long bones, the spine, chest, and pelvis; the deformity is associated with fractures but can probably occur without them. The radiological appearance of the bones changes rapidly with age. The face appears triangular, with a large vault, prominent eyes, and small jaw. The sclerae may be blue in infancy but take on a normal colour in childhood. Eventual disability and deformity is considerable. Such patients rarely walk, even after multiple operations, and have a very short stature (–4 to –6 standard deviations (**SD**) below the mean). The changes in the long bones are often bizarre, with long, thin diaphyses and comparatively wide metaphyses. Cartilaginous islands often develop at the end of the long bones in the epiphyses and the metaphyses, spreading into the diaphysis, giving the appearance of 'popcorn' bone. Early death may occur from respiratory infections superimposed on the restrictive reduction in vital capacity associated with severe kyphoscoliosis (Fig. 15). Progressive deformity requires specialized orthopaedic care.

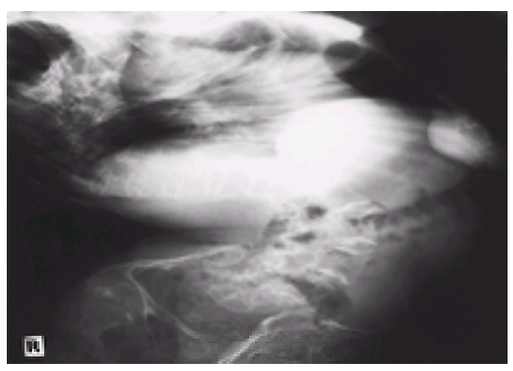

Fig. 15 Severe kyphoscoliosis in type III osteogenesis imperfecta.

Type IV osteogenesis imperfecta is clinically intermediate between type I and type III and is inherited as a dominant trait. The sclerae are of normal colour after infancy. Overall stature is reduced and disability is variable. The rare complication of hyperplastic callus occurs most often in this form (Fig. 16). This begins with a swollen, painful, and vascular swelling, most often over the long bones, an increase in plasma alkaline phosphatase, and sometimes a systemic illness. Recent investigations of osteogenesis imperfecta-affected families with hyperplastic callus have failed to find collagen mutations in affected children. Some classify this form as type V osteogenesis imperfecta.

Fig. 16 The appearance of hyperplastic callus in a patient with osteogenesis imperfecta.

Diagnosis

In the perinatal period, the concern is with alternative causes of lethal, short-limbed dwarfism. These include severe hypophosphatasia (see below), achondrogenesis (see below), thanatophoric dwarfism, and the asphyxiating thoracic dystrophies. A perinatal whole-body radiograph is essential.

In the first few years of life non-accidental injury, 'the battered baby syndrome', is the main differential diagnosis. This is suggested by multiple fractures at different sites and of different ages, especially if associated with clinical signs of neglect. Some fractures, such as metaphyseal 'corner' fractures and posterior rib fractures are more often seen in non-accidental injury, but any type of fracture can occur in osteogenesis imperfecta. The distinction between osteogenesis imperfecta and non-accidental injury is legally important and can be difficult.

Idiopathic juvenile osteoporosis needs to be distinguished during late childhood and adolescence. This begins during growth, with fractures of the long bones, reduction in growth rate (due to vertebral collapse), and metaphyseal compression fractures. In adult life, mild osteogenesis imperfecta may go unrecognized.

Biochemistry

It is impossible to generalize about the clinical effect of a collagen gene mutation but some patterns are emerging. In type I osteogenesis imperfecta there appears to be a null allele for collagen I, so that only 50 per cent of collagen is produced but this is of normal composition. Lethal osteogenesis imperfecta (type II) may result from large gene deletions but more commonly from single base changes in *COL1A1* or *COL1A2*. Such changes convert a glycine codon to one for another amino acid with a side chain. The effect on the triple helix of incorporating such a mutant chain appears to be most marked when the substitution occurs near the carboxy-terminal end of the chain (the helix winds up from this end), when the substituting amino acid is large; and when it occurs in the a-1 rather than the a-2 chain. Such mutations delay helix formation and render collagen mechanically unsound, and also lead to overhydroxylation and overmodification of the lysine residues, detectable by slowing and widening of the a-chains run on conventional polyacrylamide gels. Such abnormalities are common in type II osteogenesis imperfecta and less well defined in type III, which may rarely result from a failure to synthesize a-2 chains. Type IV osteogenesis imperfecta is most often due to changes in the a-2 chain.

Since the genes for a-1 and a-2 collagen have now been mapped and polymorphic sites identified, the mutant locus for osteogenesis imperfecta can be followed through large, dominantly inherited families. Such information can provide the basis for accurate prenatal diagnosis using fetal DNA derived from a chorionic villus biopsy. Methods are also now becoming available which make it possible to identify the mutation directly in the fetal DNA.

Genetic advice

Parents who have already had an infant with osteogenesis imperfecta need accurate advice about further pregnancies. This can be difficult, because the facts are not clear. Where the mutant gene is dominant (type I and IV) and where one parent is affected, the likelihood of affected children is 50 per cent. Difficulties arise where neither parent is clinically affected, and in the lethal and progressive deforming varieties of the brittle bone syndrome. It is impossible to give a statistically accurate prediction of the likelihood of another affected child, particularly since the strict application of Mendelian principles may be inappropriate because of germline and somatic-cell mosaicism. However, there are some guidelines. Where one offspring of clinically unaffected parents has a form of osteogenesis imperfecta which fits into type I or type IV, this is likely to be a new dominant mutation (50 per cent of whose offspring will be affected) and risk of a further affected sibling is probably no more than normal. It used to be considered that infants with the severe lethal form of osteogenesis imperfect (type II) had inherited a mutant gene from both clinically normal parents and were, therefore, homozygous recessives, so that the risk of a further affected infant was 25 per cent. The evidence is now that the great majority (if not all) result from a new dominant (and lethal) mutation. To allow for the possibility of some recessives, the likelihood of phenotypically normal parents having a second baby with lethal osteogenesis imperfecta is put at approximately 7 per cent (more than normal, but significantly less than 25 per cent).

The recurrence risk in progressively deforming osteogenesis imperfecta (type III) is unknown. If recessive inheritance is included in the definition, it is 25 per cent; if not, it is considerably less.

It is now recognized that germline and somatic-cell mosaicism are important factors in the inheritance and expression of osteogenesis imperfecta, and probably in many other disorders. In brief, germline mosaicism means that the sperm (or ova) of an apparently normal person may contain a proportion of mutant genes for lethal (or other forms) of osteogenesis imperfecta. This accounts for those pedigrees where a phenotypically normal man has two or more babies with lethal osteogenesis imperfecta by separate partners. Somatic mosaicism, with variable proportions of mutant cells in different tissues, likewise provides one (but not the only) explanation for phenotypic variability and differing tissue expression. The many factors that control the regulated expression of the vertebrate collagen genes in different tissues are only partly understood.

Prenatal diagnosis

This may be done from the second trimester by ultrasound and appropriate radiographs, and in the first trimester by analysis of fetal DNA from a chorionic villus biopsy. The appropriateness of such an investigation depends on the information previously available. In a dominantly inherited form of osteogenesis imperfecta, analysis of DNA from affected and unaffected family members can establish linkage to a particular collagen gene polymorphism. In such a situation, analysis of chorionic villus DNA is the most direct approach. Alternatively, the cells from such a biopsy may be cultured and the synthesized collagen examined for abnormalities. Where the collagen mutation is known in a previously affected family member, this method may directly confirm the presence of the mutation in the fetus. Except in well-organized laboratories, culture of cells and analysis of collagen will introduce unacceptable delays. Further, it is usually not possible to exclude an affected fetus merely on the grounds of apparently normal collagen. The rapid direct detection of the mutation in DNA from the chorionic villus is an eventual aim.

Amniocentesis also provides amniocytes for DNA linkage analysis and mutation detection. Amniotic fluid cells tend to produce an a-1(I) homotrimer and are not, therefore, appropriate for collagen analysis.

Diagnosis by ultrasound is possible only in the more severe forms of osteogenesis imperfecta (types II and III). Since the severe forms of osteogenesis imperfecta are sporadic and therefore unsuspected, it is important to be able to detect them early and rapidly by routine scanning. Ultrasound features suggestive of osteogenesis imperfecta are shortness and deformity of the limbs, an abnormal skull shape with lack of mineralization, which makes the intracranial structures abnormally visible, and deformity of the ribs leading to a 'champagne cork' appearance on the anteroposterior projection.

Prognosis and management

For an infant born with manifest osteogenesis imperfecta, important questions are asked: how long will he or she survive; what will be the likelihood of further offspring being affected? The immediate prognosis may already be answered by perinatal death, so that it remains to deal with the prognosis of survivors. Not all born with multiple fractures succumb immediately and radiographic appearances can give a good guide to outcome.

It is in those severely affected survivors classified as type III that management will be a lifelong and specialized problem. Such individuals are of normal intelligence and prolonged admission to hospital, either for repeated surgery or for investigation, should not necessarily take precedence over education. Intramedullary rodding and osteoclasis to correct deformity and improve mobility should be very selective since the bones are often so abnormal as to take no advantage from such procedures. An organized programme of rehabilitation is important. Analysis of life expectancy and cause of death in osteogenesis imperfecta show that survival is normal in type I osteogenesis imperfecta and near-normal in type IV. It is those with type III who have the most disability, of which basilar impression with neurological complications is a newly recognized problem, and the shortest lifespan. There is no convincing evidence that fluoride or calcitonin is beneficial, but cyclic intravenous pamidronate (APD) may alleviate symptoms and increase bone density. In severe osteogenesis imperfecta, attempts to transplant normal stromal cells from bone marrow into severely affected infants with osteogenesis imperfecta have been reported.

The Marfan syndrome (see Chapter 19.2)

The Marfan syndrome (Marfan's syndrome) is most often regarded as an inherited disorder of connective tissue rather than as a metabolic bone disease. Where connective tissue disorders significantly affect the skeleton, this distinction is blurred. For many years, it was thought that the defect underlying the Marfan syndrome involved collagen but recent research excludes this.

Pathophysiology

It is now recognized that Marfan's syndrome is caused by mutations in the epidermal growth factor-like regions of the fibrillin gene on chromosome 15. Fibrillin is the major constituent of the microfibrillar system and of the suspensory ligament of the lens; and it is also associated with elastin-containing tissues such as the aorta. This explains the association between dislocation of the lens and dissection of the aorta. The aorta dilates at its proximal part at the sinuses of Valsalva, and returns to normal diameter below the innominate artery, unless a dissection is present. The cusps of the aortic valve do not close efficiently. Dissection is most often above the aortic valves in the area of greatest dilatation. The dissection may progress forwards or backwards. Retrograde dissection may tear the attachment of the coronary arteries and rupture into the pericardial sac. Histopathology shows a reduction in elastic fibres which are swollen and fragmented. The valve cusps are usually diaphanous and redundant. In the eye, the suspensory ligament of the lens is disorganized.

Clinical features

Marfan's syndrome is dominantly inherited. Its main effects are on the skeleton, cardiovascular, and ocular systems. There is considerable phenotypic variation. In the typical patient with Marfan's syndrome, overall height is increased (relative to unaffected siblings or a matched population) and the limbs are long relative to the trunk (so that the crown to pubis measurement is less than pubis to heel). Long, thin fingers (arachnodactyly) are common. Together with hypermobility, this disproportion forms the basis of clinical signs of variable utility. However, not all patients with Marfan's syndrome are long and thin. The skeletal phenotype differs from one family to another and within families. Asymmetrical anterior chest deformity is associated with either depression or prominence of the sternum. Scoliosis is common, may be severe, and worsens during preadolescent growth as in the idiopathic form. The hard palate is often narrow and high-arched (gothic).

Dislocation of the lens is the main ocular feature of Marfan's syndrome. Typically, this occurs upwards or sideways (in contrast to the downward dislocation in homocystinuria), and this may be present at birth or occur later. Dislocation causes the unsupported iris to wobble on movement (iridodinesis). Less important ocular features are myopia and retinal detachment. The axial length of the globe is increased and the cornea tends to be flattened.

The most severe complication of Marfan's syndrome is dilatation of the ascending aorta leading to aortic incompetence and dissection. Progressive widening of the aorta can be readily measured by serial echocardiography. Less well-known manifestations of Marfan's syndrome include cutaneous striae, hernias, spontaneous pneumothorax, and dural ectasia. The mean life expectancy in those with Marfan's syndrome is reduced by nearly 50 per cent, predominantly due to cardiovascular catastrophe.

Diagnosis

At present, there is no certain biochemical way of excluding or confirming Marfan's syndrome, although this is likely to change. In those with few clinical features and no family history, the diagnosis of Marfan's syndrome can be difficult.

The requirements for the diagnosis of Marfan's syndrome have been revised. Where the family history is not helpful, it is necessary to have major criteria in at least two different organ systems and involvement of a third organ system. Where there is an unequivocally affected relative or a mutation known to cause Marfan's syndrome has been detected, one major criterion in an organ system with involvement of a second organ system is necessary for the diagnosis. Homocystinuria (see below), which has a recessive mode of inheritance, should be excluded. Other important alternative diagnoses include congenital contractural arachnodactyly, familial tall stature, isolated mitral valve prolapse, familial or isolated annuloaortic ectasia, and Stickler's syndrome. The latter is a dominantly inherited connective tissue disorder that affects the eyes, ears, and skeleton with severe myopia in childhood, sensorineural hearing loss from adolescence, and degenerative arthritis from early adult life. The diagnosis can be made at birth if cleft palate and micrognathia are present. There is considerable phenotypic variation. In some families the disorder is linked to the type II collagen gene.

Contractures can occur in Marfan's syndrome but are of a late onset. In congenital contractural arachnodactyly, which is inherited as an autosomal dominant trait, contractures involving the hands, feet, and larger joints are present from birth and tend to improve. Abnormal ears are described. Limited studies suggest that this disorder involves mutations of an additional fibrillin gene on chromosome 5.

Treatment

There is no specific treatment for the underlying defect, but many of the clinical manifestations require attention. Scoliosis may be progressive and severe, particularly in adolescence. Bracing is largely ineffective and operative stabilization may be necessary. Excessive height in girls may be prevented by giving oestrogen together with progestogen in the prepubertal years. Marked sternal deformity may need correction for cosmetic or cardiopulmonary reasons, but opinions on the value of surgery vary widely. In the eyes, it is rarely necessary to remove dislocated lenses unless they prolapse into the anterior chamber, but myopia should be corrected. The main decisions concern the management of the cardiovascular problems: when and if to operate on the dilated ascending aorta or to replace incompetent valves; and whether aortic dilatation can be prevented by reducing the intermittent force on its walls due to left ventricular systole. As far as the second point is concerned, giving a b-blocker such as propranolol probably reduces the rate of aortic dilatation. As regards surgery on the aorta, it is clear that progressive aortic widening (measured regularly by echocardiography), together with progressive aortic incompetence and left ventricular strain, provide strong indications for replacement of the proximal aorta by a prosthesis. Mitral valve replacement may also be necessary.

Since both aortic and mitral valves are susceptible to endocarditis, prophylactic antimicrobials must be given at the time of dentistry.

Genetic advice

Genetic advice is at present based on clinical observations and the knowledge that inheritance is of the autosomal dominant pattern. Numerous mutations in the fibrillin genes have now been described. There is no clear relationship between genotype and phenotype.

Ehlers–Danlos syndrome (see Chapter 19.2)

This syndrome initially included only those conditions with the common clinical features of abnormal velvety hyperelastic skin which healed poorly, hyperextensible joints, and lax ligaments. However, the disorders included in this syndrome have now been increased and have brought with them additional specific features, amongst which is vascular rupture, especially in type IV Ehlers–Danlos syndrome, associated with various mutations in type III collagen. In the currently expanded Ehlers–Danlos syndrome the skeleton is particularly affected in types VI and VII (Table 11).

In type VI (ocular scoliotic) Ehlers–Danlos syndrome) the first disorder in which an inborn error of collagen metabolism was identified, the clinical features are due to lysyl hydroxylase deficiency. Since hydroxylation of peptide-bound lysine is an essential post-translational step in collagen synthesis and a necessary precursor to crosslink formation, this defect weakens collagen structure. The main clinical features are severe scoliosis, microcornea, and ocular fragility.

In type VII (arthrochalasia) there is excessive mobility, perinatal joint dislocations (especially of the hips), and short stature. There is persistence in the tissues of collagen molecules with a retained amino-terminal propeptide which leads to defective fibrillogenesis.

Homocystinuria (see also Chapter 11.3)

Homocystinuria is phenotypically similar to Marfan's syndrome but with a different cause and additional important complications. It is due to a deficiency of cystathionine b-synthase, an enzyme whose gene is located on chromosome 21, and firmly bound pyridoxal phosphate (vitamin B_6) is a feature. Homocystinuria is inherited as an autosomal recessive condition. The amount of residual cystathionine synthase varies from 0 to 10 per cent in patients, and in obligate heterozygotes it is less than 50 per cent of normal.

Pathophysiology

Homocysteine lies at the cross-roads of two metabolic pathways and is converted to cystathionine by the addition of serine. This reaction is controlled by

cystathionine b-synthase. The alternative fate of homocysteine is methylation to methionine. Cystathionine b-synthase activity is controlled by pyridoxine, but not all patients with cystathionine-deficient homocystinuria are pyridoxine-sensitive, although this sensitivity or dependency is constant in sibships. In homocystinuria, there is an increase in both homocysteine and homocystine, which accumulate proximal to the metabolic block. Cystathionine, normally present in the brain, is no longer detectable and cysteine (normally made from methionine) becomes an essential amino acid.

The pathological findings include fraying and disruption of the zonular fibres of the lens, defective bone formation, and multiple central nervous system infarcts. It is not known how the biochemical changes lead to the clinical features. The increased thrombotic tendency is not fully explained by changes in platelet function, cellular endothelium, or soluble factors, although abnormalities have been described in all of them. The neurological abnormalities and mental backwardness have not been proven to be due to the biochemical consequences of cystathionine b-synthase deficiency or to repeated vascular thromboses. Homocyst(e)ine may increase the solubility of collagen and interfere with its synthesis; for some, this explains the dislocation of the lens due to failure of the ciliary zonule. Since it is now known that this structure is composed largely of fibrillin, a further explanation is required. There is current interest in the possibility that young adults with premature vascular disease may be heterozygotes for a mutant cystathionine synthase gene. Elevated plasma homocysteine levels are a risk factor for coronary heart disease.

Clinical features

The clinical features of cystathionine b-synthase deficiency involve four systems and develop some time after birth; they are ocular, skeletal, central nervous, and vascular. The main ocular manifestation is downward dislocation of the lens. Myopia, glaucoma, retinal degeneration, and detachment also occur, and cataracts, optic atrophy, and corneal abnormalities are described. Some skeletal features suggest Marfan's syndrome. They include a long, thin habitus, pectus excavatum, scoliosis, and genu valgum. There is often radiological osteoporosis and abnormal modelling of the long bones with epimetaphyseal widening. Many subjects with homocystinuria are mentally backward and may also have seizures and strokes. It is unknown how closely these follow the increased tendency to thrombosis or the biochemical changes, especially a lack of cystathionine. Thromboembolism may occur in any vessel and at any age.

Any patient who has the phenotypic features of Marfan's syndrome associated with thrombosis, mental simplicity, and affected siblings should have a cyanide–nitroprusside test performed on their urine, together with an amino acid analysis of the urine and plasma.

The outlook for patients whose biochemical abnormalities are corrected by large amounts of pyridoxine (that is, those with pyridoxine-sensitive homocystinuria) is usually better than those who are pyridoxine-resistant. The main cause of death is thromboembolism.

The management of patients with homocystinuria differs according to the time of diagnosis and whether or not the patient responds to pyridoxine. In pyridoxine-responsive patients diagnosed after the newborn period, giving pyridoxine, in doses that vary from 250 to 1200 mg a day, appears to prevent thromboembolism.

When homocystinuria is detected in the newborn infant (most are discovered by screening and are pyridoxine non-responsive), a diet low in methionine appears to reduce the incidence of low intelligence. After the newborn period, in those who are unresponsive to pyridoxine, methionine restriction and the administration of betaine (as a methyl donor) are also possibly useful lines of approach.

Alkaptonuria (see also Chapter 11.2)

In this rare autosomal recessive disorder, decreased activity of homogentisate oxidase leads to accumulation of homogentistic acid in the urine and increased pigmentation (ochronosis) in cartilage and connective tissues. Darkening of the urine, alkaptonuria, is due to the presence of 2,5-dehydroxyphenylacetic acid derived from the oxidation and polymerization of homogentisic acid. Polymerization increases in alkaline urine and is slowed down by antioxidants such as vitamin C. The structure of the pigment which causes ochronosis is not known. It is granular or homogeneous and may occur within or outside the cell. It is said to be associated with a reduction in lysyl hydroxylase in the tissue concerned, and impairment of the crosslinks of collagen.

Alkaptonuria is more frequent in the former Czechoslovakia and in Germany than elsewhere and occurs equally in the sexes. It is recessively inherited. The mutant gene has now been identified (*HGO*, chromosome 3q2). Abnormal pigmentation is found in the cartilage of the ear (which may be calcified), the nasal cartilage, and the sclerae. The most important effects of this disease are on the spine (Fig. 17) and later on the larger joints. The intervertebral discs lose height and later calcify; they may also herniate acutely. The spine becomes rigid and short and the lumbar lordosis is lost. In the large joints, such as the knees, shoulders, and hips, there are effusions and loose bodies. The symphysis pubis may be affected but not the sacroiliac joints. Ochronotic 'arthritis' is described with episodes of acute inflammation which resemble those of rheumatoid arthritis. Calcification of the aorta is an additional feature.

Fig. 17 The appearance of the spine in a man with alkaptonuria. There is universal calcification of the intervertebral discs.

The diagnosis of alkaptonuria—often made late—should be suspected where there is a premature disc degeneration, even if there is no excessive darkening of the urine. Early degenerative arthritis suggests the disease, confirmed by finding deeply pigmented articular cartilage at the time of operation. In those patients with a lifelong discoloured urine, the differential diagnosis is from other rare causes of urinary pigmentation. The urine of a patient with alkaptonuria contains reducing substances and will therefore give a positive result suggesting glycosuria except where glucose oxidase is used. An increase in homogentisic acid in the urine and plasma confirms the diagnosis.

In theory, it should be possible to reduce the amount of homogentisic acid, and presumably the side-effects, by cutting down the protein intake to 30 or 40 g/day, thereby reducing tyrosine intake. There is no evidence that such a procedure alleviates the symptoms of alkaptonuria.

Hypophosphatasia (see also Chapter 12.6.2)

This rare disorder has similarities with rickets and osteomalacia. It is due to a reduction in the tissue non-specific alkaline phosphatase (**TNSAP**), which leads to defective mineralization and a triad of biochemical disturbances: increased urinary phosphoethanolamine, plasma pyrophosphate, and plasma pyridoxal phosphate.

Studies on members of the Mennonite sect in Manitoba, in whom the incidence of hypophosphatasia is high, have linked the defective gene to chromosome 1. Numerous mutations have now been described in the *TNSAP* gene. Although TNASP is widely distributed, its absence leads to lesions only in the bone and teeth.

Pathophysiology

The characteristic biochemical changes result directly from the alkaline phosphatase deficiency. Increased urinary pyrophosphate excretion is more reliable than urinary phosphoethanolamine as a marker for carriers of the hypophosphatasia gene. Often, there is also hypercalcaemia and hypercalciuria in childhood; and up to half of affected children and adults have increased plasma phosphate levels. Hyperphosphataemia is described in carriers of the hypophosphatasia gene. The

recorded plasma alkaline phosphatase level must be compared with age-matched control values.

Histological examination of bone shows an excess of osteoid with abnormal tetracycline labelling without evidence of secondary hyperparathyroidism. Matrix vesicles do not contain alkaline phosphatase or hydroxyapatite crystals. The primary dental defect is in the cementum; additionally, the predentine is widened and the dentinal tubules are enlarged and few.

Clinical features

Hypophosphatasia occurs in all races. Since the severe forms are inherited as autosomal recessive traits they are more frequent where there is consanguinity. It has been estimated that hypophosphatasia occurs in 1 in 100 000 live births in Toronto. The four clinical types provide a continuous spectrum, from a lethal perinatal disorder to an asymptomatic disease in adults.

The first is an important cause of lethal, short-limbed dwarfism (see above). Some newborn infants survive for a few days, but fever, failure to thrive, anaemia, seizures, and intracranial haemorrhages occur. Radiographs show grossly defective mineralization, especially in the skull, where only the base may be mineralized, and in diaphyses of the long bones which, rarely, may have bony spurs.

In the infantile form (within the first 6 months), hypotonia, failure to thrive, hypercalcaemia, and hypercalciuria occur. Clinical rickets is noticed and the fontanelle appears wide, but there is a functional synostosis. Craniostenosis can produce optic atrophy, exophthalmos, and raised intracranial pressure requiring surgery.

The most variable expression occurs in childhood. Early loss of deciduous teeth, due to defective cementum, may be the only feature (ondontohypophosphatasia). The pulp chambers are enlarged, the root canals short (shell teeth). If bone disease is present, walking is delayed and deformities occur; for instance, bow legs, knock knees, short stature, and enlargement of the epiphyses at the wrist, knees, and ankles.

In adults, progressive stiffness, pain in the bones, and apparent 'stress' fractures can occur. Approximately 50 per cent of such patients have a childhood history of bone disease resembling rickets, or premature loss of deciduous teeth, or both. There may also be premature shedding of adult teeth, short stature, and abnormal skull shape. Recurrent poorly healing metatarsal fractures occur. Partial fractures of the long bones characteristically occur on the convex outer surface (in contrast to the concave inner position of the Looser's zones in osteomalacia), most often in the upper one-third of the femoral shaft, and are often bilateral; other sites include the ribs, tibias, and ulnas. They may be unaltered for years or increase in size and eventually fracture. Secondary hyperparathyroidism is not seen. Chondrocalcinosis is common and in a proportion is associated with clinical pyrophosphate gout (pseudogout).

Management

In the management of hypophosphatasia, premature synostosis leading to raised intracranial pressure requires surgical relief. Hypercalcaemia may be dealt with by reducing dietary calcium and by giving prednisone. Replacing the defective enzyme by the transfusion of alkaline phosphatase-rich plasma does not produce consistent results. Intramedullary rods may prevent and treat fractures of the long bones. Dental abnormalities, which can occur in biochemically normal members of hypophosphatasia families, may require treatment.

Prenatal diagnosis of a severely affected child can be made by ultrasound. There is also reduced alkaline phosphatase activity in the amniotic fluid cells.

Lysosomal storage diseases (see alsoChapter 11.8)

This large group of diseases is due to various inborn errors that affect the function of specific lysosomal enzymes normally responsible for the breakdown of a variety of complex molecules. As a result, these molecules, or their partially degraded derivatives, accumulate in the lysosomes and the tissues that contain them. The effect of this accumulation varies from one tissue to another according to the particular disorder, and the skeleton is significantly involved in only a proportion of them. They include some mucopolysaccharidoses and Gaucher's disease.

Mucopolysaccharidoses

Failure of the normal lysosomal breakdown of complex carbohydrates leads to their accumulation in the tissues, and produces many clinical abnormalities. The disorders may be divided into two main groups according to the chemistry of the accumulated substance, namely the mucopolysaccharidoses and the mucolipidoses. Specific biochemical defects are described elsewhere in this book (see Section 11). Since some of these disorders have a prominent effect on the skeleton, they are briefly mentioned here; they are the Hurler syndrome (mucopolysaccharidosis type IH; **MPS IH**), the Hunter syndrome (MPS II), and the Morquio syndrome (MPS IV). With certain exceptions the bone changes themselves do not permit precise diagnosis of the type of dysplasia present, or distinction from the mucolipidoses.

The Hurler syndrome (MPS IH)

This is the most severe type of mucopolysaccharidosis and causes death at an early age. The enzyme defect is recessively inherited and all patients have the same appearance, to which the term 'gargoylism' was previously applied. Affected infants appear to develop normally in the first few months of life, but then deteriorate mentally and physically. Death often occurs in late childhood, commonly due to pneumonia or to coronary artery disease associated with mucopolysaccharide deposits.

The physical features include proportionate short stature (Table 3), a typical facial appearance, a short neck with a lumbar gibbus and chest deformity, and a protuberant abdomen. The facial features are coarse and ugly, with flattening of the nasal bridge, with large open mouth and tongue, and often with hypertrophied gums over enlarged alveolar ridges. The eyes are prominent with corneal clouding. There is noisy breathing and variable deafness. The vault of the skull may show scaphocephaly or acrocephaly. Other striking features include the stiff, broad trident hands and the large abdomen with hepatosplenomegaly. Radiographs show the abnormal shape of the skull, the slipper-shaped sella turcica, the beaking of the vertebrae with the thoracolumbar kyphosis, and the bullet-shaped phalanges. Similar but less severe features are seen in the Hunter syndrome, which is inherited as an X-linked recessive.

The Morquio syndrome (MPS IV)

In this disorder the orthopaedic manifestations are striking, but intelligence is normal. Although the disorder is probably heterogeneous and only a proportion of cases excrete an excess of keratan sulphate in the urine, the skeletal changes are uniform. In the first years of life the child becomes progressively more deformed and dwarfed. Characteristically the neck is short, the sternum is protuberant, and there may be a flexed stance with knock knees. There is a striking loss of muscle tone in comparison to the stiffness of MPS IH; hypermobility and a loose skin are features. Radiographs in infancy show a spine similar to that seen in those with Hurler syndrome, but later flattening of the vertebrae with anterior beaking lead to relative shortening of the trunk. The small bones of the hands are very different from those of MPS IH and the metacarpals show diaphyseal constriction (Fig. 18).

Fig. 18 The appearance of the hands in MPS IV (Morquio syndrome).

Importantly, the odontoid may be hypoplastic, leading to atlantoaxial instability, compression of the long spinal tracts, and paraplegia.

Gaucher's disease (see also Chapter 11.8)

This is a rare lysosomal storage disorder in which glucocerebroside-containing macrophages accumulate within the bone marrow, spleen, liver, and other organs. It is recessively inherited and over-represented in Ashkenazi Jews, where the incidence of the adult form (type I) is about 1 in 2500 births. The skeletal manifestations are often severe and disabling. They vary from a characteristic but clinically insignificant failure of remodelling in the lower femora (Erlenmeyer-flask appearance) to diffuse and localized bone loss and osteosclerotic and osteonecrotic lesions, which cause pain and pathological fracture, often requiring precocious joint replacement surgery.

Skeletal dysplasias

The term 'skeletal dysplasia' has traditionally been used to cover a wide range of generalized disorders of the skeleton, often of unknown cause, affecting both cartilage and bone. With increasing knowledge one can distinguish the chondrodysplasias, which are primarily due to mutations affecting cartilage, from such disorders as diaphyseal dysplasia and assorted dense bone diseases, where the causes are less well known. Since osteopetrosis is a well-defined disorder of osteoclast function, it is dealt with separately below.

The mutations in many of the skeletal dysplasias have been described (Table 1) and the skeletal dysplasias can be classified into biochemical families according to their cause (Table 12). The supposition that many of them could be due to mutations in specific collagens has been partially confirmed with mutations found in type I, IX, X, and XI collagens. Achondroplasia is a striking example of a skeletal dysplasia caused by a non-collagen mutation, that is a mutation in fibroblast growth factor (**FGF**)-receptor 3. Further details can be found in reviews (see the Further reading list) and in Table 12.

Clinical features

The physician confronted by a patient with a skeletal dysplasia is unlikely to make the correct diagnosis without much additional help unless it is clearly one of the most frequent, for instance achondroplasia. However, accurate classification of the dysplasias is important and will make clinical and biochemical advance possible. The most convenient simple classification is a clinical one (Table 13). Most patients with skeletal dysplasias have restricted growth, and most are short-limbed. The bodily proportions of people with skeletal dysplasias will provide a clue about whether the limbs are mainly affected, or the spine, or both. In the short-limbed group, achondroplasia and achondroplasia-like dwarfs are the most typical. Those disorders without conspicuous dwarfing include various inherited epiphyseal dysplasias, diaphyseal dysplasias, and some, but not all, metaphyseal dysplasias. An alternative classification, not based on height, groups the dysplasias according to whether they are predominantly epiphyseal or metaphyseal, whether the spine is predominantly involved, and whether single limbs or segments are involved. Radiographs, taken as soon as possible and, where possible, consecutively, are essential to determine whether the metaphyses of the long bones or the epiphyses are primarily affected.

For the purpose of this Section, osteopetrosis (marble bones disease) is dealt with separately as a disorder of bone-cell biology. Other sclerosing disorders of bone, in some of which biochemical abnormalities have been described (Engelmann's disease, van Buchem's disease), receive brief mention.

Achondroplasia

This is the prototype of short-limbed, short stature. It is inherited as an autosomal dominant, with a high mutation rate and the incidence increases with paternal age. It is due to a specific mutation in the gene encoding the FGF-receptor 3. The way in which this produces the skeletal changes is largely unknown. Until recently, any undiagnosed patient with excessively short limbs was given the label of achondroplasia. This explains the apparent high frequency of achondroplasia and its high mortality, since different forms of lethal, short-limbed dwarfism were then included.

As the clinical definition of achondroplasia has not always been exact, its true incidence and natural history are not well defined. There is a failure of the epiphyseal growth cartilage, and bulbous masses of cartilage appear at the ends of the long bones. In contrast, periosteal and membrane bone formation and bone repair are normal. This selective effect on growth cartilage accounts for the skeletal deformity.

Achondroplasia can be diagnosed at birth or within the first year of life, when the disparity between the large skull and short limbs becomes obvious. There is a striking disproportion between the normal length trunk and the short arms and legs. Thus the fingertips may only come down to the iliac crest. The shortness of the limbs particularly affects the proximal segment. The limbs themselves look very broad, with abnormally deep creases, and the hands are trident-like. In contrast to the short limbs is the enlarged bulging vault of the skull, the small face, and flat nasal bridge or 'scooped out' glabella. There is a marked lumbar lordosis and also sometimes some wedging of the upper lumbar vertebrae, which may later lead to a thoracolumbar kyphosis. Radiological features include metaphyseal irregularity and flaring in the long bones, irregular and late-appearing epiphyses, a narrow pelvis in its anteroposterior diameter, with short iliac wings and deep sacroiliac notches, and a spine that shows progressive narrowing of the interpedicular distance from above downwards, which is the reverse of normal.

Children with achondroplasia are of normal intelligence, and the complications of this disease arise particularly from the skeletal disproportion. This may lead to early osteoarthritis, to obstetric difficulties and the need for caesarean section, to hydrocephalus, and to paraplegia. Eventual height can vary between about 80 and 150 cm. Recent reviews emphasize how often narrowing of the spinal canal produces symptoms of spinal stenosis.

Homozygous achondroplasia (the offspring of two affected parents) is severe and lethal. In the condition of hypochondroplasia, which is included in the same *FGFR3* molecular family, the skeletal disproportion and the spinal abnormalities are less and the skull is unaffected.

Achondroplasia-like dwarfism

For details of these and other causes of short-limbed dwarfism the reader should consult more specialized texts). Those that most closely resemble achondroplasia at birth are thanatophoric dwarfism, achondrogenesis, severe hypophosphatasia, and type II osteogenesis imperfecta. All can be distinguished radiologically.

Spondyloepiphyseal dysplasias

This is a heterogeneous group of disorders in which the spine is predominantly affected and the short stature is partly due to shortness of the trunk. The most severe type is spondyloepiphyseal dysplasia (**SED**) congenita; milder forms are referred to as SED tarda. There are various forms of inheritance. Some forms are due to mutations in type II collagen.

SED tarda often has an X-linked mode of inheritance, so that only males are affected and females are carriers. In affected males the disproportionately short trunk becomes obvious at adolescence. Failure of ossification in the anterior part of the so-called ring epiphyses leads to central and posterior humps on the upper and lower parts of the flattened bodies. The condition needs to be distinguished from multiple epiphyseal dysplasia, which involves other major joints more than the spine.

SED congenita can be diagnosed at birth because of the short stature associated with a short trunk. There may be a close resemblance to Morquio's disease (MPS IV, see above). The severe form may be distinguished from the age of about 4 years. The appearance of the capital femoral epiphyses is delayed (in some patients it may never be seen, except by arthrography). Marked lumbar lordosis, waddling gait, back pain, and progressive disproportion may occur. The odontoid is hypoplastic, kyphoscoliosis may develop, and the interpedicular distances of the vertebrae do not increase in the lumbar region. Paraplegia may occur as a result of all these changes. In this disorder there is often myopia and retinal detachment.

There is a form of SED, pseudoachondroplasia, which resembles achondroplasia because of the short limbs, but here the facial appearances are normal. The short stature becomes obvious from about 2 years of age. Lumbar lordosis and scoliosis may develop. The tubular bones are short with irregular metaphyses and small, deformed epiphyses. Hypermobility is marked and early osteoarthritis occurs. The causal mutation is in the gene for the cartilage oligomeric protein (*COMP*, chromosome 19p16).

Proportionate dwarfism

Although it is clinically important to classify short stature into proportionate and disproportionate, there are many conditions in which this distinction is difficult to make. Hypophosphataemic rickets, mucopoly-saccharidoses, vitamin D-dependent rickets, and osteogenesis imperfecta may come into both categories.

Bone dysplasias without conspicuous short stature

The height of patients with multiple epiphyseal dysplasia may be only slightly reduced. Although many epiphyses are affected, the spine is virtually normal. There are also variable forms of inheritance. Some are due to mutations in collagen type IX; others to mutations in cartilage oligomeric protein.

In patients with multiple hereditary exostoses (often referred to as diaphyseal aclasis) there is a juxtaepiphyseal disorder of bone growth, limited to bones developed in cartilage, which gives rise to cartilage-capped exostoses that point away from the joint. Inheritance is autosomal dominant and stature is normal. It is likely that there are causal mutations in putative tumour suppressor genes.

The metaphyseal disorders are rare; some, such as the Jansen type of metaphyseal dysostosis (associated with a mutation in the gene for the PTH/PTHrP receptor) do cause severe dwarfing. In others with less severe growth disturbance, such as Type Schmid (due to a mutation in the type X collagen gene), rickets is simulated, and confusion with inherited hypophosphataemia is possible. In progressive diaphyseal dysplasia (see below) the limbs are disproportionately long.

Sclerosing disorders of bone

Apart from marble bones disease (see below) the experience of most physicians of the osteoscleroses is limited by their extreme rarity.

Engelmann's disease (progressive diaphyseal dysplasia: Camurati–Engelmann disease)

This rare condition is autosomal dominantly inherited. It affects endocrine and muscular systems in addition to the skeleton, where the main feature is a variable but progressive endosteal and periosteal thickening of the diaphyses of the long bones. In severely affected subjects the spine, skull, and axial skeleton are all affected. The cause is unknown.

There is a waddling broad-based gait, muscle wasting and weakness, loss of subcutaneous tissues, and pain in the legs during childhood. The appearance is characteristic; the head is large with a prominent forehead and proptosis, the muscle mass is reduced, and the bones are palpably thickened. Cranial nerve palsies, deafness, and blindness with raised intracranial pressure can occur. Puberty is delayed. Bone pain resistant to analgesia is often a presenting and troublesome feature.

Radiographic appearances vary, from limited thickening of the diaphyses (often in the lower extremities) to widespread new bone formation, affecting all bones, including the skull, demonstrated by scintigraphy.

The increased bone turnover causes a moderate increase in plasma alkaline phosphatase and urinary hydroxyproline levels. There may be a markedly positive calcium balance, associated with hypocalcaemia and hypocalciuria. Hyperphosphataemia has been recorded.

Pathological examination confirms gross thickening of the bone with disorganization of internal structure and external shape. The peripheral subperiosteal new bone is woven. The muscles show non-specific, type-II fibre atrophy.

In the differential diagnosis the proximal myopathy and abnormal gait simulate muscular dystrophy. The radiographic appearances are diagnostic, although idiopathic hyperphosphatasia may present some difficulties.

The course of this disorder is unpredictable and remission of symptoms may occur during adolescence or adult life, so it is difficult to assess treatment. Bone pain may respond to corticosteroids in small, alternate-day doses. Etidronate (20 mg/kg daily) has produced hypocalcaemic tetany, but intermittent administration is reported to reduce pain. Limb pain may be relieved by surgical removal of a cortical window in the diaphysis.

Pyknodystosis

In contrast to Engelmann's disease, pyknodystosis has an autosomal recessive mode of inheritance, with parental consanguinity in some 30 per cent of subjects. It has some similarities to osteopetrosis. Since the disease is caused by mutations that lead to deficiency of cathepsin K, an enzyme necessary for osteoclast function, this is not unexpected. Marked reduction in stature with short limbs is a particular clinical feature.

The vault of the skull is large, the face and chin small, the palate high-arched, and the teeth crowded, with retained deciduous teeth. The anterior fontanelle (and other cranial sutures) remain unfused. The painter Toulouse-Lautrec is regarded as a typical example of this disease. The fingers may appear to be clubbed because of associated acro-osteolysis. The chest is deformed with kyphoscoliosis and pectus excavatum. Recurrent fractures of long bones occur, and occasionally rickets. Radiologically, there are similarities to osteopetrosis with generalized osteosclerosis and fractures. However, the osteosclerosis is uniform; there are no defects of modelling and no endobones. In addition to delayed closure of the cranial sutures there are also wormian bones; the bony fragility, wormian bones, and blue sclerae simulate osteogenesis imperfecta.

Idiopathic hyperphosphatasia

This very rare condition is also labelled 'juvenile Paget's disease'. It has autosomal recessive inheritance. The long bones are abnormal, thickened, and bowed from the first year of life, and the skull may be enlarged. Muscular weakness is common and the plasma alkaline phosphatase level is continuously very high.

Sclerosteosis

This condition is due to an autosomal recessive trait. There is progressive overgrowth and sclerosis of the skeleton, including the skull and the mandible. There are similarities to van Buchem's disease (endosteal hyperostosis), but the skeletal problems are more severe and there is often syndactyly. Prophylactic craniectomy may be necessary to reduce the increased intracranial pressure.

van Buchem's disease

In this rare hyperostosis, endosteal thickening of the shafts of the long bones is associated with generalized hyperostosis, including the base of the skull and the mandible. Bilateral facial nerve weakness, deafness, and optic atrophy may ensue. Severe recessive and mild dominant forms are described.

Cleidocranial dysplasia

In this rare condition the clavicles are hypoplastic or absent, the fontanelles remain open, and there are supernumerary teeth. The heterozygous mutation causes a loss of CBFA1, the osteoblast transcription factor (see above).

Osteopetrosis (marble bones disease)

Among those disorders with increased bone density, marble bones disease or osteopetrosis (Albers–Schönberg disease) is the best known. It is a heterogeneous disorder with a widespread increase in bone density. In most cases, the basic defect lies in the osteoclasts which, for various reasons, are unable to resorb mineralized bone. Many animal models of osteopetrosis exist.

Until recently two main forms were distinguished: recessively inherited severe osteopetrosis causing death in childhood; and the dominantly inherited mild form, in which the diagnosis can be made on radiological grounds alone. This distinction is not absolute—two distinct dominantly inherited forms exist, as well as intermediate forms. Deficiency of carbonic anhydrase II can also cause osteopetrosis associated with cerebral calcification, renal tubular acidosis, growth failure, and mental simplicity.

Severe osteopetrosis

In severe recessively inherited osteopetrosis there is widespread increased density of the bones without modelling or remodelling. This produces the Erlenmeyer-flask deformity of the metaphyses. The increase in bone density is often intermittent, producing alternating bands of sclerosis. The failure of resorption leads to a reduction in bone marrow space with a leucoerythroblastic anaemia and hepatosplenomegaly. It also produces nerve compression, with blindness and often deafness. Other clinical features in this severe form can include hydrocephalus, delayed tooth eruption, and osteomyelitis. Fracture of the dense bones is common. The affected infant is short with an apparently large head with frontal bossing, hepatosplenomegaly, and knock knees. The plasma calcium level appears to alter with the dietary intake and may be sufficiently low to contribute to rickets. The acid phosphatase concentration (derived from the defective osteoclasts) is increased. Secondary hyperparathyroidism leads to an increase in calcitriol levels. Apart from transplantation of bone marrow, as a source of normal osteoclasts, from an appropriate donor, other forms of medical treatment deal only with complications; these include surgery for fractures, blood transfusions for anaemia, and antibiotics for frequent infections.

Mild osteopetrosis

The mild forms vary from subjects with an increased number of fractures affecting both the long bones and the small bones of the hands and feet, to those in which the disorder is so mild that the diagnosis is made by radiology alone (accounting for apparently unaffected generations with the dominant form of the disease). There are more severe forms of dominantly inherited osteopetrosis with nerve compression, deafness and blindness, and anaemia at times of increased physiological requirement, such as pregnancy. Other established features include osteomyelitis and facial nerve palsy.

Recent studies of Danish families define two dominantly inherited forms: one with uniformly dense bones with sclerosis of the cranial vault and the spine and no increase in the plasma acid phosphatase level, and another with variable bone density (giving rise to an endobone appearance, Fig. 19) and lack of modelling, with a significant increase in the plasma acid phosphatase level.

Fig. 19 The appearance of the bones in a boy with dominantly inherited osteopetrosis and a raised plasma acid phosphatase level. There are variations in bone density ('endobones') with recent and old pathological fractures.

Carbonic anhydrase II deficiency

The association of carbonic anhydrase II deficiency with osteopetrosis, renal tubular acidosis, cerebral calcification, some degree of mental retardation, growth failure, and dental malocclusion is of considerable interest because of the clues it provides to the normal function of carbonic anhydrase II in bone resorption. Carbonic anhydrase II is part of the carbonic anhydrase gene family and is widely distributed. It is found in the kidney, brain, red cells, and elsewhere, and its gene is on chromosome 22. Deficiency of carbonic anhydrase II is autosomal recessively inherited, and apparently normal parents of affected offspring have 50 per cent of normal carbonic anhydrase II levels within their red cells. The bone disease is not distinguishable from other forms of osteopetrosis, and fractures occur until adulthood. There is always growth retardation, and height may be more than four standard deviations below the mean. The bone age is also delayed. Radiographic appearances improve in adult life.

The renal tubular acidosis is mixed, both proximal and distal. Cerebral calcification affects the basal ganglia within the first decade. It increases during childhood to include the cortical grey matter and is similar to that occurring in idiopathic or pseudohypoparathyroidism. Bone histology shows unresorbed calcified cartilage and osteoclasts without a ruffled border.

The diagnosis of carbonic anhydrase II deficiency should be considered in any neonate with renal tubular acidosis. Genetic counselling is possible since adult heterozygotes have reduced levels of the enzyme in their red cells. However, the concentration of carbonic anhydrase II is normally very low at birth and cannot be used as a reliable neonatal test for the affected homozygote.

The treatment of carbonic anhydrase II deficiency is symptomatic; it is possible that correction of the renal tubular acidosis temporarily increases the rate of growth.

In the differential diagnosis of osteopetrosis there are many disorders with an excessive amount of bone in various parts of the skeleton; these include other skeletal dysplasias, Caffey's disease (infantile cortical hyperostosis) which causes a temporary increase in bone density from birth, and myelofibrosis, renal glomerular osteodystrophy, inherited hypophosphataemia, and fluorosis in adult life.

Fibrous dysplasia

Fibrous dysplasia of bone is a condition in which areas of immature fibrous tissue, either single or multiple, are found within the skeleton. Recent research has shown a widespread postzygotic activating mutation in the gene for a subunit of the G-protein signalling system. The extent to which this activating mutation affects the bone and other tissues depends on the degree of mosaicism, in other words the proportion and distribution of cells that carry the mutation. It is proposed that such a mutation in the germline would be lethal; certainly the condition is not inherited.

Monostotic fibrous dysplasia

This disorder is relatively common in orthopaedic practice. Although the lesions may occur in any bones, and particularly in the facial bones and ribs, the most frequent presenting symptom at any age is a fracture, often of the upper end of the femur (Fig. 20). The biochemistry is usually normal, and the diagnosis is made from the radiographic and pathological appearances. There is a smooth-walled translucent area within the bone, often with thinning of the cortex and sometimes with associated deformity. Pathologically, areas of disorganized fibrous tissue are are found, associated with woven bone and wide osteoid seams. This represents mosaic

tissue with some normal mesenchymal cells and some carrying the mutation. The differential diagnosis is from other causes of bone cysts, from Paget's disease, and from hyperparathyroidism with osteitis fibrosa cystica. In the monostotic form treatment is largely orthopaedic. However, the large size of some of the defects in the shafts of the long bones may make conventional stabilization of fractures very difficult. Improvement with intravenous pamidronate (APD) has been reported.

Fig. 20 Polyostotic fibrous dysplasia in a 23-year-old woman. A large cyst in the upper femur led to a spontaneous fracture which subsequently united with conservative treatment. Two ribs on the same side of the body show similar abnormalities. Puberty was precocious but pigmentation absent.

Polyostotic fibrous dysplasia (see Chapter 12.8.6)

Interest in this condition, in which the bone lesions are multiple, arises from its frequent association with pigmentation and sexual precocity, especially in females (McCune–Albright syndrome). The bone lesions and the brown pigmentation are typically associated in position (but not in extent), and may be restricted to one side of the body. Sexual precocity is present in about 50 per cent of females with polyostotic disease, and is then the presenting complaint. It may occur at a very early age, with menstruation and the appearance of secondary sexual characteristics from infancy. Where sexual precocity is not a feature, deformity and fracture are often the first symptoms. Gross deformity of the upper femur and femoral neck produces the 'shepherd's crook' appearance. Asymmetry of the long bones and of the skull are also seen; and in about half of the cases the base of the skull is thickened. The macular pigmentation tends to have smooth borders (in contrast to those of neurofibromatosis) and often does not cross the midline. In a recent long-term follow-up of 15 patients with two or more features of the McCune–Albright triad, the bone lesions tended to increase in size and number, but less rapidly after growth had ceased. Skin lesions were generally bilateral and did not correlate with the site of the bone lesions. There are a number of other features which, like the sexual precocity, are explained by the activating mutation. These include thyrotoxicosis, acromegaly, and Cushing's syndrome. The skeletal lesions may cause complications such as spinal cord compression, and may be associated with hypophosphataemic osteomalacia. Sarcoma formation has been reported, but only after irradiation.

In the polyostotic disease both the plasma alkaline phosphatase and the urinary hydroxyproline levels may be slightly increased and that of plasma phosphate slightly reduced. The pathology is similar to the monostotic form, but it is said that cartilage- and fluid-filled cysts are more common. Microscopically, there is an abundance of woven bone and an increase in osteoblasts and osteoclasts. The cortex and marrow may be virtually replaced by fibrous tissue, so that the bones are fragile. Healing is rapid with abundant callus formation. Radiologically, the bones are deformed, the cortex may be difficult to detect, and the medullary bone takes on a 'ground glass' or 'smoky' appearance.

In polyostotic fibrous dysplasia the main differential diagnosis is from osseous neurofibromatosis; in the former condition there is also pigmentation, bone deformity, and sometimes hypophosphataemic osteomalacia. The borders of the pigmentation are less smooth than in fibrous dysplasia, and there are other cutaneous features of neurofibromatosis; the bone deformity in neurofibromatosis can be quite bizarre, with overgrowth or undergrowth of isolated bones. In neurofibromatosis the characteristic spinal change is a very sharp upper thoracic kyphoscoliosis. Finally, neurofibromatosis often shows clear evidence of dominant inheritance pattern.

The medical treatment of the McCune–Albright syndrome is complex. As for the monostotic from, polyostotic fibrous dysplasia may be improved by pamidronate (APD).

Ectopic mineralization

Deposition of calcium in the soft tissues (ectopic calcification) and on ectopic bone matrix (ossification) has many causes (Table 13). These are nearly always pathological, but often the cause is unknown. In the elderly, calcification in the tissues such as the arteries is so common that it may be regarded as a feature of ageing, in the same way as age-related bone loss. There are some disorders in which calcification and/or ossification are associated with biochemical abnormalities.

Ectopic calcification without bone formation

Calcification can result from previous damage in soft tissues (dystrophic calcification) or from an increase in the circulating concentration of calcium or phosphate (metastatic calcification as, for instance, in advanced renal osteodystrophy).

Dystrophic calcification

This occurs in inherited and acquired disorders involving connective tissue, such as alkaptonuria (intervertebral discs), pseudoxanthoma elasticum (blood vessels), systemic sclerosis, and dermatomyositis, and also after infection, tumours, and trauma. In systemic sclerosis, subcutaneous calcification, often around the phalanges (calcinosis circumscripta), may be part of a syndrome with Raynaud's phenomenon and telangiectases (**CRST**; calcinosis, Raynaud's phenomenon, sclerodactyly, telangiectasia) syndrome; see also Chapter 18.10.3). The calcific deposits can be sufficiently extensive to break through the skin as toothpaste-like material. In dermatomyositis, sheets of subcutaneous calcification can be deposited some time after the initial inflammatory episode characterized by a systemic illness and painful weak muscles; the calcification can be very extensive (calcinosis universalis), but can also disappear rapidly, sometimes in adolescence. Rarely this is associated with hypercalcaemia.

Metastatic calcification

The distribution of the calcification varies inexplicably with its cause; for example, in hypoparathyroidism there is subcutaneous and basal ganglia calcification and in hyperparathyroidism vascular calcification, suggesting that metastatic calcification is not only related to the Ca:P product. Calcification and ossification may also coexist.

Calcification and hypocalcaemia

This occurs in idiopathic and postsurgical hypoparathyroidism, as well as in pseudohypoparathyroidism. There may be extensive ectopic calcification, calcification within the basal ganglia (and outside it), and cataract formation. Pseudohypoparathyroidism is inherited as an autosomal dominant disorder with variable expression; additional clinical features include mental simplicity, round face, short stature, and short third and fourth metacarpals. An important feature is subcutaneous endochondral ossification. End-organ resistance to parathyroid hormone may be due to mutations in the gene responsible for one component ($G_s a$) of the G-protein signalling system (Table 1).

Calcification in hyperphosphataemia

Idiopathic hyperphosphataemia is a rare autosomal recessive disorder, with an increase in the maximal tubular reabsorption of phosphate and an inappropriate increase in the plasma $1,25(OH)_2D$ concentration. Masses of ectopic mineral, which form around the joints from childhood (tumoral calcinosis), may discharge through the skin. Treatment with large oral doses of aluminium hydroxide or other phosphate-binding agents can reduce the plasma phosphate level and the size of the

deposits.

Calcification in inherited hypophosphataemia

A particular feature of X-linked inherited hypophosphataemia is the widespread calcification and ossification of ligaments and tendons at their insertions into the periosteum (so-called Sharpey fibres). This is termed an enthesiopathy. Calcification and new bone formation in the ligamenta flava may produce spinal cord compression.

Idiopathic soft-tissue calcification

This includes calcific tendinitis and so-called calcinosis circumscripta.

Ectopic ossification

Acquired ectopic ossification may occur at the site of injury, such as after hip replacement or at a distance from it, for instance, following paraplegia; or in tumours and in a variety of other disorders. Fibrodysplasia (myositis) ossificans progressiva is a very rare disorder inherited as an autosomal dominant (see below).

Acquired ectopic ossification

Post-traumatic ossification

Local ossification can occur after total hip replacement. The quoted incidence varies widely, depending on the method used to detect it. It is said to occur more often in men than in women and in certain individuals; for instance, where ossification follows hip replacement on one side, it is likely to occur if the contralateral hip is also replaced. The reason for this is unknown. The bone mainly forms in the hip abductors and ossification is classified according to its severity. Disodium etidronate may delay mineralization, but only while it is being given, and non-steroidal anti-inflammatory drugs are also useful. A small dose of radiotherapy may also delay ectopic ossification after total hip replacement.

Ossification after neurological injury

Extensive myositis ossificans can also occur 1 to 4 months after injuries to the head or spinal cord, in muscles distant from the injury such as the major muscles of the thigh. Affected muscles become swollen, red, and warm, and, unless the cord lesion is complete, pain and tenderness also occur. At this time the differential diagnosis may include cellulitis, arthritis, and thrombophlebitis. Radiological calcification is initially absent (appearing at about 6 weeks or more after the injury), but an isotope bone scan will show increased uptake before that. Later there is progressive mineralization, with the eventual appearance of organized bone. Because the bone affects the major periarticular muscles, it leads to joint fixation, particularly of the hips. The plasma alkaline phosphatase level may be increased in the early stages.

Attempted surgical removal of ectopic bone is technically difficult and produces little increase in movement. The ectopic bone recurs, especially if it is removed too early. Oral disodium etidronate at full dose (20 mg/kg body weight per day) may delay the onset of mineralization, but only while it is being given. Likewise, the prevention of further ectopic bone formation after its removal may be delayed by non-steroidal anti-inflammatory drugs or radiotherapy, which should be commenced as soon as possible.

Myositis ossificans can also occur after other neurological diseases, such as poliomyelitis and meningitis, and also after prolonged coma. The reason why ectopic ossification occurs after head injury is unknown; interestingly head injury is associated with an increased rate of fracture healing and excessive callus formation. In such patients the serum contains increased mitogenic activity for osteoblast-like cells; the source of this activity is unknown, but there could be an increase in bone morphogenic proteins.

Ossification can coexist with calcification, and, for instance, extensive ossification of the spinal ligaments in hypoparathyroidism can lead to progressive stiffness. The enthesiopathy in inherited hypophosphataemia (vitamin D-resistant rickets) is a form of ectopic ossification. Ossification of the posterior longitudinal ligament and sternoclavicular hyperostosis is particularly described in Japan. Ligamentous ossification has been noted in patients treated with vitamin A analogues, such as etretinate, for dermatological disorders. The term 'osteoma cutis' covers a number of rare conditions of uncertain cause. Finally, ectopic bone may complicate varicose veins, chronic venous insufficiency, and surgical incisions.

Inherited ectopic ossification

The main inherited cause of ectopic ossification is myositis ossificans progressiva. This disorder is currently classified as a 'heritable disorder of connective tissue'.

Histology suggests (to some) that it is the connective tissue within muscles that is primarily involved and therefore the alternative term 'fibrodysplasia ossificans progressiva' is widely used.

Fibrodysplasia ossificans progressiva is rare, with an incidence of between 1 and 2 per million, which increases with paternal age. Since patients rarely reproduce, most instances represent new mutations. The few family histories demonstrate that the mutant gene is inherited as a dominant with full penetrance but variable expression. Diagnosis depends on the combination of progressive myositis, leading to ossification in the major skeletal muscles, and characteristic bony skeletal abnormalities.

Pathophysiology

Initially there is oedema and cellular infiltration throughout the muscle, with myofibrillar breakdown. Later endochondral ossification leads to mature bone, within which is haemopoietic marrow. Information on the earliest histological appearances is scanty because biopsies are often taken after the acute phase of myositis; for this reason there is still doubt about the primary lesion. Ectopic ossification occurs when mesenchymal or stromal cells take on the behaviour of osteoblasts. This form of cell differentiation could result from an increase in bone-inducing substances or (for unknown reasons) a change in stromal-cell expression. Although the timing of myositis differs widely from one affected patient to another, there is a specific order in which they are affected, from the upper paraspinal to the lower, and from the centre to the periphery. Recent work suggests overexpression of the bone morphogenetic proteins (**BMP**-4). Localization of the mutant gene is hampered by the lack of affected families.

Clinical features

Episodes of myositis are the non-skeletal hallmark of this disease. Typically, the affected muscle becomes swollen and hard, sometimes following injury; after a week or two these features subside, but the apparent improvement is followed in a month or so by ossification within the muscle and progressive joint fixation. Myositis usually begins in the upper paraspinal muscles. By late childhood or adolescence ossification will have occurred within the muscles around the shoulders, hips, and knees, to fix these joints and to complete the disability. The large, striated muscles are affected; ossification does not involve the small muscles of the hands and feet, the diaphragm, the cardiac, or the smooth muscles. Ossification in the muscles around the jaw may fix it almost completely. Although the overall sequence of ossification is characteristic from large upper paraspinal to lower limb muscles, it varies considerably in its rate. For instance, neonates may have sufficient ossification to produce torticollis while, in contrast, late and slow ossification producing stiffness may delay the correct diagnosis until adolescence. Likewise, there may be long symptom-free periods.

The diagnostic skeletal abnormalities affect the big toes (Fig. 21) (and to a lesser extent the thumbs), the cervical spine (Fig. 22), and the metaphyses. The big toes are always abnormal; in the infant, bony changes produce bilateral hallux valgus and, in the adult, fusion produces a short fixed monophalangic big toe. In the cervical spine the vertebral bodies are small and the laminae large. Both are variably fused; and this fusion is independent of nearby ossification of the cervical muscles. Finally, the femoral necks are short and wide and there are exostoses from the metaphyses.

Fig. 22 Fusion of the cervical spine in a young woman with fibrodysplasia ossificans progressiva.

Rare clinical features include early onset baldness, difficulty in hearing, and mental retardation.

Differential diagnosis

Bilateral hallux valgus in the neonate should suggest the possibility of fibrodysplasia ossificans progressiva. In childhood, myositis may be mistaken for soft-tissue sarcoma; and a biopsy showing oedema and increased cellularity may support this or suggest an aggressive fibromatosis. Painful swelling of the masticatory muscles simulates mumps; and progressive stiffness with a fixed abnormal neck suggests the Klippel–Feil syndrome or childhood rheumatoid arthritis.

Management

Once the diagnosis has been made, and this is often delayed, there are four main questions: can the myositis be prevented; if myositis does occur, can subsequent ossification be prevented; what will be the eventual disability; and should ectopic bone be removed?

Since the onset of myositis is quite unpredictable, it is almost impossible to assess the effect of any form of therapy. Corticosteroids have been used, sometimes associated with symptom-free periods. Myositis often follows injury, which should be avoided where possible. It seems likely, but difficult to prove, that myositis is normally followed by ossification. It is to prevent or slow down this ossification that the bisphosphonate EHDP (disodium etidronate) can be given in full doses (20 mg/kg body weight daily by mouth), but there is little evidence that this is effective. In children, continued high-dose etidronate interferes with mineralization, disorganizes the growth plates, and delays fracture healing so that it is not an acceptable long-term treatment. Surgical removal of ectopic bone is technically difficult and recurrence at the site of surgery worsens the disability.

The eventual disability produced by fibrodysplasia ossificans progressiva is severe (Fig. 23). The body moves as in one piece with the legs usually fixed in partial extension. All major joints become completely fixed. The help of a specialized rehabilitation centre is essential.

Fig. 23 Extensive ectopic ossification in the paraspinal muscles fixing the shoulders in a patient with fibrodysplasia ossificans progressiva.

Familial osteoma cutis

This has been reported as a dominantly inherited disorder in a New Zealand family. The proposita had extensive subcutaneous ossification in one leg; relatives had insignificant multifocal subcutaneous ossification in childhood. Similar patients have been described under the name of progressive osseous heteroplasia.

Miscellaneous bone disorders

The skeleton is affected in many systemic diseases (for example, scurvy and the haemoglobinopathies), by the methods used to treat them (for example, parenteral nutrition), and by excessive ingestion of minerals, vitamins, and metals (for example, fluorosis, overdose of vitamins A and D, and metal poisoning). In some, the skeletal changes are clinically important; in others they are a minor aspect of the general illness. This Section ends with a brief description of the obscure disorder fibrogenesis imperfecta ossium.

Scurvy

Vitamin C (ascorbic acid) is necessary for intracellular hydroxylation of peptide-bound proline. In its absence, formation of the collagen molecule is defective, structurally incompetent precursors accumulate within the cell, and collagen-containing tissues are weak. Scurvy is very rare, occurring most often in neglected infants who do not receive fruit juice or ascorbic acid for several months. Extensive subperiosteal haemorrhage leads to pain and immobility; the legs are held in a 'frog-like'

position. In the adult, there is perifollicular haemorrhage, purpura, and bleeding gums. Radiographs in infancy show a widened zone of provisional calcification in the metaphyses, with a proximal disordered area representing the destroyed primary spongiosa and failure of new bone formation. The edges of the metaphyses may show small spurs, and epiphyseolysis may occur. With healing the subperiosteal haematoma calcifies.

The clinical picture of scurvy may suggest non-accidental injury, but scurvy is far less common. Similar radiographic appearances have been described in cases of copper deficiency.

The haemoglobinopathies

In the inherited disorders of haemoglobin (see Section 22) the skeleton is often abnormal. This may result from a hyperplastic bone marrow and overactivity of the osteoblasts, so that the skull, facial bones, and long bones are thickened. Additional features include collapse of the weight-bearing bones and disorganization of the joints following bone infarction. This is especially seen in sickle-cell disease, haemoglobin C disease, and haemoglobin SC compound-heterozygotes. In b-thalassaemia an increase in osteoid thickness has been described which resembles that of osteomalacia.

Parenteral nutrition

Prolonged parenteral nutrition can produce a form of bone disease with similarities to osteomalacia. The main symptom is periarticular bone pain, particularly in the ankles. Histology shows impaired mineralization of bone, and biochemistry an increase in plasma alkaline phosphatase, in urinary calcium, and sometimes in plasma calcium levels. The radiographic appearances suggest osteoporosis. Since patients on total parenteral nutrition are invariably ill to begin with, and many have malabsorption, there are several probable causes for this disorder; aluminium intoxication may contribute.

Fluorosis

Deposition of excess fluoride in the skeleton can result from an excess in the diet (endemic fluorosis), from industrial exposure (during the manufacture of aluminium, steel, and glass, and from exposure to the dust of fluoride-containing rock), and from the administration of sodium fluoride in treatment. The most severe effects are seen in endemic fluorosis, well described from the Punjab.

There is considerable disability, with spinal rigidity, restricted movements of the joints, and flexion deformities of the hips and knees. There is a generalized increase in bone density (with loss of the normal corticomedullary junction), and the tendons, ligaments, and sometimes muscles may be mineralized. This can produce compression of the spinal cord and its roots, with progressive neurological disability. Mineralization of tendon insertions may be seen in other situations, such as inherited hypophosphataemia (see above), retinoid treatment, and fibrogenesis imperfecta ossium (see below).

Increased levels of fluoride can affect the enamel of developing teeth, producing chalky-white patches, yellow-brown discoloration, and other defects.

The diagnosis of fluorosis depends on the radiographic changes and an increased urinary excretion of fluoride (which is an index of current exposure). When a bone biopsy is performed (most often to exclude other causes of increased bone density), histology shows an increase in new bone formation with an increase in the width of osteoid borders. There is also an increase in fibrous tissue and bone resorption. When the biopsy includes an area of tendinous insertion, this may be mineralized.

Sodium fluoride has been given widely to treat osteoporosis and produces increased vertebral density. Current evidence does not suggest that this increases vertebral bone strength and suggests that there is an increase in appendicular bone fracture. The main effect of the fluoride ion is to stimulate new bone formation, while fluoroapatite may also reduce resorption. The new bone appears to be mainly woven in character and imperfectly mineralized. Although there is no doubt about the anabolic effects of fluoride on bone, current controversies about its clinical usefulness depend, in part, on the dose used.

Vitamin A

Retinoic acid and its derivatives have profound effects on osteoblast function . Vitamin A poisoning produces characteristic periostitis in the young skeleton, and therapeutic retinoids (such as etretinate) causes widespread ligamentous calcification. Acute and chronic forms of vitamin A overdosage are described. In infants, it is uncommon under the age of 1 year. There is anorexia and failure to thrive; other features include pruritus, hepatosplenomegaly, jaundice, alopecia, dry skin, and fissures around the lips. Hard, tender masses appear in the limbs, and radiographs show periosteal new bone formation, especially in the diaphyses of the tibias, which later blends into the cortex. A number of other radiological features include shortening of the shafts of the long bones, splaying of the metaphyses, enlargement and premature fusion of the ossification centres, and flexion deformities of the legs.

The prolonged use of retinoids for the treatment of skin disease, such as psoriasis and ichthyosis, leads particularly to calcification of the spinal ligaments, causing stiffness and reduced mobility. There is a resemblance to Forestier's disease (diffuse idiopathic skeletal hyperostosis).

Vitamin D

Vitamin D poisoning can result from inappropriate therapeutic overdosage or accidental overconsumption. This leads to the features of hypercalcaemia (see Chapter 10.3 and Chapter 12.6.2) without detectable effects on the skeleton. The main opportunities for overdose exist when potent preparations of vitamin D are used inappropriately (as, for instance, to treat skin conditions and tuberculosis). Chronic vitamin D overdosage leads to soft-tissue calcification, especially in the arteries and kidneys. After several years, progressive stiffness in the spine, major joints, and feet lead to difficulty in walking. Radiographs show ligamentous calcification. Another cause of hypercalcaemia is an excess of $1,25(OH)_2D$ produced by granulomas, especially those of sarcoidosis following exposure of the skin to sunlight. The biochemical effects are the same as those of vitamin D poisoning. The $1,25(OH)_2D$ concentration increases with that of 25(OH)D, and the hypercalcaemia of sarcoidosis often occurs during the spring in persons with outdoor jobs (such as farmers, window cleaners) or after foreign holidays in the sun. Treatment with corticosteroids and removal from sunlight rapidly reduces the hypercalcaemia and the elevated $1,25(OH)_2D$ levels.

Idiopathic hypercalcaemia can occur in infancy. Now named the Williams syndrome, it is associated with an unusual 'elfin face', mental simplicity, and congenital heart disease. Radiographs of the long bones show increased density of the metaphyses. The cause is not fully understood, but the concentration of 25(OH)D may be increased when the patients are hypercalcaemic. Deletion of the elastin locus on chromosome 7 has also been described and may explain the cardiac abnormalities.

Lead (see also Chapter 8.1)

Lead has unique effects on the skeleton, which may be combined with the other manifestations of lead intoxication. Lead deposition in the growing skeleton produces a radiologically dense line near the growth plate. When exposure to lead has been intermittent, or the condition has been treated, this may be a single, relatively narrow line, which is superseded by apparently normal bone. If exposure to lead recurs, a further line will appear.

Lead poisoning due to industrial pollution is thought to be widespread, but the skeleton is affected only when lead exposure has been considerable. In children, one recognized source is lead-containing paint. Other sources include contaminated water from old lead pipes, eye blackener used by Asian women (which contains up to 88 per cent lead sulphide), inhalation of lead fumes from burning old battery cases, and alcoholic drinks stored in vessels of lead glass or coated by lead enamel glaze.

Clinical features involve: the gastrointestinal tract (abdominal pain, colic with constipation, and a blue pigmentation of the gingival margin); the neuromuscular system, with weakness; and encephalopathy, with restlessness, irritability, and lethargy. Renal manifestations are described in Section 20.

Characteristic radiological features include widened skull sutures (due to raised intracranial pressure in infants), dense deposits in the gastrointestinal tract indicating heavy-metal ingestion, and dense lines in the metaphyses (lead lines). Such lines are an important clue to lead poisoning in infants and children up to about the age of 6 years. They occur most commonly around the knees, wrists, and ankles, and appear after about a month of chronic poisoning. The diagnosis of lead poisoning is confirmed by an increase in plasma and urinary lead levels. There are other causes of radiologically dense metaphyses. These include: other heavy metals—bismuth, mercury, or phosphorus; vitamin D intoxication and idiopathic hypercalcaemia of infancy; cretinism; and healing rickets. In practice, there is often difficulty in deciding

on the significance of dense metaphyses due to excessive calcium in an otherwise well child, since this appearance can occur in the normal growing skeleton.

Aluminium (See also Chapter 8.1)

Aluminium in water is not significantly absorbed through the intestine, but this barrier was effectively removed in the early days of haemodialysis treatment for endstage renal failure. The resultant accumulation of aluminium in the skeleton in patients in some units where the aluminium content of tap water was high led to the occurrence and recognition of 'dialysis bone disease'. There was a close clinical association with dialysis dementia, also related to aluminium poisoning. The clinical features of this bone disease were proximal myopathy, multiple painful spontaneous fractures with radiographic evidence of osteopenia (osteoporosis), histological evidence of excess osteoid with aluminium deposition near the calcification front, and an absence of response to vitamin D metabolites.

In renal glomerular failure, aluminium may also accumulate in patients given oral aluminium hydroxide to reduce plasma phosphate (in order to lessen hypocalcaemia and subsequent secondary hyperparathyroidism). Aluminium bone disease can also occur in patients on prolonged parenteral nutrition.

The pathology of aluminium bone disease is not fully understood, but it seems likely that in some instances aluminium reduces osteoblast activity. Two different forms are described: in the first, there is excessive osteoid (with an appearance like that of osteomalacia); and in the second, there is little increase in osteoid with reduced osteoblastic activity. It is likely that the different histological features are related to the amount of aluminium in the bones.

Cadmium (See also Chapter 8.1)

Contamination of drinking water by cadmium and its accumulation in the body causes renal tubular damage with multiple biochemical defects. Cadmium intoxication is one of the acquired causes of the Fanconi syndrome which leads to rickets or osteomalacia. Industrial exposure to cadmium fumes can produce hypophosphataemic osteomalacia.

Exceptionally, chronic lead poisoning can also produce osteomalacia by the same mechanism as cadmium; and copper 'poisoning' causes the Fanconi syndrome and bone disease of Wilson's disease.

Fibrogenesis imperfecta ossium

This is a very rare, apparently acquired disorder, characterized by excessive bony fragility due to the replacement of normal bone with a fibre-deficient, poorly mineralized matrix. The cause is unknown. In recorded cases, the main clinical feature has been pathological fractures first presenting in adult life. In most patients, progressive disability has followed, with more fractures that fail to unite. Radiologically, the trabeculae throughout the skeleton appear to be thickened. There is also ectopic mineralization around large joints and tendon insertions. Biochemically, plasma calcium and phosphate levels are normal, but the alkaline phosphatase level is moderately raised. In the urine, monoclonal light chains may be present. The diagnosis is confirmed by the examination of undecalcified bone. This shows defective mineralization and wide osteoid seams suggesting severe osteomalacia, but the osteoid is not birefringent under polarized light and the normal structure of bone collagen under electron microscopy is absent. The differential diagnosis is from those disorders that produce widespread coarse trabeculation throughout the skeleton, and those that produce the histological changes of osteomalacia. In the first category, Paget's disease of bone, renal glomerular osteodystrophy, and fluorosis should be excluded, and in the second, axial osteomalacia has some similarities; in this very rare osteosclerotic disorder, both histology and radiographs suggest that the osteomalacia is limited to the spine, pelvis, and ribs.

Since the cause of fibrogenesis imperfecta ossium is unknown, treatment to date has been largely empirical. The occasional finding of an excess of plasma cells in the bone marrow, or a monoclonal gammopathy, or light-chain proteinuria, has led to apparently successful treatment with melphalan and prednisolone. Where surgery is indicated for fractures, particularly of the femoral neck, this is difficult because of the extreme fragility of the bones.

Although it seems likely that the defect may be related to an acquired disorder of bone collagen, no consistent abnormality has been detected.

Sudeck's atrophy

This is one of many synonyms of what is more often referred to as 'algodystrophy' (painful dystrophy). Its features are pain, swelling, and tenderness, most often of a limb, which is persistent and recurrent. Early oedema and erythema may be replaced by a dystrophic phase that may last for months, with pallor or cyanosis. The skin and subcutaneous tissues may atrophy and there is increased sweating and often worsening of the pain. The main known precipitating cause of algodystrophy is trauma, such as forearm (Colles) fracture. In at least one-quarter of patients there is no identifiable cause. The recorded prevalence of algodystrophy varies widely, depending on its definition and how closely it is looked for; in a specific study made to identify algodystrophy it was found in 25 per cent of patients 9 weeks after Colles fracture, a frequency far higher than normally recorded.

The treatment of algodystrophy is difficult and requires consideration of the whole patient. Adequate pain relief, reassurance, and explanation are essential. Numerous other measures have been proposed; these include courses of corticosteroids and calcitonin, regional sympathetic block, and surgical sympathectomy, none of which is consistently useful. Bisphosphonates, such as pamidronate, may prove to benefit symptoms and outcome, but no controlled trial data are currently available to substantiate their general use where bone loss occurs (see below).

Algodystrophy is often associated with localized bone loss, and some include so-called regional and transient migratory osteoporosis within the algodystrophy syndrome, although the reasons for doing so are tenuous. Characteristically, there is severe localized osteoporosis associated with pain which recurs in different limbs. The increased bone resorptive activity associated with bone loss may be identified by the use of bisphosphonate skeletal scintigraphy, which may assist diagnosis in the early phases of this condition. Further investigation may show that the osteoporosis is more widespread than suspected with, for instance, vertebral compression fractures. Rarely, osteoporosis occurs in pregnancy (see above) predominantly affecting the spine, but also other peripheral bones, leading, for instance, to femoral neck fractures.

19.2 Inherited defects of connective tissue: Ehlers-Danlos syndrome, Marfan's syndrome, and pseudoxanthoma elasticum

F. M. Pope

Introduction

Ehlers–Danlos syndrome, pseudoxanthoma elasticum, and the Marfan syndrome are characterized by the fragility of connective tissues and thus cause diverse clinical disease. These inherited defects disrupt the integrity of structural proteins found in the skin, ligaments, cartilage, and vasculature and share common clinical features (Table 1). Connective tissue is also affected in the pleura, peritoneum, heart valves, gastrointestinal system, muscles, and other tissues with similar scaffolding components. Moreover, defects of connective tissue also disrupt basement membranes present in the eyes, skin, and kidneys.

A notable feature of connective tissues is the existence of molecular interactions between structural proteins and extracellular matrix. These interactions are important early in development and involve early embryonic patterning co-ordinated by the expression of homeobox proteins, including those of the hedgehog family. Inherited defects of protein constituents in connective tissues may thus disturb many tissues during development and organogenesis.

For all these reasons, inherited defects of connective tissue impinge widely on the practice of medicine. In the ageing population, increased fragility of the skin, rupture of blood vessels, and laxity of ligaments, as well as defects of cartilage and bone, overlap to form a series of disorders that declare themselves in adult life. Such 'degenerative disorders' include osteoporosis, osteoarthritis, and arterial aneurysms. In the light of spectacular advances in the understanding of the molecular structure and genetics of connective tissue components, it seems likely that many aspects of medicine hitherto ascribed to age-related degeneration, will ultimately prove to have strong genetic components. A valid, molecular understanding of these processes may well emerge. It also appears likely that discrete clinical conditions now recognized as the Marfan syndrome, Ehlers–Danlos syndrome, and pseudoxanthoma elasticum will prove to have diverse and genetically determined counterparts that are responsible for the so-called degenerative disorders in the population at large.

Ehlers–Danlos syndrome (EDS)

Many clinical subtypes of Ehlers–Danlos syndrome have been recognized and increasingly these variants are being associated with distinct abnormalities of collagen structure. Abnormal collagen structure in EDS leads to multisystem disease (Table 2). Common features of this syndrome include fragile skin and laxity of the joints and ligaments (Fig. 1). In certain subtypes there is a particular fragility of tissues including arteries, the wall of the intestine, spinal ligaments, or even teeth; these propensities have led to discrete syndromic recognition (Table 3). The classical form of Ehlers–Danlos syndrome is characterized by excess cutaneous extensibility, bruising, and molluscoid pseudotumours. Careful examination of the skin of patients with EDS may show laxity, pendulousness, and fragility with easy splitting at different stages. In childhood, the skin tends to be hyperelastic but with advancing age, laxity combined with pendulousness, becomes obvious. Other forms of EDS may show hyperelastic and droopy skin in the same or different sites from the outset. The EDS V subtype is now obsolete.

Fig. 1 Ehlers–Danlos syndrome. (a) Hyperelasticity of the skin (EDS II); (b) atrophic and pigmented papyraceous scars (EDS II); (c) joint hypermobility (EDS III); (d) severe pes planus (EDS VI); (e) dentinogenesis imperfecta (EDS VII), this patient had a deletion of exons 3–6 of the *COL1A1* gene; (f) premature periodontitis (EDS VIII).

After the original description, it was realized that some patients with EDS were susceptible to spontaneous arterial rupture with its associated lethal consequences. Affected women suffered fetal prematurity, and examination of their skin showed depletion of collagen and an increase in elastin fibres. This particular condition, which is associated with early fatality from vascular rupture, is correlated with defects in a type III collagen, as shown below. There are obstetric, rheumatological, orthopaedic, and abdominal complications of this vascular form of Ehlers–Danlos syndrome (type IV)—as well as an appreciable incidence of bladder-neck obstruction and ureteric reflux. Representative clinical features of EDS subtypes are illustrated in Fig. 1 and Fig. 2 (and see also Plate 1).

Fig. 2 EDS type IV (vascular type). (a) Acrogeria—a specific clinical feature of EDS IV. Note the large eyes and thin nose (Madonna facies) with perioral wrinkling. (b) Premature wrinkling of the skin on the dorsum of the hands; note also the joint contractures superficially resembling rheumatoid arthritis. (c) Pretibial bruising and haemosiderosis. (See also Plate 1.)

Clinical genetics

Ehlers–Danlos syndrome type VI is caused by a recessively inherited deficiency of lysyl hydroxylase leading to underhydroxylation of collagen molecules (see Fig. 4(b)). Ehlers–Danlos type IV is due to defects and a deficiency of type III collagen in blood vessels, and is inherited as an autosomal dominant disorder. The biochemical defect in autosomal dominant Ehlers–Danlos syndrome type VII results from a failure to remove the N-terminal procollagen extensions of collagen. Defects in type III collagen are now implicated in the cutaneous ligaments and arterial fragility of the three major EDS variants. These defects compromise the assembly of collagen fibrils and provide an important biological model for other EDS subtypes that have now been identified, thus allowing diagnostic criteria to be married to an understanding of the molecular defect in collagen and connective tissue matrix.

Ehlers–Danlos syndrome may show classical X-linked, autosomal recessive or autosomal dominant transmission. These patterns reflect the complex assembly of the helical collagen molecule and its susceptibility to protein suicide. Because it is a complex structure, mutations in a single glycine located in the collagen helices disrupt up to seven-eighths of the assembled homocollagen trimers and 75 per cent of collagen heterotrimers, depending on the particular stoichiometry. For these reasons, collagen defects of this type behave as autosomal dominant traits, while the enzymatic deficiencies of collagen formation segregate as autosomal recessive traits with little or no expression in heterozygotes. Convincing autosomal recessive inheritance is common in EDS type VI associated with pronounced cutis laxa, due to gross distortions of the assembly of type I collagen that lead to a hieroglyphic appearance to these fibres under electron microscopy (Fig. 3(a)). In contrast, mutations leading to EDS type IV result from dominant mutations of type III collagen.

Ehlers–Danlos syndrome types I and II

EDS I and II are associated with the classical features outlined in Table 3. Easy skin-splitting, especially over bony prominences on the forehead, elbows, knees, and chin, shows itself in childhood. Notable features of the condition include epicanthic folds, blue sclerae, and fibrous nodules over the knees and ankles. Mitral valve prolapse is common but does not usually result in dilatational rupture of the valve. Unlike Ehlers–Danlos syndrome type IV, fragile blood vessels do not occur, but venous varicosities, premature bilateral hallux valgus, and distortion of the cornea leading to astigmatism, as well as premature osteoarthritis, are common. Most EDS type I or II families show linkage to the collagen V a-1 or V a-2 genes; which are located, respectively, on human chromosomes 9 or 2q34. Mutation analysis usually reveals substitutions of glycines and exon-skipping events. In some instances, null alleles lead to the deficiency of type V collagen domains. It seems likely that defects in the interactive properties of the N-terminus of type V collagen, which normally protrudes from the surface compound fibres comprising types I, III, and V collagen, impair normal interactions with other matrix components. Misdirection of the collagen fibrils leads to the generation of the so-called 'cauliflower' fibrils of EDS types I and II (Fig. 3(b) and (c)). The clinical consequences being of fragile skin, ligaments, tendons, and corneas, as well as defective articular surfaces.

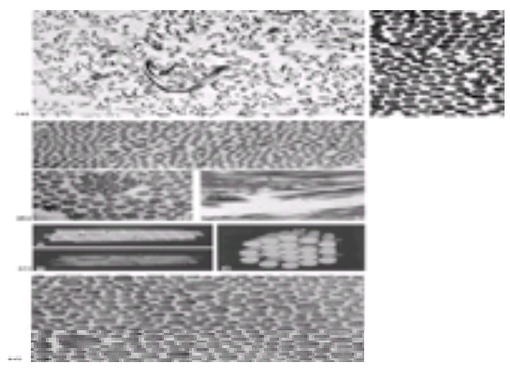

Fig. 3 Ultrastructural abnormalities of collagen in EDS. (a) 'Hieroglyphic' collagen fibres in EDS VII, indicating very severe disruption of fibril packing—compare with healthy collagen shown on the right of the figure. (b) Misassembled 'cauliflower' fibrils of skin and ligaments in EDS II. The left panel shows transversely fused fibres, which in longitudinal sections appear to splay distally. They resemble transversely sectioned cauliflower heads (from Nicholls *et al*. (1996) with permission). (c) Diagrammatic representation (in a) of compound collagen I and III fibres, composed of quarter-staggered individual triple helices. The dark collagen type V molecules (b) regulate fibril diameter; their protruding N-termini (shown in (c)) can interact with other matrix components (from Birk *et al*. (1990) with permission). (d) Dual distribution of collagen fibre size in EDS type IV.

Ehlers–Danlos syndrome type III/benign hypermobile syndrome

This is the most common and least differentiated variant of Ehlers–Danlos syndrome and, for this reason, its diagnosis is frequently overlooked. The disorder is associated with tall stature, ready bruising, blue sclerae, and osteoporosis. Occasionally, more severe defects including osteogenesis imperfecta and Marfan's syndrome occur. Occasionally pseudoxanthoma and other Ehlers–Danlos syndrome variants occur as part of this disorder. As yet uncharacterized defects in collagen, elastin, fibrillin, proteoglycan, and connective tissue-modifying enzymes may all be responsible for the hypermobility of joints and other manifestations in this category of Ehlers–Danlos syndrome (Fig. 1(c)). Patients with Marfan's syndrome may show extensible skin and osteoporosis that complicate Ehlers–Danlos syndrome types III, VI, and VII; Marfan-like stature may be observed in patients with osteogenesis imperfecta.

Ehlers–Danlos syndrome type IV—'vascular form'

This autosomal dominant vascular form of Ehlers–Danlos syndrome is typically accompanied by pretibial ecchymoses over the knees and shins as well as acrogeria (Fig. 2). Acrogeria refers to prematurely aged extremities with thinning of the skin on the dorsum of the hands, feet, and shins. The features are combined with the so-called 'Madonna' facial appearance of large eyes, nasal thinning, and small earlobes. Some patients may have a Marfanic appearance. Rarely there is acro-osteolysis with unexplained androgenic alopecia in females as well as congenital talipes, hip dislocations, and tendon contractures; displacement of the metacarpophalangeal joints in the hands may superficially resemble the changes of rheumatoid arthritis. Fragility of pleuroperitoneal membranes or the colonic wall is a common feature in this vascular subtype but occasionally it may complicate other types of EDS, including types I, II, and III.

The main concern with type IV Ehlers–Danlos syndrome is of spontaneous rupture of medium or large arteries, which may be lethal at any point from mid-adolescence to late-adult life. Aneurysms of small, medium, and large arteries, including the aorta, are common. Angiographic studies reveal a dilatated and tortuous arterial tree, including the carotid bifurcation, and major aortic or iliac disease. Dissections are common especially after ill-advised angiography or surgery; these present with unexplained abdominal pain that proves to be due to intestinal ischaemia. Histological examination of the skin reveals dermal thinning with depletion of dermal

collagen and an overproliferation of elastic fibres. Examination of the skin by electron microscopy usually reveals marked variability in collagen fibril size (Fig. 3(d)).

In a recent review by Pepin and colleagues of the medical and surgical complications in 220 index patients and 199 of their affected relatives with biochemically confirmed EDS type IV, the underlying COL 3A1 mutation was identified in 135 propositi. One-quarter of the index patients had had a first complication by the age of 20 years and more than 80 per cent had at least one complication by the age of 40. Most deaths resulted from arterial rupture but bowel rupture, usually of the sigmoid colon was frequent. It was noteworthy that in 81 women with EDS IV who had become pregnant, 12 died as a result of disease complications during pregnancy. Overall the median lifespan of the whole group was reduced to 48 years.

Molecular pathology

Collagen III is the dominant collagen in skin, blood vessels, tendons, ligaments, gastrointestinal tract, and pleuroperitoneal cavity linings. This explains the diverse multisystem phenotype of type IV EDS. Disturbed assembly, as well as haploinsufficiency of type III collagen explains the wide-ranging severity of EDS type IV, although some affected patients suffer a mild clinical phenotype resembling EDS type III (Fig. 4(a)). Numerous mutations in the type III collagen gene have been found in EDS type IV; most of these mutations are private, although several are associated with 'hot spots' in the complex collagen gene structure that are located in exons 7, 16, and 24. The complications of EDS type IV cannot be predicted from the nature of the specific mutations in COL 3A1.

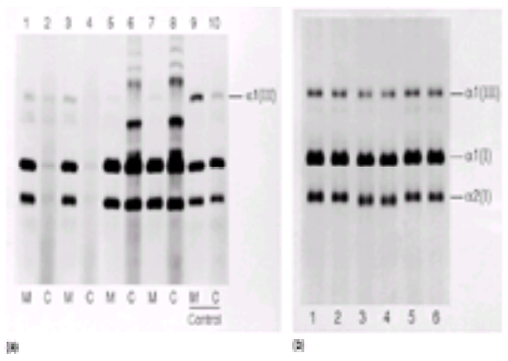

Fig. 4 Molecular analysis of collagen in EDS. (a) Typical collagen type III electrophoretic profile in fibroblasts after biosynthetic labelling in culture. There is virtually complete deficiency (tracks 5–8) or haploinsufficiency (tracks 1–4) compared with the normal pattern (9–10). M, collagen in culture medium; C, collagen recovered from cells. (b) Electrophoresis of radiolabelled collagen proteins in fibroblasts obtained from a patient with severe pes planus due to EDS VI, showing accelerated migration (tracks 3–4) of underhydroxylated, compared with normal, collagen molecules (tracks 1–2; 5–6).

Ehlers–Danlos syndrome types III, IV, and VI, with overlap to pseudoxanthoma elasticum

Much overlap is seen between these syndromes and others that affect connective tissue, including Stickler syndrome.

A characteristic feature of Ehlers–Danlos syndrome type III is the absence of scarring after skin injury; none the less, the skin is doughy and extensible but without fragility. The benign hypermobile syndrome is associated with joint hypermobility but without extensible skin. While this syndrome may be adapted to extreme sporting skills and gymnastics, it may also indicate heterozygosity for other collagen defects such as Ehlers–Danlos syndrome type VI, or even pseudoxanthoma elasticum.

The syndrome is associated with persistent arthralgia without evidence of inflammatory joint disease and is difficult to treat. Treatment includes physiotherapy, rest, and graded exercise combined with conventional pain relief. Later, joint-stabilizing exercises or supports combine with proprioceptive enhancement, and cognitive therapy may be beneficial. It is unknown whether these patients have defective pain receptors or whether they have acquired or inherited disturbed pain reception as a result of their long-standing collagen abnormality.

Marfan's syndrome

The Marfan syndrome is an archetypal defect of connective tissue with a strong hereditary basis causing characteristic skeletal, cardiovascular, and ocular disease. Patients with Marfan's syndrome are disproportionately tall and thin with abnormally long extremities and, often, a cadaverous physique (Fig. 5). Abraham Lincoln was possibly affected. Marfan's syndrome is caused by mutations in the human fibrillin gene and is an autosomal dominat trait.

Fig. 5 Marfan's syndrome. Early illustration of a family with skeletal and ophthalmic features transmitted from the affected father to his daughter and two sons.

Marfan's syndrome is not rare; it affects both sexes and occurs with a frequency of about 1 in 10 000. Marfan's syndrome has been reported in nearly all ethnic groups.

Diagnostic criteria

The Marfan syndrome overlaps with other inherited connective tissue disorders including Ehlers–Danlos syndrome type III, benign hypermobility syndrome, pseudoxanthoma elasticum, osteogenesis imperfecta, and homocystinuria. Typically, there is joint hypermobility, hyperextensibility of the skin with striae, blue sclerae, and tall stature. Combinations of one major and two minor criteria are sufficient to diagnose Marfan's syndrome. Marfan's syndrome also overlaps with ectopia lentis and Beals' syndrome (congenital contractural arachnodactyly)—both of which are unassociated with aortic dilatation and rupture but are caused, respectively, by mutations in the genes encoding fibrillin I or II.

Clinical features

It seems likely, in retrospect, that the patient originally described by Marfan may have suffered from Beals' syndrome with congenital contractural arachnodactyly, elongated feet, and crumpled ears. Classical Marfan's syndrome arises from mutations in fibrillin I. Typically, there are long, elegant (though spidery) fingers and toes with dislocated lenses caused by a rupture of the ciliary zonules early in life. The syndrome is associated with mitral valve prolapse and aortic dilatation. Aortic disease is associated with dissection and rupture; rarely, dissection and rupture of the pulmonary artery occurs in Marfan's syndrome.

Detailed manifestations diagnostic of Marfan's syndrome (Table 4)

- *Skeletal*—anterior chest deformity, including asymmetrical pectus excavatum or carinatum (Fig. 6); dolichostenomelia, arachnodactyly, scoliosis lordosis, tall stature, narrow arched palate and dental crowding, protrusio acetabuli, congenital flexion contractures, hypermobility, ocular ectopia lentis (Fig. 7), flat cornea, elongated globe, retinal detachment, myopia;
- *Cardiovascular*—dilatation of the ascending aorta (Fig. 8), aortic dissection, aortic regurgitation, mitral regurgitation with prolapse, calcification of mitral annulus, abdominal aortic aneurysm, arrhythmia, endocarditis;
- *Pulmonary*—spontaneous pneumothorax, atypical bullae;
- *Skin*—abdominal striae and abdominal hernias, including diaphragmatic and umbilical hernias;
- *Central nervous system*—dural ectasia, meningocele, dilatation of cisterna magna, learning disability and hyperactivity.

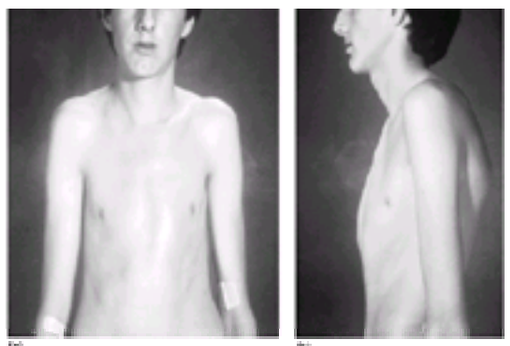

Fig. 6 Marfan's syndrome. (a) Frontal and (b) lateral views showing pectus deformity and mild kyphosis; the abnormal sternum and ribs are laterally compressed.

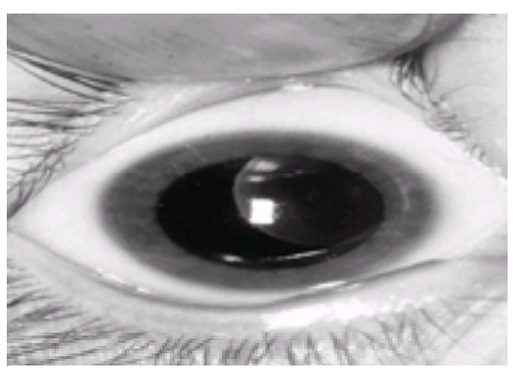

Fig. 7 Ectopia lentis in Marfan's syndrome. The lens is displaced upwards and medially; typically strong concave spectacle (aphakic) lenses are required to correct the high myopia.

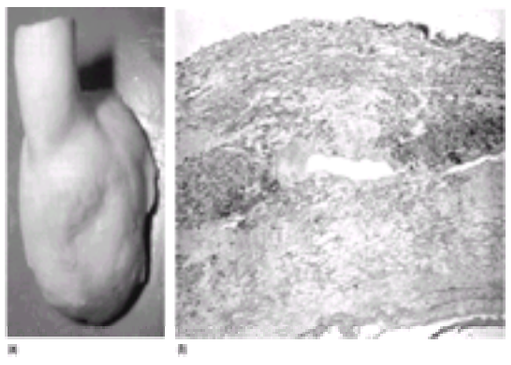

Fig. 8 Aortic disease in Marfan's syndrome. (a) Excised dilatated aortic root; (b) histological section of the aorta showing elastic degeneration of the aortic media.

The diagnosis of Marfan's syndrome may be confirmed by the involvement of at least two systems with at least one major manifestation as listed in Table 4; urinalysis (in patients not receiving vitamin B_6 supplements) should confirm the absence of homocystinuria.

The differential diagnosis includes: Stickler syndrome (vitreoretinal changes); osteoarthroses; mid-facial hypoplasia; Shprintzen–Goldberg syndrome (craniocarniosynostosis and retarded neurodevelopment, with Marfanoid features); and homocysteinuria. Since homocystinuria and Marfan's syndrome are distinct disorders—and because many patients with homocystinuria respond to specific therapies, for example pyridoxine supplements—clear distinction is necessary. Confusion between these two conditions is particularly likely in tall young patients with ectopia lentis and, except in unequivocal cases, patients with suspected Marfan's syndrome should always undergo appropriate biochemical testing for homocystinuria due to cystathionine b-synthetase deficiency or other causes.

Genetics

Marfan's syndrome is typically inherited as an autosomal dominant trait (see Fig. 5) and belongs to that group of genetic diseases in which a strong paternal-age effect occurs. The mean age of fathers of individuals who appear to harbour 'new' mutations is 5 to 10 years greater than average. Approximately one-third of all patients with Marfan's syndrome appear to be sporadic cases.

The gene responsible for Marfan's syndrome maps to chromosome 15. Mutations in the gene encoding fibrillin, a novel elastin-matrix protein, are responsible for Marfan's syndrome (Fig. 9). A second fibrillin gene maps to chromosome 5, mutations in which are responsible for Beals' syndrome (congenital contractural arachnodactyly that is not associated with defects in the ciliary zonules).

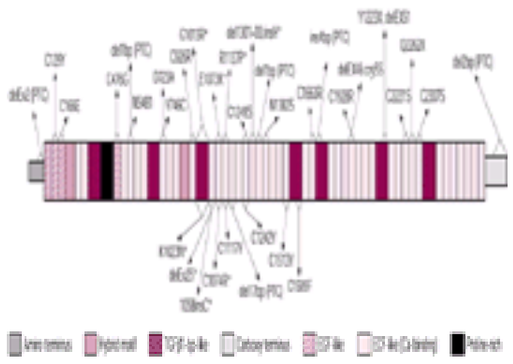

Fig. 9 Organization of the human fibrillin I gene (see text). Mutations associated with Marfan's syndrome are depicted.

The fibrillin I gene has a complex multi-exon organization and encodes calcium-binding, epidermal growth-factor-like and non-calcium binding, epidermal growth-factor regions. The gene encodes 65 exons encoding several conserved cysteines, common mutations of which are responsible for Marfan's syndrome; other fibrillin mutations have also been identified. Mutations in certain cysteines between exons 59 and 65 appear to be responsible for mild Marfan's syndrome that lacks aortic dilatation and is only associated with ectopia lentis. However, substitutions of cysteine codons elsewhere in the fibrillin gene may be responsible for more severe clinical phenotypes. Despite these findings, however, phenotype–genotype correlations in Marfan's syndrome are at present very loose. It is clear, however, that fibrillin mutations responsible for Marfan's syndrome are associated with disruption of the assembly of the fibrillin gene product and that dominant-negative mechanisms operate, as in the collagen defects. It seems likely that mutations of regions encoding epidermal growth-factor domains will disturb important homologous as well as heterologous, protein-matrix interactions of fibrillin.

The fibrillins are elastin-associated microfibrils, which assemble autonomously to form beaded microfilaments with ordered quasi-crystalline structures that can be studied by electron microscopy and other methods. Mutations that lead to the premature termination of the fibrillin I gene also appear to result in a milder phenotype than those mutations that cause small in-frame deletions or insertions. Exon-skipping events lead to the formation of in-frame mutant fibrillins lacking small protein sections which tend to interact normally with their wild-type congeners. In contrast, truncated mutants of fibrillin I typically disrupt the formation of the fibrillar structure. Most mutations in fibrillin I are private, and the presence of 65 exons in this large and complex genetic structure greatly impedes the molecular analysis of the fibrillin gene in patients with suspected Marfan's syndrome.

Treatment

The main causes of death in patients with Marfan's syndrome result from cardiovascular disease and complications elsewhere in the vascular system. Vigorous and regular surveillance is recommended with careful monitoring of aortic-root width and of the function of aortic and mitral valves by transthoracic echocardiography and periodic electrocardiography.

In patients with evidence of progressive aortic disease, including dilatation of the ascending aorta and valve ring, a Dacron graft, with or without an artificial or reconstituted aortic valve (the Bentall procedure), may be considered. There is also a strong case for joint management with experienced cardiac surgical colleagues in special clinics dedicated to the treatment of patients with Marfan's syndrome. Insertion of a Dacron graft to the aortic valvular ring, after excision of a terminally dilated aorta, requires reimplantation of the coronary arteries; in the best hands, the mortality rate of this procedure is less than 5 per cent, more than three-quarters of patients surviving 5 years. Scrupulous joint cardiac monitoring including echocardiography and magnetic resonance and CT imaging is recommended. A recent report by Gott and colleagues from Johns Hopkins Hospital, in the United States describes the results of aortic root replacement in 271 patients with Marfan's syndrome over the period 1976 to 2000. Most (> 85 per cent) patients underwent the Bentall procedure involving composite graft replacement of the aortic root. There were no 30-day deaths and more than 80 per cent of the operated patients were alive at the time this report was submitted for publication.

Patients with Marfan's syndrome benefit from the early introduction of adrenergic b-blockers to reduce the mean arterial pressure and pulse rate. Serial studies show that the mortality rate for aortic rupture in Marfan's syndrome is significantly reduced by the introduction of prophylactic b-blocking therapy; those so treated have a slower rate of aortic root dilatation. b-Adrenergic blockade should probably be introduced at an early age.

More than half of the patients with Marfan's syndrome suffer from dislocation of the optic lens—often in early childhood. Typically, the lens dislocates upwards. Thus surgical removal is indicated only if cataract or secondary glaucoma, due to the unusual lens position, intervenes. Upward dislocation may also lead to a greatly diminished visual acuity that cannot be corrected with spectacles; extraction of the lens is recommended under these circumstances.

Other complications of Marfan's syndrome including unstable joints, dislocation of the patella, progressive kyphoscoliosis, and recurrent pneumothoraces require surgical intervention. Clearly, many patients with Marfan's syndrome will require support from the psychological aspect and in the light of their diminished life expectancy. Women with Marfan's syndrome require counselling, not only about the genetic risk to their offspring but also because of the intrinsic risks of carrying a pregnancy to term. Re-evaluation of the heart during pregnancy may be recommended as a means of providing reassurance; the introduction of propanolol may be required during the course of labour and delivery to reduce cardiovascular stress.

Patients with Marfan's syndrome are at risk if they participate in competitive athletics. Indeed, the presence of Marfan's syndrome is a common cause of fatal aortic dissection and rupture in young adults. Those individuals with a clear diagnosis of the condition should be advised on an appropriate lifestyle and referred for genetic, as well as cardiological review, upon diagnosis. Several charities exist to support patients with Marfan's syndrome: the National Marfan Foundation in the United States as well as other lay groups in Europe and other countries provide critical information as well as psychological support for these patients and their families. Marfan's syndrome is a complex condition but, as a subject of intensive genetic and clinical study, benefits from active intervention with specific therapy (for instance, b-blockers) as well as rigorous monitoring, counselling, and supportive therapy.

Prognosis

Patients with Marfan's syndrome have a reduced life expectancy, principally as a result of the cardiovascular complications. Indeed, about 80 per cent of all deaths are due to aortic dilatation and its complications; the mean age of death in a series of 257 patients published in 1972 was 32 years. However, with the introduction of b-blocking agents and improvements in vascular and cardiac surgery, the prognosis has improved greatly and the early cohort studies were almost certainly subject to bias, since outcome was better in patients ascertained on the basis of family studies compared with those with sporadic disease.

Men with Marfan's syndrome have a lower survival rate than affected women—a conclusion based on several cohort studies. In a study of patients with Marfan's syndrome in Wales and Scotland between 1970 and 1990, the median survival for men was 53 years and for women, 72 years; the median age at death was 45 ± 16.5 years.

In a trial of 70 adolescent and adult patients with classical Marfan's syndrome, Shores and colleagues reported the results of treatment with propanolol. The treatment group received individualized doses of propanolol sufficient to induce negative inotrophy. When compared with the control group, those treated showed a reduced rate of aortic dilatation and improved survival—fewer of the treated patients reached clinical endpoints as determined by death, congestive cardiac failure, aortic regurgitation, aortic dissection, or the need for cardiac surgery.

Recently, several reports in the surgical literature describe the outcome of aortic root replacement in many hundreds of patients with Marfan disease: about one-third have had aortic dissection and in approximately one-half, aortic dilatation, 6.5 cm or less, was documented. Late operative death occurred in less than one-fifth of patients but subsequent series suggest that the prophylactic repair of smaller aortic aneurysms is preferable.

Pseudoxanthoma elasticum

Pseudoxanthoma elasticum (**PXE**) is an inherited defect of connective tissue with specific histological characteristics that reflect abnormally fragmented and calcified

elastic tissue. Fragmented elastin fibres occur principally in the skin, arteries, and retina where they are responsible for the main clinical effects of the disorder. Electron microscopy shows abnormalities of elastic fibres as well as associated collagen fibres. Pseudoxanthoma is now defined principally as a result of examination of the mutational spectrum of the responsible *ABCC6* gene and rigid clinical criteria. The systemic manifestations result principally from premature arterial stiffening and calcification; hypertension, thrombosis, and haemorrhage thus occur with widespread effects. Gastrointestinal bleeding, retinal disease causing visual loss, and stroke phenomena are among the most frequent complications of PXE.

Clinical genetics

The mode of transmission of PXE has been puzzling and controversial. This is reflected in the assignment of several Mendelian inheritance in man (**MIM**) catalogue numbers for autosomal dominant and recessive disease, respectively (MIM 177850, 177860; and 264800). In most (about 85 per cent) affected patients, the disease appears to occur sporadically without an overt family history. A minority of patients with PXE belong to pedigrees in which several siblings are affected in one generation; their parents (and other heterozygotes) often show generalized laxity of the joints, similar to Ehlers–Danlos syndrome type III. Transmission of authentic PXE through two or more generations consistent with an autosomal dominant pattern of inheritance occurs in no more than 5 per cent of cases.

Puzzling segregation patterns are frequent and obligate heterozygotes may show premature atherosclerosis. It is probable that homozygous or doubly heterozygous PXE is relatively common and that the carrier frequency may be as high as 0.5 to 1 per cent. Thus most families exhibiting anomalous inheritance of PXE may prove to be pseudodominant with matings between homozygotes or double heterozygotes and randomly distributed heterozygotes. In practical terms, the sibling recurrence risk for sporadic PXE lies between 1 in 800 and 1 in 4000; for authentic known autosomal recessive disease, this is 1 in 4. The risks of recurrent disease in the offspring of affected or potentially heterozygous children of known heterozygote parents are, providing no matings occur with consanguineous relatives, twice or the same as the odds for the sporadic cases—that is to say, no greater than 1 in 400. In due course, uncertainties about the transmission of PXE and genetic counselling will be clarified by mutation testing of the *ABCC6* gene responsible for this disease (see below).

Clinical features

Until recently there has been a lack of connection between the cutaneous and ophthalmological manifestations of PXE.

Although the typical orange–yellow xanthomatous appearance of flexual skin with underlying fragmentation of elastic had been long known, the association between this syndrome and the development of retinal angioid streaks due to elastic fragmentation of Bruch's membrane was not initially recognized. Pseudoxanthoma elasticum is associated with disease of both large and small arteries, as shown in the retina. Indeed, widespread involvement of the arterial media with attendant thrombotic complications is referable to many organs. Pseudoxanthoma is associated with bleeding from the gastrointestinal tract as well as stroke and, occasionally, lung disease.

Cutaneous

Typical changes of PXE in the skin develop in the face, neck, and flexual regions, including the axillas, antecubital fossas, inguinal folds, as well as the umbilicus. Similar changes may be observed around the mouth and nasolabial creases (Fig. 10 and Plate 2). The first changes are of thickening with a raised yellow discoloration between grooves, leading to plaque formation and an appearance resembling the skin of a plucked chicken, ' *peau d'orange*'. With time, the skin becomes inelastic and lax, thus causing considerable cosmetic alarm. In full-blown cases, an unattractive hound-dog appearance to the face and skin folds around the neck and groins develops, 'cutis laxa'. These changes may be aggravated by sun exposure and smoking.

Fig. 10 Skin lesions in pseudoxanthoma elasticum (PXE). (a) Typical flexural skin lesions of PXE of the lateral neck. (b) Widespread cutis laxa in PXE. (c) Mucosal infiltration of the lower lip in PXE. (d) Elastic van Gieson's stain of skin section showing mid-dermal elastic fragmentation and degeneration. (See also Plate 2).

Examination of the palate may show similar changes. Endoscopy of the stomach may reveal nodular submucosal lesions comparable to those present in peripheral skin.

Ophthalmic

The characteristic features of pseudoxanthoma elasticum in the eye are revealed by ophthalmoscopy (Fig. 11 and Plate 3). There may be only minor pigmentary changes, extending to disruption of the fibres in the preretinal membrane of Bruch causing angioid streaks. These retinal streaks vary in colour from dark red or maroon to black. Pressure on the eye, however, may discolour the streaks that underlie the retinal vessels and radiate from the optic disc.

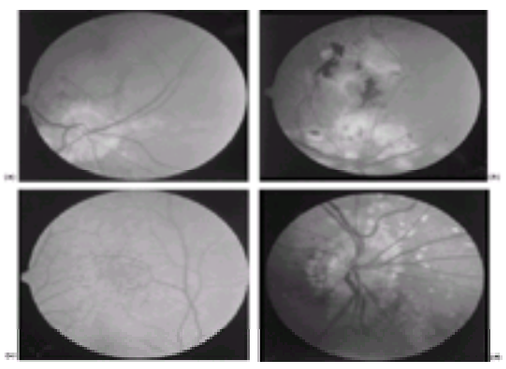

Fig. 11 Retinal changes in PXE. (a) Angioid streaks caused by fracture of the retroretinal Bruch's membrane—an early feature. (b) Macular haemorrhage with consequential choroideretinitis. (c) Specked *peau d'orange* mottling. (d) Salmon spotting and drusen. (See also Plate).

Angioid streaks occur in most patients beyond the age of 50 years but only in about one-third of patients with pseudoxanthoma ascertained in childhood.

In a cross-sectional study of 186 British patients with pseudoxanthoma elasticum conducted by the author in 1973, normal visual acuity was present in two-thirds: central visual loss occurred in 6 per cent; moderate visual impairment in 15 per cent; and mild impairment in 10 per cent. In contrast, fundoscopy was normal in less than 10 per cent of the patients: about one-third had angioid streaks and 13.5 per cent had degenerative maculopathy—a few patients had signs of haemorrhage. Myopia occurred in more than one-third of the patients and appeared to be at least three times more prevalent than in the general population. This implies that PXE

may predispose to myopia, perhaps by effects on corneal curvature, lens power, optical length, or vitreous composition.

Cardiovascular

In the cardiovascular system, the most striking abnormality of PXE is hypertension associated with an absence or weakness of peripheral arterial pulses. The author's cross-sectional survey of 186 British patients with PXE showed that 40 per cent had systemic hypertension: one in five of the patients experienced angina pectoris and one in ten had intermittent claudication; slightly more than 5 per cent had suffered transient ischaemic attacks; and 5 per cent had residual hemipareses following stroke episodes.

Occasionally, ischaemic features develop in the hands associated with resorption of digital tufts; these abnormalities are associated with a diminished Doppler pulse-wave velocity, reflecting a reduced amplitude of the systolic pulse wave. Other features include mitral valve prolapse and episodic and often torrential gastrointestinal haemorrhage usually from the stomach with or without a coincidental hiatal hernia or peptic ulcer. Bleeding may occur at other points including the renal, retinal, uterine, bladder, or subarachnoid spaces.

Many patients with PXE are hypertensive. This appears to increase the risk of bleeding, which may also be associated with premature arterial calcification in peripheral arteries as well as coronary vessels. Women with pseudoxanthoma elasticum often develop severe hypertension during pregnancy and complain of rapid progression of skin changes. Joint manifestations are not a feature of pseudoxanthoma elasticum.

Diagnosis

Several clinical criteria for the diagnosis of PXE have been defined by different authorities. The major and minor criteria preferred by this author are set out in Table 5; any two major, or one major and two minor, criteria are sufficient to diagnose the disease. The most important criteria for establishing the diagnosis are the presence of the appropriate skin eruption with histological evidence of elastic degeneration and calcification as determined by tissue biopsy.

Differential diagnosis

Angioid streaks may be seen in Paget's disease and sickle cell anaemia but are rarely as florid as those occurring in pedigrees affected by pseudoxanthoma elasticum. Rarely, diabetic retinopathy may be associated with angioid streaks. Angioid streaks have also been reported in patients with neurofibromatosis and tuberous sclerosis. Cutaneous manifestations of pseudoxanthoma elasticum may resemble those of extreme solar injury to skin associated with ageing. Characteristically, long-term penicillamine therapy leads to a syndrome that is a close phenocopy of pseudoxanthoma elasticum: elastosis serpingiosa perforans is frequently associated with pseudoxanthoma elasticum-like features. Pseudoxanthoma elasticum may also be considered in patients with Ehlers–Danlos syndrome in which cutis laxa is the sole manifestation.

Pathology

Pseudoxanthoma elasticum is diagnosed principally because of the occurrence of the constellation of clinical features, the family history, and a skin biopsy that reveals a characteristic fragmentation and disruption as well as calcification of the elastic fibres of the middle and deep zones of the corium. The use of von Kossa's stain, which identifies carbonate and phosphate complexes of calcium, together with Van Gieson's stain for elastic fibres is usually diagnostic; electron microscopy usually reveals electron-dense deposits throughout elastin fibres in the skin with a central core of mineral.

Molecular genetics

The gene responsible for pseudoxanthoma elasticum has been mapped in some affected pedigrees to a single locus on the short arm of chromosome 16 (16p31.1) (Fig. 12). Unexpectedly, the gene proved to be a multidrug-resistance and membrane ion transporter rather than an integral structural matrix protein. It spans 31 exons and encodes at the ATP-binding cassette and is a member of the cystic fibrosis-transmembrane regulator, *CFTR*, gene family.

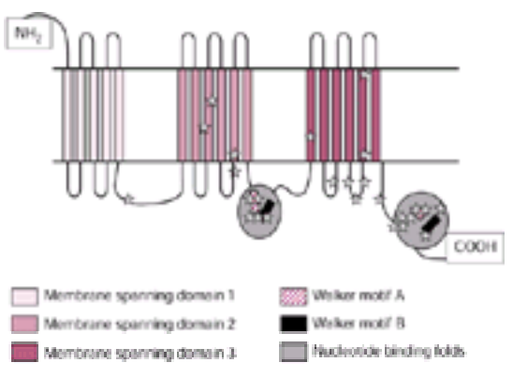

Fig. 12 Organization of the human PXE gene, *ABCC6*, a member of the ABC transmembrane ion transporter family. There are three membrane-spanning domains, each of which contains nucleotide-binding folds.

As discussed above, many patients with pseudoxanthoma elasticum belong to healthy families and are the only member with the condition, thus having no overt family history of the disease. Of the remaining 15 per cent of PXE patients, the most common family pattern is of several affected siblings in one generation showing diverse clinical expression.

Some families appear to show either autosomal recessive or dominant patterns of transmission. The relationship between these defects and mutations in the *ABCC6* gene implicated in pseudoxanthoma is unclear. Most patients appear to be homozygous for a defect in the *PXE* gene and some shared mutations appear to segregate with homozygosity for stop codons. At present, it is unclear what proportion of mutations in the *ABCC6* gene account for pseudoxanthoma elasticum and what proportion of patients are homozygous or compound heterozygotes at this locus. Despite the ambiguities, however, molecular analysis of the *ABCC6* gene provides an opportunity for systematic testing and clarification of the risk of transmission of the disease in affected pedigrees.

Disease frequency

At present, the population frequencies of pseudoxanthoma elasticum and mutations in the *ABCC6* gene are unknown, but in the United Kingdom at least 400 families are members of a PXE self-help patient association. Systematic analysis will be needed to provide additional information for diagnosis and genetic counselling in the population affected by PXE at large. So far, no clear correlation between the genotype and phenotype of the complex pseudoxanthoma syndromes has been possible.

Treatment and management

With time, patients with pseudoxanthoma elasticum are prone to premature-ageing phenomena in their skin and cosmetic embarrassment as a result. Patients with PXE are likely to suffer the results of vascular disease with stroke complicating hypertension and subretinal haemorrhages with visual loss; they are at increasing risk from severe gastrointestinal bleeding. Women with pseudoxanthoma elasticum should be advised to limit their family size. Excess exposure to ultraviolet light should be avoided as far as possible and sunscreen lotions used when this is not possible. Regular light exercise and avoidance of cigarette smoking are simple measures that also likely to be beneficial.

Although the skin and vascular lesions of pseudoxanthoma are associated with calcification, there is no evidence that calcium restriction influences the development of the disease. Nonetheless, some authorities recommend restricting calcium intake without evidence that this impedes the progression of the disorder. Because of

their severe systemic arterial disease, patients with pseudoxanthoma elasticum are advised to undergo regular monitoring of their vascular integrity and blood pressure. The rapid onset of severe systemic hypertension that is refractory to treatment may be due to unilateral renal artery stenosis—a well-described abnormality in PXE.

Contact sports, including boxing, and arduous exercise such as cross-country running should be avoided. Regular monitoring by a cardiologist and ophthalmologist may be beneficial, in that the occurrence of new vessel formation in relation to angioid streaks can be arrested by ocular laser therapy to prevent or diminish the risk of retinal haemorrhage. Similarly, regular blood pressure monitoring with the prompt use of b-blockers for hypertension where possible may delay the onset of peripheral vascular insufficiency and coronary heart disease.

Prompt treatment of systemic hyperlipidaemia, which may independently complicate the arteriopathy of PXE, is indicated to arrest arterial narrowing and prevent thrombosis. Antiplatelet drugs such as aspirin are contraindicated because of the increased risk of visual loss due to retinal bleeding and of gastrointestinal haemorrhage. Coronary bypass surgery is as successful and no riskier than for the general population; there is little evidence to judge the outcome of vascular surgical procedures that may be indicated for stenoses of carotid or other major peripheral arteries.

Patients with pseudoxanthoma elasticum may benefit from plastic surgery to remove redundant skin around the neck and groins, abdomen and breasts. This is particularly applicable to women who become embarrassed by rapid cutaneous changes after pregnancy or the menopause. Keloid formation may complicate such cosmetic surgery and it is advisable that those who operate are apprised of this risk in PXE.

Special problems in pregnancy

Pregnancy usually proceeds with only minimal difficulties; the theoretical risks of recurrent gastrointestinal haemorrhage and perineal tearing at delivery result only rarely in adverse outcomes in women with pseudoxanthoma elasticum. Maternal PXE does not appear to increase the risk of fetal abnormalities. However, scrupulous monitoring of systemic arterial blood pressure is recommended in pregnant patients with this disorder and during the peripartum period.

Prognosis

In some patients with pseudoxanthoma elasticum, premature death results from vascular disease which may cause critical occlusion of the arterial supply to essential organs or fatal bleeding. Death from a recurrent massive gastrointestinal haemorrhage was recorded in a 13 year-old patient and severe bleeding due to PXE has been reported in many younger children. McKusick has shown that many patients may live beyond 70 years and die of conditions unrelated to their connective tissue disorder; his study of 52 patients with PXE from the case records of the Johns Hopkins Hospital in the early 1970s showed that the median survival of this selected cohort was about 46 years. All the patients in this early group were dead by the age of 76 years.

19.3 Osteomyelitis

Anthony R. Berendt and Martin McNally

Introduction

Osteomyelitis is an ancient disease with a formidable reputation for persistence and relapse. It has been diagnosed in human fossil remains from the late Neolithic and was described by many classical writers including Hippocrates. The term indicates infection of the marrow (the suffix 'myelitis'), but will be used here to indicate any infection of bone, even if confined to the cortex (sometimes called 'osteitis').

Aetiology

The pathogens causing osteomyelitis are dominated by *Staphylococcus aureus*, but there are many other known causes as shown in Fig. 1.

Fig. 1 Microbiological causes and contexts in pyogenic arthritis and osteomyelitis.

Epidemiology

Classical acute haematogenous osteomyelitis has its peak incidence in childhood. Males are more commonly affected than females. In children, there appears to be a greater incidence in the Southern hemisphere and among certain racial groups (for example, aboriginal Australians), with rates varying from 10 to 100:100 000/year. Socioeconomic factors may contribute to this. Chronic osteomyelitis is such a diverse disease that an overall incidence and prevalence rate is not available, but incidence rises with age due to numerous causes including diabetes, peripheral vascular disease, infirmity, and ulceration.

Pathogenesis and pathophysiology

The critical step in pathogenesis is the access of bacteria to the bone. This may occur from a contiguous focus such as chronic ulceration, surgery, trauma, or soft tissue infection. Alternatively, the route may be haematogenous, with bacteria reaching bone via the circulation. The exact mechanism by which this occurs is uncertain. It is believed that the tortuous capillary loops in the metaphysis of the long bones, a favoured site for haematogenous osteomyelitis, are particularly vulnerable to thrombosis, leading to bacterial seeding. This is supported by a history of recent blunt trauma to the affected part in some 30 per cent of cases, and by observations that in most animal models it is necessary to injure bone to infect it. Even minor bone and soft tissue trauma exposes components of blood clot, extracellular matrix, and bone matrix to the bloodstream. Many pathogens, notably *S. aureus*, can adhere to such host proteins through specific receptors, and hence to tissues and cells, including endothelial cells and osteocytes.

An acute inflammatory response is elicited once bacteria gain access to bone and begin to multiply. This causes oedema within bone and soft tissue, and the procoagulant effect of inflammation may also cause thrombosis in vessels. The result can be bone infarction, possibly contributed to by bacterial toxins.

As infection progresses, it propagates within the bone marrow, and through the cortical bone via the Haversian canals. Pus may form within cancellous bone and beneath the periosteum (see Fig. 2 for a schematic diagram). It may break into the soft tissues and even extend to the surface as a sinus tract. Subperiosteal pus under pressure will strip off the overlying periosteum, tracking along the length of the bone and around its circumference. The vascular consequences of this are critical to the evolution of the disease, since the outer aspect of the cortical bone is vascularized by the periosteum, the inner by the endosteal circulation. If the endosteal blood supply is already compromised, periosteal stripping causes bone death. Thus, large pieces of bone, segments, or even whole long bones can die.

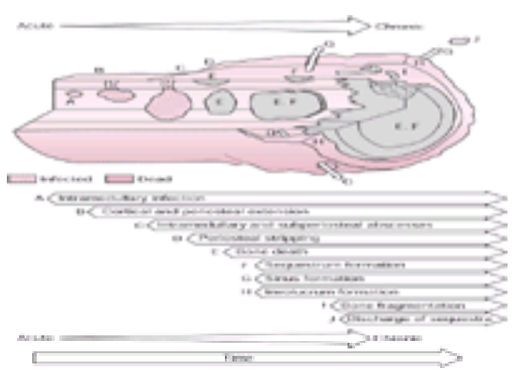

Fig. 2 Schematic diagram showing the evolution from acute to chronic osteomyelitis, with progressive necrosis, sequestration, and sinus formation.

Dead bone can potentially be revascularized and remodelled, but only if it remains in physical continuity with living bone. However, the action of bone-resorbing cells,

recruited and activated by inflammation and some bacterial products, is frequently to separate dead from healthy bone. This produces a detached piece of dead bone called a sequestrum. Small sequestra can be extruded from sinuses or wounds and the episode of osteomyelitis may arrest spontaneously; larger sequestra result in continuing infection and inflammation. Over time more bone tends to be involved, sometimes resulting in new sinuses, with extension into soft tissues and contiguous joints. As bone is resorbed and killed, the loss of structure may lead to pathological fracture.

Chronicity and relapse result both from this host response and from features of bacterial physiology. The body cannot mount effective inflammatory responses in dead tissue or chronic abscesses. Bacteria adhere to the inanimate surfaces of dead bone and, as in implant-related infections, form complex structures in which they are enmeshed in an antiphagocytic polysaccharide matrix (the whole known as a biofilm). Their growth state alters within this, rendering them phenotypically resistant to almost all antibiotics. They may even be able to persist as metabolically crippled forms called small-colony variants: these can exist within cells and are also resistant to many antibiotics that would otherwise kill wild-type organisms.

If periosteum has been stripped and remains viable, it produces new bone called the involucrum. This may develop circumferentially, producing a shell of living bone around the dead segment, thus preserving mechanical strength. Defects in the involucrum, through which sinuses communicate with sequestra, are called cloacae.

Variations on this theme occur when flat bones or those of the spine are involved in haematogenous infection. In discitis and vertebral osteomyelitis, infection of the disc space is rapidly followed by involvement of the two adjacent vertebral bodies. The infection may arrest as disc material is replaced by granulation tissue, eventually leading to fusion of the two involved vertebral bodies. In flat bones such as the pelvis or the skull, infection can spread very rapidly in the cancellous bone between the two tables, before exciting a periosteal reaction.

The 'inside-to-out' nature of haematogenous osteomyelitis is in distinction to the 'outside-to-in' nature of contiguous focus osteomyelitis. In this case, periosteum is destroyed as part of the same process that has destroyed the overlying soft tissues. Cortical bone is killed and infection can enter the medullary cavity, thereafter extending as for haematogenous disease. Sequestra may separate and be discharged, but the adverse biological factors that led to the initial soft tissue loss may impair subsequent healing and permit further bone infection to occur.

Clinical features

Acute osteomyelitis presents as a rapid onset of pain and loss of function in the affected limb, usually accompanied by high fever and malaise. It predominantly affects the metaphyses adjacent to the large weight-bearing joints. Prostration, sweating, rigors, and vomiting from accompanying bacteraemia (in 50 per cent of cases) may also be present. In neonates and infants, extension from the medullary cavity of the metaphysis through the cortex leads into the joint space, since the joint capsule extends beyond the growth plate. Thus in this age group an acute septic arthritis can be an early complication, or a presenting feature, of an acute osteomyelitis (see Chapter 18.7.1). In older children, the joint capsule is much tougher and inserts at the growth plate, the cartilage of which forms a barrier to the passage of infection from the metaphysis to the epiphysis and the joint.

Chronic osteomyelitis presents more variably. Pain is the rule, unless there is underlying neuropathy, and there may be severe disability in the context of an ununited fracture or when the spine is involved. Wound or sinus tract drainage is usually present when osteomyelitis complicates ulceration, instrumentation, or other surgery. Bone may be visible, palpable with a gloved finger or located with a sterile metal probe in the base of an ulcer or sinus. There may be evidence of soft tissue swelling or induration, and bony tenderness on palpation or percussion. Some patients experience repeated flares of fever and acute illness due to inadequate drainage of deep pus or rapid extension into previously uninvolved soft tissue or bone. Minor ill health is common, manifesting as weight or appetite loss, general malaise, or poor glycaemic control in diabetics. This is often only noticeable in retrospect, once the infection has been treated.

Patients with vertebral osteomyelitis may present with bacteraemia and acute back pain (raising the possibility of spinal epidural abscess and the need for urgent diagnosis and treatment), but more often they present with chronic back pain and non-specific illness. Differential diagnoses of degenerative back pain, osteoporotic fracture, metastatic disease, and myeloma should be considered. The presence of severe back pain at rest, often of a deep and unremitting character that patients can distinguish from previous back pains, and of night pain, should prompt consideration of the diagnosis. Spinal tenderness is an unreliable sign. Deformity and the development of neurological signs are late features.

Special forms of osteomyelitis include chronic multifocal osteomyelitis (this presents with pain but, despite radiological and histological features of osteomyelitis, is culture-negative), unifocal osteomyelitis with a similar behaviour, and Brodie's abscess (a well-defined chronic abscess in bone with a very indolent presentation). The interested reader is referred to specialist texts for details.

Laboratory diagnosis

The white-cell count, erythrocyte sedimentation rate (**ESR**), and C-reactive protein (**CRP**), though generally elevated in acute infection and flares of chronic disease, are non-specific and occasionally normal in chronic disease. It is helpful to see elevated inflammatory markers fall after treatment, but this may take several weeks. The alkaline phosphatase level is of no value, being neither sensitive nor specific for bone infection. Blood cultures are essential in acute infection, when they may be the only means of obtaining a microbiological diagnosis. Serological tests are useful for the diagnosis of syphilis, yaws, brucellosis, and occasionally bartonellosis.

Plain radiography of chronic osteomyelitis typically shows patchy osteopenia or frank bone destruction, loss of definition of the cortex, areas of sclerosis, or periosteal reaction with new bone formation. These changes take many weeks to develop fully. In acute infection, the earliest changes visible on plain radiography are soft tissue swelling (minimum 2–3 days), followed by periosteal reaction (7 days), and last, bone destruction (10 days). If radiographs are abnormal, the changes need to be distinguished from those of a tumour, trauma, or degenerative bone disease. Repeat imaging at an interval of 2 to 4 weeks can sometimes help as osteomyelitis is usually an aggressive process. For more rapid clarification of diagnosis, however, specialized imaging is needed.

Ultrasound can identify subperiosteal collections and soft tissue abscesses, and demonstrate sinuses. Computed tomography (**CT**) scanning may be able to identify cortical erosion that has been missed on plain films and can demonstrate sequestra within bone. Reformatted images make it possible to produce saggital or coronal images (for example, to view vertebral body endplates) and three-dimensional images for surgical planning. Soft tissue collections are easily identified. Other than a lack of sensitivity early in the disease, the principal pitfalls of CT scanning are the radiation dose, its lack of ability to determine the extent or activity of infection, and its sensitivity to image degradation from orthopaedic metalware.

Isotope scanning is widely used, but there is a lack of consensus on the utility of various tests. Conventional, three-phase, technetium bone scans are sensitive but non-specific. Specificity may be increased by the addition of indium-labelled leucocyte scanning. Other reagents include labelled immunoglobulins, anti-leucocyte monoclonal antibodies, and even radiolabelled antibiotics, but the performance of these tests has not yet been rigorously evaluated.

Magnetic resonance imaging (**MRI**) is the standard and best method for diagnostic imaging of osteomyelitis (Fig. 3 and Fig. 4). It can detect intra- and extraosseous oedema, abscesses, dead bone, and sinus tracts. It can distinguish active from inactive infection. Other than cost (rapidly falling) and availability (rising), the main problem with MRI is its extreme sensitivity to physiological changes that may persist long after surgery or treatment and to metal artefact from orthopaedic implants (and even to microscopic metallosis when they have been removed).

Fig. 3 Acute osteomyelitis of the femur in a child. (a) The plain radiograph, after one day of illness, is normal. *S. aureus* was isolated from blood cultures. (b) MRI

scan (STIR sequence) of the same patient at day 2. There is marked soft tissue and intraosseous oedema (high signal). Subperiosteal abscesses can clearly be seen as linear areas of high signal just outside the cortex, tracking proximally up the femur from the metaphysis.

Fig. 4 (a) A plain radiograph showing chronic osteomyelitis of the proximal tibia in an adult. There is patchy sclerosis and lysis. (b) MRI of the same patient (*T*1 sequence) showing oedema (low signal) in the area corresponding to plain film changes, but also an additional, distal, intramedullary satellite lesion.

The microbiological standard for the diagnosis of osteomyelitis is the growth of bacteria from samples of bone, taken with precautions to prevent contamination from superficial flora. Pus or soft tissue associated with infected bone may be acceptable, but sinus tract or wound swab cultures are not. The bacteria isolated from wounds are poorly predictive of the deep flora because of asymptomatic colonization. Cultures of this kind should be reserved for detecting multi-resistant organisms (such as methicillin-resistant *S. aureus* (**MRSA**)) for infection control purposes. Fluid for microscopy and culture can be aspirated from periosteal or subperiosteal abscesses. In infants, needle aspiration of bone itself is safe and well tolerated if performed by someone experienced in the technique. Bone biopsy can be performed surgically or percutaneously (by needle biopsy). In neuropathic ulcers, bone can be obtained by curettage. The laboratory must be made aware of the importance and nature of any specimen sent so that it can be appropriately processed and interpreted.

Bone histology is also an important diagnostic test: the presence of inflammatory cells, dead bone, and active bone remodelling are hallmarks of infection. They may provide the only confirmation of infection in cases where the culture results are unhelpful.

Treatment

Acute osteomyelitis

Acute osteomyelitis may respond to antibiotics alone, and with better outcomes, if treated before the onset of bone death or abscess formation. It is therefore an orthopaedic emergency. Treatment should be initiated on the basis of the clinical diagnosis, with investigations used to confirm the diagnosis once treatment has begun. Following blood cultures, high-dose intravenous antibiotics effective against *S. aureus*, b-haemolytic streptococci, and aerobic Gram-negative rods should be given. Appropriate regimens include a cephalosporin or the combination of an antistaphylococcal penicillin and gentamicin. Vancomycin and gentamicin will be necessary if the patient has risk factors for infection with MRSA. Antibiotics can be modified based on culture results. For patient comfort, the limb should be splinted and elevated, and analgesia given.

Surgery is indicated if abscesses are present: these must be opened, and the bone is usually drilled to allow free drainage of contained pus. The soft tissues are protected to avoid further devascularization and consequent bone death.

The necessary duration of antibiotic therapy is unclear. Treatment for less than 4 weeks is associated with higher rates of relapse.

In children, oral therapy can be considered when:

- the patient is afebrile after an initial 48 to 72 h of intravenous treatment;
- there is no evidence of abscess formation, metastatic infection, or bacteraemia;
- there is no suspicion from the history or imaging that infection has been prolonged or is associated with dead bone;
- the organism is sensitive to reliably bioavailable oral antibiotics; and
- compliance with therapy can be assured.

Less information is available for adults. The greatly lower rates of bone blood flow and turnover make revascularization and absorption of necrotic bone, and delivery of antibiotics and white cells, less certain. For these reasons it is common, but not universal, to treat adult acute osteomyelitis with intravenous therapy for periods of at least 4 weeks. Certain drugs, notably clindamycin and ciprofloxacin, are highly bioavailable and have proved useful in the treatment of osteomyelitis. There are no randomized studies to inform decisions about the requisite total duration or duration of intravenous therapy.

Chronic osteomyelitis

To achieve long-term arrest of infection, the management of chronic osteomyelitis usually requires multiple, co-ordinated inputs. The aims of treatment are to:

- remove dead bone and soft tissue;
- drain abscesses;
- eliminate cavities (which act as surgical 'dead spaces');
- ensure skeletal stability;
- restore soft tissue cover (if necessary using plastic surgery);
- define pathogens from high-quality specimens and administer appropriate antibiotics;
- correct adverse local and systemic host factors;
- support the patient physically and psychologically;
- reconstruct the skeleton if need be; and
- rehabilitate the patient.

Surgery

Detailed consideration of surgical methods is beyond the scope of this book, but major surgical advances include the use of free-tissue transfer and bone transport techniques to close very large bony and soft tissue defects. These permit much more radical approaches to the resection of diseased and dead tissues. In this way, surgery can potentially convert chronic infected wounds with dead bone and soft tissue into contaminated wounds of living bone with healthy soft tissue cover.

Antibiotics

These play an important role in increasing success after surgery, though the 'added value' they confer is uncertain and may depend on the extent of surgical resection. Some conditions often respond well without surgery including:

- discitis and vertebral osteomyelitis, with surgery reserved for abscess formation, progressive pain or deformity, instability, spinal cord compression, or persistent

sepsis;
- tuberculous osteomyelitis, reserving surgery for mechanical complications, pain, or persistent infection;
- osteomyelitis of small bones such as the phalanges. In the treatment of a diabetic patient with foot osteomyelitis, accompanied only by limited podiatric debridement of bone, some authorities quote that chronic osteomyelitis can be arrested in 70 to 80 per cent of cases, but recurrences are common.

Antibiotics may also help when the patient refuses surgery, when there is no clearly definable surgical 'target', or when the risks and consequences of surgical resection would be worse than the disease itself.

The choice of antibiotics should be guided by the culture results. Intravenous therapy may need to be prolonged (for up to 6 weeks) where there is thought to be a risk of unreliable compliance, absorption, or efficacy with oral therapy. If properly supervised, many patients can be discharged from hospital while remaining on intravenous therapy. Periods of total antibiotic treatment vary from weeks to many months, but there is a growing trend to shorten the duration of treatment when an expert surgeon has achieved a radical surgical clearance, provided that local and systemic host factors are favourable. Antibiotics can also be delivered locally, by implanting antibiotic-loaded bone cement or collagen fleece at the time of surgery. The relative efficacies of intravenous, oral, or local antibiotics have received little attention and treatment protocols vary widely.

Adjunctive treatment

It is important to correct other host factors that may affect wound and bone healing. These include ischaemia (which may need intervention), anaemia, diabetes, hypoxia from respiratory or cardiac failure, peripheral oedema, poor nutrition, and smoking. Where neuropathy has contributed to ulceration, appropriate pressure relief is essential for healing and for secondary prevention. This must be continued indefinitely through the provision of specialist footwear, cushions, or beds. The patient must be taught about neuropathy and trained in methods to prevent further ulceration. Hyperbaric oxygen therapy has been widely employed with anecdotal success, but its efficacy and precise role are unclear and definitive randomized trials are awaited.

Prognosis

Chronic osteomyelitis can be arrested in 80 to 90 per cent of cases, usually when surgery has been combined with antibiotic treatment. Though most common within the first year, delayed recurrence is well recognized, and relapse can occur up to 50 years after an initial infection has apparently been treated successfully. This poses major difficulties for the design of trials on new treatment, as extended follow-up is needed to make definitive statements about success or failure. Chronic multifocal osteomyelitis has a good prognosis, usually self-arresting, albeit after some years. Longstanding active disease may be associated with the eventual development of squamous metaplasia or carcinoma in a sinus, and rarely with the deposition of amyloid.

Prevention and control

There are no proven means of preventing haematogenous osteomyelitis, but prompt treatment can prevent chronicity. Contiguous osteomyelitis can be prevented by the appropriate management of open fractures, of infective foci close to bone, and of chronic wounds whenever these are close to a bone or joint. Pressure-area care in immobile patients and of a diabetic patient's foot can prevent ulceration and subsequent osteomyelitis.

Occupational, quality of life, and psychosocial aspects

Pain, chronic sepsis, and physical disability have a significant impact on quality of life. Psychological well being is further affected by issues common to all chronic diseases, together with anxiety and depression over:

- risks of death, paralysis (e.g. in spinal infection), and limb loss;
- stigmatizing effects of chronic discharging wounds; and
- feelings of anger or failure where infection has resulted from an accident or surgery.

Areas of uncertainty needing further research

There is a need to define the true health, psychosocial, and economic burden of osteomyelitis. More information is needed on pathogenetic mechanisms and on molecular diagnosis. The optimal duration and route of administration of antibiotics and their place alongside differing forms of surgery needs clarification, as does the role of adjunctive medical treatments such as hyperbaric oxygen.

19.4 Osteoporosis

Juliet Compston

Introduction

Osteoporosis is characterized by a reduction in bone mass and disruption of bone architecture, resulting in increased bone fragility and an increase in fracture risk. These fractures are widely recognized as a major health problem in the elderly population, resulting in an estimated annual cost to British health services of £1.5 billion. One in three women and one in five men surviving to the age of 80 years will suffer a hip fracture due to osteoporosis; demographic changes over the next 50 years are predicted to lead to at least a doubling in the number of these fractures, largely as a result of increased longevity.

Epidemiology

Osteoporotic fractures are termed fragility fractures (defined as occurring after a fall from standing height or less). They may occur at a number of skeletal sites but fractures of the distal radius (Colles' fracture), spine, and proximal femur are most characteristic. The incidence of osteoporotic fractures increases markedly with age; in women, the median age for Colles' fractures is 65 years and for hip fracture, 80 years. The age at which vertebral fracture incidence reaches a peak has been less well defined but is thought in women to be between 65 and 80 years. In men, no age-related increase in forearm fractures is seen but hip fracture incidence rises exponentially after the age of 75 years. The prevalence of vertebral fractures rises with age in men, although less steeply than in women.

The remaining lifetime risk of osteoporotic fracture in 50-year-old British white women has been estimated at 14 per cent for the hip, 11 per cent for the spine, and 13 per cent for the radius; for any osteoporotic fracture, this risk approaches 40 per cent in women and 13 per cent in men. For women this risk is similar to that of cardiovascular disease and is approximately six times higher than that of breast cancer. In the United Kingdom it is estimated that approximately 60 000 hip fractures and 50 000 Colles' fractures occur annually; for vertebral fractures, the figure of 40 000 reflects only those which are clinically diagnosed and probably represents only about one-third of all fractures. There are marked geographical variations in the incidence of osteoporotic fractures, the reasons for which remain only partially defined. The condition is most common in Asian and Caucasian populations but rare in African and American black populations.

Clinical features

Colles' fractures typically occur after a fall forwards on to the outstretched hand. They cause considerable inconvenience, usually requiring 4 to 6 weeks in plaster and long-term adverse sequelae are seen in up to one-third of patients. These include pain, sympathetic algodystrophy, deformity, and functional impairment.

Spinal fractures are characterized by varying degrees of vertebral deformity (Fig. 1) and may occur spontaneously or as a result of normal activities such as lifting, bending, and coughing. A minority of vertebral fractures (possibly around one-third) present with acute and severe pain at the site of the fracture, often radiating around the thorax or abdomen. The natural history of this pain is variable; in general, there is a tendency for improvement with time but resolution is often incomplete. Multiple vertebral deformities result in spinal deformity (kyphosis), height loss, and corresponding alterations in body shape with protuberance of the abdomen and loss of normal body contours. These changes are commonly associated with loss of self-confidence and self-esteem, difficulty with daily activities, and increased social isolation. The clinical impact of spinal fractures is thus substantial, although often underestimated.

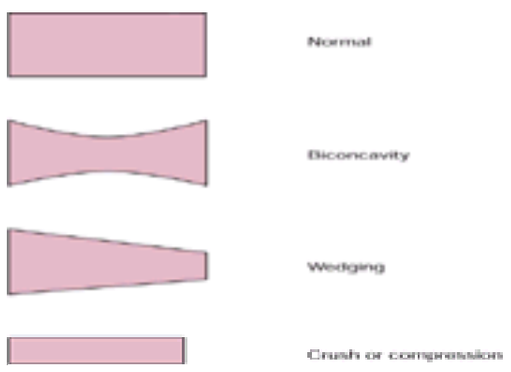

Fig. 1 Vertebral deformities associated with osteoporosis. It should be noted that some degree of biconcavity can be a normal variant and wedge and crush deformities are most commonly associated with symptoms.

Of all the osteoporotic fractures, hip fractures cause the greatest morbidity and mortality. They almost always follow a fall, either backwards or to the side, and require admission to hospital and surgical treatment. Because hip fractures characteristically affect frail elderly people, postoperative morbidity and mortality are high; at 6 months after fracture, mortality rates of 12 to 20 per cent have been reported. Only a minority of patients regain their former level of independence following a hip fracture and up to one-third require institutionalized care.

Pathogenesis

Lifetime changes in bone mass are shown in Fig. 2. Peak bone mass is attained in the third decade of life and age-related bone loss is believed to start in both men and women around the beginning of the fifth decade; thereafter bone loss continues throughout life. In women, there is an acceleration of the rate of bone loss around the time of the menopause, the duration of which is poorly characterized but may be 5 to 10 years.

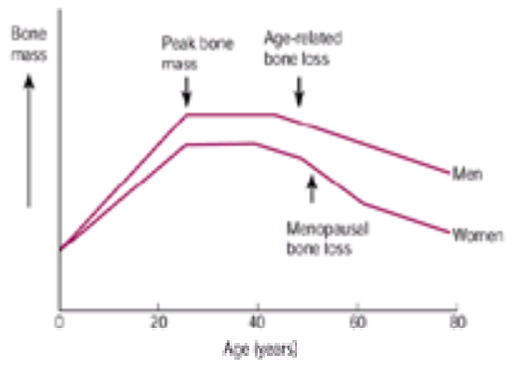

Fig. 2 Schematic representation of lifetime changes in bone mass in men and women. (Reprinted with permission from Compston JE, 1995, Osteoporosis, corticosteroids and inflammatory bowel disease. *Alimentary Pharmacology and Therapeutics* **9**, 237–50.)

Bone mass in later life thus depends both on the peak bone mass achieved in early adulthood and on the rate of age-related bone loss. Genetic factors strongly influence peak bone mass, accounting for up to 70 to 80 per cent of its variance. A number of genes are likely to be involved; a polymorphism of the collagen type IA1 gene has been shown to be associated both with low bone mineral density and fracture and it is likely that other genes will be identified in the near future. Sex hormone status, nutrition, and physical activity also influence peak bone mass.

In women, oestrogen deficiency is a major pathogenetic factor in menopausal bone loss. In men, the relationship between age-related bone loss and declining testosterone levels is less well documented. In the elderly, vitamin D insufficiency and secondary hyperparathyroidism are common and contribute to age-related bone loss. Other potential pathogenetic factors include declining levels of physical activity and intestinal calcium malabsorption.

A number of endogenous and exogenous risk factors for osteoporosis have been identified. In the former category, advancing age, female gender, Caucasian or Asian race, and a family history of osteoporosis (particularly a maternal history of hip fracture) are the most important. Strong exogenous risk factors include hypogonadism in either sex, glucocorticoid therapy, low body weight, and previous or prevalent fragility fracture. Several diseases, including hyperthyroidism, hyperparathyroidism, inflammatory bowel disease, and chronic renal or liver dysfunction are also associated with increased risk of osteoporosis. Finally, low dietary calcium intake, vitamin D deficiency, immobilization, cigarette smoking, and excessive alcohol intake have adverse effects on bone mass.

Risk factors for falling are major determinants of fracture risk, particularly for hip fracture in the elderly. Their recognition is important, since many are modifiable. They include poor visual acuity, neuromuscular weakness or incoordination, reduced mobility, cognitive impairment, and the use of sedatives, tranquillizers, and alcohol. There are also many environmental hazards that increase the risk of falling, such as uneven paving stones, poor lighting, and loose carpets and wires.

Pathophysiology

The mechanical competence of the skeleton is maintained by the process of bone remodelling, in which a quantum of bone is removed by osteoclasts followed by the formation, in the cavity so created, of new bone by osteoblasts. Under normal circumstances resorption always occurs before formation and the amounts of bone resorbed and formed within each bone remodelling unit are similar.

In menopausal bone loss, there is an increase in the number of bone remodelling units on the bone surface (increased bone turnover), resulting in a higher number than normal of remodelling units undergoing resorption at any one time. In addition, within each of these units less bone is formed than resorbed, leading to a negative remodelling imbalance. It is believed that one of the early, and probably transient effects, of oestrogen deficiency is to increase the activity of osteoclasts, probably by suppressing apoptosis. Increased osteoclastic activity causes an increase in the depth of erosion of bone by these cells, contributing to the trabecular penetration and disruption of bone architecture that characterizes postmenopausal osteoporosis.

The pathophysiology of other forms of osteoporosis remains to be fully defined. In glucocorticoid-induced osteoporosis, reduced bone formation and low bone turnover predominate in those treated long term, but there is evidence that in the early stages of treatment there is an increase in bone turnover and osteoclast activity. The alterations in bone remodelling responsible for osteoporosis in men have not been established, but the lesser degree of structural disruption of cancellous bone during ageing suggests that reduced bone formation plays a greater role in age-related bone loss in men than women. Whether this applies to men with osteoporosis, however, is uncertain.

Diagnosis

Several techniques are available for the assessment of bone mass; these include single and dual energy X-ray absorptiometry, quantitative computed tomography, and ultrasound. At present, dual energy X-ray absorptiometry is regarded as the optimal approach in clinical practice because of its ability to measure bone mineral density at axial and appendicular sites, its good reproducibility, and the very low doses of radiation required. However, ultrasonography is currently being evaluated and may become more widely adopted in the future.

The rationale for the use of bone densitometry in clinical practice is the demonstration, in prospective studies, of a continuous and inverse relationship between bone mineral density and fracture risk. For every standard deviation decrease in bone mineral density, there is a two- to threefold increase in fracture risk; this is quantitatively similar to the relationship between blood pressure and stroke and greater than that observed for serum cholesterol and coronary heart disease. Bone mineral density at a wide range of sites, including spine, hip, radius, and os calcis, is able to predict fracture risk, although the best predictive value, at least in the case of hip fracture, is provided by measurement at the potential fracture site.

The relationship between bone mineral density and fracture risk forms the basis for the densitometric classification of osteoporosis. This is based on T scores—standard deviation scores above or below normal peak bone mass—and defines osteoporosis as a bone mineral density T score at the hip and/or spine below –2.5. Osteopenia is defined as a T score between –1 and –2.5 and established osteoporosis as a T score below –2.5 in the presence of one or more fragility fractures. Although these are diagnostic rather than interventional criteria, a T score below –2.5 would generally be considered as an indication for intervention because of the high associated fracture risk.

Since population-based screening cannot be justified at present, patients are selected for bone densitometry in clinical practice on the basis of risk factors and/or symptoms or signs suggestive of osteoporosis. Indications for bone densitometry are shown in Table 1. Bone densitometry should only be performed where the result will influence clinical management; it is not indicated in patients with clear evidence of established osteoporosis and in the very elderly, in whom low bone mass is almost universal, bone densitometry is rarely useful in directing clinical management. In addition, the presence of osteophytes, extraskeletal calcification, and vertebral and/or spinal deformity in the elderly significantly reduces the accuracy of spinal measurements.

Secondary causes of osteoporosis should be excluded where appropriate. A full blood count, liver function tests, serum calcium and phosphate levels, thyroid function tests, plasma immunoelectrophoresis, and Bence-Jones protein determination should be performed in the first instance with further investigation if indicated. In men, in whom secondary causes are more common, serum testosterone, gonadotrophins and prolactin, and 24-h urinary cortisol should also be performed.

Biochemical markers of bone resorption (such as urinary deoxypyridinoline, pyridinoline, N-terminal and C-terminal cross-linked telopeptides of type I collagen) and formation (such as osteocalcin, bone-specific alkaline phosphatase, C-terminal propeptide of type I procollagen) have been shown to be useful in the prediction of fracture risk, particularly when combined with bone mineral density measurements, and in the monitoring of response to treatment. However, their role in clinical practice has not been firmly established.

Current therapeutic options for osteoporosis

A number of options are now available for the prevention of osteoporotic fractures in postmenopausal women (Table 2). For historical reasons the level of evidence on which the registration of these interventions is based varies widely; thus adequately powered, randomized, controlled trials with fracture as the primary end-point exist only for alendronate, raloxifene, and combined calcium and vitamin D, whereas in the case of hormone replacement therapy, evidence for antifracture efficacy is based almost solely on observational data which are subject to bias and likely to overestimate beneficial effects.

Hormone replacement therapy

Hormone replacement at the menopause, whether unopposed or combined with progestogens, prevents bone loss and there is evidence, mainly from observational studies, for protection against fracture at the hip, spine, and wrist. At least in terms of its effects on bone mineral density, oestrogen replacement is effective both when given at the menopause and if started some years later; however, it is generally less well tolerated in more elderly women and compliance is correspondingly lower.

There is growing evidence for attenuation of the beneficial effects of hormone replacement therapy on the skeleton following cessation of therapy, both in terms of its effects on bone mineral density and protection against fracture. The implications of these findings are first, that lifelong treatment after the menopause is likely to be required to maintain optimal fracture protection, and second, that the most cost-effective treatment strategies will be those which target high-risk women for treatment.

Short-term side-effects of hormone replacement therapy include breast tenderness and withdrawal bleeding. Although continuous combined 'no-bleed' preparations are now available, some vaginal bleeding is experienced by up to 30 per cent of women during the first few months of such therapy. The principal concern with long-term use is an increase in the risk of breast cancer; after 5 to 10 years of use, the relative risk increases by around 30 per cent, which is significant in terms of absolute risk for a disease which affects 1 in 12 postmenopausal women. Other adverse extraskeletal side-effects include a two- to threefold increase in risk of venous thromboembolism and there may also be a small increase in the risk of endometrial cancer.

Hormone replacement therapy also has important short-term and long-term benefits. It is effective in alleviating vasomotor and other menopausal symptoms and may also have beneficial effects on postural stability. Observational data indicate a significant reduction in morbidity and mortality attributable to coronary heart disease, although this remains to be confirmed in prospective studies. However, a recent study indicates that combined hormone replacement therapy in older women may not be effective in the secondary prevention of coronary heart disease; in that study, more deaths due to heart disease occurred during the first year in treated women than in controls. Other potential but as yet unproven benefits of long-term hormone replacement therapy include improved cognitive function, protection against Alzheimer's disease, and a reduction in risk of colon cancer.

Accurate evaluation of the risk/benefit ratio of hormone replacement therapy cannot at present be performed because of the lack of prospective data which are required to demonstrate the magnitude of potential risks and benefits. Nevertheless, many women are reluctant to take indefinite hormone replacement therapy because of the increase in breast cancer risk and treatment is thus often limited to a finite period of between 5 and 10 years.

Bisphosphonates

The bisphosphonates are synthetic analogues of the naturally occurring compound pyrophosphate. They inhibit bone resorption by complex and only partially understood mechanisms and may also inhibit mineralization. Three bisphosphonates are currently licensed for use in osteoporosis. Etidronate is administered cyclically and intermittently, the 3-month cycle consisting of 400 mg daily of etidronate for 2 weeks followed by calcium only for 76 days. In contrast, alendronate is given as a single daily dose of 10 mg and calcium is not included in the formulation; once weekly doses of 70 mg of alendronate have an equivalent therapeutic effect. Thirdly, risedronate is given as a single daily dose of 5 mg.

These bisphosphonates have been shown to prevent bone loss in the spine and hip, both in healthy perimenopausal women and in more elderly women with osteoporosis. The magnitude of this effect is similar for both agents; however, unlike the majority of antiresorptive agents, bisphosphonate therapy (at least in the case of alendronate) is associated with a sustained although small increase in bone mineral density, which is believed to be due to hypermineralization of bone. This may occur as a result of the suppression of bone turnover and its consequences for bone strength have not been established.

In a large, randomized controlled trial, treatment with alendronate for nearly 3 years was associated with a reduction of approximately 50 per cent in vertebral and non-vertebral fractures in postmenopausal women with osteoporosis. In the case of cyclic etidronate therapy, the clinical trials did not demonstrate statistically significant fracture reduction, but favourable trends for vertebral fracture were observed after 3 years of treatment and observational data also indicate protective effects against hip and other non-vertebral fractures. Finally, risedronate has been demonstrated to reduce vertebral and non-vertebral fractures, including hip fractures, in postmenopausal women with osteoporosis. A significant reduction in vertebral fractures was observed in the first year of treatment.

Bisphosphonates are generally well tolerated. Gastrointestinal side-effects may occur, especially with aminobisphosphonates, and a small number of cases of erosive oesophagitis have been reported with alendronate. It is therefore important that patients take the drug according to the instructions, namely in the morning with a full glass of water, 30 min before food, drink, or other medications, and remaining upright for 30 min after the dose. Alendronate is contraindicated in patients with oesophageal abnormalities or disease and should be withdrawn immediately if dyspepsia or dysphagia develop during therapy.

The optimum duration of bisphosphonate therapy is unknown. Despite their high skeletal retention, preliminary indications are that bone loss resumes soon after treatment is discontinued, although further studies are required in this area. There are theoretical concerns that prolonged suppression of bone turnover may have adverse effects on bone strength and, at present, treatment is usually given for a period of 5 to 10 years.

Raloxifene

Raloxifene is a selective oestrogen receptor modulator which has oestrogenic effects in the skeleton without the unwanted effects of oestrogen in the breast and endometrium. In randomized controlled trials, raloxifene has been shown to prevent menopausal bone loss in healthy early postmenopausal women; in addition, a 30 per cent reduction in vertebral fracture rate was seen after 3 years of treatment with 60 mg daily in postmenopausal women with osteoporosis. Beneficial effects on bone mineral density are seen both in the spine and proximal femur but no effect of raloxifene therapy on non-vertebral fracture has been demonstrated.

Raloxifene is taken orally as a single daily dose. Minor adverse effects include leg oedema, leg cramps, and hot flushes. As with hormone replacement therapy there is a two- to threefold increase in the relative risk of venous thromboembolism. Raloxifene does not alleviate, and may exacerbate, menopausal vasomotor symptoms; it should therefore be avoided in perimenopausal women with such symptoms.

The extraskeletal effects of raloxifene are of considerable interest. In particular, a highly significant protective effect against breast cancer which is oestrogen receptor positive has emerged in the clinical trials; overall, after 4 years of treatment there was a 75 per cent reduction in new cases of breast cancer, this figure rising to 90 per cent when only cases that were oestrogen receptor positive were considered. Raloxifene use is not associated with vaginal bleeding and does not increase the incidence of endometrial hyperplasia or carcinoma. The effects of raloxifene on cognitive function and cardiovascular disease risk have not been established; in the context of the latter, effects on serum lipid profile similar but not identical to those observed with oestrogen have been reported.

Calcitonin

Calcitonin may be administered parenterally or intranasally; both forms of treatment have been shown to prevent spinal bone loss in postmenopausal women, but treatment benefits at other sites such as the proximal femur and radius have not been clearly demonstrated. The effects of calcitonin on fracture rate are controversial although some randomized controlled trial data indicate beneficial effects on vertebral fracture risk. Adverse effects with intranasal calcitonin are rare. Nausea and flushing may occur shortly after parenteral administration of calcitonin and vomiting and diarrhoea also sometimes occur. These symptoms are usually transient but may persist for some hours after injection.

Vitamin D and calcium

There is increasing evidence that vitamin D and calcium supplementation protects against non-vertebral fractures in elderly subjects. Thus in a randomized controlled

trial of vitamin D and calcium in daily doses of 800 IU and 1.2 g, respectively, a significant reduction in hip and other non-vertebral fractures was seen after 12 to 18 months of treatment in a cohort of very elderly women (mean age 84 years) who were living in sheltered accommodation. Subsequently, a significant reduction in non-vertebral fractures was reported in community-dwelling men and women aged over 65 years in a randomized controlled trial of 700 IU of vitamin D and 500 mg of calcium daily. It is not possible from these studies to deduce the relative contribution of vitamin D and calcium to the observed benefits; vitamin D without calcium has been shown in some studies to reduce non-vertebral fracture rate in the elderly, but this finding has not been universal. The important question of whether vitamin D alone reduces hip fracture thus remains unanswered at present.

Calcitriol

Calcitriol (1,25-dihydroxyvitamin D, the active metabolite of vitamin D) preserves bone mineral density in women with postmenopausal osteoporosis and there is evidence that it also reduces vertebral fracture rate, although the latter finding has not been universal. Effects on non-vertebral fracture have not been documented. Calcitriol is given orally in a dose of 0.5 to 1.0 µg daily; hypercalciuria and hypercalcaemia may occur and serum calcium levels should be monitored at regular intervals.

Calcium

Beneficial effects of calcium on bone mineral density have been documented in children and adults, particularly at appendicular skeletal sites. In lumbar spinal bone, these effects are generally less evident and may be transient; the benefits of calcium are also less marked in perimenopausal women, presumably because of the dominant effects of oestrogen deficiency. Although several small studies have reported a reduction in vertebral fracture rate in calcium-supplemented individuals, evidence from adequately powered studies is not available and calcium should be regarded as an adjunct to treatment rather than as definitive therapy.

Non-pharmacological interventions

Hip protectors have been shown to protect against hip fracture in randomized controlled trials in the elderly and should be considered in all those at high risk, including those who have already sustained a hip fracture. Physiotherapy has an important role to play in the management of pain and restricted mobility and measures such as hydrotherapy and TENS (transcutaneous electrical nerve stimulation) are often effective. In elderly patients, occupational therapy is also often helpful and assessment of the risk of falling should be performed with advice on reducing risk where appropriate.

Weight-bearing exercise can produce modest, site-specific increases in bone mineral density in younger adults, but its skeletal effects in postmenopausal women are less certain and it should not be regarded as a definitive treatment. In the elderly, exercise may reduce the risk of falling and, if a fall should occur, improve the neuromuscular protective responses; however, the efficacy of this approach in reducing fracture risk has yet to be proved in randomized controlled trials.

Other aspects of treatment

Pain associated with acute vertebral fracture is often underestimated and can be difficult to manage. Very strong analgesics should be avoided where possible since these may increase the risk of falling and bed rest should be restricted to a minimum to avoid further bone loss associated with immobilization. Calcitonin is often effective in the treatment of pain associated with vertebral fractures; salcatonin is usually given subcutaneously in a dose of 100 IU daily or on alternate days for a period for 3 to 6 weeks.

Treatment of glucocorticoid-induced osteoporosis and osteoporosis in men

Cyclical etidronate, alendronate, and risedronate therapy have all been shown to be effective in the prevention of glucocorticoid-induced osteoporosis and are licensed in the United Kingdom for this indication. In patients receiving high doses of glucocorticoids (such as 15 mg of prednisolone daily or equivalent) for 3 months or more or who have strong risk factors for osteoporosis, bisphosphonate therapy should be started immediately; in those receiving lower doses (more than 7.5 mg) for 6 months or more, bone densitometry should be performed and prophylaxis instituted if the T score is below –1.5.

Alendronate is the only treatment currently licensed for the prevention of osteoporotic fractures in men. Beneficial effects on bone mineral density have been reported after treatment with testosterone or cyclical etidronate, but effects on fracture risk have not been reported for either agent.

19.5 Avascular necrosis and related topics

D. O'Gradaigh, C. A. Speed, and A. J. Crisp

Introduction

Osteonecrosis is a non-specific term for the death of bone, which was attributed to suppuration or trauma; Pasteur's study of bacteria in 1860 and the advent of clinical radiography led to recognition that many cases were aseptic. Phemister and others showed the importance of ischaemia in many cases and the collective term avascular necrosis has since been used. Associated disorders are the osteochondroses and osteochondritis dissecans. Although these conditions are separate entities, they are linked by the involvement of ischaemia (Table 1).

Avascular necrosis

There are 15 000 new cases of adult avascular necrosis annually in the United States. Males are more commonly affected (8:1), the majority under 50 years of age, with the exception of knee avascular necrosis, which particularly affects women over the age of 50. Any bone can be affected, the femoral head and condyles, the head of humerus, and the talus being the most commonly involved. he small cuboidal bones of the wrist and foot are less frequently affected. The unifying feature is a relatively poor vascular supply to subchondral bone through end arterioles with a limited collateral network.

Bone comprises osseous tissue and cartilage, with myeloid tissue, fatty marrow, and a sinusoidal network of vessels packing the inexpandable bone compartment. Several local mechanisms may be involved alone or in combination in vascular compromise. These include disruption of the vessel wall, raised intramedullary pressure through intraosseous venous congestion, and intravascular occlusion by atherosclerosis, thrombosis, or embolization. Death and lysis of haemopoietic cells and lymphocytes occurs with a subsequent macrophage and fibroblast response. Revascularization follows with deposition on the dead trabeculae of fibrous tissue (in traumatic cases) or of lamellar bone (in non-traumatic cases). Simultaneous formation and resorption occur, with progressive loss of cartilage. Should adequate revascularization and bone deposition not occur, articular collapse ensues.

Numerous conditions have been associated with avascular necrosis (Table 2). Alcoholism and corticosteroids are the most common, where fat embolization precipitating thrombosis is implicated. Higher doses and longer duration of steroid treatment increase the risk of avascular necrosis, though there is considerable variation. Interactions between steroids and the conditions for which they are prescribed may contribute, as some conditions (systemic lupus erythematosus, renal transplantation) appear to confer a particular risk of avascular necrosis.

Avascular necrosis should be considered in anyone presenting with bone pain, particularly those with associated risks. Since dead bone is painless and biomechanically sound, clinical symptoms of activity-related pain and joint dysfunction usually develop insidiously with the onset of repair processes or following articular collapse. Local tenderness, warmth, oedema, synovitis, and reduced range of movement may be evident. Infection must always be excluded.

Low-grade symptoms may precede radiological changes by months or years. In the early stages of avascular necrosis, radiographs are normal. Areas of mottled increase in radiodensity may be seen initially. A radiolucent crescent in subchondral bone (suggestive of fracture), cyst formation, and flattening and fragmentation of the articular surface may be noted in intermediate stages. Joint space narrowing and other degenerative signs occur in advanced stages. Bone scintigraphy is more sensitive in early, potentially reversible, avascular necrosis. A 'cold' area with a surrounding area of increased uptake is characteristic but rare, and non-specific increased uptake is more commonly seen. Magnetic resonance imaging (**MRI**) has become the first choice of investigation for early diagnosis. In addition to its high sensitivity, it is valuable for assessing the extent of the lesion.

Primary prevention is the ideal in 'at risk' groups, where a high index of suspicion must be maintained. Judicious use of corticosteroids, early diagnosis, and treatment of sickle-cell and metabolic syndromes and of alcoholism may reduce risk to bone. Guidelines are available for decompression in divers to reduce dysbaric complications.

Management of avascular necrosis depends on stage classified according to the imaging oulined above. Three main groups can be identified. Early stages (normal radiographs, positive scintigraphy or MRI) may resolve with conservative management. In some centres, raised intramedullary pressure is believed to be a critical factor, and core decompression biopsies (also useful for diagnosis) are therefore advocated; however, fracture is a significant complication. The intermediate group (crescent formation, flattening, etc.) often require surgery, including attempts at reperfusion (with vascularized pedicle grafts or an implanted artery), osteotomy, or arthroplasty. Arthroplasty is recommended in those with advanced degenerative changes. Rare complications of avascular necrosis include osteomyelitis (especially in sickle-cell disease) and malignancy.

Osteochondroses

Osteochondrosis is due to disturbance of endochondral ossification at a previously normal site of growth, involving chondrogenesis and osteogenesis. This can occur through mechanical (macro- or microtrauma) and/or vascular mechanisms which may vary according to the site involved. For example, Legg–Calvé–Perthes disease is considered to be of vascular aetiology. Osteochondrosis can occur at any epiphysis and involve the articular surface, the epiphyseal plate, or apophysis (secondary ossification centre or site of ligament or musculotendinous attachment). These areas are significantly weaker than surrounding soft tissue structures and are particularly vulnerable in growth spurts, where musculotendinous tightness (resulting in poor flexibility) contributes to apophyseal disorders. Growing children and adolescents are most commonly affected, males three times more frequently than females, the onset of symptoms occuring earlier in girls. Osteochondroses are classified into articular, non-articular, and physeal disorders (Table 1). Although they do not continue past the attainment of skeletal maturity, complications may come to light in adulthood.

Specific stages have been identified in the pathogenesis. Arrest of ossification at the affected site occurs, followed by revascularization and bone resorption. Later reossification may result in alteration in shape. It is often difficult to differentiate osteochondroses from normal ossification centres on radiography. Initial reduction in size and fissuring of the ossification centre may appear, followed by sclerosis and alteration in shape. Radiographs of the contralateral side should be obtained for comparison. In early lesions, scintigraphy may show increased uptake, and MRI may show cartilage disruption. While most cases are self-limiting, a poorer prognosis with development of osteoarthrosis is associated with larger lesions and older age at presentation. In apophysitis, radiography is not usually indicated, but may show loose ossicles or bony enlargement at the enthesis. Management is symptomatic, with reassurance, modification of activities, local application of ice, and non-steroidal anti-inflammatory drugs as required combined with a stretching regime.

Osteochondritis dissecans

Osteochondritis dissecans is a distinct form of osteochondral injury through the articular cartilage in a diarthrodial joint. It can affect all ages, but usually presents in teenage males, typically at the distal femur and particularly the lateral aspect of the medial femoral condyle. Other commonly affected sites are the patella, talus, and capitellum of the humerus. Although trauma has been identified in 50 per cent of cases, this is an unlikely aetiological factor in those under 15 years of age. A familial pattern is noted in 10 per cent, and lesions may be multiple and occur at several sites suggestive of multiple epiphyseal dysplasia.

The osteochondral fragment is susceptible to avascular necrosis. It may remain *in situ* or become partially or completely detached, which may precipitate effusion and mechanical symptoms of locking, catching, and giving way. The disorder usually presents with progressive activity-related pain. Local swelling may be evident if trauma has occurred. External tibial rotation when walking is characteristic in medial femoral involvement.

Plain radiographs may be normal and specialized views (such as the notch view of the knee) may be required, showing a typical subchondral crescent sign or loose bodies. Scintigraphic findings resemble those of the osteochondroses, while computed tomography is useful to determine the site and size of the lesion; the overlying cartilage can be evaluated by MRI.

Treatment aims to achieve union of the fragment and restoration of joint surface integrity. In young patients with open epiphyses, healing may be achieved with conservative management, as outlined for osteochondrosis. Joint immobilization may be necessary. Surgery should be considered in skeletally mature patients, those who fail conservative management, or those with detached fragments. This involves debridement and internal fixation of the fragment with drilling or vascular grafting of the base. The prognosis depends on the patient's age, and the stability and location of the fragment. Degenerative joint disease in later life is a major complication.

20.1 Structure and function of the kidney

J. D. Williams and A. Phillips

> The organs of the human body were created to perform ten functions, among which is the function of the kidney to furnish the human being with thought.
>
> Leviticus Rabba 3, Talmud Berochoth 61B

Introduction

The human kidney is formed by the fusion of a number of lobes. The structure of a single lobe is best understood by examining the unilobar kidney of a small mammal: in the rat, for example, the medulla is enfolded by the cortex on all sides other than its pelvic aspect, where it projects as a papilla into the renal pelvis. The renal cortex, containing all the glomeruli and the proximal and distal convoluted tubules appears in coronal section to be distinct from the pyramidal-shaped medulla, which contains the loops of Henle. The medulla is divided into an outer and inner medulla, the outer medulla being subdivided into an outer and inner stripe.

The nephron

The functional unit of the kidney is the nephron, which begins at the glomerulus (Fig. 1). The urinary space (the cavity between the glomerulus and its surrounding Bowman's capsule) leads into the proximal tubule, which itself can be subdivided into a convoluted segment and a straight segment. The straight segment of the proximal tubule descends into the medulla and changes abruptly into the descending limb of Henle's loop. This loop penetrates for varying distances into the medulla before returning to the cortex. The longer loops pass all the way into the inner medulla, whilst the short loops only reach the outer medulla. Generally speaking, long loops belong to nephrons of glomeruli lying adjacent to the medullary region, while the shorter loops belong to the more superficial glomeruli. The descending limb of Henle bends sharply back at its lowest point to form the ascending limb, which at another abrupt transition forms the medullary part of the thick ascending limb. This leads up into the cortex where it becomes convoluted and comes into close contact with the vascular pole of its own glomerulus, forming the juxtaglomerular apparatus. Further along the nephron the thick ascending limb becomes the distal convoluted tubule and then the connecting tubule, which joins the cortical collecting duct. Each collecting duct receives connecting tubules from about 12 nephrons and then opens onto the surface of a papilla.

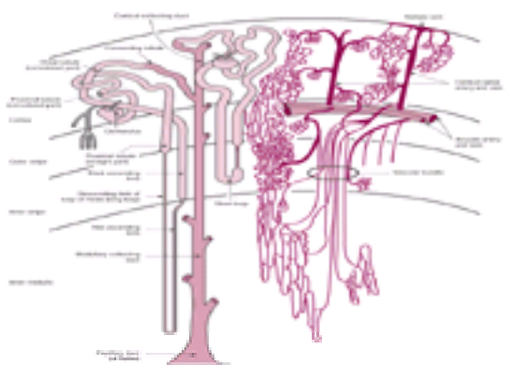

Fig. 1 The nephron and its blood supply. (Reproduced from Williams JD, *et al. Clinical atlas of the kidney*. Gower Publishing, London, with permission.)

The renal blood supply

Structure

The renal artery divides into the interlobar arteries and enters the renal substance at the columns of Bertin (the area between adjacent lobes). At the junction of the cortex and medulla the arteries divide again and form the arcuate arteries (Fig. 1). Each arcuate artery gives rise to cortical radial arteries that ascend through the cortex: there is no direct arterial supply to the medulla. The afferent glomerular arteries arise from the cortical radial arteries and directly supply the glomeruli. Efferent glomerular arteries drain the glomeruli and then supply the peritubular capillaries of the cortex and medulla, a unique arrangement meaning that the peritubular capillary supply is exclusively postglomerular. Efferent glomerular arteries can be divided into two types: those from the superficial and midcortical glomeruli supply the capillary plexus of the cortex; those from juxtamedullary glomeruli form the blood supply to the renal medulla. Within the outer stripe they divide into the descending vasa recta, which penetrate the inner stripe in vascular bundles. The renal medulla is drained by the ascending vasa recta, which traverse the inner stripe within the vascular bundle and then join the cortical radial veins. The vascular bundles of the medulla represent the vascular component of the countercurrent exchange mechanism between the blood entering and leaving the medulla. Interestingly, the vascular bundles are organized such that the perfusion of the inner medulla is kept totally separate from the perfusion of the outer medulla. The cortical radial veins join the arcuate veins to eventually form the interlobular veins, which run alongside corresponding arteries.

Function

Renal blood flow is influenced by intrarenal and extrarenal factors. Autoregulation within the kidney maintains a relatively stable blood flow to the glomerulus over a range of arterial pressure. This phenomenon seems to be mediated by events intrinsic to the kidney since it has been demonstrated in both denervated and isolated kidney preparations.

The glomerulus

Structure

On entering the glomerulus (Fig. 2(a)) the afferent arteriole divides into primary capillary branches, each of which gives rise to an anastomosing capillary network that

forms a glomerular lobule. These capillaries then coalesce into the efferent arteriole within the tuft. The structural organization of the capillaries is unlike that found in any other part of the body. The capillary basement membrane (glomerular basement membrane) forms the barrier across which filtrate is generated. Embryologically, the glomerulus is the interface between the ureteric bud (or hollow nephrogenic vesicle) and the metanephrogenic cap, which develops into the capillary plexus. The result of this is a basement membrane formed by the fusion of the basement membrane of the capillaries and the basement membrane of the nephrogenic vesicle. This glomerular basement membrane (**GBM**) forms the skeletal framework of the glomerular tuft.

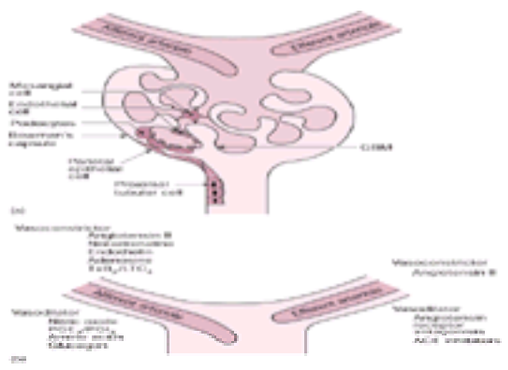

Fig. 2 The glomerulus: (a) structure; (b) regulation of glomerular blood flow by vasoactive agents.

Although on electron microscopy the GBM appears as a three-layer structure with a central lamina densa and outer lamina rara interna and externa, this is probably an artefact. Freeze–fracture studies have suggested uniformity in the basement membrane from its outer to inner aspects. The major components of the membrane include a framework of type IV collagen linked by heparan sulphate proteoglycans (**HSPG**) and laminin, the basement membrane charge being provided by the heparan sulphate component (subtypes of which include perlican and agrican). Type IV collagen consists of a triple helix of fibres with a large non-collagenous globular domain at the C-terminal end (called NC1). This NC1 domain of the collagen molecule is the target for Goodpasture's disease, and mutations of the collagen chains are responsible for Alport's syndrome.

The endothelial cells, the basement membrane, and the podocytes form the filtration barrier. The endothelial cells are fenestrated (60 and 100 nm in diameter) and the lack of a diaphragm across the fenestrations exposes the basement membrane directly to the glomerular capillary contents. The luminal surface of the endothelial cells is negatively charged by polyanionic glycoproteins, but these are not present on the fenestrae. The capillary loops are incomplete (a tube of fenestrated endothelial cells surrounded only on its epithelial aspect by a basement membrane) and are held together on their inner aspect by the mesangial cells. Thus the basement membrane has an opening on its mesangial aspect so that the endothelial cells are in direct contact with the mesangium. At the vascular pole of the glomerulus the capillary basement membrane is reflected to form the parietal epithelium of Bowman's capsule.

The outer aspect of the filtration barrier is provided by the epithelial cells (podocytes), which interdigitate on the surface of the glomerular lobules. The foot processes of adjacent podocytes are separated by the filtration slits, which are bridged by the slit diaphragms and are the sites through which the glomerular filtrate passes. The pores have a central proteinaceous core with side arms linking to each adjacent cell, forming a structure with a zipper-like appearance and a width of about 40 nm. The luminal surface of the podocyte and the slit diaphragm are rich in negative charge, being covered in glycoproteins. The podocyte surface adjacent to the basement membrane expresses a number of adhesion proteins that ensure firm anchorage to the membrane.

The mesangium forms the pillar to which the GBM scaffold is attached. The interaction between the mesangial cells and the basement membrane provides the mechanism for the contractility of the glomerular tuft, and the means whereby the surface area of the tuft can be varied. The spaces between the mesangial cells are filled by the mesangial matrix and consist of a number of different collagens, as well as glycoproteins, fibronectin, and proteoglycans. This mesangial matrix provides a channel for the migration of a variety of molecules from the glomerular capillaries, with trafficking centrally towards the vascular pole of the glomerulus.

Function

The glomerular filtration barrier, consisting of the endothelial pores, the glomerular basement membrane, and slit diaphragms, will exclude molecules on the basis of size, shape, and charge. Size selectivity is imparted by the matrix of the GBM itself, as well as by the integrity of the podocytes. The matrix, formed by the type IV collagen molecules, consists of a series of interlinking pores, the narrowest of which determines the size of molecules that can pass through. Thus any pathological change to the structure of the matrix is likely to result in a greater permeability of the GBM. The resistance to the movement of water and small molecules is provided by the endothelial pores, the basement membrane, and by the available surface area of the slit diaphragms, the last of these probably being the effective barrier. The charge barrier, whose efficiency is disputed, is provided by the negative charge of the basement membrane and to a lesser extent by the surface of the endothelial and epithelial cells.

The effectiveness of the filtration barrier is dependent not only on the integrity of the basement membrane but also on the function of the epithelial cells. Most studies have demonstrated that changes in barrier function are closely correlated with significant alteration to the podocytes. These include changes in the surface area of the slit diaphragm (slit diaphragm frequency) as well as detachment of podocytes from the basement membrane. There is now a large body of evidence to suggest that HSPGs are involved in both the charge- and size-selective properties of the GBM and, furthermore, that alterations in GBM HSPGs may be important in the development of proteinuria.

Production of glomerular filtrate

The number of functioning glomeruli and the filtration rate at each single glomerulus determines the GFR. There are approximately a million glomeruli per human kidney, of which 90 per cent are in the outer two-thirds of the cortex and are fairly homogenous in terms of structure and function. The remaining 10 per cent, which are located in the juxtamedullary region, are larger with a higher single-nephron GFR compared with cortical glomeruli.

Single-nephron GFR is determined by a number of factors. First, the pressure of blood in the glomerular capillary and the hydrostatic pressure of the fluid in Bowman's space determine the pressure difference that drives the movement of fluid across the glomerular capillary wall, the transglomerular hydrostatic pressure difference or ‡*P*. Second, the gradient in colloid osmotic pressure (‡*p*) across the filtration barrier: this is equal to the colloid osmotic pressure within the glomerular capillary less the colloid osmotic pressure in Bowman's space (which, in effect, is zero). The difference between ‡ *P* and ‡*p* is the net ultrafiltration pressure. Other determining factors are water permeability (*K*) and *f* (the area available for filtration, namely the surface area of the slit pores between podocytes), these two combined forming the glomerular filtration coefficient or *Kf*. Hence:

$$\text{single-nephron GFR} = (‡P - ‡p) \times Kf.$$

SNGFR can be regulated by alterations in the ultrafiltration coefficient *Kf*, the net ultrafiltration pressure, or both. A change in the net ultrafiltration pressure may arise due to a change in the hydraulic pressure ‡*P*, the capillary plasma oncotic pressure (‡*p*), and/or alterations in the initial glomerular capillary plasma flow rate (the latter dictates changes in protein concentration with distance along a capillary network and hence affects colloid osmotic pressure).

Glomeruli contain receptors for a number of hormones that are capable of modifying the filtration rate (see Fig. 2(b)). These include vasoconstrictors such as adenosine, angiotensin II, and endothelin as well as vasodilators including dopamine, bradykinin, prostacyclin, and nitric oxide. Some of these vasoactive molecules are produced within the kidney, whilst others are delivered by the systemic circulation, and many studies have examined the effects of hormones on glomerular ultrafiltration. It is clear from the preceding discussion that, in addition to ‡ *P* (that is, change in hydraulic pressure), the glomerular filtration rate (**GFR**) is dependent on the capillary plasma flow rate and the ultrafiltration coefficient (*Kf*), all of which may be altered by hormones. Vasoconstrictor substances such as angiotensin II and norepinephrine are capable of producing substantial reductions in renal plasma flow, generally with little change in GFR. Angiotensin II, for example, causes constriction of both afferent and efferent arterioles with a resultant decrease in capillary plasma flow, a reduction in *Kf*, but little change in the single-nephron GFR (**SNGFR**) due to an increase in ‡*P*. Increased afferent arterial tone caused by endothelin or adenosine will decrease renal blood flow, decrease ‡ *P*, and therefore

decrease GFR. By contrast, dilatation of the afferent arteriole by nitric oxide or prostaglandins will also cause an increase in ‡ *P*, but with an increase in renal blood flow and hence an increase in GFR.

In the normal adult human, water is filtered by the glomerulus at a rate of 80 to 200 ml/min. The glomerular filtration rate is critically related to all functions of the kidney and is closely regulated by mechanisms that maintain a constant high value for GFR. In practical clinical terms, the estimation of GFR is achieved by measuring the renal clearance of a substance that is freely filtered at the glomerulus and not absorbed or secreted by the renal tubules. For discussion of the methods of measuring GFR in clinical practice, see Chapter 20.3.1.

The proximal convoluted tubule

Structure

The main function of the proximal tubule is to reabsorb the bulk of filtered water and solutes, and its structure shows numerous adaptations for this purpose. Proximal tubular epithelial cells are tall and columnar with a well-developed brush border, resulting in a 40-fold increase in the apical surface area of the cells (Fig. 3). In addition they possess extensive basolateral interdigitation, increasing the basolateral cell surface area. The apices of the cells are held together by junctional complexes: these are called 'tight junctions' (zona occludens), of the leaky variety, with a low electrical resistance that allows some transepithelial transport. The bases of the cells rest on the tubular basement membrane, which separates them from the peritubular capillaries. Another characteristic feature is the presence of large numbers of mitochondria, intimately associated with the basolateral cell membranes where the Na^+/K^+-ATPase is located, and whose function is to provide the energy source for fluid and electrolyte reabsorption.

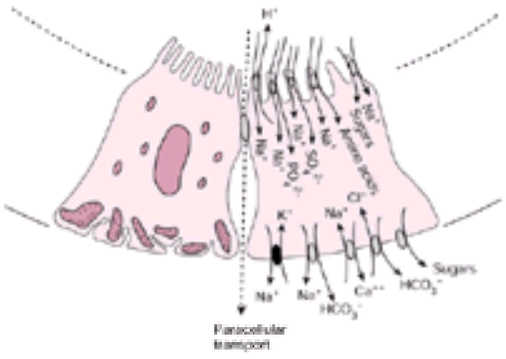

Fig. 3 Proximal tubular cell function. Principal transport processes of the proximal tubular cell.

Function

Sodium and water reabsorption

About seven-eighths of the volume of the glomerular filtrate is reabsorbed in the proximal tubule. Sodium enters the proximal tubular cells passively from the tubular fluid down an electrochemical gradient that is the driving force for fluid and electrolyte reabsorption. This gradient is produced by the action of the Na^+/K^+-ATPase on the basal surface, which transports sodium out of the cell in excess of the potassium transported into the cell, thereby generating a transmembrane potential of –70 mV. Chloride ions follow the same route by cotransport with Na^+, and the resulting increase in osmolality in the intercellular spaces results in the absorption of water by osmosis, such that the volume of the filtrate in the renal tubule is substantially reduced by the time it reaches the beginning of the loop of Henle, although its net osmolality does not change. In addition to this transcellular route for the transport of salt and water, there is also a paracellular route through the 'leaky' tight junctions.

Reabsorption of other substances

The proximal tubule is also responsible for the reabsorption of other substances such as glucose, phosphate, amino acids, and organic anions, including citrate and lactate. These enter the proximal tubular cells across the apical membrane by a series of cotransport systems, each of which binds one or more sodium ions and its specific substrate, and carries them across the cell membrane (Fig. 3). Thus, the rate of sodium entry into the cell is linked by cotransport systems to the reabsorption of these substances.

The energy for secondary active transport or cotransport of substances (glucose, phosphate, etc.) against their concentration gradient is therefore provided indirectly by Na^+/K^+-ATPase, which is responsible for the concentration gradient for sodium across the cell membrane. This is illustrated by the reabsorption of glucose, which involves brush-border, Na^+-coupled glucose transporters, termed **SGLT**, and basolateral facilitated glucose transporters (**GLUT**). In the human, the major site for glucose reabsorption is the early S1 segment of the proximal tubule, where 90 per cent of the filtered glucose is reabsorbed, such that only a small fraction of the filtered load reaches the S2 and S3 segments. Glucose reabsorption in the S1 proximal tubular segment is mediated by the low-affinity, high-capacity, Na^+/glucose cotransporter, SLGT2, whilst reabsorption in the later segments is mediated by the high-affinity, low-capacity SGLT1. Similarly, the high rate of glucose efflux characteristic of the early proximal tubular segment is mediated by the low-affinity, facultative glucose transporter GLUT2 and high-affinity GLUT1, whereas only GLUT1 is expressed in the late proximal tubule where a minor portion of the filtered glucose load is reabsorbed.

The kidneys are also involved in maintenance of the acid–base balance of the body by regulating the serum bicarbonate concentration to approximately 24 mmol/l. The proximal tubule reabsorbs between 80 and 90 per cent of the filtered bicarbonate, largely by the following mechanism. H^+ is secreted by the Na^+/H^+-exchanger on the luminal membrane. It then reacts with the filtered HCO_3^- to form H_2CO_3, which is converted to CO_2 and H_2O catalysed by carbonic anhydrase present on the luminal brush-border membrane. CO_2 diffuses passively into the cell where it is split to yield the H^+ that is secreted and OH^-, the hydroxyl ion then reacts with CO_2 (catalysed by carbonic anhydrase) to yield HCO_3^-, which exits the cell via a Na/HCO_3 synporter thus restoring filtered HCO_3^- to the plasma.

Handling of protein

In addition to its role in fluid and electrolyte balance, almost all the protein that is filtered at the glomerulus is reabsorbed by the proximal tubule via a process of endocytosis. To date, four major routes of tubular handling of peptides have been identified: (1) reabsorption of filtered protein/peptides by endocytosis and intracellular lysosomal degradation; (2) luminal hydrolysis and reabsorption of free amino acids; (3) carrier-mediated reabsorption of small intact peptides; and (4) peritubular uptake of peptides. The most important of hese is probably the endocytotic route.

In recent years there has been considerable interest in the role of proteinuria in the progression of renal disease. Amongst the hypotheses currently under investigation are those that focus on the effect of excess protein trafficking on the generation of profibrotic factors by proximal tubular cells and the subsequent initiation of interstitial fibrosis. These theories suggest that cells of the proximal tubule play a role in maintaining the normal architecture of the renal interstitium. In support are numerous studies demonstrating that tubular cells are a rich source of many components of the extracellular matrix, which may modify matrix turnover by alterations in the synthesis of both matrix-degrading enzymes and their inhibitors, as well as through the production of cytokines. More recent studies have suggested that cells of the proximal tubule may migrate into the interstitium and transdifferentiate into the cortical fibroblasts during conditions of inflammation.

Interplay between the regulation of GFR and proximal tubular function

One aspect of the control of renal function is the correlation between the volume of filtrate produced by the glomerulus and the reabsorptive capacity of the renal tubule. The movement of sodium and water from the proximal tubular lumen into the capillary network depends on the hydrostatic pressure of the blood in the peritubular capillary complex, as well as the osmotic pressure of the blood within those capillaries. An increased hydrostatic pressure will reduce reabsorption, but an increased oncotic pressure will enhance reabsorption. Thus, increased systemic blood pressure will increase the interstitial pressure within the interstitium and result

in the movement of sodium from the interstitial fluid into the lumen (pressure natriuresis).

The loop of Henle

The loop of Henle begins where the straight (S3) part of the proximal tubule changes abruptly in diameter to become the descending thin limb. Long loops pass into the inner medulla, before performing a hairpin bend and returning as the thin ascending limb, when an abrupt transition at the inner stripe of the outer medulla marks the beginning of the thick ascending limb, which is structurally distinct from its thin counterpart. In the case of the short loops the transition to ascending thick limb takes place before the bend, so that the thick part of the tubule forms the loop.

Although there are only minor structural differences between the thin segments of descending and ascending limbs, there are major differences in their permeability properties. The thin descending limb, like the proximal tubule, is highly permeable to water as a result of the presence of aquaporin 1, whereas the thin ascending limb is impermeable to water. By contrast, the descending limb is impermeable to sodium, whilst significant sodium and urea reabsorption occurs in the thin ascending limb. This allows an osmotic gradient to be established in the medulla, which is the basis of the countercurrent multiplier mechanism (Fig. 4).

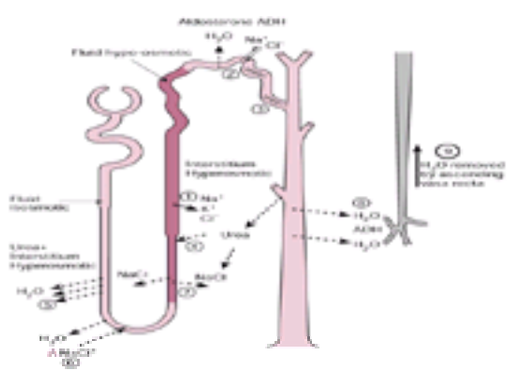

Fig. 4 Diagram to illustrate the mechanism of concentration of the urine. The darkened part of the nephron is impermeable to water. 1, Active transport of Na^+ and Cl^- into the insterstitium. 2, Reabsorption of Na^+ and Cl^-. Passive absorption of water under ADH control. 3, Increased concentration of urea in tubule following reabsorption of water. 4, Urea passes into the interstitium, thereby increasing osmolality. 5, The increased interstitial osmolality results in more water being extracted. 6, This leads to an increased salt concentration in the loop of Henle. 7, In the ascending limb, salt diffuses into the interstitium, further increasing its osmolality. 8, In the presence of ADH the permeability of the distal nephron and collecting ducts is increased and water is reabsorbed. 9, Water is removed from the interstitium by vasa recta. (Reproduced from Williams JD, *et al. Clinical atlas of the kidney*. Gower Publishing, London, with permission.)

The juxtaglomerular apparatus

The juxtaglomerular apparatus comprises the macula densa, the extraglomerular mesangium, the terminal portion of the afferent arteriole with its renin-producing granular cells, and the early portions of the efferent arteriole.

The thick ascending limb of the loop of Henle returns to its own glomerulus, where the cells that lie nearest to the glomerulus become taller to form the macula densa, the most obvious structural feature being that these cells are tightly packed and have large nuclei. The basal aspect of the macula densa is firmly attached to the extraglomerular mesangium.

The granular cells (also termed the juxtaglomerular cells) are assembled in clusters within the terminal portion of the afferent arteriole. These are modified smooth muscle cells containing cytoplasmic granules in which renin is stored. This enzyme is responsible for controlling the synthesis of angiotensin II by converting angiotensinogen to angiotensin I. This in turn is converted to angiotensin II by the action of the angiotensin-converting enzyme.

Granular cells appose the extraglomerular mesangial cells, adjacent smooth muscle cells, and endothelial cells, and are densely innervated by sympathetic nerve terminals. The secretion of renin by the granular cells is controlled by signals generated intrarenally (such as perfusion pressure and tubular fluid composition) and extrarenally, due to changes in sympathetic output and by stimuli that decrease the extracellular fluid (**ECF**) volume and blood pressure. Many factors may therefore be involved in the control of renin release, a particularly important one of these being an intrarenal baroreceptor mechanism that causes renin secretion to increase when the intrarenal arteriolar pressure at the granular cells is decreased. A major level of control also lies in the macula densa, where renin secretion is proportionate to the concentration of Cl^- or Na^+ in the tubular fluid. Decreased delivery of Na^+ and Cl^- to the macula densa is associated with increased renin secretion. Angiotensin II, by contrast, inhibits renin secretion by its direct action on the granular cells; it is also a major stimulant of aldosterone secretion, thereby stimulating sodium retention (see below), which closes the renin–angiotensin–aldosterone negative-feedback loop. In addition to these factors, increased activity of the sympathetic nervous system increases renin secretion, both by increased circulating catecholamines and by way of the renal sympathetic nerves.

It has been postulated that the intrarenal renin–angiotensin mechanism is the prime hormonal mediator of the tubuloglomerular feedback system, whereby a stimulus perceived at the macula densa, presumably related to luminal flow or ion concentration, influences filtration rate (Fig. 5). Evidence for this is inconclusive and it is almost certainly not the sole mediator of this feedback mechanism.

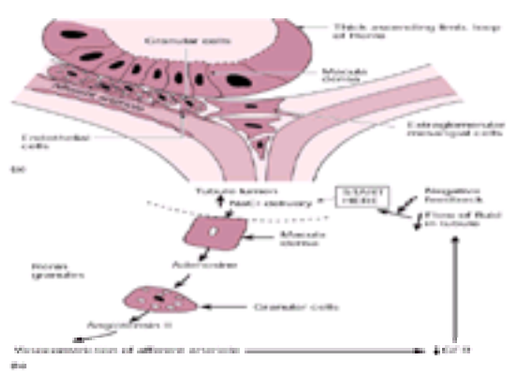

Fig. 5 Tubuloglomerular feedback: (a) anatomical basis; (b) putative mechanism.

The distal tubule and collecting duct

The bulk of sodium and water reabsorption occurs primarily in the proximal tubule, but fine regulation is necessary to maintain a precise sodium and water balance. The distal tubule and the collecting duct are responsible for the necessary final adjustments, which ultimately determine the rate of urinary water and sodium excretion, a mechanism substantially influenced by antidiuretic hormone (vasopressin, **ADH**) and aldosterone, respectively.

Structure

The distal convoluted tubule begins just beyond the macula densa and ends at the cortical collecting duct. Its structure is similar to that of the main part of the thick ascending limb of the loop of Henle. The collecting duct system includes the connecting tubule and the cortical and medullary collecting ducts. The connecting tubule

and the collecting ducts, unlike the distal tubule, are lined by two cell types: principal cells, with small basal infoldings, some mitochondria, and small microvilli; and intercalated cells with darkly staining cytoplasm that contains mitochondria, smooth endoplasmic reticulum, and prominent Golgi apparatus. There are at least two types of intercalated cells, distinguished on the basis of immunocytochemical and functional characteristics: type A cells express H^+-ATPase at their luminal membrane and secrete protons, whilst type B cells express H^+-ATPase at their basolateral membrane and secrete bicarbonate ions.

Function

Cells of both the connecting tubule and the collecting duct share sensitivity to ADH, but only those of the collecting duct are sensitive to mineralocorticoids. The renal concentrating and diluting processes are ultimately dependent on the ability of ADH to modulate the water permeability of collecting ducts. Regulation of ADH is dependent on osmoreceptors in the hypothalamus, which recognize changes in ECF osmolality, but this can also occur in the absence of changes in plasma osmolality, for example intravascular volume depletion, pain, nausea. Once released from the posterior pituitary, vasopressin exerts its biological action on water excretion by binding to receptors in the basolateral membrane of the collecting duct (Fig. 6). This results in increased adenylate cyclase activity, increased cAMP formation, and ultimately causes the apical (luminal) cell membrane to become more permeable to water through insertion of aquaporin 2 channels.

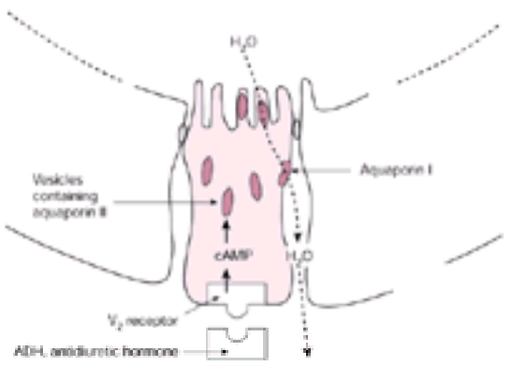

Fig. 6 Action of antidiuretic hormone.

The principal cells of the collecting duct are responsible for the modulation of sodium reabsorption. Entry of sodium into these cells occurs down a concentration gradient through specific sodium ion channels in the luminal membrane. This creates a negative potential difference in the lumen, which promotes either the secretion of potassium or the reabsorption of chloride via the paracellular route. These processes, which are the final regulators of sodium balance, are under the control of aldosterone, which increases the number of open sodium-ion channels in the luminal membrane (Fig. 7). As previously discussed, angiotensin II is a major stimulant of aldosterone secretion. Hence during periods of volume depletion, activation of the renin–angiotensin system leads to increased aldosterone production and sodium retention; whereas when volume-replete, the system is suppressed and renin release and aldosterone secretion are reduced, resulting in natriuresis. Although the acute production of aldosterone is linked to the renin–angiotensin system, other mechanisms (including that of sodium or potassium balance) can also affect the ability of the adrenal glands to produce aldosterone.

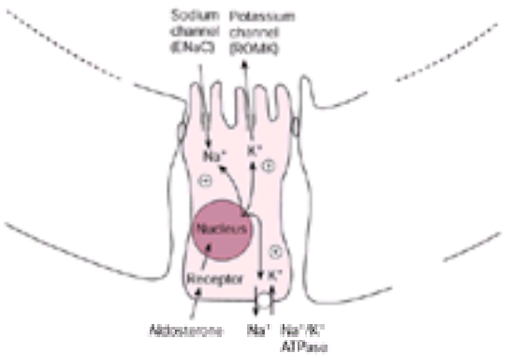

Fig. 7 The action of aldosterone on the collecting duct. Aldosterone stimulates an increase in the numbers and activity of apical ENaC and ROMK, and of basolateral Na^+/K^+-ATPase by direct and indirect effects.

The intercalated cells of the collecting duct are involved in maintenance of the acid–base balance. The method by which they excrete acid by generating ammonium ions is discussed in Chapter 11.11.

The interstitium

The renal interstitium is the space that is not occupied by the glomeruli or nephrons, and the vasculature of the kidney can be thought of as lying within it. The interstitium amounts to some 5 to 7 per cent of the volume of the cortex, 3 to 4 per cent of the outer stripe, 10 per cent of the inner stripe, and up to 30 per cent of the inner medulla. It is involved in virtually all functions of the healthy kidney, as well as in many pathological events. The transit of molecules from the tubules to the blood necessitates a crossing of the interstitial space, and vice versa. Thus, changes to the interstitium have a profound effect on the function of the tubules and indeed of the nephron itself.

The cells of the interstitium are not a homogeneous population but comprise different cell types that vary anatomically within the kidney and between health and disease. The major cellular component is the fibroblast; however, there is evidence to suggest that there is a significant difference between the phenotype of the cortical fibroblast and that of the inner medullary fibroblast. Fibroblasts are important for the integrity of the interstitial matrix and are considered to be the source of matrix component production, as well as being responsible for their turnover. The renal fibroblasts also have endocrine functions: those of the cortex are the source of erythropoietin; the inner medullary fibroblast produces significant amounts of prostaglandins, primarily PGE_2, and has a function in modifying electrolyte transport. Renal fibroblasts may have a pivotal role in renal interstitial fibrosis; it is now well established that the progression of renal disease is intimately linked to the degree of renal interstitial fibrosis, and it is likely that the key cell involved in this may well be the cortical fibroblast.

Dendritic cells are present in small numbers throughout the interstitium and express MHC class II receptors. In addition, there are a few macrophages as well as some large lymphocytes. Dendritic cells, macrophages, and lymphocyte-like cells mostly have immunological and defence-like functions.

20.2.1 Water and sodium homeostasis and their disorders

Peter H. Baylis

Introduction

Total body water accounts for about 60 per cent of the body weight of a healthy adult: two-thirds of this is intracellular and one-third extracellular. The extracellular fluid compartment is divided into the vascular (blood volume) and the interstitial fluid compartments in the ratio 1:2. For a 75 kg adult, the total volume of body water is approximately 45 litres, with intracellular and extracellular volumes of 30 and 15 litres respectively; the latter comprising the blood (5 litres) and interstitial (10 litres) compartments. Sodium is the main extracellular cation, which with its anion, chloride, contributes 95 per cent of the extracellular solute. By contrast, the major intracellular cation is potassium. Many cell membranes are freely permeable to water, but not to most electrolytes, which results in the same total solute but very different electrolyte concentrations in the extracellular and intracellular compartments (Fig. 1).

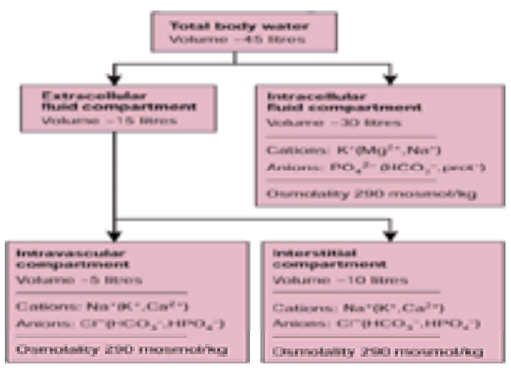

Fig. 1 Composition of body compartments. Body water is distributed uniformly throughout all compartments. Major and some minor (in parentheses) anions and cations are indicated. Osmolality remains the same inside and outside the cell.

The maintenance of stable volume and solute concentrations is essential to all complex animals, including humans. In the extracellular fluid compartment, particularly the vascular component, the control of water and sodium balance is inextricably linked. Water is distributed uniformly throughout all compartments, and is clearly a determinant of volume, but is also essential in establishing the concentration of sodium (and other solutes). Sodium, however, contributes ot only to its own concentration, but its total quantity in the extracellular fluid is the main factor determining the volume of that compartment. A variety of integrated mechanisms ensure that minimal fluctuations, probably less than 1 per cent, in blood volume and in sodium concentration occur in healthy adults.

Body water and therefore solute concentration is regulated mainly by vasopressin (antidiuretic hormone) mediated alteration of renal water excretion, but also to some extent by thirst as a motivation for drinking. The secretion of vasopressin and thirst are influenced principally by changes in circulating concentration of sodium, but also in part by significant falls in blood volume or pressure, and there are instances where these stimuli can be pulling vasopressin secretion in opposite directions (see later).

The volume of the extracellular compartment is determined by its total sodium content, which is regulated by numerous mechanisms. Sodium intake is poorly controlled in humans, although some animals do demonstrate a specific sodium appetite. The kidney is the major effector organ influencing sodium homeostasis. Complex intrarenal mechanisms contribute to the maintenance of sodium homeostasis, in addition to which are endocrine factors that either tend to reduce excretion of sodium by the kidney (for example the renin–angiotensin–aldosterone system) or which produce a natriuresis (for example atrial natriuretic peptide, ouabain-like substances). The situation is very complex. Blood volume and pressure are also influenced by a variety of vasoactive substances that act locally or systemically (for example catecholamines, prostaglandins, nitric oxide, endothelins), as well as by changes in sympathetic nerve activity. Any change in blood volume and/or pressure will, in turn, have an effect on vasopressin secretion. It can therefore be appreciated that there is an intricate network of homeostatic mechanisms controlling both sodium and water balance.

In clinical practice, the precise measurement of circulating concentrations of electrolytes, specific non-electrolytic solutes (for example glucose), and total solute is relatively simple, and approximates closely to their concentrations in interstitial fluid. Sodium is measured in molar terms (mmol/litre) using flame photometry or an ion-selective electrode. Total solute concentration is assessed by determining the depression of the freezing point of the sample plasma using an osmometer, and is expressed as the number of osmoles of solute per kilogram (osmolality). Thus, a solution of glucose at 1 mmol/litre will provide an osmolality of 1 mosmol/kg but a 1 mmol/litre solution of a salt (for example NaCl), which dissociates completely in the solvent into sodium and chloride ions, will have an osmolality of 2 mosmol/kg. The clinical assessment of volume—whether it be intravascular, interstitial, or extracellular—is extremely important, but difficult and inaccurate.

The physiology of water homeostasis

The maintenance of normal water balance is achieved through the combined action of three main factors: vasopressin, the kidney, and thirst. There needs to be secretion of adequate quantities of osmotically stimulated vasopressin, which must be able to bind to the renal tubule to modulate the flow of solute-free water and produce antidiuresis. Most healthy adults excrete 1 to 2 litres of urine per 24 h, but the normal kidney is capable of wide variation in urine output, ranging from 0.5 to (in very extreme cases) 25 litres per 24 h. Osmotically stimulated thirst must be able to promote drinking and is particularly important when the kidney is concentrating urine maximally but there is still persistent water loss from, for example, excessive sweating or copious watery diarrhoea. Under these circumstances water homeostasis cannot be maintained without adequate fluid intake.

Fine control of water balance ensures that the concentration of solutes, particularly extracellular sodium, remains stable. The extraordinary sensitivity of the function of the three homeostatic mechanisms detailed above allows plasma osmolality to be maintained within the narrow range 285 to 295 mosmol/kg (equivalent to serum sodium, 137 to 142 mmol/litre) in healthy adults.

Thirst and water intake

Drinking behaviour of humans can be divided into two types. The first, primary drinking, occurs as a result of physiological stimulation of thirst. This initiates drinking behaviour to allow ingestion of sufficient fluid to lower blood osmolality. Secondary drinking, which is far more common in our culture, occurs for social reasons (the endless cups of coffee throughout the day, or the ritual visit to the 'pub'), habit, or the need to drink with food. For the majority of adults living in temperate climates, secondary drinking ensures that they remain in a state of mild water excess, and water balance is maintained by regulating renal water excretion.

The mechanism of primary drinking is believed to be as follows: as the body loses water, blood osmolality starts to rise and stimulates thirst osmoreceptors. Studies in animals indicate that these are situated in the anterior hypothalamic structures, probably in the organum vasculosum of the lamina terminalis or the subfornical organ, where there is a defect in the blood–brain barrier. Isolated lesions in this area can occur in humans following haemorrhage from an aneurysm in an anterior communicating artery and result in loss of thirst appreciation, suggesting that human thirst osmoreceptors are located in a similar area to those in animals. The precise mechanism by which blood hyperosmolality stimulates thirst is not known, but it is believed that increase in extracellular osmolality draws water from within the osmoreceptor cells of the organum vasculosum of the lamina terminalis and subfornical organ, resulting in cellular hypovolaemia which is translated into neuronal impulses that migrate to the cortex and allow conscious appreciation of thirst.

With the use of visual analogue scales it is possible to obtain an estimate of the degree of thirst sensation. There is a simple relationship between increasing blood osmolality and the intensity of thirst (Fig. 2(b)). Furthermore, there is also a direct relationship between intensity of thirst and the amount of fluid drunk to quench thirst. The act of drinking quickly reduces thirst, usually within a few minutes and certainly before there are substantial falls in blood osmolality. Drinking is therefore able to override or inhibit osmotically stimulated thirst, probably through an oropharyngeal reflux.

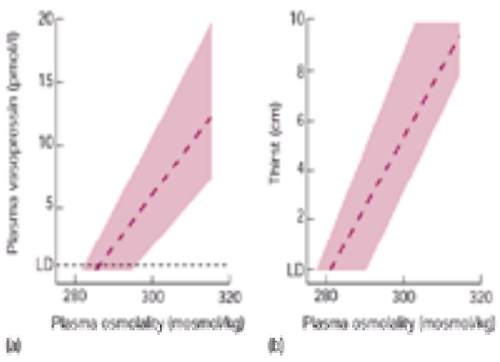

Fig. 2 (a) The relationship between plasma osmolality and plasma vasopressin during infusion of hypertonic (850 mmol/litre) saline in healthy adults. There is a linear relationship between the two variables, represented by the dashed line, termed the mean osmoregulatory line for vasopressin secretion. The abscissal intercept of the line represents the threshold for vasopressin secretion, approximately 283 mosmol/kg. LD is the limit of detection of the assay, and the shaded area is the extent of the normal response. (b) The relationship between plasma osmolality and thirst intensity assessed on a 10 cm visual analogue scale during the same hypertonic infusion. The dashed line is the mean osmoregulatory line for thirst, which has an abscissal intercept (thirst threshold) of 281 mosmol/kg. (Adapted from Thompson CJ *et al*. (1986). The osmotic thresholds for thirst and vasopressin release are similar in healthy man. *Clinical Science* **71**, 651–6, with permission.)

Thirst is not only stimulated by increases in blood osmolality, but also by acute substantial falls in blood volume and/or pressure. A sudden decrease in volume in excess of 15 per cent is required before thirst is influenced. Low-pressure baroreceptors located in the atria of the heart and great veins of the chest mediate the response. In addition, significant extracellular volume depletion is a potent stimulus to the release of renin from the juxtaglomerular apparatus of the nephron: this generates increasing concentrations of circulating angiotensin II, known to be a profound dipsogen in animals. Systemic angiotensin II therefore augments the baroregulatory influence on thirst in acute hypovolaemia. Animal studies have also revealed that intrahypothalamic angiotensin II is the most potent neurotransmitter involved in the generation of the sensation of thirst.

As humans age, so their thirst appreciation becomes blunted, and primary drinking is reduced such that individuals tend to become mildly hyperosmolar and hypernatraemic. Fortunately, most elderly people continue secondary drinking and rely on mechanisms to control renal water excretion, providing protection from significant hypernatraemia.

During human pregnancy there is a fall in plasma osmolality of the order of 10 mosmol/kg, with an appropriate fall in serum sodium. This is due to alteration in the osmoregulatory systems for both thirst and vasopressin secretion. The thirst osmoregulatory line (Fig. 2) is displaced to the left of the normal, non-pregnant position, which runs parallel—but the abscissal intercept, known as the osmotic threshold for thirst, is reset to about 275 mosmol/kg. Similar changes occur with the osmoregulatory line for vasopressin secretion (see below). The precise mechanisms for this 'resetting of the osmostat' are unknown, but they have important implications for the ability of pregnant women to handle a water load.

Vasopressin and renal water excretion

The antidiuretic hormone of humans is arginine vasopressin (in contrast to lysine vasopressin which is specific to the pig family), a nonapeptide, the gene for which is located on chromosome 20. Arginine vasopressin is synthesized from a large precursor molecule in the supraoptic and paraventricular nuclei of the hypothalamus, transported in neurosecretory granules to the posterior pituitary, median eminence of the hypothalamus and to a lesser extent to other areas of the brain and brainstem. It is secreted from the posterior pituitary into the systemic circulation to influence renal function, and into the hypothalamopituitary portal circulation to enhance pituitary ACTH secretion.

Control of vasopressin release

Secretion of vasopressin from the posterior pituitary is regulated mainly by changes in blood osmolality. The vasopressin osmoreceptors, distinct from the thirst osmoreceptors, are located in the same anterior hypothalamic area, i.e. the circumventricular structures, the organum vasculosum of the lamina terminalis, and possibly the subfornical organ. Rising blood osmolality is believed to cause water to flow out of the osmoreceptor cells, with cellular hypovolaemia then initiating a neuronal signal that passes principally to the supraoptic nucleus and stimulates the process of vasopressin synthesis and secretion. There is an exquisitely sensitive linear relationship between blood osmolality and vasopressin secretion (Fig. 2(a)), the slope of the vasopressin osmoregulatory line being a measure of the sensitivity of the system and the abscissal intercept representing the threshold for vasopressin release. At plasma osmolality values below 285 mosmol/kg, on average, vasopressin secretion is inhibited to allow a maximum water diuresis (15–25 litres/24 h) with urine osmolality of 50 to 70 mosmol/kg (Fig. 3). Increase in blood osmolality above this threshold induces progressive vasopressin release, thus increasing urine concentration, so that at plasma vasopressin values of 2 to 4 pmol/litre, maximum antidiuresis occurs. Drinking inhibits osmoregulated vasopressin secretion.

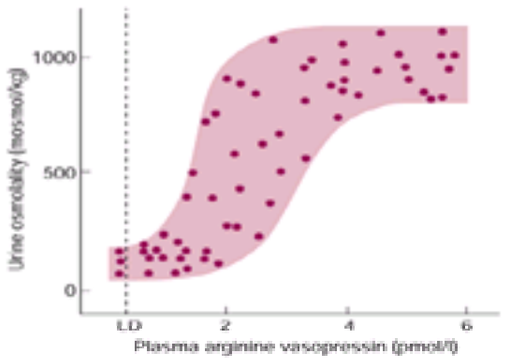

Fig. 3 The effect of vasopressin on urinary concentration during varying states of hydration in humans. Each closed circle represents a single value, and the stippled area the normal range. Values of plasma vasopressin greater than 4 pmol/litre fail to increase urinary concentration further. LD is the limit of the assay.

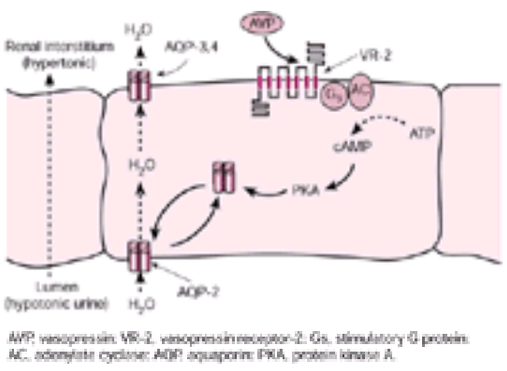
Each individual has a unique threshold and sensitivity for both thirst and vasopressin release. Circulating solutes have varying abilities to stimulate the osmoregulatory system, with sodium chloride being among the most potent and glucose having little or no effect. By contrast to osmoregulated thirst, there is no blunting of the vasopressin response to osmotic stimulation with ageing. Pregnancy is associated with a lowering of the vasopressin threshold similar to the thirst threshold, allowing osmoregulation to occur about a lower set-point of 275 rather than 285 mosmol/kg.

Non-osmotic release of vasopressin is stimulated by a number of factors: acute substantial reductions in blood volume or pressure, of the order of 10 to 15 per cent or more; nausea and/or emesis; hypoglycaemia; and a variety of circulating substances (for example angiotensin II). Low-pressure receptors in the great veins of the chest and cardiac atria mediate the effect of hypovolaemia, while receptors in the arch of the aorta and carotid vessels sense reductions in arterial pressure. The sensory information is carried via the vagus and glossopharyngeal nerves to the brainstem vasomotor centres and then transmitted to the hypothalamus, principally the paraventricular nucleus. There is an exponential relationship between the fall in blood volume/pressure and vasopressin release, such that large reductions (~40 per cent of normal) raise plasma vasopressin to huge concentrations (100 to 500 pmol/litre) that have vasoconstrictor effects. Similarly high vasopressin concentrations can be achieved with nausea/emesis.

Actions of vasopressin

The major physiological action of vasopressin is to increase urinary concentration (Fig. 3). Circulating arginine vasopressin binds to a specific renal tubular receptor, designated the V_2 receptor, of the collecting ducts. Adenyl cyclase is stimulated, via the coupled G protein, to produce cyclic 5'AMP, which activates intracellular protein kinases and accelerates the expression and trafficking of aquaporin 2, the vasopressin-sensitive water channel protein. Aquaporin 2 is organized into a tetramer and inserted into the luminal cellular membrane of the distal tubule, allowing water to flow from the tubular lumen into the cellular compartment. Two other aquaporins (aquaporins 3 and 4) are located on the contraluminal cell membrane: these are not vasopressin responsive but facilitate the flow of water across the distal tubule under the influence of the osmotic gradient between the hypotonic urine within the tubular lumen and the hypertonic renal interstitium. Thus, urine volume is decreased and urine is concentrated (Fig. 4).



AVP, vasopressin; VR-2, vasopressin receptor-2; G_s, stimulatory G protein; AC, adenylate cyclase; AQP, aquaporin; PKA, protein kinase A.

Fig. 4 A schematic diagram of the distal renal tubule indicating the effect of arginine vasopressin initiating a cascade of intracellular events after binding to the V_2 receptor. Protein kinase A is activated, which mobilizes the arginine vasopressin-sensitive water channel protein, aquaporin 2, for insertion into the luminal tubular membrane. Non-vasopressin-sensitive water channel proteins, aquaporins 3 and 4, are positioned in the contralateral membrane, which allows water to flow through the cell along the osmotic gradient. Loss of arginine vasopressin binding to its receptor promotes re-entry of the luminal aquaporin 2 into the cell, resulting in a shuttling of aquaporin 2.

Animal studies have indicated that vasopressin also stimulates the transport of urea across the collecting tubule and of sodium chloride across the medullary thick ascending limb of the loop of Henle, both of which enhance the osmotic gradient. As renal prostaglandins reduce the generation of cyclic 5'AMP, they blunt the effect of vasopressin, and therefore prostaglandin synthetase inhibitors augment the antidiuretic action of arginine vasopressin.

The first action attributed to vasopressin was the elevation of systemic blood pressure by peripheral vasoconstriction. Arginine vasopressin binds to vascular smooth muscle receptors (V_1 receptors) that activate phosphatidyl–inositol pathways, increase intracellular calcium concentration, and cause the contraction of vascular muscles. High circulating concentrations of vasopressin are necessary to achieve this pressor effect: at physiological levels it probably plays little (if any) role in maintaining blood pressure, but it is involved in the pressor response to hypovolaemia or hypotension.

Vasopressin released from the hypothalamic median eminence binds to a modified V_1 receptor on the pituitary corticotroph and acts to enhance the release of ACTH stimulated by corticotrophin-releasing factor. At high concentrations vasopressin increases circulating concentrations of the clotting factors, plasma factor VIII and the von Willebrand factor, by releasing them from vascular endothelium via a V_2 receptor. Hepatic glycogenolysis is also promoted by high concentrations of vasopressin via a V_1 hepatic receptor.

The physiology of sodium homeostasis

The volume of the extracellular compartment is determined by its sodium content, changes in which result in alterations in blood and interstitial volumes (Fig. 1) with little influence on sodium concentration. The reason is that any rise in sodium concentration causes transient stimulation of thirst and increased water intake, as well as increased vasopressin secretion and reduced renal water excretion, both leading to an increase in body water and a return of extracellular sodium concentration to normal. It therefore appears that extracellular osmolality is conserved at the expense of volume in healthy adults, this integration illustrating the close links between sodium and water homeostatic mechanisms.

Sodium intake

There is little regulation of sodium intake in humans, although some animals demonstrate a specific sodium appetite and have sodium receptors in the hypothalamus. Sodium balance is maintained largely by the kidney, which is normally capable of controlling sodium excretion over a very wide range, 1 to 5000 mmol/24 h. In Western countries, including Britain, the usual intake of sodium is grossly in excess of body needs, being about 100 to 200 mmol/24 h. There is little sodium loss from the healthy bowel and in temperate climates sweating is minimal (the sodium concentration in sweat is 40 to 50 mmol/litre). Most people are therefore at continuous

risk of sodium excess, which is prevented by the kidney.

Control of renal sodium excretion

The glomerular filtration rate of normal kidneys is 170 litres per 24 h, the filtrate containing 140 mmol of sodium per litre. Most of the filtered sodium (60–70 per cent) is reabsorbed iso-osmotically by the proximal tubule. Much of the remainder is reabsorbed in the medullary thick ascending limb of the loop of Henle and the distal nephron, such that only a small fraction of the load of sodium filtered at the glomerulus is excreted in the urine (0.1 to a few per cent).

At the single nephron level the glomerulotubular feedback mechanism operates to maintain a balance between the amount of sodium and fluid filtered by the glomerulus and the reabsorptive function of the corresponding nephron. The mechanisms responsible for glomerulotubular feedback are not known precisely, but the macula densa cells of the thick ascending limb detect changes in composition of tubular fluid entering the terminal portion of the thick ascending limb and transmit signals (possibly intrarenal angiotensin II) to modulate glomerular vascular resistance and glomerular pressure. Thus, acute changes in glomerular filtration determine appropriate changes in sodium reabsorption in the proximal tubule, such that if glomerular filtration rate increases, then reabsorption increases proportionally, and vice versa.

Most regulation of sodium balance occurs in the distal nephron, where 'fine tuning' of sodium excretion occurs under the control of a variety of mechanisms.

Renin–angiotensin–aldosterone system

In addition to their role in the glomerulotubular feedback mechanism, the macula densa cells also influence the juxtaglomerular cells of the renal afferent arterioles to synthesize and secrete renin into the systemic circulation if sodium delivery to the distal nephron drops. In addition, reductions of renal perfusion pressure appear to directly increase renin secretion, while baroreceptors within the great veins of the chest influence renin secretion via the sympathetic nerves. Renin catalyses the conversion of angiotensinogen to angiotensin I (Fig. 5), which is then converted into the highly active octapeptide angiotensin II. The activity of angiotensin III is only 30 per cent that of angiotensin II. These peptides influence body sodium content and extracellular fluid volume in a number of ways. Angiotensin II is a potent vasoconstrictor which readily increases systemic blood pressure, stimulates the secretion of aldosterone from the zona glomerulosa of the adrenal cortex to enhance sodium reabsorption in the distal nephron, increases cardiac contractility, stimulates thirst, and is involved in the glomerulotubular feedback mechanism.

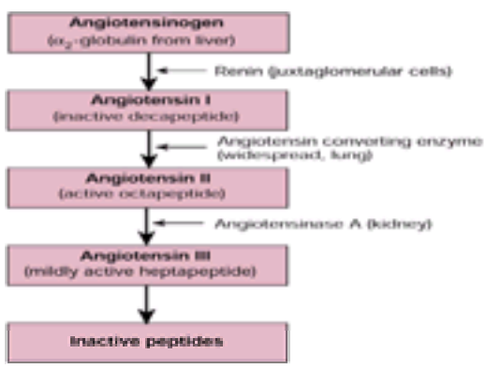


Fig. 5 The renin–angiotensin–aldosterone system. The enzyme, renin, secreted by juxtaglomerular cells of the renal afferent arterioles converts angiotensinogen to angiotensin I (inactive). The active peptides, angiotensin II and III, are potent vasoconstrictors and stimulate aldosterone secretion from the adrenal cortex to expand blood volume and raise blood pressure.

Atrial natriuretic peptide

Following the observation that expansion of blood volume caused a rise in renal sodium excretion that could not be accounted for by inhibition of the renin–angiotensin–aldosterone system, specific humoral natriuretic factors were proposed. One that has been well characterized is human alpha atrial natriuretic peptide, which is synthesized and secreted primarily by cardiac atrial myocytes. Moderate increases in blood volume and postural changes cause atrial distension, directly stimulating atrial natriuretic peptide. Its most important actions are on the kidney, where at physiological concentrations it causes a modest natriuresis, minimal diuresis, and reduces plasma renin activity, and plasma aldosterone concentration. In addition, atrial natriuretic peptide acts as a vasodilator agent, reducing systolic blood pressure and cardiac contractility, and is a potent inhibitor of aldosterone synthesis and release. Indeed, many of the effects of atrial natriuretic peptide could be explained by antagonism of the renin–angiotensin–aldosterone system, but this is not its mechanism of action: specific receptors for atrial natriuretic peptide have been identified in the kidney—on cortical glomeruli, the inner medulla, the vasa rectae in the outer medulla, and the collecting duct. Brain natriuretic peptide has similar actions.

Atrial natriuretic peptide and brain natriuretic peptide play minor roles in regulating extracellular sodium content and volume, but do counterbalance to some extent the actions of the renin–angiotensin–aldosterone system. It is likely that there are other natriuretic factors: ouabain-like substances that inhibit renal sodium–potassium ATPase activity have been described, but they have not been characterized fully and their possible significance for sodium homeostasis remains unknown. Furthermore, there are numerous other intrarenal factors that influence renal sodium excretion, including dopamine, prostaglandins (particularly prostaglandin E_2), and the kallikrein–kinin system.

Summary

In health, the control of renal sodium excretion and extracellular volume is multifactorial, complex, and not completely understood: so also in disease. It is not therefore surprising that it can sometimes be difficult to determine precisely why a particular patient has developed a particular disorder of extracellular volume or serum sodium concentration at a particular time. The physician with a good grasp of the underlying pathophysiological mechanisms stands the best chance of making the correct diagnosis.

Disorders of water and salt homeostasis

The polyuric states

Polyuria describes excessive urinary volume, normal being less than 2.5 to 3.0 litres per 24 h. This can occur due to solute diuresis, the commonest cause being hyperglycaemia in poorly controlled diabetes mellitus, but when the urine is hypotonic three basic pathogenetic mechanisms can account for polyuria. First, lack of osmoregulated vasopressin secretion, termed cranial, central, hypothalamic, or neurogenic diabetes insipidus. Second, reduction in responsiveness of the renal tubules to adequate vasopressin, called nephrogenic or vasopressin-resistant diabetes insipidus. Third, persistent excessive intake of fluid due to inappropriate thirst or drinking behaviour, known as primary polydipsia or dipsogenic diabetes insipidus.

Cranial diabetes insipidus

Cranial diabetes insipidus is a disorder of urinary concentration that is due to decreased secretion of osmoregulated vasopressin. At least 80 per cent of vasopressin-synthesizing neurones must be destroyed before overt clinical features become manifest. Cranial diabetes insipidus is rare, with an estimated prevalence of 1 in 25 000 and equal gender distribution.

Aetiology

The causes of cranial diabetes insipidus are given in Table 1.

Familial varieties account for 5 per cent of cases. Autosomal dominant familial cranial diabetes insipidus is caused by mutations of the arginine vasopressin gene located on chromosome 20. Typically the onset is in early childhood (2 to 7 years) and not infancy. A variety of different mis-sense and non-sense mutations and deletions have been identified in numerous kindreds. Mutant arginine vasopressin precursors accumulate in the magnocellular neurones where they are neurotoxic.

Approximately 30 per cent of acquired cases of cranial diabetes insipidus are idiopathic. One-third of these have circulating antibodies to the hypothalamic neurones that produce vasopressin, suggesting an autoimmune aetiology, supported by lymphocytic infiltration of the neurohypophysis that leads to thickening of the pituitary stalk. Trauma to the hypothalamus or pituitary stalk is a frequent cause of cranial diabetes insipidus, but the trans-sphenoidal surgical approach to the pituitary is less traumatic than the transfrontal approach, and rarely causes permanent cranial diabetes insipidus. Head injury may cause cranial diabetes insipidus, with some patients following a triple-phase response to trauma characterized by initial polyuria for a few hours or days, followed by antidiuresis for a variable period, then progressing to permanent polyuria. Primary pituitary tumours rarely cause cranial diabetes insipidus. Germinoma is a common cause of cranial diabetes insipidus in childhood.

Clinical features

The main clinical manifestations of cranial diabetes insipidus are polyuria, nocturia, and excessive thirst and drinking. Children may present with enuresis. Most patients have partial deficiency of vasopressin. Urine volumes range between 3 and 25 litres per 24 h, with random urine osmolalities of 50 to less than 300 mosmol/kg and plasma osmolality within the normal reference range.

Patients with cranial diabetes insipidus maintain normal values of plasma osmolality and serum sodium because they have an intact osmoregulated thirst mechanism. Defective thirst or restricted access to water leads to hypernatraemia and hyperosmolality. With severe polyuria the slightest obstruction to outflow from the urinary tract can lead to hydronephrosis and hydroureter.

Cranial diabetes insipidus may be masked by deficiency of glucocorticoid hormone due either to hypopituitarism or primary adrenal failure because cortisol is necessary for the maximal dilution function of the distal nephron and for normal secretion of arginine vasopressin. The symptoms of partial cranial diabetes insipidus are often worse in pregnancy due to the increase in metabolic clearance of arginine vasopressin caused by cysteine aminopeptidase (vasopressinase), a circulating enzyme of placental origin.

Nephrogenic diabetes insipidus

In nephrogenic diabetes insipidus the renal tubules are partially (most often) or totally resistant to the action of vasopressin.

Aetiology

Table 1 lists the causes of nephrogenic diabetes insipidus.

The X-linked form is rare. Infant males have profound polyuria, dehydration, vomiting, fever, irritability, and fail to thrive. Females, when tested, have slightly impaired urinary concentration. Molecular studies of kindreds with X-linked nephrogenic diabetes insipidus have identified mutations or deletions of the gene that encodes for the V_2 receptor located on Xq28. The V_2 receptor is a classic seven-domain transmembrane protein: genetic abnormalities have been demonstrated in external and internal segments of the receptor as well as the transmembrane portions.

Approximately 10 per cent of cases of familial nephrogenic diabetes insipidus are due to genetic defects of aquaporin 2, the water-channel protein that is encoded on chromosome 12q13. Mutant aquaporin 2 is misrouted within the distal tubule and fails to be inserted into the cellular membrane. Inheritance is autosomal recessive.

Hypercalcaemia-induced nephrogenic diabetes insipidus is thought to be due to a combination of factors: reduced medullary hyperosmolality and adenyl cyclase activity, dysfunction of aquaporin 2, and calcium deposition with scarring of the kidney. The effect of sustained hypokalaemia on renal function is complex: it inhibits sodium–potassium cotransport in the thick ascending limb, reduces adenyl cyclase activity, increases intrarenal prostaglandin synthesis (which blunts the antidiuretic effect of vasopressin) and may reduce intracellular protein kinase function. Aquaporin 2 trafficking is reduced. Reversal of these metabolic derangements often returns renal function to normal, but does not always do so.

A third of patients taking long-term lithium carbonate develop nephrogenic diabetes insipidus. Lithium blunts the generation and action of cyclic 5'AMP in the distal nephron and may reduce osmoregulated vasopressin secretion and/or stimulate thirst. Demeclocycline also inhibits the generation and function of cyclic 5'AMP.

Clinical features

Adults with nephrogenic diabetes insipidus usually have partial nephrogenic diabetes insipidus with mild symptoms. Similar to patients with cranial diabetes insipidus, these individuals have serum sodium and plasma osmolality within the normal range, but low urine osmolality (< 300 mosmol/kg). The familial forms present soon after birth with profound polyuria, dehydration, and fever (see above). Infants may become hyper-natraemic due to inadequate fluid intake.

Primary polydipsia

Some patients drink copious quantities of fluid, well in excess of body requirements, for reasons that are ill understood. This condition is termed primary polydipsia, or dipsogenic diabetes insipidus.

Aetiology

Many patients have a psychological disturbance leading to compulsive drinking, some of whom have a lowered osmotic thirst threshold but a normal threshold for vasopressin release. Up to 20 per cent of patients with chronic schizophrenia have primary polydipsia. Very rarely a structural hypothalamic lesion (for example sarcoidosis) is believed to be the cause of primary polydipsia (Table 1). Some drugs cause a dry mouth, thus stimulating thirst.

Clinical features

Although the clinical manifestations of primary polydipsia are similar to cranial diabetes insipidus and nephrogenic diabetes insipidus, nocturia is less of a feature: patients with primary polydipsia tend to sleep through the night. Individuals with primary polydipsia lower plasma osmolality sufficiently to suppress vasopressin secretion to allow polyuria. Their serum sodium therefore tends to be lower than that of patients with cranial diabetes insipidus and nephrogenic diabetes insipidus, but usually remains within the reference range. The fact that many patients with primary polydipsia can drink up to 20 litres in 24 h and still remain normonatraemic is testament to the remarkable effectiveness of homeostatic mechanisms.

Diagnostic evaluation of the polyuric patient

Before embarking on expensive and time-consuming tests, it is always wise to establish that the urine volume is in excess of 3 litres per 24 h. Urine output less than this with a normal serum sodium and plasma osmolality excludes significant disturbance of water balance. Routine biochemical investigation of glucose, calcium, and potassium may point towards some causes of polyuria (Table 1). Three types of specialized diagnostic tests are available: dehydration tests, measurement of plasma vasopressin after dehydration or osmotic stimulation, and therapeutic trial of desmopressin.

Dehydration tests

These can aid the diagnosis of severe forms of cranial diabetes insipidus and nephrogenic diabetes insipidus. Many protocols have been described: all are based on observing the responses in urine and blood to a period of fluid deprivation, followed by noting the ability to concentrate urine after exposure to exogenous vasopressin (for example desmopressin). A typical commonly used test is (briefly) as follows. The patient is encouraged to drink as usual during the night before the test which is to start in the morning. Basal measurements of urinary volume and osmolality and of plasma osmolality are made, and the patient weighed. All fluid is then withheld for 8 h, with the patient weighed and urine and blood samples taken every 1 to 2 h. The test must be stopped if the patient loses in excess of 5 per cent of their initial body weight. Thereafter 2 µg of desmopressin is injected intramuscularly, the patient being allowed to drink cautiously and eat. Urine samples are collected over the following 16 h.

A guide to interpretation of the results of the water deprivation test is given in Table 2. Substantial difficulty arises in the differentiation of partial diabetes insipidus disorders from each other, and from primary polydipsia. The reason for this is that prolonged polyuria, irrespective of its cause, leads to a reduction in the maximal concentrating ability of the kidney by removing renal medullary interstitial solute and altering aquaporin 2 function, such that exogenously administered vasopressin cannot elicit its maximal renal effect. Direct measurement of plasma vasopressin aids diagnosis of partial nephrogenic diabetes insipidus in these circumstances.

Response of plasma vasopressin to osmotic stimulation and dehydration

Measurement of plasma vasopressin and osmolality during a 2-h hypertonic (850 mmol/litre) saline infusion at a rate of 0.06 ml/kg/min will diagnose partial or complete cranial diabetes insipidus, as the vasopressin response to osmotic stimulation is subnormal (Fig. 6(a)). Patients with nephrogenic diabetes insipidus or primary polydipsia have results that fall within the normal range.

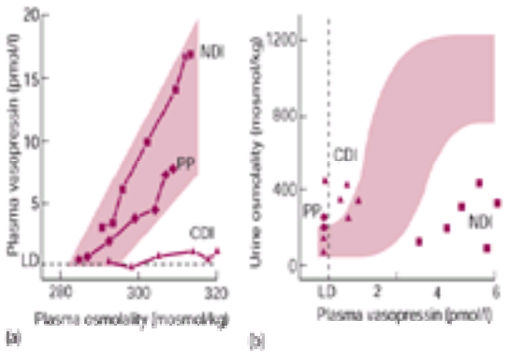

Fig. 6 (a) Relationship between plasma vasopressin and plasma osmolality during hypertonic saline infusion in typical patients with (i) cranial diabetes insipidus (CDI), (ii) nephrogenic diabetes insipidus (NDI), and (iii) primary polydipsia (PP). The shaded area represents the normal response. (b) Relationship between urine osmolality and plasma vasopressin in patients with cranial diabetes insipidus (triangles), nephrogenic diabetes insipidus (squares) and primary polydipsia (circles) after a period of dehydration. The shaded area is the normal relationship under various degrees of hydration. LD represents the limit of detection of the plasma vasopressin assay.

After a period of water deprivation, the measurement of urine osmolality and plasma vasopressin will define nephrogenic diabetes insipidus (Fig. 6(b)), as vasopressin will be inappropriately elevated with respect to the low urine osmolality.

Therapeutic trial of desmopressin

If the water deprivation–desmopressin test gives equivocal results and facilities to measure vasopressin are not available, then a formal therapeutic trial of low-dose desmopressin should be instituted to differentiate the cause of polyuria. The trial must be supervised closely, preferably in hospital, because of the potential hazard of severe water intoxication in those with primary polydipsia. After a basal period of 3 to 4 days, desmopressin (1 µg intramuscularly daily for 10 days) is administered to patients who are weighed and have urine and plasma osmolalities or serum sodium and urine volume measured daily. Patients with cranial diabetes insipidus will be identified by a reduction of thirst, little or no weight gain, a reduction in urine flow, and normal plasma osmolality. Nephrogenic diabetes insipidus is characterized by a lack of response. Primary polydipsia patients remain thirsty, continue to drink, gain weight, and become progressively hyponatraemic.

Having established the pathogenetic mechanism causing polyuria, it is important to search for a specific underlying cause (Table 1). Magnetic resonance imaging or high-resolution computed tomography scans of the pituitary and surrounding structures are invaluable in those with cranial diabetes insipidus. Patients with cranial diabetes insipidus frequently lose the posterior pituitary bright spot on T_1-weighted MRI.

Treatment

Cranial diabetes insipidus

Mild forms of cranial diabetes insipidus (urine output less than 4 litres/24 h) may not require any specific therapy other than advice to drink sufficient quantities to quench thirst. Such patients can, however, get into difficulty if they are unable to get and retain an adequate fluid intake for any reason. In more severe forms, the drug of choice is desmopressin, a synthetic vasopressin V_2-receptor agonist analogue possessing potent antidiuretic, but no pressor, activity, and with a prolonged duration of action. Desmopressin is administered orally, intranasally by spray or tube, or parenterally. There are wide individual variations in the dose required to control symptoms. Requirements for oral desmopressin range from 50 µg to 1200 µg daily; intranasal from 2.5 µg to 120 µg daily; and parenteral up to 2 µg intramuscularly daily. Dilutional hyponatraemia is a potential hazard if desmopressin is given in excess for a prolonged period: this can be avoided by instructing the patient to forgo the drug for 1 day each week. Other side-effects are minimal. Desmopressin is a safe drug in pregnancy, and is resistant to the circulating placental enzyme, vasopressinase.

Lysine vasopressin, given intranasally, is a shorter-acting alternative but as it possesses pressor activity it can cause intestinal and/or renal colic, increase blood pressure and induce coronary artery vasospasm. Pitressin is rarely used nowadays because of similar pressor side-effects.

Chlorpropamide, clofibrate, carbamazepine, and thiazide diuretics have been used either singly or in combination to reduce urine volume by up to 50 per cent, but they are rarely prescribed these days because of their side-effects and the efficacy of desmopressin.

Nephrogenic diabetes insipidus

Correction of the underlying cause of acquired nephrogenic diabetes insipidus (for example removal of drug or correction of hypercalcaemia) may allow recovery of renal concentrating ability. If matters do resolve, this typically takes a number of weeks.

Severe polyuria of the familial form of nephrogenic diabetes insipidus can be reduced by about 50 per cent using a combination of salt restriction, thiazide and/or amiloride diuretics, and a prostaglandin synthetase inhibitor (indomethacin, 1.5–3.0 mg/kg/day). A promising new therapeutic approach is the combination of a thiazide, indomethacin, and desmopressin, which may reduce urine output by up to 80 per cent.

Primary polydipsia

There is no efficacious drug treatment available for primary polydipsia although propranolol in doses up to 120 mg daily has been recommended to reduce thirst. Therapy directed towards underlying psychiatric problems may prove helpful. Clozapine has reduced polydipsia associated with hyponatraemia in those with chronic

schizophrenia.

Hyponatraemic states

Hyponatraemia, defined as a serum sodium less than 130 mmol/litre, is a common electrolyte disturbance, affecting up to 5 per cent of hospital patients. Severe hyponatraemia (serum sodium < 115 mmol/litre) is rare (< 0.5 per cent).

Pseudohyponatraemia

Spuriously low measurements of serum sodium can occur in patients with very high circulating concentrations of lipids or proteins because the volume of these substances contributes substantially to serum volume. The concentration of sodium in the water phase of blood remains normal, hence plasma osmolality is normal and its measurement proves an easy diagnostic test. Pseudohyponatraemia also arises with severe hyperglycaemia, although the mechanism is different: high blood glucose concentration draws intracellular water into the extracellular space, resulting in hyponatraemia. Plasma osmolality will be elevated due to the hyperglycaemia.

Classification and causes of hyponatraemia

In all hyponatraemic states there is an excess of extracellular water relative to the total sodium content of the extracellular compartment. The sodium content, however, can vary markedly, such that patients can be divided into three groups, forming the basis of a classification of hyponatraemia. Total extracellular sodium quantity can be:

- lower than normal, resulting in extracellular hypovolaemia,
- normal, with slightly expanded extracellular volume (not clinically evident), or
- higher than normal causing extracellular hypervolaemia.

Significant extracellular volume changes can be detected clinically:

- hypovolaemia leads to thirst, reduced skin turgor, tachycardia, low jugular venous pressure, and postural hypotension (or supine hypotension in severe cases), and
- hypervolaemia leads to dependent oedema, also possibly to elevation of jugular venous pressure, pulmonary oedema, and ascites.

Minor volume changes are difficult to assess clinically and there are no simple quick diagnostic tests to aid classification.

Table 3 presents the classification and pathogenesis of hyponatraemia. Measurement of urinary sodium helps diagnosis. The majority of hyponatraemic patients have urine osmolalities in excess of 300 mosmol/kg and, of course, plasma is hypo-osmolar (< 280 mosmol/kg).

Large sodium losses and hypovolaemic hyponatraemia commonly occur with persistent vomiting and/or diarrhoea, extensive skin burns, and excessive prolonged sweating. The healthy kidney will conserve sodium and urinary concentration will be less than 10 mmol/litre. Renal sodium loss leading to hyponatraemia can be due to renal diseases, typically those affecting the renal medulla (analgesic nephropathy, chronic pyelonephritis, polycystic kidneys, recovery from acute tubular necrosis, or post bilateral ureteric obstruction), mineralocorticoid deficiency (Addison's disease, hyporeninaemic hypoaldosteronism), or diuretic excess.

Normovolaemic hyponatraemia is usually due to the syndrome of inappropriate antidiuresis (see below) or inappropriate administration of intravenous fluid (for example 5 per cent dextrose solutions) in the postoperative period. Rarely it may be caused by isolated glucocorticoid deficiency (for example partial hypopituitarism) or severe prolonged hypothyroidism. Beer drinker's potomania occurs in some individuals who drink excessive volumes of beer over short periods, for example 10 litres in 6 h, which overwhelms the kidney's capacity to excrete water.

Hypervolaemic hyponatraemia is commonly observed in severe heart failure, decompensated cirrhosis, and nephrotic syndrome. In these disorders glomerular filtration is reduced and proximal tubular sodium reabsorption increased. Renal afferent arteriole perfusion falls leading to increased circulating angiotensin II concentrations, contributing to stimulation of thirst. Furthermore, non-osmotic release of vasopressin also contributes to water retention.

Clinical features

In addition to the features associated with extracellular (and therefore blood) volume reduction or expansion described above, there are clinical manifestations due to hyponatraemia *per se* (Table 4). The severity of hyponatraemic symptoms depends upon both the absolute serum sodium concentration and its rate of fall. Chronic mild hyponatraemia (serum sodium 120–130 mmol/litre) is often totally asymptomatic; but a sudden fall to only 125 mmol/litre from normal values (usually iatrogenic) can cause convulsions.

General principles of management

Specific therapy for mild hyponatraemia is often not necessary: treatment should be reserved for symptomatic or severe life-threatening hyponatraemia. Treatment of the underlying cause is obviously essential and will frequently correct the serum sodium concentration.

For hypovolaemic hyponatraemia, volume replacement is mandatory. Infusion of isotonic saline is usually sufficient, but occasionally intravascular volume expanders are required to raise blood pressure, particularly in an acute situation. Immediate hydrocortisone and subsequently fludrocortisone are essential to treat Addison's disease.

Treatment of normovolaemic hyponatraemia is described in the section on the syndrome of inappropriate antidiuresis.

Hyponatraemia associated with hypervolaemic disorders responds to single or combined therapy with potent diuretic drugs to remove extracellular sodium, inhibitors of angiotensin-converting enzyme to lower angiotensin II values, and water restriction to less than 1 litre per 24 h.

Irrespective of the cause, chronic severe hyponatraemia (defined as serum sodium < 120 mmol/litre lasting more than 3 days) should be corrected slowly (i.e. at a rate of less than 0.5 mmol/litre/h). Infusion of hypertonic saline should be avoided, but if used the rate of infusion should increase serum sodium by no more than 0.5 mmol/litre/h (10 mmol/litre/24 h) and infusion stopped when serum sodium reaches 120 mmol/litre. A convenient formula determines the likely rate of change of serum sodium concentration following infusion of hypertonic saline and should always be used in patient care:

$$\text{rate of infusion of 3 per cent NaCl solution (ml/h)} = \text{body weight (kg)} \times \text{desired rate of correction of serum sodium (mmol/litre/h)}.$$

Acute symptomatic severe hyponatraemia (developed in less than 3 days; with drowsiness, convulsions, or coma) can be corrected more quickly, with a rate of serum sodium increase of up to 2 mmol/litre/h, but again infusion should stop at a serum sodium concentration of 120 mmol/litre. Regrettably, this condition is almost always iatrogenic, most commonly arising when young women recovering from surgery are ill-advisedly given large quantities of 5 per cent dextrose by intravenous infusion.

Central pontine myelinolysis

The first case of central pontine myelinolysis was described in a young alcoholic. Following many similar cases, it was initially assumed that the condition was due to some form of nutritional deficiency. Association with hyponatraemia was then reported, and the view that this (or its subsequent management) might cause central pontine myelinolysis (also known as osmotic demyelination syndrome) was supported by the finding that dogs made hyponatraemic by repeated injections of vasopressin and intraperitoneal infusions of water, then given hypertonic saline, became quadriparetic with brainstem lesions indistinguishable from those seen in the human condition.

There is undoubtedly a high morbidity and mortality in those with serum sodium concentrations of less than 110 mmol/litre, but debate continues as to whether this is caused by the hyponatraemia itself, or by overzealous treatment of that hyponatraemia. The most feared outcome remains the neurological sequelae of cerebral demyelination, thought to result from large shifts of intracellular water, which occur outside the brainstem as well as in the pons. In most cases reported (if not all), serum sodium has rapidly been corrected to normal levels, hence the recommendation given above that if hypertonic saline is used to correct hyponatraemia, then the infusion must be stopped when serum sodium rises to 120 mmol/litre, allowing more gradual correction from that point onward.

Neurological signs usually develop 2 to 4 days after rapid correction of hyponatraemia. Typical features are quadriplegia and pseudobulbar palsy: these can take the form of a 'locked in' syndrome of mutism with paralysis.

Syndrome of inappropriate antidiuresis

This syndrome is due to inappropriate secretion of vasopressin and is the commonest cause of normovolaemic hyponatraemia. The diagnosis of syndrome of inappropriate antidiuresis is established by ensuring that all the syndrome's criteria are fulfilled (Table 5). This is important: too often the diagnosis is incorrectly claimed on the basis that the first two criteria are met. If they are, this establishes that the level of vasopressin is inappropriate to plasma osmolality, but for the term to be properly applied the level must also be inappropriate to the intravascular volume (it is appropriate to have a high vasopressin level in the context of volume depletion/hypotension). Measurement of urinary sodium is essential: this is persistently elevated in the range 50 to 70 mmol/litre; if it is low, then this suggests that the kidney is attempting to conserve sodium, either due to volume depletion or a sodium-retaining state. The final two criteria specifically exclude those with hypo- and hypervolaemic states, and make the point that the diagnosis can only be confidently made if renal and adrenal function are normal.

Plasma vasopressin estimations are unhelpful in differentiating the syndrome of inappropriate antidiuresis from other causes of hyponatraemia, because the majority of all hyponatraemic states (> 95 per cent) have detectable or elevated values, due to non-osmotic release of the hormone. Persistent circulating vasopressin causes the relative excess of water in all types of hyponatraemia.

Pathophysiology and causes of the syndrome of inappropriate antidiuresis

A very large number of disorders have been associated with the syndrome of inappropriate antidiuresis, some of which are listed in Table 6. In brief, they include a variety of neoplastic conditions, the commonest being small cell carcinoma of the bronchus, non-malignant chest diseases including infections, neurological disorders (infective and vascular), drugs (cytotoxic agents, chlorpropamide, carbamazepine, antidepressants, oxytocin, and thiazide diuretics), recreational agents ('Ecstasy'), and a miscellaneous group (porphyria, cortisol deficiency, idiopathic).

The persistent natriuresis, central to the diagnosis of syndrome of inappropriate antidiuresis, can be explained, in part, by the expanded total body water which is not clinically detectable, causing a reduction in aldosterone production, an increase in circulating natriuretic factors, and a decrease in proximal sodium reabsorption.

Treatment of the syndrome of inappropriate antidiuresis

Identification and successful treatment of the underlying cause of the syndrome of inappropriate antidiuresis will usually correct hyponatraemia. If chronic symptomatic or life-threatening hyponatraemia remains, specific measures to remove the excess total body water are required.

Fluid restriction to 500 ml per 24 h to increase serum sodium to about 130 mmol/litre remains the therapy to be tried first. If this approach is unsatisfactory, additional methods to remove water are justified, the most successful of which is the induction of partial nephrogenic diabetes insipidus with demeclocycline (600 to 1200 mg daily in divided doses), but the maximal effect may take 2 weeks to achieve. It is preferable to lithium carbonate, which although inducing nephrogenic diabetes insipidus is more nephrotoxic. An alternative approach is the administration of furosemide (frusemide) (40–80 mg daily) in combination with oral sodium chloride supplementation (3 g daily). Phenytoin has occasionally proved helpful by suppressing inappropriate neurohypophyseal vasopressin secretion. Infusion of isotonic or hypertonic solutions of saline are not advised because of the real danger that rapid increase in serum sodium concentration might cause the osmotic demyelination syndrome (see above).

The most logical therapy for the syndrome of inappropriate antidiuresis would be a V_2-receptor antagonist. A recently synthesized, linear non-peptide V_2-receptor antagonist, OPC-31260, increases solute-free water excretion. Clinical trials of the treatment of syndrome of inappropriate antidiuresis with this agent are encouraging. This new class of drugs, called aquaretics, should improve management of the syndrome of inappropriate antidiuresis, and other hyponatraemic states associated with excess arginine vasopressin.

Sick cell concept

This concept was formulated following the observation that hyponatraemia developed quickly in severe trauma or overwhelming infection in humans or animals, and in malnourished very ill patients. It is classified as a cause of normovolaemic hyponatraemia. There is a shift of intracellular water into the extracellular compartment due to reduction of intracellular solute either by leakage across a damaged cell membrane, enhanced intracellular catabolism, or possibly due to movement of sodium into the cell. There is no specific therapy other than treatment of the underlying cause.

Hypernatraemic states and thirst deficiency

Hypernatraemia, defined as a serum sodium concentration greater than 150 mmol/litre, is less common than hyponatraemia.

Aetiology and pathophysiology

Hypernatraemia can be classified into two categories dependent on extracellular volume states (Table 7).

Hypervolaemic hypernatraemia is caused by extracellular sodium excess, usually as a result of accidental iatrogenic overdoses of sodium-containing preparations.

Acute hypovolaemic hypernatraemia occurs when patients lose large quantities of hypotonic fluid (for example gastrointestinal). Chronic hypovolaemic hypernatraemia is the result of prolonged water deficit, usually the result of impaired or absent thirst, hypodipsia, or adipsia, which implies a lesion of the thirst osmoreceptor. It is sometimes associated with abnormal osmoregulated vasopressin secretion. Four patterns of osmoregulatory dysfunction have been described (Fig. 7):

- Type A, shows elevation of osmotic thresholds for both thirst and vasopressin. It has been termed 'essential' hypernatraemia; patients continue to dilute and concentrate urine normally, but do so around a higher serum sodium concentration.
- Type B is characterized by decreased sensitivity (slope) of the vasopressin and thirst osmoregulatory lines.
- Type C, the most serious defect, termed adipsic hypernatraemia, is due to complete destruction of both thirst and arginine vasopressin osmoreceptors. Patients never experience the desire to drink, even when serum sodium reaches values as high as 190 mmol/litre.
- Type D is very rare, with selective complete loss of thirst but vasopressin osmoregulation remaining normal.

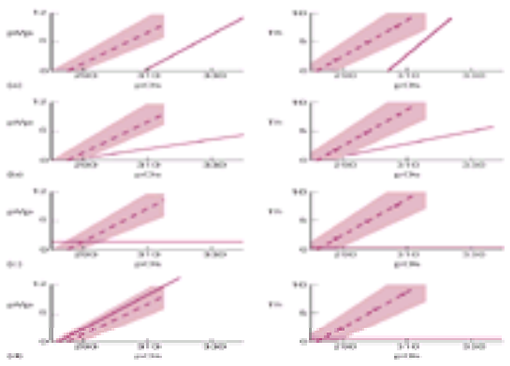

Fig. 7 Patterns of osmoregulated thirst (Th) and plasma vasopressin concentration (pVp) in hypodipsic or adipsic hypernatraemia. The units of pVp are pmol/l and of thirst are 0 to 10 on a visual analogue scale. Stippled areas are the normal responses to increases in plasma osmolality (pOs) and the dashed lines represent mean osmoregulatory lines: (a) reset thirst and vasopressin thresholds or 'essential' hypernatraemia; (b) decreased sensitivity of thirst and vasopressin release; (c) complete destruction of both thirst and vasopressin osmoreceptors; (d) absent thirst osmoregulation with normal osmoregulated vasopressin release. See text for further explanation. (Reproduced from Baylis PH and Thompson CJ (1988). Osmoregulation of vasopressin secretion and thirst in health and disease. *Clinical Endocrinology* **29**, 549–76, with permission.)

Clinical features

Hypervolaemic hypernatraemia causes severe thirst, irritability, and hypotonia and may lead to convulsions, seizures, and death. Clinical manifestations of hypovolaemic hypernatraemia relate to extracellular and intracellular fluid loss, the striking feature being lack of thirst. The slow development of hypernatraemia is often associated with minimal symptoms of confusion or drowsiness.

Treatment of hypernatraemia

Patients require water to lower serum sodium concentration slowly. The safest route of administration is oral, but unconscious patients will require infusion of 5 per cent dextrose solutions. Care must be taken to avoid rapid falls in serum sodium, with the rate of decline no greater than 10 mmol per 24 h.

'Essential' hypernatraemia (Fig. 7, type A) requires little specific therapy as patients are protected from extremes of hypernatraemia. Patients with total loss of thirst and vasopressin osmoregulation pose major management problems. They should be instructed to drink a daily volume of about 2 litres, which should be adjusted according to changes in daily body weight. Desmopressin may be required. Regular checks of serum sodium concentration are essential to avoid wide fluctuations. Constant vigilance is necessary to maintain water balance in chronic hypodipsic or adipsic patients.

20.2.2 Disorders of potassium homeostasis

J. Firth

Potassium homeostasis

Introduction

Potassium is the most abundant cation in the body. Total body potassium ranges between 37 and 52 mmol/kg body weight, and of this 98 per cent is found within cells, where its concentration is in the range 150 to 160 mmol/l. By contrast, the normal range of potassium concentration in serum is from 3.5 to 5.0 mmol/l. The ratio of intracellular to extracellular potassium concentration is a critical determinant of cellular resting membrane potential and thereby of the function of excitable tissues, particularly the nerves and muscles. Potassium tends to leak out of cells through a variety of ion-selective potassium channels found in all cell membranes. The maintenance of the intracellular to extracellular gradient is largely dependent on the ubiquitous Na^{+},K^{+}-ATPase enzyme, which pumps two potassium ions into the cell for every three sodium ions extruded.

The mechanisms of potassium homeostasis can be considered in terms of internal balance (the relationship between intracellular and extracellular potassium concentration) and external balance (which determines total body potassium).

Internal balance

A wide variety of factors modulate the distribution of potassium between the intracellular and extracellular fluid compartments. These factors either alter the function of the Na^{+},K^{+}-ATPase or the rate of efflux of potassium from cells, which together dictate intracellular potassium concentration. In view of the importance of the ratio of internal to external potassium concentration for critical neuromuscular functions, some of these mechanisms serve as essential acute defence mechanisms to counteract life-threatening hyperkalaemia. Factors modulating internal potassium balance are shown in Table 1.

External balance

Dietary potassium intake in Western society typically varies between 50 and 150 mmol/day, but balance can be attained with intake of up to 500 mmol/day if homeostatic mechanisms are intact. In normal circumstances potassium excretion in the stool is not regulated, but it amounts to only 5 to 15 mmol/day. When renal function is compromised, the absolute magnitude as well as the proportion of potassium in the faeces is increased, but variation in renal excretion of potassium is usually the only means by which the body achieves external potassium balance by ensuring that excretion equals intake.

With normal intake of potassium, 10 to 20 per cent of the load filtered at the glomerulus is excreted, but fractional excretion of potassium can vary from 1 per cent when intake is restricted to over 100 per cent when intake is excessive. Micropuncture studies have shown that the amount of potassium reaching the distal convoluted tubule does not vary in these circumstances, indicating that modulation of renal potassium excretion is normally a property of the distal nephron. Factors that modify potassium excretion by the distal nephron are shown in Table 2. These factors are clearly interrelated: it is rare that one is modified in isolation and the overall effect on potassium excretion is almost invariably the aggregate result of several complementary or competing stimuli.

Hypokalaemia

A low serum potassium concentration (3.5 mmol/l or less) is the commonest electrolyte abnormality seen in clinical practice, found in up to 20 per cent of patients in hospital. Most have mild hypokalaemia, with serum potassium in the range 3.0 to 3.5 mmol/l, but 5 per cent have a level lower than 3.0 mmol/l, and 0.03 per cent (more in some series) have very severe hypokalaemia with serum potassium concentration less than 2.5 mmol/l.

Clinical features of hypokalaemia

Patients with mild hypokalaemia often have no symptoms attributable to their low serum potassium concentration. A variety of non-specific symptoms develop with more severe hypokalaemia, including lassitude, generalized weakness, and constipation. At a serum potassium level of less than 2.5 mmol/l serious neuromuscular problems sometimes arise. Rhabdomyolysis (see Chapter 20.4) can occur, and increases in serum creatine phosphokinase activity indicative of muscle injury are frequently detectable in those with a serum potassium concentration below 3.0 mmol/l. Hypokalaemia can cause intestinal ileus, and is particularly likely to do so in the postoperative period when other factors also conspire to prevent normal gut motility. Paralysis of skeletal muscle has been reported, most dramatically in cases of hypokalaemic quadraparesis, which appears to be more common in India than elsewhere. Paraesthesias and tetany have rarely been described.

Hypokalaemia can cause polyuria and polydipsia, also a metabolic alkalosis. Severe prolonged potassium depletion is associated with chronic interstitial nephritis, the presence of renal cysts, and with the development of chronic renal failure. It is not always clear, however, whether hypokalaemia is the cause or effect of this condition.

Hypokalaemia may be suspected from the clinical context (for example the patient taking diuretics or vomiting copiously), but there are no specific physical signs. Alterations induced in the ECG include flattening of the T wave, depression of the S–T segment, and the development of prominent U waves, which can give the impression of a prolonged Q–T interval. These changes, typically observed with a serum potassium concentration lower than 3.0 mmol/l, provide a diagnostic clue to the presence of hypokalaemia, but do not have any serious clinical implications in a patient with a normal heart. However, hypokalaemia can cause problems in those whose heart is abnormal. There is a correlation between hypokalaemia and the development of ventricular tachycardia or ibrillation during the acute phase of myocardial infarction; hypokalaemia can provoke life-threatening arrhythmias in those receiving digoxin; and there is controversy as to whether the mild hypokalaemia often produced by diuretic therapy constitutes a risk factor for sudden cardiac death.

Treatment of hypokalaemia

In emergency

Emergency treatment of hypokalaemia is rarely required. In the rare circumstances of life-threatening cardiac arrhythmia or muscular paralysis, intravenous infusion of potassium (usually potassium chloride) should be given immediately. This must be administered into a central vein (internal jugular, subclavian, or femoral) since solutions containing the necessary high concentration of potassium cause pain and phlebitis if given peripherally, and can cause chemical burns if they extravasate. There is no good evidence on which to base a recommendation regarding dose and rate, but the maximum rate of infusion usually employed is 1 mmol/min, which

should be controlled with a volumetric pump. The main danger of giving potassium with such rapidity is the development of hyperkalaemia, hence the patient and their ECG should be observed continuously, the serum potassium should be checked frequently, and infusion slowed as soon as the life-threatening problem has resolved (arrhythmia settled, muscular power improved). In one study, administration of 40 mmol of potassium over 1 h was found to increase serum potassium concentration by an average of 1.1 mmol/l in hypokalaemic patients with both normal and impaired renal function.

In cases that are not emergencies

In most circumstances the management of a patient with hypokalaemia requires a methodical approach to establishing the diagnosis, which is often readily apparent (but not always so), rectification (if possible) of the underlying cause, and administration of potassium at a less hurried rate than that described above. In most cases of hypokalaemia, the fall in the serum potassium concentration represents the tip of an iceberg, a reduction of 0.3 mmol/l typically reflecting a 100 mmol deficit in body stores. This relationship is variable, but it is important to remember that patients with even modest hypokalaemia may have a very considerable deficit of total body potassium that needs to be replaced.

Potassium can be given orally or intravenously. Foods with high potassium content are listed in Table 7, but it should be noted that the potassium which they contain is almost entirely coupled with phosphate. In the absence of adequate chloride intake they are therefore ineffective in replenishing body potassium in the many and common causes of hypokalaemia associated with chloride depletion (such as diuretics or vomiting). Potassium chloride can be given in either liquid or tablet form, typically 2 to 4 g (approximately 25 to 50 mmol) daily in divided doses. Both are well absorbed, but the liquid preparations are unpalatable to many patients and slow-release tablets have been associated with gastrointestinal ulceration, bleeding, and stricture, such that they must be taken with fluid whilst sitting or standing and not just before retiring to bed for the night. If intravenous administration of potassium is required, infusions containing a concentration of 20 mmol/l can usually be tolerated through a good peripheral line. If a higher concentration than this is required, central venous access will be necessary. Care must always be taken to monitor serum levels closely.

Common causes of hypokalaemia

There are a very large number of possible causes of hypokalaemia (Table 3), but in most instances the diagnosis is immediately apparent. Whenever this is not so, it is wise to remember that common things are the most likely. In the case of patients with hypokalaemia it is also important to recognize that concealment of the diagnosis is not infrequent, with diuretic abuse or covert vomiting more likely than the more exotic and rare causes of this condition. Hypokalaemia is not a prominent feature of many of the disorders listed in Table 3: discussion in this chapter will be limited to those conditions that are common, or where hypokalaemia is an important manifestation.

A pragmatic approach is first to consider the most frequent causes of hypokalaemia—diuretic ingestion and gastrointestinal fluid loss—and then proceed to a systematic analysis if these are not evidently the cause of the problem.

Treatment with diuretics

The most common cause of hypokalaemia is diuretic therapy. All diuretics other than those acting directly on the collecting duct (amiloride, triamterene, spironolactone) block some form of chloride-associated sodium transport. As a result they increase the delivery of sodium to the collecting duct, where its reabsorption creates a favourable electrochemical gradient for and obligates potassium secretion. Hypokalaemia frequently occurs together with metabolic alkalosis (serum bicarbonate concentration 28 to 36 mmol/l). In general, the hypokalaemia is mild, with serum potassium in the range 3 to 3.5 mmol/l; the average fall after inititation of the usual doses of loop diuretics (frusemide, bumetanide, torasemide) being about 0.3 mmol/l, somewhat more with the usual doses of thiazides (bendrofluazide, chlorothiazide, chlorthalidone) at about 0.6 mmol/l. In one analysis of publications on hypokalaemia and diuretics it was found that the fall in serum potassium was little influenced by the reason for prescription (hypertension or heart failure), or by the dose or duration of treatment.

The question of whether or not patients receiving diuretics prone to induce hypokalaemia should be prescribed potassium supplements or potassium-retaining diuretics has been much debated. There is no strong evidence on which to base recommendations. It seems common sense to monitor for and intervene to prevent hypokalaemia in those considered at particular risk of hypokalaemic complications, including those with a history of cardiac arrhythmia, those on digoxin, and those with liver disease in whom electrolyte imbalance might precipitate encephalopathy. Most patients do not fall into any of these categories, and here the balance is between an attempt to prevent a hypothetical but unproven hazard and the requirement for medication that is unpalatable to many and in rare cases can have significant side-effects. As in many other aspects of medicine, the behaviour of the physician will say as much about them as about the condition that they are dealing with. Those that like all test results to be in the 'normal range' will prescribe, but short of stopping diuretic therapy, correcting diuretic-induced hypokalaemia is not easy. In one study that monitored adverse drug reactions in 5047 consecutive inpatients, 2439 were taking potassium-losing diuretics, in whom serum potassium was less than 3.5 mmol/l in 21 per cent, and below 3.0 mmol/l in 3.8 per cent. If the group taking potassium-losing diuretics was broken down into those taking them without any attempt to prevent hypokalaemia, those taking them in conjunction with potassium supplements, and those taking them together with a potassium-sparing diuretic, then serum potassium below 3.5 mmol/l was found in 24.9, 19.7, and 15.2 per cent, respectively.

Loss of gastrointestinal fluid

In one study of severe hypokalaemia (serum potassium less than 2.5 mmol/l), gastrointestinal fluid loss was the main cause in 22 per cent of cases.

Vomiting

The concentration of potassium in gastric and upper intestinal secretions is between 3 and 12 mmol/l. Reduced intake and direct loss of potassium in vomit are not, therefore, the main causes of hypokalaemia, which arises due to increased renal excretion of potassium. Why does this happen? Circumstances can arise in which the renal response to one pathophysiological abnormality takes precedence over another, and where the attempt to correct one imbalance actually has the effect of worsening another. This is the situation when the kidney responds to prolonged vomiting. Aside from modest quantities of potassium, gastric juices contain sodium ions (30 to 90 mmol/l), protons (90 mmol/l), and chloride (50 to 125 mmol/l). Loss of gastric acid (HCl) pulls the buffer equation $H_2CO_3 + Na^+ + Cl^-$ in equilibrium with $Na^+ + HCO_3^- + H^+ + Cl^-$ to the right, hence the main effect is metabolic alkalosis. Depletion of extracellular fluid volume also occurs, activating the renin–angiotensin–aldosterone system. As the bicarbonate concentration in the blood rises, more is filtered at the glomerulus and some is excreted in the urine, partly in conjunction with potassium, whose distal excretion is stimulated by high levels of aldosterone. Considerations of acid–base balance have taken precedence over those of potassium homeostasis, and hypokalaemia results.

An important point to note is that the combination of direct chloride loss in vomit and contraction of extracellular fluid volume lead to a situation where the kidney avidly retains chloride and the urinary concentration of chloride falls to a very low level (less than 10 mmol/l, sometimes as low as 1 to 2 mmol/l, when the normal range is 30 to 120 mmol/l). This has critical clinical significance in two circumstances. First, since reabsorption of filtered sodium and potassium ions by the renal tubule can only be achieved in combination with an anion, usually chloride, then if urinary chloride concentration is already close to zero there is no way in which sodium and potassium can be reabsorbed efficiently. Hence, sodium and potassium that are administered can only be retained if provided in conjunction with chloride, and not if given as other salts. Second, measurement of urinary chloride concentration can be helpful in making the diagnosis of surreptitious vomiting (see later).

Resuscitation of the patient with hypokalaemia due to vomiting requires the intravenous infusion of 0.9 per cent sodium chloride, together with potassium supplementation as described above. In severe cases the total body deficit of fluid may be in excess of 5 litres, and of potassium of many hundreds of millimoles.

Diarrhoea

The concentration of potassium in stool is 80 to 90 mmol/l. Hence, given normal stool weight of 100 to 200 g/day, faecal loss of potassium is usually in the range 5 to 15 mmol/day. The potassium concentration in the stool decreases as stool volume increases, but volume can increase massively, such that substantial potassium loss and profound hypokalaemia can complicate any severe diarrhoeal illness.

Potassium loss in diarrhoeal states is usually associated with loss of bicarbonate, resulting in a coexisting metabolic acidosis, such that serum levels of potassium may not reflect the true body deficit. In this circumstance the renal excretion of potassium is broadly appropriate, and potassium deficiency is not due to a renal leak. However, in some situations potassium is lost in conjunction with chloride, resulting in a metabolic alkalosis and a picture similar to that seen with vomiting (see

above).

A villous adenoma of the colon or rectum can rarely result in profound hypokalaemia. The mechanism seems to involve secretion of cyclic AMP and prostaglandin E_2 by the tumour, leading to disturbance of ion transport in the normal colonic mucosa. Treatment with non-steroidal anti-inflammatory agents can significantly reduce stool volume and help to correct both volume depletion and hypokalaemia. Similar disturbances probably underlie the hypokalaemia of patients with the watery diarrhoea, hypokalaemia, and achlorhydria (WDHA) syndrome, caused by excess vasoactive polypeptide (VIP) secreted by certain tumours. In addition to treatment directed at the tumour itself, somatostatin or somatostatin analogues are effective in controlling symptoms.

Ureteric diversion

Diversion of the ureters into the colon (ureterosigmoidostomy) is most commonly performed in children for the treatement of bladder exstrophy, but occasionally for other reasons. If urine remains in contact with the colonic mucosa for a long time there is a tendency for the colon to reabsorb urinary ammonium and secrete bicarbonate, leading to hyperchloraemic acidosis, and also for stimulation of colonic potassium secretion, resulting in hypokalaemia. These can have serious consequences: profound acidosis can occur with concurrent illness, and chronic renal failure can develop. Close metabolic monitoring of patients with ureterosigmoidostomies is essential, and substantial metabolic disturbance is an indication for revision of the procedure, which is performed less frequently following improvement in surgical techniques for ileal conduits and alternative urinary diversions.

Diagnosing the cause of hypokalaemia in difficult cases

The diagnosis of the cause of hypokalaemia is usually straightforward and explained by diuretic therapy or gastrointestinal fluid loss, as described above. In other patients the abnormality is mild, with the occasional serum potassium concentration measured at just below the lower limit of the normal range, such that extensive investigation is almost certainly inappropriate (and likely to be fruitless if pursued). However, some patients present with unexplained severe hypokalaemia, and these represent a considerable challenge for both diagnosis and management. The differential diagnosis in these cases usually lies between concealed ingestion of diuretics, concealed vomiting and/or usage of purgatives, and various abnormalities of tubular potassium transport.

It is important to ask directly for a history of vomiting or diarrhoea, and about present or past use of any medications, particularly diuretics or purgatives. It is also worthwhile to ask about consumption of liquorice or chewing tobacco (see below). Examination is likely to be unremarkable in cases of unexplained hypokalaemia, but pay particular attention to body weight/height/body mass index, and to any other features that might support the diagnosis of an eating disorder such as anorexia nervosa or bulimia nervosa (see Chapter 26.5.5).

One study reported the findings of extensive investigation of 27 adult patients (17 women) who presented with chronic hypokalaemia (serum potassium concentration less than 3.4 mmol/l) that was sustained for over 5 years and which had previously eluded diagnosis. The following diagnoses were established: diuretic abuse (in five patients), surreptitious vomiting (eight), laxative abuse (one), renal tubular acidosis (one), and Gitelman's syndrome (12). Medical work-up that had sought to make the diagnoses by measurement of plasma renin activity, plasma aldosterone concentration, and urinary potassium concentration failed to discriminate between these conditions. Investigations that were diagnostically helpful are given in Table 4, the most useful being the plasma pH and chloride concentration, urinary chloride concentration and screen for diuretics, and (in one case) stool weight.

The finding of a low plasma chloride concentration with the virtual absence of chloride from the urine supports the diagnosis of surreptitious vomiting. Screening the urine for diuretics is appropriate if the urinary chloride concentration is above 20 mmol/l, and if no diuretics are found in samples with a chloride concentration of above 50 mmol/l then Gitelman's syndrome is likely. Vomiting, diuretics, and Gitelman's syndrome all cause alkalosis, whereas laxative abuse is associated with acidosis, as is renal tubular acidosis. The diagnosis of renal tubular acidosis can be established by demonstrating an inability to produce acid urine in the presence of systemic acidosis (see Section 20.8 for further discussion).

The management of cases of surreptitious vomiting, or diuretic or purgative abuse is difficult. Many patients will fulfil diagnostic criteria for anorexia nervosa or bulimia nervosa, and issues other than those simply and directly related to potassium homeostasis will clearly need to be considered. The physician may well need to seek expert psychiatric help. See Chapter 26.5.3 for further discussion.

Rare causes of hypokalaemia

Altered external potassium balance

Mineralocorticoid excess

Hypokalaemia can be caused by a large number of causes of mineralocorticoid excess, as shown in Table 3. Primary aldosteronism is discussed in Chapter 12.7.1 and Chapter 15.16.2.3, congenital adrenal hyperplasia in Chapter 12.7.2, and glucocorticoid-remediable aldosteronism in Chapter 15.16.1.2. Hypokalaemia is rarely a prominent feature of the other conditions of mineralocorticoid excess listed, which are discussed elsewhere in this book.

Apparent mineralocorticoid excess

Activating mutations in the b- or g-subunits of the epithelial sodium channel in the collecting duct causes Liddle's syndrome. Disabling mutations in the type 2 11b-hydroxysteroid dehydrogenase gene cause a deficiency of the enzyme, allowing cortisol access to the mineralocorticoid receptor and the syndrome of apparent mineralocorticoid excess. Acquired inhibition of the action of 11b-hydroxysteroid dehydrogenase can be caused by liquorice, carbenoxolone, and chewing tobacco. Hypokalaemia with low plasma concentrations of renin and aldosterone are features of all of these conditions, which are discussed in Chapter 15.16.1.2.

Renal transport abnormalities

Patients with renal tubular acidosis type I are prone to hypokalaemia, as discussed in Chapter 20.8.

In 1962 Bartter described 'hyperplasia of the juxtaglomerular complex with hyperaldosteronism and hypokalemic alkalosis: a new syndrome'. Well over a hundred papers were subsequently written to describe features of what was believed to be the same eponymously named condition. The picture became immensely confused, but since 1995 has been clarified by the recognition of distinct phenotypes within the group of patients previously thought to have 'Bartter's syndrome' and the application of powerful molecular genetic methods to their study. These have revealed that most patients previously thought to have Bartter's syndrome do not have this condition, but have Gitelman's syndrome instead.

Bartter's syndrome

This is now classified into three types: each is an autosomal recessive disorder caused by mutation of an ion transporter or ion channel that is present in cells of the thick ascending limb of the nephron (Fig. 1).

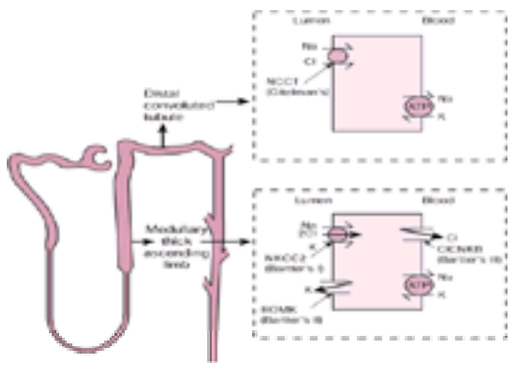

Fig. 1 Some genetic disorders of the renal tubule that cause hypokalaemia. NCCT, Na-Cl cotransporter; NKCC2, Na-K-2Cl cotransporter; ROMK, ATP-regulated potassium channel; CLCNKB, kidney-specific chloride channel.

Bartter's syndrome type I: *NKCC2* mutations

This was originally described in six consanguineous families. Affected individuals were born prematurely after pregnancies complicated by polyhydramnios and developed severe dehydration in the first few days of life. All affected individuals had severe hypercalciuria in addition to hypokalaemic alkalosis, and most had nephrocalcinosis. In all cases disease was associated with destructive mutations in the gene encoding the Na-K-2Cl cotransporter (NKCC2), which is localized to chromosome 15. Other clinical manifestations can include short stature, mental retardation, rickets, generalized weakness, and muscle cramps. Other reported abnormalities on investigation can include hyperreninism, hyperaldosteronism, increased renal prostaglandin production, erythrocytosis, a platelet aggregation defect, impaired vascular responses to angiotensin II, and hypertrophy or hyperplasia of the juxtaglomerular apparatus. Management is supportive: dehydration must be avoided and potassium supplementation is needed; non-steroidal anti-inflammatory agents may be helpful (although they tend to be more useful in type II disease). There is a high mortality rate before diagnosis, with infants often dying due to volume depletion caused by intercurrent illness, but the prognosis in cases where the diagnosis is made and where care is taken to avoid volume depletion is not known.

Bartter's syndrome type II: *ROMK* mutations

Abnormality of the *NKCC2* gene product was excluded in five families where individuals also presented with severe neonatal dehydration, hypercalciuria, and nephrocalcinosis. The only clinical distinction from Bartter's syndrome type I was that patients often had a transient initial hyperkalaemia, with serum potassium falling rapidly into the hypokalaemic range as soon as they were rehydrated. An obvious explanation was mutation in another gene or genes whose product interacted with NKCC2 in some way. In 1993 and 1994 a renal potassium channel had been cloned from rat and humans, and this apical ATP-sensitive potassium channel (ROMK) that recycles potassium back into the lumen and is critical for continued activity of the NKCC2 cotransporter was an obvious candidate. Functionally significant mutations of *ROMK* (also known as KCNJ1) were identified in all affected individuals. Management and prognosis is as for Bartter's syndrome type I.

Bartter's syndrome type III: *CLCNKB* mutations

To determine whether mutation of other genes could account for the Bartter's phenotype a large number of patients with inherited hypokalaemic alkalosis, normomagnesaemia, and normocalciuria or hypercalciuria were studied. Most (those in 44 of 66 families) did not have mutations in *NKCC2* or *ROMK*. In 1994 two highly homologous renal chloride channels were cloned, *CLCNKA* and *CLCNKB*, and the latter was shown to be the cause of the Bartter's syndrome in a number of the families. The clinical picture was more varied than that for types I or II Bartter's syndrome, ranging in severity from near fatal volume depletion with hypokalaemic alkalosis and respiratory arrest to mild disease presenting in a teenager with polyuria and weakness. None of the patients had nephrocalcinosis, distinguishing them phenotypically from those with *NKCC2* or *ROMK* mutations. Management is with potassium supplementation and care to avoid dehydration. Long-term prognosis is uncertain.

Gitelman's syndrome

Gitelman's syndrome is the commonest genetic cause of hypokalaemia. If it presents clinically, it typically does so in early adulthood with hypotension, alkalosis, and salt wasting, along with hypomagnesaemia, hypocalciuria, and hypermagnesuria (see Table 4). The marked similarity between this picture and that induced by thiazide diuretics, which are potent inhibitors of the Na-Cl cotransporter (NCCT) in the distal convoluted tubule of the nephron, led to a candidate gene approach to the condition as soon as the thiazide-sensitive NCCT gene had been cloned. Mutations in the *NCCT* gene are responsible for Gitelman's syndrome (Fig. 1), which is an autosomal recessive condition.

Since there are no dramatic clinical symptoms or signs, suspicion of the diagnosis of Gitelman's syndrome often arises only when hypokalaemia is found (or in screening of family members of a known case). However, in one recent study it was clearly shown that patients with Gitelman's syndrome are significantly more symptomatic than controls, reporting salt craving, musculoskeletal symptoms (cramps, muscle weakness, and aches), constitutional symptoms (fatigue, generalized weakness, and dizziness), nocturia, and polydipsia. Forty-five per cent of patients considered their symptoms to be a moderate problem or worse.

Management is with potassium and magnesium supplements, it being important to recognize that in the face of magnesium depletion the kidney cannot retain potassium, but these are often poorly tolerated. Diuretics that block sodium reabsorption in the collecting duct (spironolactone, triamterene, and amiloride) can reduce urinary potassium excretion and raise the serum potassium concentration, but they often need to be accompanied by salt-loading to prevent volume depletion and hypotension. Non-steroidal anti-inflammatory agents can sometimes be helpful, but their mechanism of action is uncertain. The long-term prognosis of patients with Gitelman's syndrome is not known.

Heterozygote carriers of Bartter's or Gitelman's mutations

The phenotypes that might be associated with heterozygote carriage of the Bartter's and Gitelman's mutations have not been well characterized. Heterozygote carriers of Gitelman's mutations have increased urinary sodium excretion (due to a self-selected higher salt intake), modestly lowered blood pressure (in childhood if not in adulthood), a serum potassium concentration towards the lower limit of the normal range, and increased susceptibility to hypokalaemia induced by diuretics. Similar features would be anticipated in Bartter's heterozygotes. Carriers of Gitelman's mutations have increased bone density; carriers of Bartter's may have a predisposition to osteoporosis or nephrolithiasis caused by hypercalciuria.

Abnormal internal potassium balance

Although there are many causes of hypokalaemia (Table 3), there are relatively few causes of hypokalaemia associated with extreme weakness, the commonest explanation for this rare presentation being hypokalaemic periodic paralysis. In Western countries most cases of hypokalaemic periodic paralysis are familial, termed familial periodic paralysis, whereas in Asian populations the commonest cause is thyrotoxic periodic paralysis. In all forms of hypokalaemic periodic paralysis the hypokalaemia and paralysis result from an acute shift of potassium into cells, the mechanism for which is unknown, although there is speculation that it is due to a transient hyperadrenergic state.

One study reviewed the medical records of 97 patients who presented over a 10-year period to hospital in Taiwan with severe hypokalaemia (plasma potassium less than 3.0 mmol/l, mean 2.2 mmol/l) and acute loss of muscle strength with inability to walk. The final diagnoses established are shown in Table 5.

Treatment of acute attacks of hypokalaemic periodic paralysis traditionally involves the administration of intravenous potassium, some patients recovering with as little as 20 mmol, but others requiring over 200 mmol. In all types of this condition a paradoxical fall in serum potassium concentration can occur at the start of treatment, and rebound hyperkalaemia is also seen.

Thyrotoxic periodic paralysis

The diagnosis of thyrotoxic periodic paralysis is established if hyperthyroidism is present when hypokalaemic paralysis occurs. About 50 per cent of patients give a history of thyrotoxic symptoms, but there is no family history of paralysis. Attacks are often provoked by a large carbohydrate meal (perhaps via the mechanism of an exaggerated response to insulin) or adrenergic stress. Physical findings during an attack include tachycardia (a useful diagnostic discriminator from sporadic periodic paralysis) and high blood pressure; signs of hyperthyroidism are absent in 20 to 40 per cent of cases. In 39 patients reported from Taiwan the mean serum T_3 concentration was 4.5 nmol/l (range 2.3 to 8.4, upper limit of normal being 3.0), the mean serum T_4 concentration was 201 nmol/l (range 154 to 299, upper limit of normal 154), and the mean thyroid-stimulating hormone was less than 0.06 mU/l (range less than 0.06 to 0.32; normal 0.5 to 5.0). Hypophosphataemia and hypomagnesaemia are also found, the latter also being low in patients with Gitelman's syndrome.

Although treatment of thyrotoxic periodic paralysis conventionally involves administration of potassium, recent experience suggests that patients with this condition respond rapidly to the b-blocker propanolol (3 mg/kg, given orally). This, rather than potassium, is now the preferred first-line treatment, with the expectation that serum potassium concentration will return to normal and paralysis will resolve within 2 h.

Sporadic periodic paralysis

The cause of sporadic periodic paralysis is not known: patients do not have a family history of hypokalaemic periodic paralysis and do not have hyperthyroidism. There are no obvious precipitating factors. Heart rate at presentation is lower than for those with thyrotoxic periodic paralysis (mean 76 compared with 105 beats/min). Emergency treatment is with intravenous potassium. Propanolol is ineffective. Oral potassium chloride supplements or acetazolamide are used to prevent recurrent attacks. The mechanism of action of acetazolamide is uncertain, but it has been reported in an animal model that it causes activation of the sarcolemmal calcium-activated potassium channel.

Familial hypokalaemic periodic paralysis

The diagnosis is established by finding a family history of attacks of flaccid weakness and hypokalaemia. These can be precipitated by administration of insulin or glucose and aborted by exercise, which induces an exaggerated rise in serum potassium concentration, or by administration of potassium.

Familial hypokalaemic periodic paralysis can be caused by mutations in three genes. First, the *CACNL1A3* gene, which encodes a dihydropyridine receptor that functions as a voltage-gated calcium channel and is also critical for excitation–contraction coupling in a voltage-sensitive and calcium-independent manner. Second, the *SCN4A* gene that encodes for a sodium channel and is also the site of mutations causing hyperkalaemic periodic paralysis. Third, the *KCNE3* gene, which encodes a potassium channel. The conditions are autosomal dominant, with 100 per cent penetrance in males, but much less in females.

Treatment is as for sporadic periodic paralysis. Acetazolamide usually prevents recurrent attacks, but one family has been reported where this made the condition worse (a beneficial response to triamterene was observed).

Sudden unexplained death syndrome

Between 1982 and 1990 there were a total of 235 cases of sudden unexplained death syndrome (**SUDS**) in apparently healthy male Thai migrant workers in Singapore. SUDS, known locally as *laitai*, is a leading cause of death in young men in rural north-eastern Thailand, where one study reported an annual incidence of 38 per 100 000 men aged 20 to 49 years. It is also reported elsewhere in Asia. Women are rarely, if ever, affected. Death occurs at rest and is nocturnal in most (84 per cent) cases. There is a family history of SUDS more often than would be expected by chance. In cases that are observed, witnesses often report that death is preceded by a few minutes of groaning, choking, coughing, and muscular spasticity or paralysis.

The cause of SUDS is not known; hypotheses include stress, genetic factors, dietary deficiency (perhaps of thiamine), potassium deficiency, melioidosis, and sleep disorders. With regard to potassium, survivors of SUDS-like attacks and relatives of victims of SUDS have been reported to have significantly lower activity of erythrocyte Na^+,K^+-ATPase and lower plasma potassium concentration than controls, but the reason for and significance of these findings is not certain.

Hyperkalaemia

Clinical features and treatment of hyperkalaemia

Hyperkalaemia is the most serious of all electrolyte disorders, despite being relatively infrequent, because it typically produces no recognizable symptoms before causing cardiac arrest. Some patients report muscular symptoms such as weakness, stiffness, or simply a 'funny feeling', but the significance of these is rarely appreciated. A high serum potassium concentration leads to membrane depolarization in excitable tissues, making the initation of an action potential more likely, and to increased membrane potassium conductance, which impairs recovery after an action potential. The effect is to cause electrical instability with the risk of life-threatening arrhythmia. The likelihood of such an event increases as the serum potassium concentration rises, but some patients are more resistant to the cardiac effects of hyperkalaemia than others: for instance, those with endstage renal failure on long-term dialysis may be habitually hyperkalaemic (although this is not to be encouraged) and tolerate a plasma potassium concentration that would kill a normal person if imposed acutely.

The best guide to the significance of hyperkalaemia in any particular individual is the impact that it is having on the ECG, and an ECG should be obtained immediately in any patient in whom the question of hyperkalaemia arises. The earliest change is tenting of the T wave, progressing as the plasma potassium concentration rises to P-wave flattening, prolongation of the P–R internal, widening of the QRS complex, and eventually a 'sine wave' pattern as a prelude to ventricular fibrillation and death. All involved in the care of acutely ill patients must be able to recognize this pattern of ECG changes and give effective emergency treatment for severe hyperkalaemia, as described in Chapter 20.5.

Causes of hyperkalaemia

There are many causes of a high serum potassium concentration (Table 6), but a survey of over 400 cases found that renal failure was present in 43 per cent and potassium supplements or potassium-sparing diuretics had been taken by 37 per cent. Life-threatening hyperkalaemia is almost exclusively seen in those with renal failure, often in conjunction with another exacerbating cause. Common scenarios would be the patient with acute renal failure who is hypercatabolic or has extensive tissue destruction, as in rhabdomyolysis, or the patient with endstage renal failure who has missed a dialysis treatment, not adhered to a low potassium diet (see Table 7), or suffered an upper gastrointestinal haemorrhage, thereby inadvertently consuming a high potassium meal.

Hyperkalaemia is not a prominent feature of many of the conditions listed in Table 6: further discussion in this chapter will be limited to disorders other than renal failure that are not discussed elsewhere in this textbook and in which hyperkalaemia is a common or important manifestation.

Pseudohyperkalaemia

Haemolysed samples show hyperkalaemia, which also occurs when there is considerable delay between venepuncture and separation of red cells and plasma or serum in the laboratory, allowing potassium to leak out of red cells after venesection. However, aside from these common and banal explanations, there are other reasons for pseudohyperkalaemia.

Potassium is released from white blood cells and platelets as blood coagulates, causing the serum potassium concentration to exceed, by a few tenths of a millimole per litre, that of plasma estimated in a parallel sample. This process is greatly exaggerated when gross leucocytosis or thrombocytosis is present, such that the serum potassium concentration can be over 2 mmol/l higher than that in plasma. The plasma and not the serum potassium concentration should obviously be measured in this circumstance.

There is also the rare syndrome of familial pseudohyperkalaemia, first described in 16 members of three generations of a kindred from Edinburgh who had elevated plasma potassium if the red cells were not separated promptly. Several other families have been described, in each of which there appears to be one of a variety of abnormalities in the temperature sensitivity of the ouabain-plus-bumetanide-resistant potassium flux, which reflects the passive leak. The blood film may show a few target cells, red cell survival is shortened, but there is no frank haemolysis. Other phenotypic abnormalities have been described in some families.

Abnormal external potassium balance

Mineralocorticoid deficiency

Hyporeninaemic hypoaldosteronism

It is not uncommon to find patients with chronic renal failure who have hyperkalaemia despite a glomerular filtration rate that should be sufficient to maintain

normokalaemia. Two-thirds of these will have the syndrome of hyporeninaemic hypoaldosteronism, which should be suspected in any patient with hyperkalaemia without other obvious explanation. Tubulointerstitial forms of renal disease predominate in this population and diabetes mellitus is common. Hyperkalaemia is usually asymptomatic, but presentation with cardiac arrhythmia and/or muscle weakness has been described.

Characteristics of the syndrome include low levels of plasma renin activity, which are unresponsive to sodium restriction or frusemide, low plasma and urinary aldosterone, hyperkalaemia, and hyperchloraemic metabolic acidosis. Fractional potassium excretion is low for the glomerular filtration rate, and the response to kaliuretic stimuli is blunted. Glucocorticoid metabolism is normal.

The cause of both hyporeninism and hypoaldosteronism is not known. Decreased renin secretion may be the result of pathological involvement of the juxtaglomerular apparatus, but this is not obvious histologically in cases where renal biopsies have been performed. Other hypotheses include defective prostacyclin production and disordered conversion of inactive (prorenin) to active renin, which is a well-documented observation in diabetes mellitus. Chronic expansion of extracellular fluid volume has also been blamed since plasma renin activity may be increased by prolonged sodium restriction or diuretic therapy. By contrast, acute salt restriction can worsen hyperkalaemia in these patients by diminishing the distal delivery of sodium without a concurrent rise in aldosterone secretion, and illnesses causing volume depletion can precipitate presentation with dangerous hyperkalaemia. Hypoaldosteronism is probably related to the low level of plasma renin activity, but the situation is more complicated than this since most patients secrete subnormal amounts of aldosterone in response to infusion of both angiotensin II and ACTH, suggesting a defect in the function of the adrenal gland.

Criteria for establishing the diagnosis of hyporeninaemic hypoaldosteronism are not well defined, and it is uncommon for patients to be intensively investigated in routine clinical practice since treatment is usually straightforward. However, establishing the diagnosis with certainty depends on demonstrating deficient responses of renin and aldosterone to sodium depletion. One study reported plasma renin and aldosterone concentrations in subjects in an upright posture after administration of 60 mg of intravenous frusemide: the renin concentration in those with hyporeninaemic hypoaldosteronism was 6 ± 2 ng/ml per minute (compared with 34 ± 6 in controls matched for degree of renal failure) and aldosterone concentration was 7 ±2 ng/dl (compared with 28 ±2 8 in controls).

Therapy for hyporeninaemic hypoaldosteronism includes dietary potassium restriction and avoidance of drugs that can cause hyperkalaemia. Measures to increase urinary excretion of potassium, such as the use of thiazide or loop diuretics, can be useful. Cation exchange resins can be used to increase elimination of potassium from the gut, but compliance with long-term use of these medications is difficult to achieve. Although mineralocorticoid replacement (fludrocortisone, 0.2 mg/day) effectively treats the hyperkalaemia, sodium retention and worsening hypertension are often unacceptable side-effects.

Effects of drugs on the renin–angiotensin–aldosterone system

Non-steroidal anti-inflammatory agents

Prostaglandin synthetase inhibitors produce hyporeninaemic hypoaldosteronism by interfering with prostacyclin-mediated renin secretion, with reduction in glomerular filtration rate and distal sodium delivery as potential contributory factors. These effects, as might be expected, become more important in the context of renal impairment: in one study approximately a quarter of patients with chronic renal failure developed hyperkalaemia after treatment with indomethacin.

Angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers

Angiotensin-converting enzyme (**ACE**) inhibitors and angiotensin II receptor blockers produce hyperkalaemia by impairing angiotensin II-mediated secretion of aldosterone. In one study hyperkalaemia was found in 46 of 119 (39 per cent) patients taking ACE inhibitors who were attending a renal clinic. The higher the serum creatinine concentration, the greater the chance of hyperkalaemia. Those with diabetes were also at particular risk. The treatment had to be stopped in 15 patients (13 per cent).

ACE inhibitors and spironolactone have been found to improve prognosis in heart failure, but care is needed when prescribing for those who might be prone to hyperkalaemia. One study reported life-threatening hyperkalaemia (mean serum potassium 7.7 mmol/l) in 25 patients who had received this combination of medications.

Calcineurin inhibitors

Hyperkalaemia is a well-documented complication of the immunosuppressive drugs cyclosporin and tacrolimus (FK506). Two mechanisms are possible, both of which may be exacerbated by reduction in glomerular filtration rate caused by nephrotoxicity. First, drug-induced hyporeninaemic hypoaldosteronism, which is well documented with tacrolimus. Second, in association with a distal tubular acidification defect that is caused (mechanism unknown) by both cyclosporin and tacrolimus.

Heparin

Hyperkalaemia occurs in about 7 per cent of patients given heparin, which is a potent inhibitor of aldosterone production. It can arise with doses as low as 10 000 units/day, but—as with most other hyperkalaemic stimuli—clinically important elevations in the plasma potassium concentration are found only when more than one homeostatic mechanism for potassium is deranged. Patients with endstage renal failure who receive unfractionated heparin to provide anticoagulation during haemodialysis treatments have a higher predialysis plasma potassium than those given low-molecular-weight heparin.

The most important mechanism of aldosterone inhibition appears to involve reduction in both numbers and affinity of angiotensin II receptors in the zona glomerulosa, which is reduced in width by prolonged use of heparin. Direct inhibition of the enzyme 18-hydroxylase has also been postulated. Production of other corticosteroids is not affected.

Renal transport abnormalities

Tubulointerstitial renal disease

A few hyperkalaemic patients with chronic renal failure but a glomerular filtration rate that should be adequate for potassium homeostasis have normal levels of aldosterone and plasma renin activity and seem to have a primary defect in the ability of the distal nephron to excrete potassium. They typically have tubulointerstitial types of renal diseases, the abnormality being documented in patients with obstructive uropathy, renal transplants, sickle-cell disease, systemic lupus erythematosus, amyloidosis, and medullary sponge kidney—all of which can also be associated with hyporeninaemic hypoaldosteronism. In contrast to patients with hyporeninaemic hypoaldosteronism, their hyperkalaemia is unresponsive to mineralocorticoid replacement therapy.

Type IV renal tubular acidosis

Hyperkalaemia due to impaired renal excretion of potassium may be a feature of type IV or voltage-dependent renal tubular acidosis. The lumen negative potential difference along the distal nephron normally facilitates the excretion of potassium and hydrogen ions, and hyperkalaemia and metabolic acidosis occur when this is reduced. This condition is discussed in Chapter 20.13.

Drugs

Potassium-sparing diuretics are obviously likely to cause hyperkalaemia in those with any predisposition to this condition. They should not be used in those with renal failure, and the serum potassium concentration must be monitored closely in patients taking these agents who become acutely unwell.

Trimethoprim–sulphamethoxazole

A review of 80 patients treated with standard-dose trimethoprim (up to 320 mg/day) and sulphamethoxazole (up to 1600 mg/day) showed that this increased the serum potassium concentration by an average of 1.2 mmol/l, whereas there was no change in a control group receiving other antibiotics. Some studies have shown a lesser effect than this, but even larger increases in serum potassium concentration have been reported in those receiving high-dose trimethoprim–sulphamethoxazole to

treat pneumocystis, and hyperkalaemia is also reported with use of pentamidine. Both trimethoprim and pentamidine block the apical sodium channel in the distal nephron in a manner similar to amiloride.

Pseudohypoaldosteronism

Pseudohypoaldosteronism type 1

Autosomal recessive pseudohypoaldosteronism type 1 is caused by mutations in the a-, b-, or g-subunits of the epithelial sodium channel (ENaC). Mutations of the mineralocorticoid receptor gene can cause an autosomal dominant form of this condition.

The recessive form typically presents in infancy with vomiting and feeding difficulty. There are signs of volume depletion and laboratory findings of hyponatraemia, hyperkalaemia, and acidaemia. The plasma renin concentration is usually increased and plasma aldosterone concentration is markedly elevated. The sodium concentration in urine, sweat, saliva, and stool is high. Treatment is with salt supplements that must usually be continued into adulthood. By contrast, the autosomal dominant form has a milder phenotype, with symptoms that remit with age.

Pseudohypoaldosteronism type 2 (Gordon's syndrome)

Pseudohypoaldosteronism type 2 (Gordon's syndrome) is a rare autosomal dominant condition in which there is hyperkalaemia despite normal glomerular filtration rate, hypertension, and correction of physiological abnormalities with thiazide diuretics, which may provide effective treatment.

The condition is usually asymptomatic, detected fortuitously if serum potassium concentration is measured for any reason, or in the course of family studies, but can rarely present in late childhood or adulthood with hyperkalaemic periodic paralysis. There is a hyperchloraemic acidosis, a low level of plasma renin activity, and normal or slightly low plasma aldosterone concentration. Giving exogenous aldosterone does not increase urinary potassium excretion or reduce hyperkalaemia.

Loci have been mapped to 1q (PHA2A), 12, and 17q21 (PHA2B), but the gene(s) responsible have not been identified. Because a kaliuresis can be provoked by infusion of sodium sulphate or sodium bicarbonate, but not sodium chloride, it has been suggested that enhanced reabsorption of chloride at a distal nephron site may underlie the abnormality in potassium secretion.

Abnormal internal potassium balance

Exercise

Exercise-related rises in the plasma potassium concentration are a normal phenomenon and usually modest, but increases to 7.0 mmol/l occur during acute, maximal, physical performance and levels as high as 10.0 mmol/l have been reported with prolonged exhaustive exercise such as in marathons. Exercise-induced hyperkalaemia is accentuated by b-adrenergic blockade, a-adrenergic agonists, and in patients with chronic renal failure.

Acidosis

Acidosis diminishes potassium uptake by cells (Table 1) and causes hyperkalaemia. The increase in the plasma potassium concentration is greater with metabolic than respiratory acidosis, and occurs with hyperchloraemic but not with organic acid-induced forms of metabolic acidosis. Stimulation of insulin release by organic acids appears to account for this divergent response, explaining the pathophysiology of disturbed potassium homeostasis in diabetic ketoacidosis. At presentation, when insulin is deficient, potassium is redistributed in a fashion comparable with mineral acid-induced metabolic acidosis and patients are hyperkalaemic. However, the preceding kaliuresis (caused by polyuria) has rendered the body enormously deficient in potassium, and the plasma potassium concentration falls rapidly as soon as insulin is provided, allowing potassium to return to the cells. Indeed, dangerous hypokalaemia can develop if adequate potassium is not given during treatment.

Drugs

Several drugs can produce hyperkalaemia by altering the transcellular distribution of potassium. Digitalis preparations diminish cellular potassium uptake by inhibiting the Na^+,K^+ pump and substantial hyperkalaemia can accompany digitalis intoxication. Succinylcholine and other depolarizing muscle relaxants increase the potassium permeability of muscle: the plasma potassium concentration typically increases by 0.5 to 1.0 mmol/l, but in patients with burns or neuromuscular diseases, hyperkalaemia can be more severe. Infusion of 30 g of the cationic amino acid arginine HCl increases plasma potassium concentration by 0.5 to 1.0 mmol/l and can produce life-threatening hyperkalaemia in individuals with deranged potassium metabolism. Fluoride intoxication appears to increase the plasma potassium concentration by provoking leakage from the intracellular compartment: associated hypocalcaemia enhances the cardiac risks of fluoride-induced hyperkalaemia.

Although b_2-adrenergic stimulants cause hypokalaemia and can be used to treat hyperkalaemia (see section 20.5), the administration of b-blockers typically increases the plasma potassium concentration only modestly (by 0.1 to 0.2 mmol/l). However, the hyperkalaemic effect can be much more prominent when other potassium homeostatic mechanisms are deranged, for example in patients receiving intermittent haemodialysis, the predialysis plasma potassium concentration is increased on average by 1.0 mmol/l.

Hyperkalaemic periodic paralysis

Hyperkalaemic periodic paralysis is a rare autosomal dominant condition in which mutations in the sodium channel gene *SCN4A* are associated with episodes of flaccid generalized weakness (rather than paralysis) and elevation of the serum potassium concentration, typically into the range from 6.0 to 8.0 mmol/l. Mutations in the same gene can cause hypokalaemic periodic paralysis and paramyotonia congenita. Attacks of weakness last from minutes to hours, occurring without any obvious precipitant but sometimes following exercise or administration of potassium.

Treatment with kaliuretic diuretics (not potassium sparing) is used to prevent attacks. b_2-Agonists can be used both to prevent and abort paralytic attacks.

Myotonia of the ocular muscles and tongue is sometimes observed both between and during attacks, the former demonstrable as slow opening of the lids after forced active closure of the eyes, or as myotonic lid lag lasting 15 to 20 s after elevation of the eyes. There can be generalized muscle wasting and progressive myopathy. In some families cardiac arrhythmia, cardiac sudden death, short stature, microcephaly, and clinodactyly (typically a bent little finger) are reported.

20.3.1 The clinical presentation of renal disease

Alex M. Davison

Introduction

Effective diagnosis has four essential requisites: an awareness of the patterns of clinical presentation; obtaining a complete history; undertaking a structured clinical examination; and formulating an appropriate investigative plan. In many instances, the clinical symptoms of renal disease are non-specific, the underlying condition may not be suspected from the history alone, and the physical examination may be surprisingly unrevealing. It is often routine investigations, such as urine analysis or estimation of renal function, that suggest the presence of renal pathology. Clinicians therefore need to be aware of the symptoms and signs that give a clue to an underlying renal disease, and which act as a prompt for appropriate initial diagnostic investigations.

The presence of renal disease in a patient may be detected because of:

1. presentation with a symptom or clinical sign that indicates an underlying renal disorder;
2. the presence of a systemic disease known to involve the kidneys;
3. a family history of inherited renal disease;
4. the finding of asymptomatic urinary abnormalities or disordered renal function tests.

Many patients remain asymptomatic, even with advanced renal disease, hence the importance of urine analysis and the estimation of blood urea and serum creatinine in anyone suspected of having renal disease. Unlike most other organ systems, patients with renal failure may remain asymptomatic despite the loss of up to 80 per cent of excretory function. Not surprisingly they may therefore be unaware of the presence of advanced renal disease, and as a consequence find it difficult to come to terms with the severity and seriousness of their illness.

Clinical syndromes

Asymptomatic urinary abnormalities

Asymptomatic proteinuria

Urinary protein excretion can amount to 150 mg daily in normal persons, consisting of albumin, Tamm–Horsfall protein, and secretory IgA. An accurate 24-h urine collection is difficult to obtain, particularly in outpatients, and therefore it is frequently more convenient to estimate the urinary protein/creatinine ratio on a mid-morning sample of urine, a normal value would be less than 130 (as this is a ratio it is without units). Approximately half consists of low molecular weight proteins or protein fragments, with the rest being albumin.

The most common method of detecting proteinuria is by using dipstix. These paper strips are impregnated with tetrabromophenol blue which changes colour from yellow-green to blue-green in the presence of protein. This test is very observer-dependent, and it should be remembered that Bence-Jones protein will not be detected and that false-positive results can occur both in alkaline urine and in urine contaminated with antiseptics (see Section 20.4 for further discussion).

Urinary protein excretion can increase during pyrexial illnesses, with strenuous exercise, congestive cardiac failure, and hypertension. In such patients the proteinuria is commonly mild (generally less than 1.5 g daily) and resolves with remission of the underlying cause. If proteinuria is detected in these circumstances the test should be repeated once the potential cause has resolved. If persistent proteinuria is detected then further investigation to determine the nature of the underlying disease is indicated.

Microalbuminuria

'Microalbuminuria' is the term used for urinary protein excretion greater than normal but still less than that detectable by dipstix testing. The excretion of more than 30 µg/min of albumin in an overnight collection or 70 µg/min in a 24-h collection in a patient with diabetes mellitus is indicative of early diabetic nephropathy. It is, however, not specific for diabetes: microalbuminuria may also be present in hypertension, obesity, systemic lupus erythematosus, and following exercise. Specifically designed stix tests are now available for screening purposes, but these remain only semiquantitative.

Postural (orthostatic) proteinuria

In some patients it has been noted that the proteinuria is present in samples obtained during the day, but absent from samples obtained first thing in the morning after overnight recumbency. This has been termed postural or orthostatic proteinuria. It is most common in children and young adults, and, although the pathogenesis is uncertain, it most likely represents an exaggerated intraglomerular haemodynamic response to a change in posture and/or entrapment of renal veins. Urinary protein excretion in such patients rarely exceeds 1.0 g/24 h. A renal biopsy may be normal or reveal only minor abnormalities.

The long-term prognosis is excellent, hence in patients with minor proteinuria it is important to obtain an early morning sample for testing. If this is found to be negative on stix testing then a diagnosis of postural proteinuria can be made, no biopsy is necessary, and the patient can be reassured that they do not have a sinister renal problem. As the majority of patients with this condition are young adult males this diagnosis may be of value in obtaining employment or insurance.

Investigation of asymptomatic proteinuria

The Scottish Intercollegiate Guidelines Network (**SIGN**) have produced a reasonable guideline for the investigation in primary care and by non-nephrologists of adult patients with asymptomatic proteinuria (Fig. 1). Different nephrologists will take different views regarding further investigation. If there are no symptoms, blood pressure is normal, the glomerular filtration rate (**GFR**) (usually estimated from serum creatinine by the Cockcroft and Gault formula, or from a 24-h creatinine clearance) is within the normal range, and there is no clinical suspicion of a multisystem disorder, then most will adopt a 'watching brief' (reviewing in 6 months and annually thereafter if all parameters remain stable) and perform a renal biopsy only in the event of a change in one or more of these parameters. The justification for this approach is that the chances of a renal biopsy revealing a diagnosis that alters management are extremely small in this context, and that the benefit does not outweigh the risk.

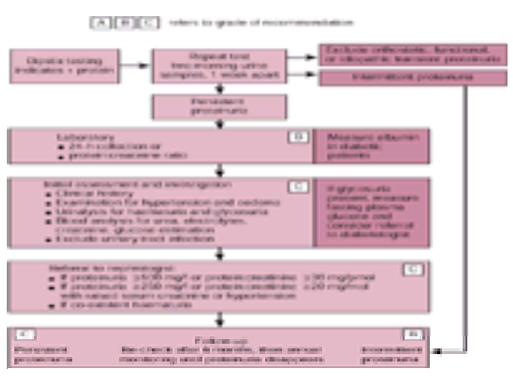

Fig. 1 Summary of the Scottish Intercollegiate Guidelines Network (SIGN) recommendations for the investigation of asymptomatic proteinuria in adults. Evidence required: A, at least one randomized controlled trial as part of the body of literature of overall good quality and consistency, addressing specific recommendations. B, availability of well-conducted clinical studies but no randomized clinical trials on the topic of recommendation. C, expert committee reports or opinions and/or clinical experiences of respected authorities. Note that these recommendations for investigation and referral are made solely on the basis that significant pathology may be detected. It is presently unproven whether there is any effect on patient outcomes. (Reproduced with kind permission from the SIGN Secretariat. Copies of the full text can be obtained from the SIGN Secretariat, Royal College of Physicians, 9 Queen Street, Edinburgh EH2 1JQ, Scotland.)

Microscopic haematuria

There is no agreed definition of microscopic haematuria as all urine samples contain some red blood cells. The Scottish Intercollegiate Guideline Network (SIGN) has suggested the presence of a positive result on dipstix testing and/or the presence of more than five red blood cells per high-power field on urine microscopy. Asymptomatic microscopic haematuria is occult haematuria, however detected, and excludes haematuria visible to the naked eye or associated with urinary tract pain, infection, or other symptom.

Asymptomatic microscopic haematuria is most commonly detected during routine medical examinations, such as for employment or insurance purposes, in well-person clinics, and when visiting general practitioner or hospital clinics where urine samples are examined by dipstix testing. The dipstix detects the peroxidase activity of haem from its reaction with orthotoluidine, which shows the presence of haemoglobin, whether in red cells or as 'free' haemoglobin, and myoglobin. False-positive results may be obtained from oxidizing contaminants (for example, from bacteria and from iodine or hypochlorite in antiseptic solutions). In obtaining urine samples for analysis it is important that the labia or prepuce are not first washed with any antiseptic solution. False-negative results may occur in the presence of excess ascorbic acid or the presence of rifampicin or phenolphthalein: if such substances are suspected to be present then a repeat sample should be obtained after appropriate withdrawal of these agents (see Chapter 20.4 for further discussion).

If a positive result is obtained it is important to repeat the test on a different occasion to confirm the result. Tests that are positive in women who are menstruating should be repeated between menses. In many patients stix testing for blood may be positive after exercise, particularly strenuous exercise, and a repeat sample should be obtained after 2 days without exercise. A positive result in the latter situation is probably due to the presence of myoglobinuria—urine microscopy is likely to be negative.

The further investigation of a patient found to have asymptomatic haematuria depends on a number of factors. As haematuria can arise from any part of the urinary tract from the glomerulus to the urethra, the first issue is to determine whether further investigations should be urological or nephrological. In men, particularly those over the age of 50 years, it is most likely that urological investigations will be required because of the increasing incidence of prostatic problems and urothelial malignancy, and in such patients clinical examination must include a rectal examination to determine whether any prostatic abnormality can be detected. By contrast, the presence of significant proteinuria, clinical evidence of renal disease, and/or impaired renal function indicate the need for nephrological investigation.

Urine microscopy can be of value if performed on a fresh sample. Red cell casts are diagnostic of glomerular bleeding and do not arise from bleeding anywhere else in the renal tract. Consideration of the morphology of red cells in the urine can also be useful (Fig. 2): dysmorphic red cells, in particular those appearing as a ring form with bubbles (Fig. 2(d)), are probably the consequence of glomerular bleeding, whereas red cells of normal appearance are more likely to arise from a site in the lower urinary tract. However, discrimination is not always straightforward (Fig. 2(a)), considerable interobserver variability is reported, and the technique is not robust enough to be routinely applied in most centres.

Screening for and investigation of asymptomatic microscopic haematuria

Background

Should patients or the population in general be screened for microscopic haematuria, and what should be done if they test positive and this is confirmed on repeat testing? There is no consensus.

Studies of apparently healthy populations indicate that asymptomatic microscopic haematuria has an incidence of between 2.5 and 13 per cent, the incidence increasing with age, as does the chance of finding an underlying cause. In men over the age of 50 years conditions such as transitional-cell tumours, stones, outflow obstruction, and infections are the most common explanation. However, the chance of a patient with asymptomatic microscopic haematuria detected by population screening having a serious and curable condition is small. A retrospective study using dipstix to screen 10 050 men for asymptomatic haematuria in the United Kingdom found that 2.5 per cent tested positive. Questionnaires were subsequently sent to the general practitioners of all those who were registered, asking what further investigations had been performed. In 39 per cent (59 of 152 respondents) no further investigations had been undertaken. Abnormalities of some sort were found in 28 per cent of those who had undergone some investigation. This rose to 50 per cent in the few patients (24) who were 'fully investigated' by examination of an midstream urine (**MSU**) specimen, intravenous urography, and cystoscopy: two of whom were found to have bladder cancer. Long-term follow-up of all participants in this study would clearly be of great interest, but is not available. In another study, similar screening was performed in 20 571 men (35 years or older) and women (55 years or older) who were members of a prepaid United States health plan: 867 (4.2 per cent) tested positive, of whom 278 were known to have urological disease to account for this, leaving 589 (2.9 per cent) with newly discovered asymptomatic microscopic haematuria. Over the next 3 years two of these individuals developed prostatic cancer and one bladder cancer. However, the likelihood of developing urological cancer was the same in those whose urine had tested negative for blood on screening. The sensitivity of microhaematuria detected on a single dipstix analysis for urological cancer within 3 years was 2.9 per cent, specificity was 96.7 per cent, and positive predictive value was 0.5 per cent. Multivariate analysis that adjusted for age, gender, and race showed that the relative risk of 2.1 (95 per cent confidence intervals, 0.7 to 6.6) for urological cancer was not significantly increased among patients with asymptomatic microhaematuria compared with patients who had negative test results.

The picture derived from hospital-based studies is rather different. A recent study described the outcomes in 1930 patients referred to a urological clinic because of haematuria, including 982 with microscopic haematuria. Evaluation in all cases consisted of basic demographics, history and examination, routine blood tests, urinalysis and cytology, plain abdominal radiography, renal ultrasound, intravenous urography (**IVU**), and flexible cystoscopy. Of the 982 cases of microscopic haematuria, 53 (5.4 per cent) had cancer, including three with renal and one with urothelial carcinoma.

Recommendations

The report of the American Urological Association Best Practice Policy Panel on Asymptomatic Microhematuria in Adults suggested: 'that the patient's history and physical examination should help the physician decide whether testing is appropriate', and that 'patients with asymptomatic hematuria who are at risk for urological disease or primary renal disease should undergo an appropriate evaluation. In patients at low risk for disease, some components of the evaluation may be deferred'. Risk factors for significant disease are specified as smoking history, occupational exposure to chemicals or dyes, history of gross haematuria, age >40 years, history of urological disorder or disease, history of irritative voiding symptoms, history of urinary tract infection, analgesic abuse, and a history of pelvic irradiation. For patients with any of these risk factors 'complete evaluation' is recommended, comprising upper tract imaging, urinary cytology, and cystoscopy. However, in those with none of these risk factors and thereby at low risk of urological malignancy, the report does not specify clearly which components of the evaluation may be deferred, or for how long.

The Scottish Intercollegiate Guideline Network has also produced recommendations for the investigation of adults detected as having asymptomatic microscopic haematuria (Fig. 3). These do not, however, describe usual practice in many centres, and the implications of employing them would be considerable since they advocate radiological imaging (plain film and ultrasonography of the urinary tract, or intravenous urography) and cystourethroscopy for all those with genuine microscopic haematuria (that is to say, false and known benign positive causes excluded) who do not have clinical suspicion of renal disease. This would mean that (on the figures given above) up to 13 per cent of the population would require cystourethroscopy, which is scarcely sensible and certainly not practicable in most healthcare systems. Given the epidemiology of urothelial malignancy, all would recommend such investigation in patients over the age of 50 years with asymptomatic microscopic haematuria. Some would advocate cystourethroscopy in those over the age of 45, or sometimes 40 years, but many renal physicians and urologists would not do so in their routine practice in those under this age. However, all have seen unfortunate cases of urothelial malignancy in young patients, and prudent instruction to all with microscopic haematuria is that they should report any new symptoms, in particular macroscopic haematuria, immediately. It is also worth noting that knowledge of the length of time for which microscopic haematuria is or has been present is very helpful: malignancies declare themselves eventually, and the patient who is documented retrospectively or prospectively to have microscopic haematuria for more than a few years can almost invariably be reassured with confidence that they do not have urinary tract malignancy.

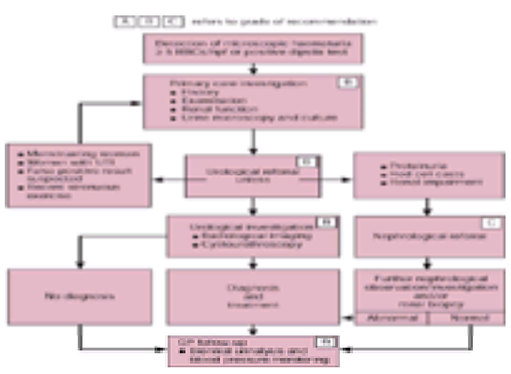

Fig. 3 Summary of the Scottish Intercollegiate Guidelines Network (SIGN) recommendations for the investigation of asymptomatic haematuria in adults. See text for further discussion and caption to Fig. 1 for explanation of grades. (Reproduced with kind permission from the SIGN Secretariat. Symptomatic presentations

Nephrotic syndrome

The nephrotic syndrome is a common mode of presentation of glomerular disease. It is not a diagnosis but rather a term used to describe a clinical syndrome that arises when the urinary protein excretion is sufficient to produce hypoproteinaemic oedema. The correlation between urinary protein excretion, plasma albumin concentration, and the presence of oedema is poor. In adults it is uncommon to develop oedema unless the plasma albumin is less than 30 g/l, but many patients will remain oedema-free with a plasma protein of less than 25 g/l. Similarly, the degree of proteinuria needed to cause hypoprotinaemia is variable: some quote a urinary protein excretion of 3.5 g/day as being 'nephrotic', but it is best to avoid a particular value as some patients develop oedema with an excretion of less than 3.5 g/day, whereas others will excrete greater amounts and remain oedema-free.

Clinically, the presentation is with peripheral oedema. In adults this is commonly of the lower limbs and tends to be progressive throughout the day, in children facial oedema is more common. Ascites and pleural effusions may be present in severe cases. Some patients may mention that they have noticed their urine becoming frothy. Commonly, patients complain of an inexplicable tiredness and lethargy: the cause for which is unknown. Other clinical features include anorexia, muscle wasting, susceptibility to infections, and nail changes (with prolonged severe nephrotic syndrome the nails become white). These latter symptoms and signs are uncommon: they are a feature of prolonged protein loss and the majority of patients present for investigation before they develop. Hypertension and impairment of renal function, if present, will, to a large extent, depend on the underlying cause of the syndrome.

Pathophysiology

Mechanisms of proteinuria

The mechanisms whereby the filtration of protein by the glomerular capillary wall is restricted is poorly understood. The barrier consists of an inner endothelial cell, presenting little in the way of restriction to filtration, a basement membrane consisting of matrix proteins arranged in a complex three-dimensional pattern that allows the passage of small molecules by convection and of larger molecules by diffusion, and an outer cellular layer of epithelial cells producing a complex barrier to filtration. There is also a charge on the surface of the basement membrane due to the presence of negatively charged heparan sulphate that allows the penetration of cationic molecules to the basement membrane but repels anionic (negatively charged) molecules. In addition, the podocytes of the epithelial cells play an important role in controlling glomerular filtration: these adhere to the outer surface of the basement membrane, there being a complex interaction between the podocyte and the basement membrane in maintaining glomerular wall integrity. In patients with proteinuria there is frequently flattening and detachment of the podocyte of the epithelial cell from the basement membrane. The pathogenesis of this is unknown. Proteinuria most likely results from a combination of disruption of the charge barrier, an alteration in the spatial configuration of the basement membrane, and disruption of the normal podocyte–basement membrane interaction. A greater understanding of this may lead to improved methods of controlling proteinuria. (See Chapter 20.1 for further discussion.)

Oedema formation

The mechanisms of oedema formation in the nephrotic syndrome are complex. Initially the loss of protein in the urine will stimulate an increased production of proteins by the liver, but if the proteinuria is sufficient the loss will exceed the capacity to replace them and so the plasma protein concentration will decline. The diminution in plasma protein concentration reduces the plasma oncotic pressure and, as a result, there is accumulation of fluid in the extravascular space, resulting in oedema. Traditional teaching proposes that this is accompanied by a reduction in the intravascular volume and, as a consequence, there is reduced renal perfusion. This results in enhanced renin secretion, and thus through the renin–angiotensin–aldosterone system there is increased sodium retention by the distal tubule. The reduced intravascular volume also stimulates ADH secretion, the net result of these effects being an avid retention of salt and water, which because of the continuing low oncotic pressure increases oedema formation. This proposed mechanism is attractive but does not adequately explain the clinical findings. In the majority of patients with the nephrotic syndrome the plasma volume is not diminished, and in some it is even expanded. In addition, in many patients with the nephrotic syndrome there does not appear to be increased plasma renin, and, furthermore, blocking of the renin–angiotensin system with angiotensin-converting enzyme (**ACE**) inhibitors is not accompanied by a diuresis. It is possible that the retention of sodium and water is due to an intrarenal mechanism involving proximal and distal tubular function, in addition to physical factors such as peritubular oncotic pressure. Hence, oedema formation does not appear to have a uniform mechanism and it is more than likely that it results from a complex of effects within the kidney, the intravascular volume, and possibly the peripheral capillary integrity.

Investigation of patients with the nephrotic syndrome

The presence of the nephrotic syndrome indicates that the patient has at least one of a wide range of glomerular pathologies, which may reflect primary or secondary renal disease. The different conditions have very variable prognoses and responses to treatment, hence making a precise diagnosis is essential to guide management. Aside from the estimation of GFR (usually estimated from serum creatinine by the Cockcroft and Gault formula, or from a 24-h creatinine clearance), quantitation of proteinuria, and measurement of serum albumin, the routine investigation of all patients with the nephrotic syndrome should include a full blood count, tests for systemic lupus erythematosus (**SLE**) (antinuclear antibody tests, anti-double-stranded DNA (- **dsDNA**), estimation of serum complement, hepatitis B and hepatitis C serology, serum immunoglobulins, and protein electrophoresis. Further serological tests may be indicated in some cases. Given the association of membranous glomerulonephritis with malignancy (see Chapter 20.7.9), older patients with the nephrotic syndrome should undergo chest radiography, and there should be a low threshold for the investigation of gastrointestinal symptoms. However, a precise diagnosis of most cases of the nephrotic syndrome can only be made histologically, and renal biopsy should be performed after checking platelets and a coagulation screen, and imaging—usually by ultrasonography—to confirm the presence of two anatomically normal kidneys. Such extensive investigation is not required when a confident diagnosis of the cause of the nephrotic syndrome can be made on clinical grounds, for example in the patient with diabetes and long-standing proteinuria who becomes nephrotic.

Treatment of patients with the nephrotic syndrome

Specific causes of the nephrotic syndrome may require specific treatments: these are discussed in the relevant subsections of Section 20.7, but some general measures are applicable to all nephrotic patients.

Patients with the nephrotic syndrome may feel generally 'washed out' and exhausted, and they may suffer psychologically from uncertainties and fears surrounding their diagnosis and prognosis, but the main concern in all cases is likely to be oedema. This can be massive: over 10 litres of excess fluid is not infrequent, and some have over 20 litres, when the patient is bed-bound with massively swollen and weeping legs, distressing genital oedema, and pitting of the abdominal and sometimes the chest wall.

Patients with the nephrotic syndrome are unable to excrete salt or water normally, hence it is prudent to recommend moderation in the consumption of both. Strict limitation of salt intake renders the diet unpalatable, but patients should be advised not to add salt to food at the table and to avoid foods that are rich in salt. It seems reasonable to suggest a total fluid intake of no more than 1.5 litres per day for those who are very oedematous, and perhaps no more than 1 litre per day in the most severe cases. The mouth can be kept moist using swabs or by sucking boiled sweets, and the daily fluid ration will go much further if the patient is given an ice cube to suck rather than a jug of water if they feel thirsty.

Diuretics are the mainstay of oedema removal, with loop diuretics often the only effective agents. The aim should be to reduce the patient's weight by 0.5 to 1 kg daily. Oral frusemide (furosemide), 40 to 80 mg daily (or other loop diuretic), would be the usual starting dose, but some patients require much higher doses, with up to 250 mg twice daily not uncommon. If oral frusemide proves ineffective, then the addition of oral spironolactone (usually 100 to 200 mg daily, with particularly close monitoring of the serum potassium level) or oral metolazone (usually 2.5 to 20 mg daily, with close monitoring to ensure that it is stopped promptly in the event of massive diuresis) can be helpful. If these fail then admission to hospital for bed rest and intravenous diuretic (usually frusemide 250 to 500 mg) is required, and some would also give daily intravenous infusions of concentrated albumin. There is little evidence that the latter is effective in adult practice, but there is theoretical justification in giving it to those who appear to have intravascular volume depletion (postural hypotension, low jugular venous pressure), and it is reasonable to give it (for example, human albumin solution 20 per cent, 100 ml daily) as a therapeutic trial for a few days to all with severe refractory nephrotic oedema. However, many studies would suggest that the likely effect is simply an increased proteinuria, and if this is indeed the case and no benefit in terms of diuresis/weight loss is seen, then albumin infusion should be abandoned. It is interesting to note that when nephrotic oedema has been removed the patient is often able to sustain a new steady state with a much reduced burden of oedema, with no change in serum albumin or proteinuria.

A number of agents, including ACE inhibitors, non-steroidal anti-inflammatory agents, and ciclosporin, can reduce proteinuria at the expense of some reduction in the glomerular filtration rate. These drugs, most commonly ACE inhibitors, are sometimes used for this purpose (after deliberately inducing volume depletion with diuretics) in managing patients with severe nephrotic syndrome when the difficult judgement has been made that the benefits of reducing proteinuria (and hopefully thereby oedema) more than outweigh the disadvantage of reducing the GFR. This is a step that should never be taken lightly: the reduction in GFR may induce endstage renal failure (so-called 'medical nephrectomy'), and whilst renal replacement therapy may be preferable to intractable massive oedema, this possibility clearly needs to be thoroughly discussed with the patient beforehand.

There is considerable debate about the protein intake that should be recommended for those with the nephrotic syndrome: protein restriction diminishes proteinuria and a high protein diet increases it, but the impact on oedema or long-term prognosis of either manoeuvre is unknown. It is probably reasonable to suggest that patients with the nephrotic syndrome should consume about 1 g/kg per day of mainly first-class protein.

The management of specific complications of the nephrotic syndrome such as infection, thromboembolism, and hyperlipidaemia are discussed below.

Complications of the nephrotic syndrome

A number of complications are recognized in patients with the nephrotic syndrome: these result from the metabolic consequences of prolonged protein loss.

Infections

The incidence of infections, particularly bacterial, is increased in the nephrotic syndrome. Peritonitis is well recognized in children and is an important cause of

mortality. Cellulitis, particularly streptococcal, is common and may spread rapidly. The cause of the increased susceptibility to infections is a combination of physical factors such as the accumulation of fluid in the interstitial space, the peritoneal and/or pleural space, and the impairment of defence mechanisms, such as the reduction in immunoglobulin concentration and impaired white cell function. Impairment of the alternative pathway of complement activation through loss in the urine of Factor B, which has a molecular weight of only 55 kDa, is crucial in causing impairment of the phagocytosis of encapsulated organisms. This leads in childhood to the particular vulnerability to *Streptococcus pneumoniae* described above: most adults are protected by virtue of having acquired antibodies against a variety of pneumococcal capsular antigens.

Prompt induction of remission of oedema and proteinuria is the best method of preventing infection. When this cannot be achieved, good skin care is important, and there is a good case for using prophylactic penicillin to prevent pneumococcal infection in oedematous children. Antipneumococcal vaccines against capsular antigens induce an adequate response when given to patients in remission. Any suspicion of infection should be treated aggressively in those with the nephrotic syndrome, with a low threshold for starting a parenteral antibiotic regimen, including benzylpenicillin in children, as soon as necessary cultures have been taken.

Thromboembolism

There is an increase in both arterial and venous thromboses in patients with the nephrotic syndrome, which may be aggravated by the use of excessive diuretic therapy and corticosteroids. There is an increase in the plasma concentration of a number of factors involved in the coagulation cascade, notably fibrinogen, and in addition plasminogen concentration is commonly reduced, thereby increasing the tendency to thrombus formation. Other factors include increased platelet aggregation and alterations in endothelial-cell function.

The increased thrombotic tendency is manifest by an increased risk of deep leg vein thromboses and pulmonary embolism and an increase in arterial thrombotic episodes. Deep leg vein thrombosis is clinically evident in about 6 per cent of nephrotic adults and can be detected in about 25 per cent if Doppler ultrasonography is used. Pulmonary embolism is also clinically evident in around 6 per cent of cases, but if ventilation/perfusion scans are used as a screening test the figure rises to 12 per cent, or even higher in some series. Nevertheless, mortality from thromboembolism appears to be low (only one death in 2100 years of patient follow-up in a series reported by Cameron) and very few nephrologists would routinely anticoagulate all patients with the nephrotic syndrome, although most would have a low threshold for doing so (for instance, during periods of immobility in hospital). Likewise, after any thromboembolic event they would advise anticoagulation for as long as the nephrotic state persisted.

Renal vein thrombosis may occur, presenting acutely with loin pain, haematuria, deterioration in renal function, and with swelling of the kidney detectable on imaging (usually by ultrasonography). It can also present more insidiously with a significant increase in urinary protein excretion and a gradual reduction in renal function. Some one-third of cases are associated with pulmonary embolism. Renal vein thrombosis can be associated with all causes of the nephrotic syndrome but, for reasons that are unknown, is most common in membranous glomerulonephritis, when it is clinically apparent in 6 to 8 per cent of cases and detectable on imaging in 10 to 45 per cent. It is not routine practice to investigate patients with the nephrotic syndrome, even that caused by membranous glomerulonephritis, for renal vein thrombosis: when there is clinical suspicion the diagnosis can be made by magnetic resonance imaging (**MRI**), computed tomographic (**CT**) scanning or renal arteriography (looking at the venous phase). Treatment of symptomatic renal vein thrombosis is by anticoagulation with full-dose therapeutic intravenous heparin or low molecular weight heparin (although there is little experience of using the latter in this condition) followed by warfarinization. Thrombolysis has also been used, although the indications for this are not well defined. The prognosis is usually benign, with recanalization of the veins and recovery of renal function.

Alterations in lipid metabolism

Alterations in lipid metabolism are well recognized in patients with nephrotic syndrome. There is concern that these changes might lead to atheromatous vascular disease and also be an adverse factor with respect to the development of progressive renal function impairment. Moreover, there is some evidence that patients with the nephrotic syndrome have an increased incidence and prevalence of vascular disease, particularly coronary vascular disease leading to ischaemia and infarction, although not all studies have confirmed this.

Patients with the nephrotic syndrome have an increased concentration of both free cholesterol and cholesterol esters, which have an inverse correlation with plasma albumin concentration. There is an increase in phospholipids, although this is not marked, and in severe cases fasting triglycerides are elevated. Plasma free fatty acid concentrations are reduced. The changes are not determined by the nature of the underlying glomerular disease but are closely linked to the degree of hypoproteinaemia. There are alterations in lipoproteins: very low-density lipoproteins (**VLDL**) and low-density lipoproteins (**LDL**) are increased, whilst high-density lipoprotein (**HDL**) concentrations are less predictably affected.

The causes of the alterations in the lipid profile are incompletely understood. There is an increase in the hepatic production of VLDL and LDL, the stimulus for which is unknown but may be related to plasma oncotic pressure. In addition there is evidence for the diminished removal of LDL, possibly due to a reduction in the activity of lipoprotein lipase. The changes in HDL concentrations are probably related to the reduction in lecithin cholesterol acyl transferase (**LCAT**) activity that occurs in nephrotic patients.

Should patients with nephrotic hyperlipidaemia be treated for this? There is no good evidence. It seems reasonable to give dietary advice, although there have been few studies to show how effective (or not) this is in reducing lipid levels, and none looking at cardiovascular outcome. Statins are effective at reducing serum cholesterol, which is virtually always elevated in the nephrotic syndrome, sometimes massively so, but most would not prescribe these as a routine for the following reasons:

1. Given that the aetiology of hyperlipidaemia in the nephrotic syndrome is different from that in the primary hyperlipidaemias, it is not certain that the biological impact is the same, for example it might not be as deleterious from a cardiovascular point of view.
2. Few patients remain nephrotic for years: they either go into remission (spontaneously or after treatment) or develop endstage renal failure.
3. Many patients with the nephrotic syndrome are young and, aside from their hyperlipidaemia, at low absolute risk of vascular events.
4. Many patients will require complex drug therapy, such that there is a reluctance to add further medication, particularly since there is a suspicion that those with the nephrotic syndrome may be more likely to experience side-effects from lipid-lowering medications.

Proteinuria and the progression of renal disease

It is well recognized that prolonged profuse proteinuria is associated with a poor prognosis in patients with glomerulonephritis. In experimental studies proteinuria is associated with interstitial damage, tubular injury, and glomerulosclerosis. Heavy proteinuria is associated with progressive glomerular scarring, and intervention to reduce proteinuria is accompanied by reduction in sclerosis. It is possible that the prolonged and heavy proteinuria has an adverse effect on mesangial cells leading to mesangial sclerosis and eventually global sclerosis, but it is likely that proteinuria is only one of many factors responsible for progressive renal disease.

Acute nephritic syndrome (haematoproteinuria syndrome)

Acute nephritis is a clinical syndrome characterized by the acute onset of haematuria, proteinuria, hypertension, and oliguria. The urine typically appears 'smoky' due to the presence of red blood cell casts, and rarely it will appear frankly red. Proteinuria is variable in amount, but is rarely sufficient to produce a nephrotic syndrome. Hypertension is variable and oliguria depends to a large extent on the degree of glomerular involvement. Not all four clinical features may be present simultaneously. In some patients there is oedema due to salt and water retention in the oliguric phase. Encephalopathy, particularly in children, may occur due to hypertension or electrolyte disorders such as hyponatraemia.

The 'classical' cause of acute nephritis is poststreptococcal glomerulonephritis: this is described in detail in Chapter 20.7.5 and other infective causes in Chapter 20.7.8. However, these diseases are becoming less common, particularly in developed countries, and it is more usual to see patients who have proteinuria and haematuria accompanied by variable hypertension and renal functional impairment in whom no identifiable preceding infection can be identified. The presence of blood and protein in the urine is a sign of glomerular inflammation and is not indicative of any particular glomerular pathology. On investigation such patients have a wide variety of glomerular appearances (Table 1), hence renal biopsy is essential for precise diagnosis. For further discussion of the conditions listed in Table 1 see the relevant subsections of this section.

Recurrent haematuria

'Recurrent haematuria' is the term used to describe patients who have episodic macroscopic haematuria. This most commonly is due to IgA nephropathy, described in Section 20.8.2, where episodes are immediately preceded by mucosal inflammation, usually of the upper respiratory tract but sometimes of the gastrointestinal tract. Some patients with Alport's syndrome may present with episodes of recurrent haematuria but these are usually unrelated to mucosal inflammation. It must also be remembered that other causes of repeated episodes of macroscopic haematuria include polycystic renal disease, renal stone disease, sickle-cell disease, and tumours of the renal tract. In such patients there are frequently other clinical indications to allow confident differentiation from IgA nephropathy.

Loin pain haematuria syndrome

This is a relatively uncommon but well-recognized syndrome, which can only be diagnosed by excluding other conditions that can be associated with pain in the loins and microscopic or intermittent macroscopic haematuria (Table 2).

Patients present with intermittent or persistent loin pain accompanied by persistent microscopic haematuria, although on very rare occasions macroscopic haematuria can occur, even to the extent of causing clot colic. Most are young women, many of whom will have undergone numerous investigations. Symptoms are frequently unilateral but usually become bilateral, although one side may predominate. Clinical examination is unremarkable, although there may be some loin tenderness, and blood pressure is normal. The urinary red cells are dysmorphic, suggesting a glomerular origin, but red cell casts are not present. There is no evidence of urinary tract infection, normal urinary protein excretion or only minor proteinuria (occasionally up to 1 g daily), normal GFR (usually estimated from serum creatinine values by the Cockcroft and Gault formula, or from a 24-h creatinine clearance), and no clear structural abnormality on thorough imaging (cystoscopy and at least one of intravenous urography/ultrasound/CT scanning/MRI). Indices of inflammation such as a raised erythrocyte sedimentation rate (**ESR**) or C-reactive protein (**CRP**), or elevated plasma viscosity are notable by their absence.

A radiological abnormality consisting of focal or generalized tortuosity, beading, and occlusion of intrarenal medium-sized arteries leading to cortical infarcts has been described, but these findings are not universal. On renal biopsy the glomeruli appear normal or show only minor changes: a number of reports describe complement deposition (C3 and C4) in arterioles, but the significance of this is uncertain and it may be a non-specific finding.

The syndrome runs a relapsing/remitting course over a number of years, with symptoms gradually subsiding with time. The loin pain can vary greatly in severity, ranging from a mild ache to disabling colic requiring opiate analgesia. There is no effective specific treatment and, not surprisingly, some patients can be difficult to manage as it is difficult for them to accept that there is no 'cure' for their symptoms. Renal denervation and renal autotransplantation have been tried, but pain typically returns over 6 to 12 months, and even after nephrectomy pain can develop in the remaining kidney. These procedures should not be performed, and other methods of pain control (transcutaneous nerve stimulation, amitriptyline, carbamazepine, and similar agents) are usually ineffective. In most cases pain control can be obtained using regular opiate analgesia, after which the dosage can usually be reduced and the patient eventually weaned off medication. Although this can take a long time, it is rare for pain to persist into the patient's forties or fifties.

Disorders of micturition

Frequency

'Frequency' is the term applied when the bladder is emptied more often than normal, hence in obtaining a history it is therefore necessary to determine how often the patient passes urine. This may be associated with a normal or increased 24-hour urine volume. It is important to distinguish between these two situations as frequency in the presence of a normal output indicates a bladder (lower urinary tract) problem, whereas an increase in output is indicative of a disorder of urinary concentration or excessive fluid intake (see 'polyuria').

Frequency in the presence of a normal urine volume is most commonly due to bladder inflammation from a bacterial infection (cystitis), when dysuria is a common accompanying symptom. It can also be produced by chemical irritation (for example, as sometimes occurs during treatment with cyclophosphamide), or from a calculus or tumour involving the bladder wall. A reduction in bladder capacity is uncommon but may result from radiation-induced fibrosis following treatment to a pelvic malignancy. In males, prostatic hypertrophy, benign or malignant, is associated with frequency and a diminution in urinary stream, together with hesitancy (a difficulty in initiating micturition) and dribbling (a difficulty in terminating micturition).

Nocturia

Nocturia may arise from the many conditions that cause frequency. On lying down there is an increase in renal perfusion resulting in increased urine flow, but ADH is secreted during sleep, thereby increasing urinary concentration and meaning that urine volume diminishes during sleep. In patients with sleep disturbance there is less ADH production and thus urine concentration is reduced, with increased urine volume such that nocturia may occur. Enquiry should be made regarding sleep patterns in patients presenting with nocturia, in addition to considering those conditions that cause polyuria and frequency.

Dysuria

Dysuria is pain or discomfort on micturition and one of the most frequent symptoms, accounting for about 2 per cent of consultations in primary care. It is more common in women, and is usually described as a burning, scalding, or tingling sensation in the urethra or at the urethral meatus occurring during or immediately after micturition. Most commonly it is due to urinary infection, but it may also be caused by chemical irritation such as rarely occurs with cyclophosphamide. If associated with frequency and urgency of micturition it indicates bladder irritation such as cystitis. In young women this is usually associated with sexual activity, but in older persons it may indicate a lesion in the bladder or prostate. Prostatic inflammation usually gives rise to perineal or rectal pain. Very young children will be unable to complain of dysuria but urethral irritation may be inferred if the child cries during micturition. (See Chapter 20.12 for further discussion.)

Polyuria

Polyuria is an increase in the daily volume of urine and may arise from a number of different conditions. The normal daily urine volume varies considerably depending on fluid intake and insensible loss, but is normally in the range of 1 to 2 litres. Most patients have no idea of their urine volume and so it is necessary to obtain a 24-h collection to verify urine output. Excessive fluid intake, as occurs in compulsive water drinking, results in an increased volume. An increase in solute load, most commonly due to hyperglycaemia, reduces tubular reabsorption and increases urine production. Inadequate ADH secretion, such as following a head injury or associated with tumours or infection, result in an impaired urinary concentration and increased output (central diabetes insipidus). Conditions that impair the tubular response to ADH, such as potassium depletion, lithium toxicity, and some rare inherited diseases, also increase urine volume (nephrogenic diabetes insipidus), as do renal disorders that impair medullary concentration, such as analgesic nephropathy, papillary necrosis, medullary cystic disease, and nephrocalcinosis.

Oliguria and anuria

Oliguria is a reduction in urine volume to such an extent that there is inability to excrete the residues of normal daily metabolic functions. This normally means to a volume of less than 400 ml daily in an adult, usually indicating acute renal failure of whatever cause (see Chapter 20.4). Anuria is the lack of any urine output and is indicative of obstruction, although it may occur in some forms of severe acute renal failure. If anuria is present it is essential to perform a rectal examination to determine if there is any pelvic malignancy, such as a rectal or cervical carcinoma, to account for the obstruction.

Pain

Renal pain

Stretching of the capsule of the kidney causes renal pain that is felt in the loin ('renal angle'). It can be produced by any condition that distends the kidney, such as inflammation, mass lesions, or an obstruction. The last is the most common cause, particularly obstruction of the pelviureteric junction, when the patient may give a history that anything that causes an acute increase in urine volume (for example, drinking a large quantity of water, beer, or lager or taking a diuretic) precipitates the pain. Inflammatory pain, such as in pyelonephritis and (uncommonly) in glomerulonephritis, develops gradually, is usually constant in nature, and is variable in severity. A perirenal abscess, which may not always be associated with fever or tenderness, can give rise to symptoms and signs of diaphragmatic irritation and/or

psoas irritation. In the latter case, the patient usually prefers to rest with the hips flexed, and reports that extension of the hips is accompanied by an increase in pain.

It can be difficult to distinguish renal pain from musculoskeletal pain, hence the history should enquire specifically about the relationship of pain to movement or position, neither of which greatly affects renal pain. Clinical examination of the back and spine should determine any limitation of movement or localized point tenderness, which would suggest a musculoskeletal problem.

Some patients with polycystic renal disease complain of a constant dull loin ache. They may also suffer from the sudden onset of renal pain if there is bleeding into a cyst, or from pain of a more gradual onset if there is cyst infection.

Ureteric colic

Pain arising from an acute obstruction is frequently sudden in onset, severe, colicky, and may radiate to the groin, scrotum, labia, or upper thigh. Many describe it as 'the worst pain that they have ever had', and the patient with ureteric colic typically thrashes about, unable to find comfort, looks pale and sweaty, and often vomits, which can lead to diagnostic confusion. The pain is due to acute distention of the pelvis of the kidney and the upper ureter and the associated increased peristalsis. If the obstruction is ureteric the pain resolves rapidly once the cause is extruded into the bladder, although when in the bladder it may result in bladder irritation with strangury or further obstruction if it becomes impacted at the urethral orifice. The most common differential diagnoses of right-sided renal colic are biliary colic and appendicitis: diagnostic difficulty is less likely on the left side, although colonic pain requires consideration. (See Chapter 20.14 for further discussion.)

Chronic obstruction may be surprisingly asymptomatic. Retroperitoneal fibrosis is accompanied by a dull-aching back discomfort but is not associated with colic in spite of an obstruction.

Disorders of renal function

Acute renal failure

An acute deterioration in renal function may arise in patients with normal renal function or in those with known renal insufficiency, the latter being known as acute on chronic renal failure. The clinical features depend to a large extent on the underlying cause. Patients may be seriously ill with profound hypotension from such causes as multiple trauma or severe sepsis, or they may appear remarkably well, such as with rapidly progressive glomerulonephritis. The diagnosis may be suspected or proven in patients with the following clinical features:

1. *Diminished urine volume.* This is not invariable and some patients have a normal volume but a reduction in urinary concentration to such an extent that there is retention of urea, creatinine, and other substances that are normally excreted. It should be remembered that the quality of urine is as important as the volume.
2. *Increasing blood concentrations of urea and creatinine.* This usually indicates impaired excretion and is the usual way in which the diagnosis of acute renal failure is established. Creatinine is a more accurate reflection of renal function than urea, as its concentration is influenced to a lesser extent by protein catabolism and the state of hydration. An important clinical indicator as to whether a patient has acute or chronic renal failure can be the state of consciousness at a given serum creatinine concentration. If renal function declines rapidly, the patient is often obtunded once the creatinine is in excess of 800 µmol/l, whereas if the creatinine concentration has increased slowly with time the patient is unlikely to have any impairment of consciousness with a creatinine of 1000 µmol/l.
3. *Electrolyte disturbance.* Hyperkalaemia may be the first indication that a patient is developing acute renal failure. In the presence of normal renal function it is difficult to produce hyperkalaemia.
4. *Acidosis.* This is most commonly detected by measurement of a declining serum bicarbonate concentration, reflecting the development of a metabolic acidosis and clinically manifested by tachypnoea.
5. *Pulmonary oedema.* Most patients with acute renal failure are prone to this as their ability to excrete fluid is limited, but it is most commonly iatrogenic, when an oliguric patient is ill-advisedly given inappropriate intravenous fluids.
6. *Appropriate clinical circumstances*. In some instances there is an obvious risk for the development of acute renal failure, such as in septicaemic shock, severe multiple trauma, prolonged hypotension, and indeed any clinical circumstance that impairs normal kidney function.
7. *Consumption of certain medications.* Some medications have the ability to reduce renal function. The most common mechanism is by reduction of effective renal perfusion, such as can be caused by non-steroidal anti-inflammatory agents (**NSAIDs**), ACE inhibitors, and angiotensin II-receptor blockers. Less common mechanisms include the induction of acute interstitial nephritis (for example, caused by NSAIDs, penicillins) or acute toxic tubular dysfunction (for example, aminoglycosides, paracetamol overdose). Rare mechanisms include the precipitation of acute vasculitis (for instance, hydralazine) or stimulation of retroperitoneal fibrosis (for example, methysergide). Commonly it is a combination of medications such as analgesics, antibiotics, and non-steroidal drugs together with radiocontrast agents that result in acute renal failure, because during an illness one agent after another is added without the recognition that renal function is declining.

It must be remembered that to maintain normal renal excretory function there is a need for effective cardiac output and renal perfusion, glomerular filtration, tubular function (reabsorption and excretion), and the drainage of urine from the renal pelvis via the ureters, bladder, and urethra. It is thus possible to acutely disrupt this function in many different ways, and accurate diagnosis is dependent upon obtaining a good history, paying particular attention to detail, followed by a thorough clinical examination supported by a structured investigative protocol. See Section 20.5 for further discussion.

Chronic renal failure

Patients with a slow progressive deterioration in renal function may remain remarkably free from symptoms until renal function is seriously impaired. When symptoms of renal failure do develop, they are non-specific, such that many patients attribute them to increasing age or being less physically active than previously. This can make diagnosis difficult and renal impairment may be unsuspected until the results of some screening investigations, such as haemoglobin and blood urea, are obtained. (See Section 20.5 for further discussion.)

History

Presenting complaint

Obtaining a clear and concise history is about one of the most difficult things to achieve in clinical medicine. It is important to elicit carefully the nature and chronological sequence of all the symptoms experienced by the patient, who should be encouraged to describe each symptom in detail and—if medical terminology is used—the physician needs to determine what exactly the patient understands by the particular word or phrase used. It is not uncommon for a patient to describe their symptoms using words that their friends or previous medical practitioners have used, which may not be appropriate. For each symptom it is necessary to make specific enquiry regarding the mode of onset, whether sudden or gradual, and the nature of any associated features such as precipitating and relieving factors. If the patient describes pain then additional enquiry needs to be made regarding its position, nature, and radiation.

In patients with proteinuria and/or haematuria it is essential to ask about the results of any previous urine testing, even from years previous. It is standard practice to test urine during pregnancy and during employment and insurance medical examinations. It is often profitable to review all available medical notes: frequently urine will have been tested and the results recorded, even if no notice has been taken of an abnormal result.

In most instances the pattern of the symptoms will follow a recognized syndrome; in some an apparently unconnected number of symptoms will suggest the presence of a systemic disease; while in others there will be a condition known to affect the kidneys. In any event, it is important to document carefully all symptomatology and subsequently to record all new or changing symptoms.

Past history

The past medical history of a patient can provide much useful information to aid diagnosis. It is important to obtain as full a history as possible detailing childhood illnesses, all major illnesses, and hospital admissions. A history of unexplained febrile illnesses in childhood or prolonged enuresis suggests the possibility of recurrent urinary infections due to structural urinary abnormalities such as vesicoureteric reflux.

A number of chronic conditions may be associated with renal involvement, either directly as in systemic diseases, or indirectly as in the development of amyloidosis in prolonged inflammatory diseases such as chronic osteomyelitis, bronchiectasis, or rheumatoid arthritis. In addition, certain drugs used to treat chronic conditions may have adverse renal effects such as gold, penicillamine, ciclosporin, NSAIDs and analgesics used in the management of rheumatoid arthritis and similar conditions.

Systemic vasculitides frequently have multisystem manifestations with variable renal involvement. As a general rule the prognosis of any systemic disease is significantly and adversely influenced once there is renal involvement. Diabetes mellitus, either insulin or non-insulin-dependent, may result in glomerulopathy. In the patient with insulin-dependent diabetes the first manifestation of glomerular involvement typically occurs about 10 years after onset. In the non-insulin-dependent patient, however, renal involvement may be detected at or soon after diagnosis, not because of more aggressive glomerular involvement but rather because the condition may well have been present in an undiagnosed form for many years. (See Chapter 20.10.1 for further discussion.)

It is important to obtain details regarding a woman's menstrual, contraception, and pregnancy histories. A delayed menarche may indicate the presence of renal failure, as may the unexplained development of amenorrhoea. Hypertension is more likely in patients taking a combined oestrogen–progesterone oral contraceptive if there is an underlying renal disease. Similarly, hypertension during pregnancy is much more common in patients with renal disease, particularly in the third trimester. Patients with asymptomatic proteinuria will have an increase in proteinuria during pregnancy, which may come to medical attention when the urine is tested for the first time or because it becomes sufficient to produce the nephrotic syndrome. In the latter circumstance it is sometimes difficult to differentiate between a simple nephrotic syndrome and the development of pre-eclampsia. The proteinuria of pre-eclampsia resolves following delivery, usually with 3 months, whereas in patients with glomerular disease, although the proteinuria will diminish, it does not completely resolve (see Chapter 13.5). Recurrent fetal loss may be associated with antiphospholipid antibodies and so prompts appropriate investigations.

It is not uncommon to find that patients are unable to remember significant events in their past medical history. It is important, therefore, to obtain any previous medical notes to obtain the maximum information. It is surprisingly common to find that urinary abnormalities such as proteinuria or haematuria have been documented previously, perhaps during medicals for work or insurance purposes, but not investigated. This can be a reassuring finding, because if it is known that haematuria has been present for many years then it is a safe bet that it is not due to a serious condition (assuming that renal function is normal).

Drug history

It is essential to obtain a detailed history of all medications recently consumed, whether obtained by prescription, over the counter, or from health shops: all have the potential for precipitating adverse renal effects. Many patients do not consider that medications they can buy from their local chemist, such as analgesics, are drugs. In some patients it may be necessary to obtain information from the family practitioner. There may be covert drug use, such as with laxatives and diuretics, which is particularly difficult to detect. The presence of unexplained hypokalaemia may provide the only clue that the patient is abusing diuretics or taking excessive amounts of liquorice (see Chapter 20.2.2). Frequently the patient has some connection to the medical profession and thus access to medications. In addition, some who take diuretics unnecessarily experience oedema on withdrawal of the drug, reinforcing their belief that such medication is necessary and resulting in continued ingestion.

Factors that increase the risk of adverse drug effects include age, impaired renal function, and multiple drug therapy. The elderly are at particular risk as renal function declines with age, and with a diminishing muscle mass this may not be obvious from an estimation of the serum creatinine alone; they may also have multiple pathologies resulting in an increased chance that they are taking many drugs. The pharmacokinetics of drugs are altered in elderly patients and so caution is required when prescribing.

All compartments of the kidney can be involved in adverse drug reactions. In the situation where there is a constraint on renal blood flow there is enhanced secretion of renin from the juxtaglomerular apparatus, activating angiotensin and thereby causing vasoconstriction of the efferent arteriole, resulting in an increase in intraglomerular pressure to maintain filtration. If there is vascular stenosis, whether of the main renal artery or of intrarenal arteries, the introduction of an ACE inhibitor or angiotensin II-receptor blocker may result in a significant reduction in glomerular filtration as a consequence of the abolition of this constrictive effect of angiotensin II. A number of patients, particularly the elderly and those with renovascular disease, are particularly susceptible to this adverse effect of these medications. When the renal circulation is compromised glomerular blood flow is also supported by the action of vasodilator prostaglandins, and in these circumstances NSAIDs can cause substantial decrement in the filtration rate. Much more rarely, the blood vessels may exhibit vasculitis following treatment with hydralazine or propylthiouracil.

Glomerular changes may be induced by gold or D-penicillamine, resulting in proteinuria and, in certain cases, the nephrotic syndrome. The glomerular changes usually revert once the drug is withdrawn.

Tubular function can also be adversely influenced. Lithium is associated with a nephrogenic diabetes insipidus-like syndrome due to inhibition of the action of ADH on the cells of the distal tubule and collecting duct. This may be accompanied by an incomplete distal renal tubular acidosis and, in some patients, with a chronic interstitial nephritis. Acute renal failure due to an acute reversible reduction in glomerular filtration occurs in lithium toxicity.

Interstitial nephritis may occur as an acute allergic reaction occurring shortly after the introduction of a drug, or in a more chronic form after several months of ingestion. In the acute form there may be other manifestations of an allergic reaction such as rash, eosinophilia, and the detection of eosinophils in the urine. In the more chronic form there may be no such indication of an allergic reaction. A wide variety of medications, including antibiotics and analgesics, may give rise to interstitial disease, as can certain herbal remedies, as evidenced by the nephropathy that has been associated with Chinese herbs used as a slimming aid. Analgesic abuse may give rise to papillary necrosis, which may present as polyuria due to impairment of renal concentration or from obstruction if a sloughed papilla occludes the ureter.

Some medications have the ability to elevate blood pressure, and so a drug-induced cause should be considered in any patient presenting with hypertension: this is well recognized in patients receiving oestrogen/progesterone preparations, corticosteroids, ciclosporin, and erythropoietin.

In patients with renal disease there may be a greater propensity for adverse reactions. In the nephrotic syndrome the diminished plasma albumin concentration will result in a lessening of protein binding and thus an increased availability of the 'free' drug. If there is impaired renal function there may be diminished excretion, thus prolonging the half-life of the drug and increasing the risk of toxicity if the dose is not adjusted appropriately. In addition, some treatments given for some renal diseases may have adverse interactions with other drugs, for example high-dose corticosteroids have the ability to displace protein-bound drugs, thereby increasing the concentration of 'free' drug.

Dietary history

A carefully obtained dietary history can, in a few cases, be helpful in reaching a diagnosis. Excessive sodium intake may be associated with hypertension or apparent resistance to antihypertensive medication. Idiopathic, stone-forming patients seem to have a greater than average protein intake, resulting in increased excretion of calcium, oxalate, and uric acid, all of which are risk factors for stone formation. Some patients have a preference for acid-tasting foods that they may consume in excessive amounts: fruit juices and rhubarb, which are high in oxalate, may be the cause of oxalate deposition in the kidney if taken to excess. Other patients consume an excessive amount of liquorice that interferes with the inactivation of cortisol by blocking the enzyme 11b-hydroxysteroid dehydrogenase, and, as a consequence, the cortisol binds to mineralocorticoid receptors mimicking hyperaldosteronism.

There are differences in the composition of some ethnic diets compared to a 'standard' Western diet: Japanese food is high in sodium, whereas Indian food is high in potassium. In addition, some foods may aggravate the effects of renal failure. Unleavened bread, chapattis, with a high phytate content bind intestinal calcium reducing absorption and thereby stimulating parathyroid hormone secretion which, in addition to other effects, increases the metabolism of vitamin D and as a consequence aggravates the osteomalacic or rachitic component of renal osteodystrophy.

Family history

It is important to obtain as full a family history as possible as this can significantly aid diagnosis. If an inherited renal disease is identified, the diagnosis is of value to other members of the family, allowing the identification of affected members and appropriate clinical review to control any associated complications such as hypertension and anaemia. In any patient with suspected renal disease it is advisable to enquire about familial renal disease, deafness (Alport's syndrome), and whether the parents were related (all recessive conditions are much more common with inbreeding). It may be necessary to examine medical notes and obtain death

certificates. Sometimes it is possible to infer inherited renal conditions that were unsuspected: a patient with polycystic renal disease may give a history that some relatives have died suddenly from a 'stroke', indicating the possibility of subarachnoid haemorrhage from a ruptured cerebral aneurysm. Similarly, most, if not all, cases of vesicoureteric reflux are familial, when a history of troublesome urinary infections in family members can be informative.

Not all familial conditions seem to have a clear inherited pattern. There is a familial predisposition to systemic lupus erythematosus, other autoimmune diseases, and IgA nephropathy. In some families there is a greater than expected incidence of hypertension or diabetes mellitus, indicating genetic influences as yet undetermined. In some conditions there is considerable genetic heterogeneity: Alport's syndrome is classically an X-linked dominant condition, but an autosomal recessive form has been described, as has a form associated with macrothrombocytopenia (Epstein's syndrome). Furthermore, not all diseases that have similar features are the same condition, for example nerve deafness and urinary abnormalities may be due to Alport's syndrome or to the Muckle–Wells syndrome (heredofamilial amyloidosis), Refsum's syndrome, a rare form of Charcot–Marie–Tooth syndrome, or Cockayne syndrome.

Social history

Socioeconomic factors are important in patients with renal disease. Increasing affluence is associated with an increasing incidence of renal stone disease, possibly related to an increase in protein intake. Low socioeconomic status is associated with an increased incidence of bacteriuria during pregnancy.

Smoking is a risk factor for the development of atherosclerosis, renovascular hypertension, and accelerated hypertension. It is also associated with anti-glomerular basement membrane (**anti-GBM**) nephritis and the risk of developing nephropathy in patients with diabetes mellitus.

Intravenous drug abuse is a risk factor for septicaemia that may lead to bacterial endocarditis with associated glomerulonephritis. In addition, such patients may develop acute renal failure due to septicaemia, rhabdomyolysis or (rarely) vasculitis, or chronic renal failure due to amyloidosis. They are also at risk from needle-transmitted infections such as hepatitis B and C and human immunodeficiency virus (**HIV**) that may lead to vascular and glomerular disease. Many patients will not admit to drug abuse and so obtaining an accurate history may be difficult: on clinical examination particular attention needs to be taken of any skin indication of intravenous needling.

Occupational history

Some renal diseases may be work related, hence specific enquiry should be made with respect to the working environment and, in particular, to exposure to any chemical substances: for example, the use of chemicals, pesticides, exposure to fumes, and the need to wear protective clothing. A full occupational history, proceeding in chronological order from the time of leaving school to the present day, needs to be taken. Aniline dye workers have an increased risk of developing urothelial tumours; exposure to solvents may be causally associated with anti-GBM glomerulonephritis; vaporized lead fumes, as occur in the welding of lead pipes, may cause lead nephropathy and chronic renal failure, which is being associated with exposure to an increasing number of toxic substances. As information becomes available, appropriate health and safety regulations are introduced to lessen the risk to workers, but some workers ignore advice, and in some countries—particularly in the developing world—preventive measures are not enforced or are deliberately ignored.

Acute renal failure may arise from leptospirosis in miners, sewage workers, farm workers, and those recreationally exposed, or from hantavirus infection in laboratory technicians and farmers in endemic areas.

Ethnic and geographical factors

Geographical factors are important in a number of renal diseases. Hantaviruses infect various animal species worldwide, but the incidence of clinical infection is variable. In Asia it is due mainly to the Haantan and Seoul viruses, in China it is known as epidemic haemorrhagic fever, and in Korea as Korean haemorrhagic fever. In Europe infections are mainly caused by the Puumala serotype and result in acute renal failure, whereas in North America, although two serotypes have been identified, no cases of renal disease have been reported. Other infections, such as malaria and schistosomiasis, also have particular geographical prevalence. It is important to obtain a full history of travel abroad, as this will alert the clinician to the potential of diseases not frequently seen in everyday practice but which may have an infective basis. (See Chapter 20.7.10 for further discussion of aspects of renal disease particular to developing countries.)

Patients of African or Asian origin are likely to have been exposed to tuberculosis at some time, which may give rise to clinical disease if they are immunosuppressed for treatment of glomerular disease or following transplantation. It is common practice to treat with prophylactic therapy in such circumstances, generally using isoniazid (with pyridoxine).

Some renal diseases have an ethnic association. The amyloidosis that complicates familial Mediterranean fever occurs in Arabs from the Mediterranean area, Turks and Sephardic Jews, whereas Sephardic Jews from Baghdad, southern Russia, the Balkans, and Ashkenazic Jews are rarely affected. IgA nephropathy is more common in Caucasians and people from some Asian countries (Japan, Singapore, and China) and is apparently less common in Afro-American and African peoples. Systemic lupus erythematosus is more common in those from the Middle East and the Orient than from Europe. Diabetes mellitus has an increased prevalence in Asian communities and in some of the Indian communities of North America.

Tubulointerstitial diseases such as Balkan nephropathy have a particular geographical distribution. Analgesic nephropathy, associated with the regular consumption of compound analgesics, particularly but not exclusively those containing phenacetin (before the use of this drug was restricted or banned), was particularly common in Australia where renal effects may be aggravated by minor dehydration due to increased insensible fluid loss. Less easy to explain is the increased prevalence in Switzerland and certain towns in Belgium.

20.3.2 Clinical investigation of renal disease

A. Davenport

Introduction

The key to making any correct diagnosis depends upon a careful history and thorough examination. In patients with renal failure the history and examination should attempt to differentiate acute from chronic renal disease, single-organ system involvement from multisystem disease, and obstruction from intrinsic or prerenal disease. Renal disease may be associated with preceding infections and the ingestion of drugs or herbal remedies. An accurate history and careful examination will determine the sequence and spectrum of clinical investigations required to make a diagnosis.

Examination of the urine

Urine collection

To minimize contamination, standard investigation is of a midstream urine (**MSU**) sample. Voiding from a full bladder containing at least 200 ml of urine should remove urethral organisms before the MSU is collected. Even so, in women, vaginal leucocytes and bacteria may contaminate the urine, and men should retract the foreskin to minimize contamination. Suprapubic aspiration is the technique of choice in babies and infants, and occasionally in adults who can not co-operate to provide an MSU. The second urine of the morning is the best for microscopy as it is still acidic and concentrated, but without the overnight stay in the bladder that results in the degeneration of casts and cells. Cell lysis can occur in both hypotonic and alkaline urine. Only the first 10 ml of the stream are collected in cases of suspected urethritis.

Macroscopic appearance

Fresh urine usually has a yellow colour due to the presence of urochromes. Occasionally urine will have a milky appearance due to pus, spermatozoa, insoluble phosphates in alkaline urine (sometimes seen following heavy meals), or occasionally in cases of chyluria, or urate crystals in acid urine. Foamy or frothy urine is typical of heavy proteinuria.

Certain agents and conditions can discolour urine:

•*Pink to red coloration*—haematuria may result in a range of colours from smoky pink through to port-wine red in cases of frank macroscopic haematuria. Other causes of a pink or red urine include eating sweets containing aniline dyes, beetroot or other foodstuffs containing anthocyanins, haemoglobin, myoglobin, some drugs such as phenindione and phenolphthalein, and (if the urine is left to stand) porphyrins in cases of acute intermittent porphyria.

•*Blue or green coloration*—can be caused by pseudomonas urinary sepsis, methylene blue, biliverdin, triamterene, amitriptyline, chlorophyll-containing breath mints (Clorets®), excessive use of mouthwash and deodorants, magnesium salicylate (Doan's pills®), phenyl salicylate, guanicol (in cough remedies), thymol (in volatile oils and horesemint), iodochlorhydroxyquin, tolonium, Evans blue, methocarbamol, Diagnex blue, indigo blue, resorcinol, azuresin, bromoforium, and occasionally propofol. Phenol and lysol can result in a green or black discoloration.

•*Orange coloration*—can be caused by anthraquinone-containing laxatives, rifampicin, and excess urobilinogen.

•*Yellow urine*—may be found in patients prescribed mepacrine, phenacetin, and those taking excessive amounts of riboflavin, as well as icteric patients with conjugated hyperbilirubinaemia.

•*Black or brown urine*—alkaptonuria results in black or brown urine, whereas myoglobin and melanin only lead to black urine on standing. Other causes of a brown urine include bilirubin, L-dopa, niridazole, furazolidone, and phenazopyridine, and, following standing, haemoglobin and myoglobin. As mentioned above, phenol and lysol can result in a black or green discoloration.

Stick testing

The upper limit of normal for protein excretion in the urine is 128 mg/24 h. Although albumin is the largest single component, more than half of the protein content comprises low molecular weight proteins and protein fragments. Commercial sticks such as Albustix™ are very sensitive, detecting protein in urine starting at concentrations around 100 mg/l. Since these sticks detect protein on a concentration basis, using bromocresol green as an indicator dye, the results they give are affected by urine flow rate and urine dilution or concentration. The sticks are treated with a buffer to keep their pH constant. An elevated urinary protein concentration can erroneously be recorded if the buffer is washed off by leaving the stick in the urine for too long, and with very alkaline urine. Some antiseptics used to clean the skin, including cetrimide and chlorhexidine, may also react and cause a false-positive result.

pH

Normal urine is slightly acidic, but can vary between pH 4.5 and 8.0. If an early morning urine specimen is under pH 5.3, then there is unlikely to be a significant defect in urinary acidification. Alkaline pH is often found in urine infected with urea-splitting bacteria. In some cases of renal calculus disease, particularly in cystinuria and urate nephropathy, crystal solubility is greater in alkaline urine, and patients should regularly check their urine pH. Haemoglobin and myoglobin are also more

soluble in alkaline urine. Thus maintaining a forced alkaline diuresis is important in the management of patients following tumour lysis and those with rhabdomyolysis or haemoglobinuria.

Glycosuria

The stick reaction is based on glucose oxidase, which releases hydrogen peroxide from glucose, so producing a graded colour change by oxidizing an indicator. This reaction is specific for glucose, and does not detect other sugars. The reaction can be blocked by large doses of ascorbic acid. A positive stick test for glucose must be interpreted in light of the plasma glucose level, as glycosuria may reflect a defect in renal tubular glucose absorption.

Specific gravity

Specific gravity is a measure of the number of particles dissolved in a litre, whereas osmolality is the number of particles per kilogram. Protein and glucose increase the specific gravity more than the osmolality as they are dense particles. In normal patients the early morning, or concentrated, urine sample should have a specific gravity of 1.024 or more.

Nitrite stick test

Nitrite sticks contain an aromatic amine which reacts with nitrites, produced by bacterial reduction of nitrate, to form a pink-coloured diazonium complex. More than 90 per cent of the common urinary pathogens are nitrite-forming bacteria. However, *Pseudomonas* spp., *Staphylococcus albus*, *Staphylococcus saprophyticus*, and *Streptococcus faecalis* may have minimal or no nitrite producing capacity. Other false-negative results may be obtained in alkaline urine, in patients taking large doses of vitamin C, and with frequent voiding of dilute urine when the urinary nitrite concentration is too low.

Leucocyte esterase stick test

This stick test is based on the presence of a leucocyte esterase, and is very specific for the presence of urinary leucocytes, both intact and lysed. This test may be more accurate than microscopy when the urine is alkaline or hypotonic. However, the test can be inhibited by high concentrations of glucose (³30 g/l), ketones, and antibiotics including cefalexin, cephalothin, nitrofurantoin, tetracycline, and tobramycin. The sensitivity of this test is also reduced when the specific gravity of the urine is high, for instance in the presence of a heavy proteinuria.

Urine microscopy

To obtain reproducible results urine should be processed in a standard manner and examined under the microscope as soon as possible. In our own institution a few drops of acetic acid (10 per cent v/v) is added to ensure a pH of 6.0 or less; then 10 ml of urine is centrifuged for 5 min at 1500 r.p.m. (750 *g*); following which, 9.5 ml of supernatant is removed and the deposit resuspended. One drop (50 µl) is placed on a microscope slide and covered with a standard coverslip (24 × 32 mm). Although phase-contrast microscopy is an advantage in identifying red cells and casts, a standard microscope will suffice. A semiquantitative assessment of casts is made at low power (160 ×) and other elements at high power (400 ×), expressing the counts as numbers per field. Normal urine contains 1 or 2 leucocytes per high-power field (**HPF**), 1 erythrocyte per 2 or 3 HPF, 1 tubular cell per 10 HPF, and both hyaline casts (1 per low-power field, **LPF**) and granular casts (1 per LPF). Physical exercise can result in haematuria and cylinduria for several hours. Stains such as modified Sternheimer's stain (Sedi-stain™) can be used to help differentiate renal tubular cells from leucocytes. To improve the detection of casts, urine can be filtered through a 5-µm Millipore™ filter, and the retained casts stained with Papanicolaou's stain.

Cellular elements

The morphology of the erythrocytes in the urine can give valuable information as to the source of bleeding. Erythrocytes which have passed through the glomerulus and then along the renal tubule can become distorted or dysmorphic. Those originating from other sources within the urinary tract, such as the bladder, typically show much less signs of damage so that they more closely resemble erythrocytes in the peripheral blood, these are termed isomorphic. To establish a diagnosis of glomerular haematuria there should be a minimum of three different forms of dysmorphic erythrocytes present. One particular type of dysmorphic erythrocyte, the acanthocyte, is reported to have 52 per cent specificity and 98 per cent sensitivity for glomerular haematuria when the acanthocyte count is 5 per cent or more. However, not all workers have found erythrocyte morphology to be useful in discriminating glomerular from non-glomerular bleeding, and the physician who only occasionally examines urine under the microscope is unlikely to obtain clear, reproducible, and useful discrimination between dysmorphic and isomorphic cells.

Some centres use automated haematological cell counters (Coulter Counter™) to assess red cell morphology in both urine and peripheral blood. The red cell size-distribution pattern for lower urinary tract haematuria is similar to that of the peripheral blood, with a relatively narrow size range and a high-frequency distribution curve. Whereas the typical pattern for dysmorphic haematuria is one of a broader range of red cell sizes, with a lower frequency distribution. To have any reliability, urine samples must be processed rapidly by those who do it regularly.

Microscopy may also reveal renal tubular epithelial cells. These cells are shed into the urine in acute tubular necrosis; in response to certain drugs, both nephrotoxic and ischaemic; and also in acute renal allograft rejection. In patients with nephrotic syndrome, these cells are seen as oval fat bodies, laden with lipid droplets. Squamous epithelial cells from the urethra and vagina and transitional cells from the ureter and bladder may also be present in normal urine.

During infection, the urine may contain large numbers of leucocytes and bacteria. When large numbers of leucocytes are present in the absence of bacteria, so called sterile pyuria, then a variety of conditions should be considered: renal calculus disease, analgesic nephropathy, interstitial nephropathy, proliferative glomerulonephritis (rarely), renal tuberculosis, schistosomiasis, and partially treated bacterial urinary tract infection. Phase-contrast microscopy can distinguish lymphocytes from neutrophils, but eosinophils can only be identified with specific stains (Hansel's stain). Classically, urinary eosinophilia occurs in cases of acute interstitial nephritis, typically due to drugs, and also in cholesterol atheroembolic disease.

Urinary casts

Casts form from the transformation of Tamm–Horsfall glycoprotein, secreted by the distal tubular cells, into a gel matrix. They typically assume a tubular structure. Hyaline casts only contain Tamm–Horsfall glycoprotein, and are found in a variable amount in the urine of normal subjects (Fig. 1 and Plate 1). Fever, cardiac failure, strenuous exercise, and some drugs, such as furosemide and ethacrynic acid, increase hyaline cast excretion. During passage through the distal tubule and collecting duct a variety of proteins, pigments, and cells adhere to the Tamm–Horsfall protein, producing a wide variety of casts. Granular casts have deposits of either fine or coarse protein granules (Fig. 2 and Plate 2). Although they may occur in normal subjects, or after exercise, they are typically found in cases of parenchymal renal disease. In patients with proteinuria, the protein deposited comes from the glomerulus, whereas in acute tubular necrosis the protein comes from degenerate tubular cells. Broad waxy casts are much larger than normal casts and have clear-cut edges: they are formed in dilated hypertrophied tubules, as found in patients with chronic renal failure. Casts containing erythrocytes (red cell casts) indicate renal bleeding and are typically found when there is acute glomerular inflammation caused by glomerulonephritis or vasculitis (Fig. 3 and Plate 3). White cell casts (containing leucocytes) can be found in proliferative glomerulonephritis, acute interstitial nephritis, and acute pyelonephritis.

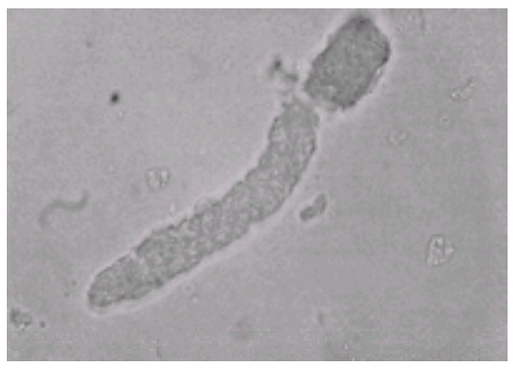

Fig. 2 Unstained urine specimen showing a granular cast. (See also Plate 2.)

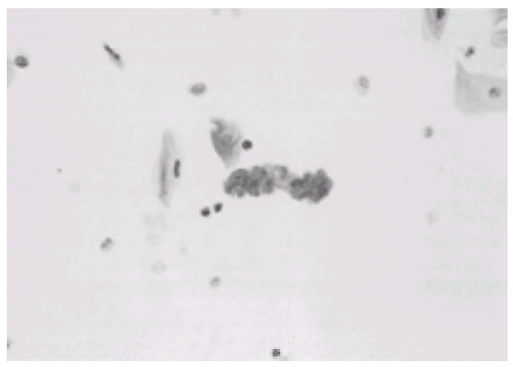

Fig. 3 Papanicolaou-stained urine deposit showing a red cell cast. (See also Plate 3.)

Measurement of proteinuria

Quantification of proteinuria is important as the risk for progression of underlying renal disease to renal failure is related to the amount of protein in the urine. Traditionally, proteinuria has been measured using 24-h urine collections and expressed as grams per day (g/day). This has the advantage that it averages-out protein excretion, and is not therefore affected by the normal diurnal variation in protein excretion (less overnight and first thing in the morning) or urine concentration. Several different methods are used to measure the protein content of 24-h urine collections, ranging from the Biuret method, which uses a copper-based method to precipitate proteins, to dye-binding methods using Coomassie Brilliant Blue as the indicator. These are more accurate than the turbidimetric methods, which use trichloroacetic or sulphosalicylic acid and measure turbidity with a densitometer. Radiocontrast media, and some drugs (including penicillin, sulphonamides, and tolbutamide) may give false-positive results for proteinuria with the sulphosalicylic acid method. The Biuret method measures total proteins, the turbidimetric method provides different readings for albumin and globulins, and the dye-binding methods may do so also.

Testing spot urine samples for protein has been introduced to overcome the inherent problems of patient accuracy and reliability with 24-h urine collections. The urinary albumin concentration is measured by radioimmunoassay. Under resting conditions, urinary creatinine excretion is relatively constant throughout the day. Thus to overcome the problems of timing urinary collections, proteinuria in spot urine samples is expressed as an albumin:creatinine ratio (normal <2.0 mg/mmol creatinine in a daytime urine or 24-h collection, and <1.5 mg/mmol for an overnight or early morning sample). An albumin:creatinine ratio of 100 mg/mmol approximately corresponds to 1.5 g/day, and 350 mg/mmol to nephrotic-range proteinuria. Aside from their use to replace 24-h urine collections, spot urine collections are particularly useful in the diagnosis of orthostatic proteinuria, in other words where the patient has a normal urinary protein excretion when recumbent, or overnight, but has marginally increased proteinuria in the ambulant or daytime sample.

Microalbuminuria

Radioimmunoassays for albumin can detect an increased urinary albumin excretion in patients with normal levels of proteinuria. Normoalbuminuria is defined as an excretion rate of 20 µg/min or less. Proteinuria is usually detectable on dip-stick testing at rates of 200 µg/min or more, and thus microalbuminuria is defined as an excretion rate between 20 and 200 µg/min. The albumin excretion rate (**AER**) is some 25 per cent higher during the day than the night. There is a good correlation between the morning AER and the albumin:creatinine ratio in the first urine sample of the morning. The advantage of spot urines is that all patients can provide a sample when they attend the clinic. Provided the urine samples are taken at the same time, and the patient's dietary intake is relatively constant, then these samples are very useful in assessing patients over time. The advantage of measuring the albumin: creatinine ratio is that it eliminates the timing of urinary samples, which is important in calculating the AER. The albumin:creatinine ratio can also be used to assess the progress of patients with proteinuria, especially if patients fail to collect 24-h urine samples properly.

Microalbuminuria is not only an adverse factor for the progression of diabetic renal disease, but is also predictive of cardiovascular events in both the diabetic and non-diabetic population. In addition to diabetic subjects, microalbuminuria may be found in those with hypertension, cardiac failure, and following a pyrexial or viral illness. Similarly, microalbuminuria may be present in healthy subjects after exercise and during normal pregnancy.

Selectivity of proteinuria

Patients with glomerular disease typically have a non-selective proteinuria, with a similar clearance of both high and low molecular weight plasma proteins. However, those with minimal-change disease may have selective proteinuria, with clearance of predominantly small molecular weight proteins. The demonstration of selective proteinuria is useful in paediatric practice, where patients are often treated with steroids without a renal biopsy.

Most laboratories compare the clearance of IgG, as the large molecular weight protein (mol. wt 150 kDa), to that of albumin (or transferrin, mol. wt 88 kDa) as the low molecular weight protein. Both plasma and spot urine samples are required. Protein concentrations are measured either by laser nephelometry or radial immunodiffusion. Non-selective proteinuria is taken as a [IgG]U/[IgG]P × [transferrin]P/[transferrin]U ratio of 0.20 or more, whereas selective proteinuria is taken as a ratio of 0.10 or less (U is the protein concentration in urine, P the protein concentration in plasma).

Spill-over proteinuria

Patients with myeloma, some types of amyloidosis, and those with reticuloendothelial disorders may have a spill-over proteinuria, due to glomerular filtration of complete and incomplete kappa (_) and lambda (l) chains and immunoglobulin light chains. These small molecular weight proteins are not detected by simple urine stick-testing, or by standard biochemical methods to determine urine protein concentration. Thus, when clinically appropriate, urine should specifically be sent for immunoelectrophoresis to exclude myeloma. However, light chains in particular may still not be detected, hence further investigation with specific antisera may be

required if their presence is suspected.

Renal tubular proteinuria

Interstitial renal disease can result in proteinuria, usually less than 2 g/day. Proximal tubular injury leads to increased low molecular weight proteinuria, characterized by an excess of intestinal alkaline phos-phatase, *n*-acetylglucosaminidase, retinol binding protein, tissue-specific alkaline phosphatase, a-glutathione *S*-transferase, a_1-macroglobulin, and b_2-microglobulin. By contrast, Tamm–Horsfall glycoprotein and a-gluta-thione *S*-transferase are increased in distal tubular injury.

b_2-Microglobulin is freely filtered at the glomerulus and then reabsorbed in the proximal tubule, such that less than 1 per cent of the filtered load is excreted in the urine of normal subjects (normal <370 µg/24 h). Thus urinary b_2-microglobulin excretion has been used as a marker of proximal tubular damage. However, b_2-microglobulin is unstable in urine, and its excretion can be affected both by an increased production rate (found in cases of myeloproliferative disease, chronic inflammatory states, and acute liver disease) and by saturation of b_2-microglobulin tubular uptake due to an excess of dibasic amino acids.

More reliable markers of tubular proteinuria are now available. These include a-glutathione *S*-transferase, a_1-macroglobulin, and retinol binding protein. Turbimetric or enzyme assays are now available. Results are expressed as either excretion rates (for example, normal a-glutathione *S*-transferase, <12.5 ng/min or <11.5 µg/l) or as a ratio to urinary creatinine (for example, normal reference range for retinol binding protein:creatinine, <0.019 mg/mmol).

These tests of renal tubular proteinuria are helpful in investigating patients with suspected Chinese herbal nephropathy, Asian subcontinent nephropathy, and Balkan nephropathy. Industrial workers exposed to heavy metals and organic chemicals, such as those used in the dry-cleaning industry, may develop interstitial renal disease characterized by increased urinary low molecular weight proteinuria.

Estimation of renal function

Biochemical tests

Measurement of plasma creatinine is the standard biochemical test used to assess renal function. Unfortunately the plasma creatinine concentration is not linearly related to the glomerular filtration rate. Thus some 30 per cent of patients with significantly impaired renal function still have a plasma creatinine value within the normal range (<120 µmol/l).

Creatinine

Creatine, which is endogenously synthesized in the liver or exogenously supplied by meat in the diet, is transported to muscle and converted to creatinine by non-enzymatic dehydration. Muscle mass represents some 98 per cent of the total body creatine pool. Thus gender, racial and age-related differences in body composition, physical training and exercise, muscle-wasting diseases, paralysis, and intercurrent illnesses will all affect the production rate of creatinine, and therefore both the plasma creatinine concentration and urinary creatinine excretion. Hence, in young children there is a steady increase in the plasma creatinine level as their muscle mass increases. Dietary influences will affect plasma creatinine levels, with a reduction in strict vegans and increased values in those with a high meat intake (particularly stewed meat: cooking leads to the conversion of creatine to creatinine) or those taking creatine supplements. For any individual, the plasma creatinine level is relatively constant throughout the day, although there is a tendency for it to increase slightly in the afternoon.

Creatinine is not only freely filtered by the glomerulus, but is also secreted into the renal tubule. Creatinine reabsorption may occur at low urinary flow rates, such as in congestive cardiac failure. The relative proportion of renal tubular creatinine secretion to that filtered increases as renal function declines. In addition, in oedematous states such as nephrotic syndrome, calculated creatinine clearance exceeds inulin clearance, suggesting increased tubular creatinine secretion. Several drugs are known to block the tubular secretion of creatinine, and thus cause an increase in the serum creatinine level: these include the diuretics amiloride, spironolactone, and triamterene; and also cimetidine, aspirin, probenecid, and trimethoprim.

Most laboratories measure plasma creatinine using standard automated analysers, which assess the chromagenic product of creatinine and alkaline picrate (Jaffé reaction). Table 1 lists some substances which in high concentration can act directly or indirectly as chromogens, or affect the background control blanks, and so result in a spurious increase in the plasma creatinine level. In clinical practice these may lead to an overestimation of creatinine in poorly controlled diabetics, and an underestimation in deeply jaundiced patients, such as those with primary biliary cirrhosis. Under these circumstances a more accurate method is to determine the plasma creatinine level enzymatically.

Reciprocal creatinine or logarithm of creatinine values

As the plasma creatinine level roughly doubles for every 50 per cent reduction in glomerular filtration rate (**GFR**), expressing (transforming) the results as the reciprocal or logarithm is useful in assessing serial plasma values—this changes the graph from an exponential to a straight-line plot. The advantage of using a straight-line plot of plasma creatinine is that it allows the rate of renal decline to be calculated, which can then be used to predict the onset of endstage renal failure and the requirement for dialysis treatment in many patients. The reciprocal creatinine plot assumes a constant rate of loss, whereas the logarithm a constant fractional loss of renal function.

Patients with diabetic nephropathy tend to have a faster rate of decline in renal function than those with glomerular disease, who, in turn, have a faster rate than those with tubulointerstitial renal disease. In addition, it is easier to assess the effect of treatment interventions on the progression of renal disease by analysing transformed data, and also to recognize when there has been a sudden and unexpected deterioration in function that requires urgent investigation.

Prediction of creatinine clearance from the plasma creatinine level

Despite the potential inaccuracies in the determination of plasma creatinine, variations in endogenous creatinine production rates, and the relative increase in renal tubular and intestinal creatinine secretion with deteriorating renal function, formulas based on the plasma creatinine level are used in clinical practice to estimate creatinine clearance. The most common equation, validated in adults, is the formula of Cockcroft and Gault, later modified by Gault:

$$\text{GFR ml/min} = 1.2 \times [140 - \text{age (years)}\ ] \times \text{weight (kg)}]/[\text{plasma creatinine concentration}]\ (\mu\text{mol/l}).$$

In the original formula, there was a different equation for women, with a factor of 0.85 (instead of 1.2) to allow for the lower rate of creatinine production in women due to differences in their body composition. Although these formulas may be helpful in clinical practice to provide an estimation of renal function, they are not always accurate, particularly in diabetic subjects and Afro-Americans (due to differences in body composition).

Creatinine clearance

In clinical practice, creatinine clearance remains the most commonly used parameter for assessing the GFR. However, this depends upon patient compliance to provide an accurate 24-h urine collection. Even when patients are in a steady state, urinary creatinine excretion varies from day to day, and reliability can be increased by performing consecutive daily clearances.

Creatinine clearance is calculated thus:

$$\text{creatinine clearance (ml/min)} = [\text{urine volume (ml/24 h)} \times \text{urine creatinine concentration (µmol/l)}/\text{plasma creatinine concentration (µmol/l)}\ ] \times 24 \times 60.$$

As regards the use of the creatinine clearance measurement as an estimate of GFR, two errors tend to balance each other out. The chromagenic assay tends to overestimate the plasma, but not urinary, creatinine concentration, leading to an underestimation of GFR. By contrast, creatinine is not only excreted by glomerular filtration: some is secreted by the renal tubules, leading to an overestimation of the GFR. However, in patients with impaired renal function these contrasting effects are not balanced, and the relative increase in tubular creatinine secretion results in creatinine clearance exceeding GFR. This problem can be overcome by the

administration of 400 mg of cimetidine to block renal tubular creatinine secretion, but this manoeuvre is rarely (if ever) performed in clinical practice solely for this purpose. By convention, creatinine clearance values are commonly corrected for body surface area to adjust for differences in muscle mass, assuming a fixed mathematical relationship between body surface area and the relative proportions of fat to muscle. However, body composition is not only age- and gender-dependent, but also varies from race to race, and other inaccuracies occur in oedematous states.

Cystatin C

Cystatin C is a low molecular weight basic protein (13.26 kDa) produced by all nucleated cells. The cystatin gene is a housekeeping gene and a member of the cystatin superfamily of cysteine proteinase inhibitors. Cystatin C is produced at a constant rate, and is not affected by acute inflammation, nutrition, gender, race, or changes in body mass. The production rate is stable over a wide age range, from infants older than 1 year through to the elderly, although there is a slight increase in the latter age group. As cystatin C is freely filtered by the glomerulus and is unaffected by renal tubular degradation or tubular secretion, it can be used as a marker of GFR. Rapid and fully automated accurate assays are now available, which have a superior analytical specificity and precision to that of serum creatinine.

Carbamylation

Urea accumulates with deteriorating renal function. In plasma, urea can spontaneously dissociate to form a reactive cyanate species which can react with the terminal valine of haemoglobin a and b chains (and also similar valine molecules in other proteins). This reaction is termed 'carbamylation' and the product 'carbamylated haemoglobin' (or other protein). Whereas glycosylated haemoglobin has proved useful in clinical practice for assessing time-averaged diabetic control, carbamylated haemoglobin or carbamyl-lysine adducts have not been shown to be superior to simple serum creatinine measurements in determining stable renal function. However, they are useful in helping to differentiate acute from chronic renal failure, because of the time course of the carbamylation reaction, and also in the assessment of time-averaged urea levels in the dialysis patient with endstage renal failure. However, until the relevant assays are commercially available, their use will remain experimental.

Isotopic methods

The glomerular filtration rate can be determined by the clearance of a compound which is freely filtered by the glomerulus and then passes through the nephron without tubular reabsorption or secretion. Traditionally, inulin—a naturally occurring polyfructose—was given as a constant infusion to achieve a constant plasma concentration, and then clearance determined from timed urinary collections. This was a considerable laborious technique. Furthermore, the biochemical estimation of inulin was initially tedious and difficult, with significant interassay variation, and accurate timed urine collections are unreliable in patients with urinary tract anomalies. To overcome these and other difficulties, compounds other than inulin are generally used to estimate GFR, and methods other than constant infusion.

Following a single bolus injection, depending on the compound used, the fall in plasma concentration follows either a single- or two-compartment model related to renal clearance. Chromium-labelled ethylenediaminetetraacetic acid ([^{51}Cr]EDTA) is the most commonly used isotope. After the single injection, three timed plasma samples are taken to calculate the plasma decay rate, and thereby the GFR. More recently it has been showed that for a GFR over 30 ml/min, only a single blood sample at 4 h is required. At GFRs above 30 ml/min there is a very good correlation between inulin and [^{51}Cr]EDTA clearance, but below 30 ml/min the accuracy of the isotope techniques is reduced, there being some renal tubular reabsorption. Accuracy can be improved in this situation by taking a delayed (24 h) plasma sample.

Other isotopes that have been used to estimate GFR include [^{125}I]iothalamate, which when given as a subcutaneous injection results in a constant plasma concentration equivalent to the infusion technique, and Tc ^{99m}-diethylenetriaminepentaacetic acid (**DTPA**), which is less accurate due to its short half-life (6 h) and dissociation of DTPA from the radionuclide.

With all the isotopic methods, it is conventional for the GFR to be corrected for the size of the patient. This correction assumes a fixed relationship between the weight and height of an individual: hence serial estimations to detect a change in renal function are more likely to be accurate than single estimations.

Radiological methods

Iohexol is a non-ionic, low-osmolality, radiocontrast dye. It can be used to estimate glomerular filtration rate following a single bolus injection of between 2 and 5 ml. In patients with a clearance of over 30 ml/min, a single plasma sample taken 3 h after injection provides an accurate estimation, whereas additional later samples are required to improve the accuracy in those with severely impaired renal function.

Summary

When the plasma creatinine concentration is below 150 µmol/l, it cannot be used as an accurate assessment of renal function. When appropriate, an isotopic assessment of GFR is the most accurate method of determining GFR. Otherwise, two 24-h urine collections with corresponding plasma samples should be used to calculate the GFR, although in some centres cystatin C has replaced creatinine for the assessment of renal function. To examine changes in renal function, creatinine concentrations should be transformed to either the reciprocal or the logarithm to assess trends in serial results.

Renal blood flow

Renal blood flow can be estimated non-invasively using Doppler flow probes, provided there is a single renal artery and adequate imaging is possible. This is technically easier for the transplanted kidney than the native kidney. The recent development of contrast agents for ultrasound may increase the reliability of these estimations. Alternatively, renal blood flow can be estimated from the measurement of the renal plasma flow and the haematocrit. However, the haematocrit of peripheral venous blood may not be the same as that entering the renal artery.

Renal plasma flow

Ideally any compound used to assess renal plasma flow should have 100 per cent uptake by the kidney. Thus that fraction not filtered by the glomerulus must be extracted by the tubules and secreted. *p*-Aminohippurate is the most commonly used compound, but is only 85 per cent extracted during a single passage through the kidney, and thus at best only provides an estimate of renal plasma flow. Continuous infusion of *p*-aminohippurate provides a more accurate estimation of renal plasma flow than single injection techniques.

Renal blood flow varies in normal subjects with pain, stress, physical exercise, normal pregnancy, and following a high protein meal. In patients with impaired renal function, the decline in renal plasma flow generally corresponds to the decrease in GFR. However, in some conditions where there may be renal tubular hypoxia or toxicity, such as in patients with severe heart disease or those with ciclosporin nephrotoxicity, the reduction in estimated renal plasma flow is greater than that expected for the change in GFR, due to a reduction in the renal tubular uptake of *p*-aminohippurate. Similarly, *p*-aminohippurate uptake is reduced in small children. [^{125}I]*o*-Iodohippurate has also been used to estimate renal plasma flow, but this has a lower extraction than *p*-aminohippurate (75 per cent), and is less reliable.

Investigation of tubular function

In a normal subject, some 180 litres of glomerular filtrate is produced each day and less 3 per cent of this is excreted, due to reabsorption by the tubules. The proximal and distal tubules have different functions, and traditionally each is considered separately.

Proximal tubular function

Defects in proximal tubular function may be isolated or generalized, as in the Fanconi syndrome. Glucose, amino acids, phosphate, and organic ions are reabsorbed by the apical border of proximal renal tubular cells by sodium-dependent cotransporters, and then cross out from the basolateral membrane by different, sodium-independent, cotransporters.

Glucose

There is a maximum reabsorption rate for glucose (T_MG) in the proximal tubule of 15.1 ± 2.5 mmol/l (T_MG/GFR), above which glycosuria will be present. To determine TMG/GFR, a 20 per cent glucose infusion is administered at increasing rates to produce a slow rise in the plasma glucose up to a maximum of 30 mmol/l, which is maintained for a minimum of 1 h. Plasma and urine samples are collected every 30 min. Renal function is determined by [^{51}Cr]EDTA-GFR. The glucose absorption rate is calculated as the difference between the filtered load in urine (urine volume × $[glucose]_{urine}$) and the filtered load in plasma (GFR × $[glucose]_{plasma}$). Patients with type A renal glycosuria typically have a reduced threshold of around 5 mmol/l.

Phosphate

Phosphate is normally filtered at the glomerulus and reabsorbed in the proximal tubule, with only 10 to 20 per cent of the filtered load being excreted. The normal tubular reabsorption of phosphate (**TRP**) is above 85 per cent and can be calculated from:

$$\%TRP = \{1 – (\text{phosphate clearance/GFR or creatinine clearance})\} \times 100.$$

If renal function is normal, then this can be simplified by collecting an early morning specimen of urine, and:

$$\%TRP = \{1 – ([phosphate]_{urine} \times [creatinine]_{plasma}/[creatinine]_{urine} \times [phosphate]_{plasma})\} \times 100.$$

Alternatively, the theoretical maximum tubular threshold of phosphate (T_MP) can be estimated from:

$$T_MP/GFR = [phosphate]_{plasma} – ([phosphate]_{urine} \times [creatinine]_{plasma}/[creatinine]_{urine}),$$

or measured directly as for T_MG, following an infusion of phosphate (1.0 litre of 0.1 M sodium phosphate at pH 7.4) with a corresponding [^{51}Cr]EDTA-GFR.

Excessive urine phosphate losses occur in proximal tubular disorders such as the Fanconi syndrome, primary and secondary hyperpara-thyroidism. In the various forms of hypophosphataemic rickets, phosphaturia occurs with a characteristically reduced T_MP/GFR of less than 0.56 mmol/l.

Amino acids

Apart from the reabsoption of histidine (90–95 per cent), that of other amino acids is almost complete (97–99 per cent). Although amidoaciduria can occur as a result of overflow when the plasma concentration exceeds the tubular transport maximum, this is very rarely the cause of aminoaciduria in adults. In general, five types of renal aminoaciduria are distinguished: dibasic amino acids, neutral (monoaminomonocarboxylic acids) amino acids, glycine and imino acids, dicarboxylic amino acids, and generalized amino aciduria in the case of the Fanconi syndrome. Generalized and specific amino acidurias can be detected and quantified by thin-layer chromatography. In the Fanconi syndrome amino acids from all four groups are present, whereas there is only excess glycine in glycinuria. Classic cases of cystinuria have increased urinary arginine, ornithine, lysine, and cystine; and patients with Hartnup disease have an excess of neutral amino acids.

For more detailed discussion of other aspects of proximal tubular function and their diseases, see Chapter 20.8.

Distal tubular function

Patients with primary or secondary nephrogenic and/or cranial diabetes insipidus and those with primary polydipsia may present with polyuria. A water-deprivation test can help to differentiate between these conditions, and should be performed as follows. The patient should be admitted to a metabolic ward on the evening prior to the test, be weighed, and have samples taken for baseline plasma osmolality, chemistries, and arginine vasopressin measurement (**AVP**). An osmolality above 295 mosmol/kg and a sodium concentration above 143 mmol/l, excludes a diagnosis of primary polydipsia. After midnight, no oral fluids are allowed until completion of the test. The early morning urine osmolality is measured, and if it is above 800 mosmol/kg (normal response) the test is abandoned. Thereafter the weight, plasma and urine osmolality, and plasma AVP concentration should be recorded regularly. If weight loss exceeds 5 per cent, then the test should be abandoned to prevent dangerous dehydration. Once urine osmolality reaches a plateau (an hourly increase of less than 30 mosmol/kg for 3 consecutive hours), then 5 units of aqueous vasopressin is administered subcutaneously and urine and plasma osmolality measured after a further 30 min, and then at hourly intervals.

Comparison of the last urine osmolality reading prior to the administration of vasopressin with the maximum osmolality following vasopressin helps to categorize patients. Those with nephrogenic diabetes insipidus will produce a urine osmolality under 300 mosmol/kg with no response to exogenous vasopressin and have high AVP levels. Those with severe cranial diabetes insipidus will have dilute urine, again less than 300 mosmol/kg, but they will respond to exogenous vasopressin by increasing urine osmolality by 50 per cent or more, accompanied by low endogenous AVP levels. Both cranial and nephrogenic diabetes insipidus can occur as partial forms, which show some response to dehydration, but they can be discriminated by analysing the relative changes in endogenous AVP and the urinary and plasma osmolalities. Patients with primary polydipsia do not show pituitary suppression, and have little or no response to exogenous vasopressin.

Renally induced electrolyte imbalances

Sodium and water

Hyponatraemia may occur both in patients with a reduced effective circulating plasma volume and those with the syndrome of inappropriate ADH secretion (**SIADH**). Patients with reduced renal perfusion, such as those with cardiac failure, chronic liver disease, nephrotic syndrome, and prerenal acute renal failure, will have a reduced fractional excretion of sodium (FE_{Na}) of less than 1 per cent (normal 1–2 per cent), where:

$$\%FE_{Na} = ([Na]_{urine}/[Na]_{plasma} \times [Cr]_{plasma}/[Cr]_{urine}) \times 100.$$

Those with SIADH preferentially retain water and have a normal FE_{Na}. However, when interpreting measurements of FE_{Na} it must be remembered that this is increased by diuretic administration and in chronic renal failure.

Both those with a reduced effective circulating plasma volume and those with SIADH have impaired free-water excretion, which can be tested by giving the patient 20 ml of water/kg body weight to drink after voiding. More than 75 per cent of the water load should be excreted within 3 h, and the urine osmolality should fall to under 100 mosmol/kg (specific gravity <1.003). This test can be affected by gastrointestinal disease, smoking, and emotional factors. The free-water clearance (C_{H2O}) can be quantitated from:

$$C_{H2O} = \text{urine volume (ml/min)} – [\text{osmolality}_{urine}/\text{osmolality}_{plasma} \times \text{urine volume (ml/min)}].$$

A positive free-water clearance occurs when the urine is more dilute than plasma, and a negative free-water clearance when the urine is more concentrated.

For further discussion of these issues, and the clinical approach to disorders of sodium and water homeostasis, see Chapter 20.2.1.

Potassium

To determine whether there is a renal tubular cause for potassium disturbances, the transtubular potassium gradient (**TTKG**) can be calculated. This attempts to estimate the potassium concentration in the cortical collecting duct.

Using $TTKG = [potassium]_{urine} \times$ osmolality plasma/urine, a TTKG under 2 suggests a non-renal cause of hypokalaemia, whereas a high TTKG (>10) is associated with mineralocorticoid excess, Liddle's syndrome, or drugs such as acetazolamide, fludrocortisone, and amphotericin. A TTKG above 10 implies a non-renal cause of hyperkalaemia and a low TTKG (<2) would be found in cases of potassium-sparing diuretics, hypoaldosteronism, and pseudohypoaldosteronism. Whilst having

theoretical attraction, it is doubtful whether such analysis helps greatly in the diagnosis or management of patients with hypokalaemia or hyperkalaemia. For further discussion of these issues, and the clinical approach to disorders of potassium homeostasis, see Chapter 20.2.2.

For more detailed discussion of other aspects of distal tubular function and their diseases, see Chapter 20.8 and Chapter 20.13.

Imaging of the patient with renal disease

Plain radiography

Plain abdominal radiographs may demonstrate opaque renal stones, nephrocalcinosis, and the renal outlines. Ultrafast, non-contrast CT scanning with three-dimensional reconstruction has generally replaced nephrotomograms for detecting low-opacity renal stones.

Chest radiography may be helpful in the diagnosis of pulmonary oedema, and also in demonstrating the cardiac silhouette and lung pathology sometimes associated with renal disease, such as pulmonary haemorrhage and cavitation. Multiple rib fractures may suggest multiple myeloma.

Intravenous urography

Although intravenous urography (**IVU**) is no longer the standard investigation in nephrology, it still has an important place in the investigation of patients with suspected obstruction of the urinary tract, as it does provide imaging of the entire urinary tract. As with all radiographic procedures, potential fetal irradiation should be avoided. Bowel preparation is no longer standard, due to the risks of dehydration in the elderly and of gaseous distension of the bowel obscuring the urinary tract. Even the newer non-ionic contrast media can cause nephrotoxicity in some patients, and care should be taken to ensure that those at risk (elderly and those with diabetes, myeloma, or a pre-existing renal impairment) are adequately hydrated. Normal renal length is between 3 and 4 lumbar vertebrae, with a width approximately half that of the length.

The IVU may provide valuable information about renal size and possible intrarenal masses. It remains the best method for investigating the patient with acute renal colic, and for assessing the level of any obstruction. Other techniques, such as ultrasound and ultrafast computed tomography (**CT**) scanning, can also be used to investigate renal colic—the main advantage of CT scanning being that it can detect other pathologies which mimic this condition.

The calyces and papillae are well demonstrated on the IVU, which may be diagnostic in cases of medullary sponge kidney, papillary necrosis, and sloughed papillae. Similarly, intraluminal radiolucent foreign bodies may be demonstrated surrounded by contrast, typified by radiolucent stones, blood clots, fungal ball, tumour, or sloughed papillae.

Abnormalities of the ureteric wall such as localized thickening are found in cases of transitional-cell carcinoma, oedema, tuberculosis, and parasitic granuloma. The IVU may also demonstrate external compression: this can be due to aberrant blood vessels in the upper tract, retroperitoneal fibrosis affecting the middle ureter, or prostatic pathology in the lower tract.

Other conventional uroradiological techniques

Further information about the site and nature of any obstruction can be obtained by ureteropyelography. This may be performed by an antegrade or a retrograde approach. An antegrade study involves percutaneous puncture of the renal pelvis, with immediate relief of the obstruction by nephrostomy, and allows demonstration of the site of obstruction following an injection of contrast media (antegrade ureteropyelography). A retrograde study requires cystoscopy, allowing direct visualization of the distal ureter, the possibility of removing an obstructing stone, and the passage of double JJ stents from below to relieve the obstruction. Injection of contrast media from below demonstrates the site of any obstruction (retrograde ureteropyelography). Antegrade techniques are usually more successful in relieving obstruction, particularly in those with pelvic malignancy or obstruction of a renal transplant. In cases when renal obstruction is considered, but investigation inconclusive, then a pragmatic trial of antegrade stent insertion should be undertaken. Improvement of renal function confirms obstruction.

Retrograde urethrocystography is performed in female patients to detect lower urinary tract abnormalities, such as fistulas or urethral diverticulae. Sequential films taken during micturition may detect active reflux. In males, urethrocystography can be complicated by trauma and infection to the lower urinary tract, and therefore suprapubic bladder puncture is recommended.

Renal ultrasonography

The normal kidney and chronic renal disease

The normal adult kidney is between 10 and 12 cm long, with a thin, bright capsule surrounded by highly reflective perinephric fat. The healthy cortex returns mid-level grey echoes, the pyramids are darker, and the renal sinus, containing fat and the major vascular pedicle, is bright with high reflectivity. Colour, flow Doppler can be used to visualize the flow of urine from the native ureters into the bladder. In most causes of chronic renal disease the kidneys become smaller, with reduced cortical thickness and increased reflectivity. Diastolic blood flow is reduced on the Doppler scan. The renal ultrasound appearances are characteristic in some conditions: these include focal segmental glomerular sclerosis secondary to HIV infection in which the kidney is reported to be large and the cortex uniformly of a high reflectivity, greater than that of the renal sinus. Scars, either vascular or infective, may often be too small to be detected by ultrasound examination, especially in the neonate.

Renal masses

Ultrasound is useful in the assessment of renal masses. Benign cysts have a smooth outline with well-demarcated borders and an echo-free centre, whereas renal tumours are usually irregular with heterogeneous echo reflectivity. Most tumours are vascular, with high flow during both systole and diastole on colour-Doppler scanning, and adenocarcinomas in particular may be seen to extend into the renal vein. Renal transitional-cell carcinomas are not readily detected unless large, as ultrasound does not visualize individual calyces well. Angiolipomas may have a characteristic appearance due to their fat content which has high reflectivity, but confirmatory CT scanning is required.

In adult polycystic kidney disease, the kidneys are typically enlarged with multiple bilateral cysts. Middle-aged women may also have hepatic cysts. It is important to remember that, if patients are scanned in their teenage years or before, then cysts may not have developed or they may be below the level of resolution for ultrasound detection. Haemorrhage, infection, or malignant change all result in complex echoes within cysts, which cannot be differentiated by ultrasound scanning. Autosomal recessive, polycystic renal disease can be detected *in utero* with antenatal scanning.

There is an increased incidence of cystic change in the kidneys of patients with endstage renal disease, and occasionally these cysts may become malignant. It has been recommended that dialysis patients should be screened by ultrasound every 3 years, and then annually if cystic changes develop.

Urinary obstruction

In most centres, ultrasonography of the urinary tract is the first investigation performed when an obstruction is suspected. When urinary obstruction has been present for some time, the high reflectivity of the central renal sinus becomes replaced by echo-free urine, with distention of the calyces. However, it is important to recognize that in acute obstruction, and in cases where the kidney and ureter are encased (usually the result of tumour), the standard ultrasound examination may appear normal. In these circumstances, a colour-Doppler scan may show reduced diastolic blood flow due to increased intrarenal pressure; also absence of the normal pulsatile jets of urine from the ureter into the bladder on the side with the acute obstruction. Ultrasound is not usually diagnostic of the cause of obstruction, but it may detect para-aortic nodes, a bladder mass, prostatic enlargement, or a ureterocele. Further investigation with transvaginal, transrectal, or transurethral ultrasound may confirm the cause of obstruction, transrectal ultrasound being particularly useful in the detection of local invasion from prostatic carcinoma.

Urinary tract stones

Renal stones appear on ultrasound as a bright echogenic focus with a distal acoustic shadow. Ultrasound can be used to follow up patients with renal calculus

disease by assessing the number and size of stones. Nephrocalcinosis may result in an increase in medullary echoreflectivity due to calcium deposition, which usually affects the whole medulla, whereas calcification from papillary necrosis has an appearance more like that of a renal stone.

Renovascular disease

Colour Doppler can be used to investigate renal arterial and venous disease. Thrombosis of major vessels produces absent flow or changes to the intrarenal blood flow pattern. More recently, colour-Doppler scanning has being used as a screening test for renovascular disease, with changes at the site of stenosis characterized by an increase in the peak systolic frequency followed by a diastolic spectral broadening. The sensitivity and specificity of this test has not been determined, and it remains a 'research' rather than a 'standard' clinical investigation.

Renal transplantation

Ultrasound examination is an important investigation in the management of the renal transplant recipient. Early graft dysfunction mandates investigation to exclude a technical problem with either the renal artery or vein, or a urinary leak. Colour-Doppler scanning provides valuable information about the vascular supply of the graft (Fig. 4). Fluid collections (commonly lymphoceles) appear as echo-free or echo-poor areas, and perinephric collections can be drained under ultrasound guidance for diagnostic purposes or to relieve obstruction. As with the native kidney, percutaneous nephrostomy is the emergency treatment of choice for obstruction of the renal transplant. Colour-Doppler scanning can detect the presence of arteriovenous fistulas, not uncommon following transplant biopsy.

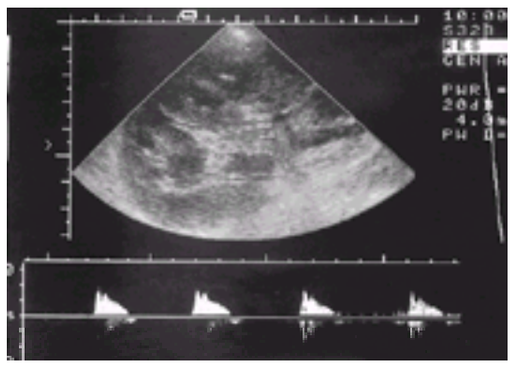

Fig. 4 Doppler ultrasound of a renal transplant showing normal systolic and diastolic wave forms.

Contrast agents for ultrasound

Colour-Doppler ultrasound can detect bubbles present in injected contrast medium. Application of this technique can change the use of ultrasound from simple anatomical visualization of the kidneys to dynamic testing. This will allow ultrasound to determine relative renal function, and improve investigation for obstruction and renovascular disease.

Computed tomography (CT) scanning

Computed tomography has advantages over conventional intravenous urography by imaging the perirenal and retroperitoneal spaces, and differentiating soft tissues within the kidney. Ultrafast CT scanning, without contrast, is being used more frequently to image ureteric renal stones and define the site of ureteric obstruction. In addition, CT provides vital information regarding the cause of ureteric obstruction by imaging the ureter, retroperitoneal space, and pelvis. Spiral, or helical CT scanning allows a three-dimensional reconstruction of the images, overcomes respiratory artefacts, and is useful in the investigation of congenital and anatomical abnormalities of the renal tract, such as renal agenesis. High-resolution CT scanning may detect early nephrocalcinosis, before calcification can be detected on plain films. These imaging techniques can be enhanced by contrast to give additional information: for example, simple renal cysts do not change in density following contrast, but occlusion of vessels may be demonstrated (Fig. 5).

Fig. 5 Contrast-enhanced CT scan showing thrombosed aorta and renal arteries.

Apart from the investigation of cystic renal disease, CT scanning is used to investigate renal masses. Renal-cell carcinomas vary in appearance: some show calcification both within and surrounding the tumour on non-enhanced scans, some are solid, and others are cystic or have necrotic centres. The majority of tumours are vascular and readily enhance with contrast, but those with heavy calcification may not. CT scanning is important in tumour staging, in determining the extent of perirenal spread, renal vein involvement, and enlargement of local lymph nodes. Occasionally, secondary deposits due to metastatic spread and secondary involvement in lymphomas and leukaemia, can be found on contrast-enhanced scans. These are usually small multiple intrarenal masses, often bilateral, typically homogenous, and solid in lymphomas. Although ultrasound is used to screen and assess Wilms' tumours in children, CT scanning is important in excluding pulmonary metastases.

Angiolipomas can be recognized with ultrasound, but should be confirmed on CT scanning as some renal-cell carcinomas may contain small amounts of fat. In tuberous sclerosis, angiolipomas may be associated with renal cysts. Although angiolipomas are benign mesenchymal tumours, they can rarely rupture, especially those with intrarenal haematomas and aneurysms. Early detection by CT scanning allows prophylactic embolization of these vascular lesions.

Renal oncocytomas, are another benign renal tumour, and on CT scanning may have a central lucent area due to fibrosis. However, a proportion of oncocytomas may become malignant. Thus any small renal lesion which is not a simple cyst or angiolipoma must be regarded as potentially malignant and therefore surveillance with repeat CT scanning (or ultrasound) should be recommended.

Renal tract imaging in patients with acute pyelonephritis is usually requested to exclude the presence of an obstruction, or when there has been an inadequate response to treatment. CT scanning defines the extent of disease better than ultrasound, detects abscesses, and can also exclude obstruction. Whereas focal acute bacterial pyelonephritis should respond to antibiotics, renal abscesses may require drainage. CT scanning may also detect gas bubbles within the renal parenchyma or perirenal space, characteristic of emphysematous pyelonephritis, typically found in diabetics. Similarly, CT scanning may establish a diagnosis of xanthogranulomatous pyelonephritis, with an enlarged kidney containing areas of scarring, focal loss of renal parenchyma, and multiple low-density masses, often following recurrent infections in patients with staghorn calculi.

In cases where renal trauma is suspected, contrast-enhanced CT scanning provides information not only about renal anatomy and function, but also perirenal collections, differentiating blood from urine. In addition, CT scanning provides valuable information about trauma to other intra-abdominal structures.

Magnetic resonance imaging (MRI)

CT scanning and ultrasound are good reliable techniques for detecting and evaluating renal masses. MRI is an alternative in patients who are allergic to conventional iodine-based radiocontrast media or those at risk of contrast nephropathy. The gadolinium contrast used in MRI is taken up by the proximal tubule, in a similar manner to aluminium, but has not been shown to cause nephropathy. MRI is expensive, but does have some advantages over conventional CT. Tissues surrounded by fat, such as enlarged lymph nodes, or tumour extension into the renal vein, are better demonstrated on MRI than CT. Thus MRI is useful in staging renal-cell carcinoma, and by being able to distinguish blood from tissue can help to differentiate simple cysts complicated by haemorrhage from those that are malignant.

The whole of the urinary tract can be visualized, in a manner similar to an IVU, by using a heavily weighted T_2 fast spin–echo sequence. This rapid acquisition and relaxation enhancement scan can be used to assess potential live donors for renal transplantation, by demonstrating the renal vasculature, renal anatomy, and urinary drainage with one investigation.

The quality of image provided by MRI can be very high (Fig. 6 and Fig. 7).

Fig. 6 Gadolinium-enhanced MRI showing left-sided pyelonephritic scarring, with a reduction in cortical thickness and scarring.

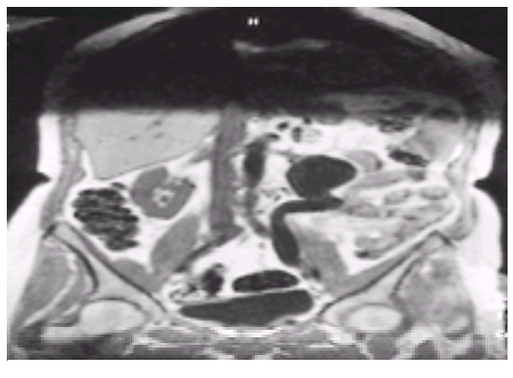

Fig. 7 Gadolinium-enhanced MRI showing a hydronephrotic left kidney and dilated upper two-thirds of the ureter following gynaecological surgery.

Angiography and digital subtraction angiography (DSA)

Formal renal angiography remains the 'gold standard' technique for assessing renovascular disease (Fig. 8). With the advent of expandable renal artery stents, it is important to determine precisely the anatomy of any stenosis, so that appropriate intervention can be planned. Direct pressure measurements can be made either side of any stenosis, so that the degree of stenosis can be assessed both anatomically and functionally. However, renal angiography is not without hazard: it involves an arterial puncture, the use of potentially nephrotoxic contrast agents, and carries the risk of dislodging aortic and renal artery plaques, which can result in intrarenal, intra-abdominal, and peripheral cholesterol embolization.

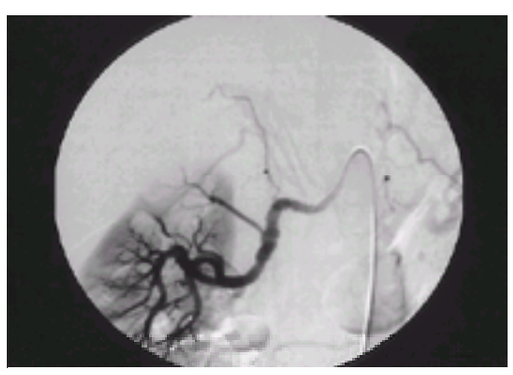

Fig. 8 Renal arteriogram showing fibromuscular hyperplasia of the renal artery.

Aside from the investigation of suspected chronic renovascular disease, renal arteriography can be indicated in the investigation of sudden renal ischaemia due to renal artery thrombosis or dissection, aortic dissection with extension into the renal arteries, or trauma to the renal artery. In addition, renal and coeliac arteriography can establish a diagnosis of classical macroscopic polyangiitis nodosa. Occasionally renal angiography is helpful in assessing renal tumour vascularity, and in determining whether partial nephrectomy can be performed. In some cases of persistent non-glomerular haematuria, formal renal angiography reveals a vascular abnormality as the underlying cause.

Digital subtraction angiography (DSA) uses a venous injection of contrast and computer-derived images to view the major renal arteries and intrarenal vessels. High doses of contrast media may be required, even so insufficient anatomical definition is obtained in between 5 and 20 per cent of cases. Thus, with appropriate indications, DSA is a good screening test but may need to be followed by formal angiography.

Interventional renal arteriography

Interventional renal arteriography should only be undertaken by experienced interventional radiologists with the support of vascular surgeons, as renal artery dissection or rupture may occur. Embolization with gel foam or metal coils can be used to selectively control renal haemorrhage, which is particularly useful when this

follows renal biopsy, and also in cases of arteriovenous malformation or tumour. Occasionally a whole kidney is embolized. Some renovascular stenotic lesions can be usefully treated by transluminal angioplasty or stenting.

Spiral CT angiogram

Spiral CT, by taking pictures which are then reconstructed by computer to provide a three-dimensional picture, can be used to investigate renal vascular disease. Radiocontrast is required, which can be administered by arterial or peripheral venous injection. To reduce the risk of contrast-induced nephropathy, or the possibility of 'flash pulmonary oedema' due to an intravenous volume load, some centres use carbon dioxide gas as the contrast agent. Compared to standard renal angiography, spiral CT renal angiography tends to overestimate any stenosis. The overestimation is greater with carbon dioxide than conventional contrast. However, this is a useful technique for excluding significant renovascular and intrarenal vascular disease.

Magnetic resonance angiography

Magnetic resonance angiography (**MRA**) using gadolinium chelates is indicated when there is a clinical risk of the patient developing contrast-induced nephropathy with standard renal or spiral CT angiography. MRA overemphasizes any stenotic area or other vascular abnormality. Thus MRA is useful in confirming normality, and is used in the preoperative assessment of living related kidney donors. A normal MRA of the renal arteries excludes renal artery stenosis, intrarenal vascular disease, and polyarteritis nodosa.

Magnetic resonance venography

As with MRA, magnetic resonance venography (**MRV**) using gadolinium contrast can be used to assess renal venous patency. Patients with nephrotic syndrome, and those with renal adenocarcinoma, may develop renal venous thrombosis, which can be difficult to positively diagnose with other imaging techniques.

Renal venography

Selective renal venous catheterization for blood sampling is still useful in patients with severe renovascular disease. The relative renal vein renin concentrations may aid the decision-making process in deciding whether to perform a surgical or medical nephrectomy in a patient with a small poorly functioning kidney due to severe renal artery stenosis.

Nuclear medicine

Static imaging

Radiolabelled dimercaptosuccinic acid (DMSA)

Technetium-labelled dimercaptosuccinic acid binds to renal proximal tubular cells, and after an intravenous injection some 70 per cent of the dose is taken up by viable tubules within 3 to 4 h. This can be detected by a gamma camera. DMSA scans provide information about the relative function of each kidney, and show areas of scarring due to renal stone disease, infection, and vascular disease. In children with urinary tract sepsis, suspected of reflux nephropathy, then serial DMSA scans are used to assess progressive cortical scarring. During acute pyelonephritis the DMSA scan may appear to show scars. These photopenic areas are due to inflammation and increased intrarenal pressure and can return to normal following resolution of infection. DMSA scans are also used to confirm the congenital absence of a kidney, to detect ectopic kidneys and other congenital malformations such as horseshoe kidney, and to confirm absence of renal function.

More recently, the introduction of single-photon emission computed tomography (**SPECT**) DMSA scans has improved resolution. These have shown that renal scars occur more frequently than previously thought, both in patients with acute pyelonephritis and also following lower urinary tract infection in renal transplant recipients.

Dynamic imaging

Radiolabelled diethylenetriaminepentaacetic acid and hippuran

Technetium-labelled diethylenetriaminepentaacetic acid (**DTPA**) or ^{131}I-labelled hippuran are both filtered by the glomerulus and then rapidly excreted by the kidney. These renograms have three phases: vascular, accumulation within the kidney, and excretion. Renal artery stenosis and acute tubular necrosis can reduce uptake, flattening the second and third phases of the renogram. Similarly, intrinsic renal disease flattens the second phase, and makes interpretation difficult when renal function is impaired.

Radiolabelled DTPA and hippuran scans are used to assess urological obstruction (Fig. 9). Occasionally patients with polycystic kidney disease present with severe pain due to the obstruction of a cyst, and DTPA scanning provides a dynamic test to confirm obstruction. In patients with dilated collecting systems, it is important to a differentiate congenital megaureter from an obstructed system. Excretion may be slow due to pooling in a dilated system, but obstruction is unlikely if there is a brisk wash-out following the administration of intravenous furosemide. Patients with impaired renal function may have a reduced response to furosemide, making interpretation of the renogram less reliable. Thus, in cases with impaired renal function, direct pressure measurement within the renal pelvis following percutaneous puncture may be required to exclude partial obstruction (Stamey test).

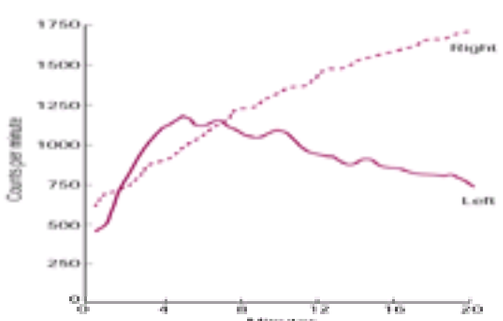

Fig. 9 DTPA renogram showing increasing uptake by the right kidney in a case of right-sided ureteric obstruction.

DTPA scans are also used to detect reflux in children, as reflux may be demonstrated during the 'emptying' phase of the renogram. If not, then an indirect micturating cystogram can be performed using the radioactivity which has passed into the child's bladder.

Following renal transplantation, DTPA and hippuran isotope scans can be used to monitor graft function. In cases of major arterial or venous thrombosis, and hyperacute rejection, the graft appears to have no perfusion. Acute tubular necrosis, rejection, and immunophylin toxicity may all have similar appearances. Serial scans can help to differentiate these conditions. DTPA scans may also reveal perirenal and urinary leaks before they are clinically manifest. Later isotope scans may detect obstruction due to ureteric stenosis.

Radiolabelled mercaptoacetyltriglycine (MAG3)

Technetium-labelled mercaptoacetyltriglycine ([^{99}Tc]MAG3) is protein-bound, and renal excretion is both by glomerular filtration and renal proximal tubular secretion. The excretion pattern is similar to that of hippuran and DTPA. The advantage of MAG3 is that it provides better image definition than DTPA and hippuran, especially

in those with impaired renal function. Thus MAG3 can be used to provide both anatomical (as DMSA) and functional (as DTPA and hippuran) information (Fig. 10).

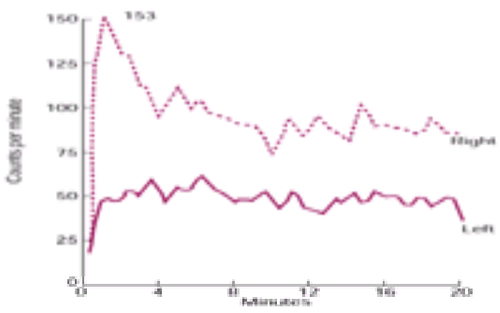

Fig. 10 MAG3 renogram demonstrating reduced uptake by the left kidney in a case of left-sided renal artery stenosis.

Patients with renal artery stenosis may have a delay in uptake time (the time taken from injection to peak activity) and an increased intensity and duration of MAG3 accumulation (due to increased tubular salt and water reabsorption, not seen in the case depicted in Fig. 10). If there is major stenosis of a major branch artery, then perfusion to one pole may be delayed. To improve the sensitivity and specificity of the MAG3 renogram in the detection of renal artery stenosis, some centres employ a method whereby two scans are performed—one with, and one without, prior administration of captopril. The captopril–MAG3 renogram can also be used as a screening test to determine whether the use of angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers might be detrimental to renal function in patients with an increased risk of atheromatous renovascular disease, including those with severe cardiac failure or diabetes and elderly hypertensive patients.

Other isotopes

Methyldiphosphonate (**MDP**) is filtered by the glomerulus, providing an immediate dynamic renogram. It is later taken up by inflamed muscles (found in patients with myositis and rhabdomyolysis) and the skeleton (detecting single or multiple bone metastases, and also metabolic bone disease in patients with endstage renal failure).

Renal biopsy

Indications

A renal biopsy should be considered in any patient with disease affecting the kidney when the clinical information and other laboratory investigations have failed to establish a definitive diagnosis or prognosis, or when there is doubt as to the optimal therapy. All renal biopsies have the potential to result in morbidity and (on rare occasions) mortality. The risk of biopsy must therefore be outweighed by the potential advantages of the result to the individual patient. Biopsies which would be 'of interest', but 'not in the patient's interest', should not be performed. Indications for renal biopsy should therefore be considered on an individual basis. Table 2 sets out the clinical presentations that warrant native renal biopsy.

Diabetic patients with proteinuria would not normally be biopsied, unless they had other conditions suggesting there might be an alternative or additional diagnosis to diabetic nephropathy. Most paediatricians would treat small children presenting with nephrotic syndrome with steroids, and only consider renal biopsy if they did not respond to treatment. Some conditions, in particular lupus nephritis and membranous glomerulonephritis, may change histological grading, so requiring repeat biopsy.

Renal biopsy is an important investigation in the management of the renal transplanted patient. Postoperative oliguria requires urgent investigation to differentiate acute ischaemic tubular necrosis from immunophylin (ciclosporin or tacrolimus) or other drug toxicity, acute rejection (vascular and/or cellular), or even frank infarction. Further biopsies may be required to monitor the response to antirejection therapy, and at a later stage to examine for recurrence of the original renal disease, or *de novo* glomerulonephritis in the graft.

Contraindications

Percutaneous renal biopsy should not be undertaken in patients with polycystic kidney disease. Similarly, patients with renal masses, such as tumours or cysts, should only be biopsied under direct vision, either by real-time ultrasound or CT scanning, or by formal open surgical biopsy. Patients with a solitary (or solitary functioning) native kidney are normally considered for open surgical biopsy.

Haemorrhage is more likely to occur in patients with uncontrolled hypertension, hereditary or acquired coagulation disorders, and those taking anticoagulants or antiplatelet agents. Blood pressure should be controlled and coagulation abnormalities treated before biopsy. Patients with renal amyloid also have an increased risk of haemorrhage, as may those with classic polyarteritis nodosa.

Patients with chronic renal failure and bilaterally small kidneys should not undergo biopsy. This would be technically difficult (the kidneys are small and hard) and the biopsy appearances of endstage renal failure are exceedingly unlikely to provide any information that might alter the clinical course or management. Percutaneous renal biopsy should not be performed in patients with untreated acute pyelonephritis due to the risk of developing a perinephric abscess.

Technique

'Blind' biopsy of the native kidney, meaning biopsy without imaging for localization, should not be performed unless there are truly exceptional circumstances. It is possible to visualize the kidney and biopsy under fluoroscopic control after injection of radiocontrast medium as for an IVU, but the most commonly used method for directing biopsy is ultrasound guidance. This can either be used to record the depth of the lower pole from the skin and mark the surface position vertically above it on inspiration, or to provide real-time guidance. The latter technique is described below.

Percutaneous renal biopsy should be carried out using sedation and local anaesthesia. Children may require general anaesthesia. The patient should be placed prone on top of pillows or folded sheets to compress the upper abdomen and lower ribs and fix (to some degree) the position of the kidneys. Under real-time ultrasound the kidneys are visualized, the patient asked to take and hold a deep breath in inspiration, and the kidney which is thought to be technically the most easy to biopsy is targeted. To avoid the major vessels, the aim should be for the lateral border of the lower pole. Either 14- or 18-gauge, trucut-type needles are commonly used, some centres now use an automated spring-loaded biopsy gun. Under direct vision the needle tip is advanced to the renal capsule, and with the kidney fixed in inspiration, biopsy is performed. The advent of colour Doppler means that the operator can deliberately avoid the major intrarenal vessels.

Transjugular biopsy can be performed in patients who have an increased likelihood of bleeding complications. Technical developments have now allowed biopsy needles to be passed reliably from the renal vein into the renal cortex, such that in our own institution all such biopsies in the last 3 years have been diagnostic. Occasionally, open surgical biopsy is required, with the biopsy taken under direct vision and local bleeding controlled.

Renal transplants, usually placed in one or other iliac fossa, are biopsied in the supine position. Pillows can be placed under the side with the transplant to help move bowel and fat pad away from the transplant. Biopsies are taken from the lateral border of the upper pole, avoiding the major vessels and ureter.

The obvious risk of renal biopsy is haemorrhage. All patients should be placed on strict bed rest for at least 6 h after the procedure, and pulse and blood pressure should be checked frequently during this period. Hypotension, tachycardia, abdominal/back pain, and macroscopic haematuria are indications for urgent medical review.

Complications

Postbiopsy scanning has shown that the vast majority of patients develop a perirenal haematoma, which is usually asymptomatic. Arteriovenous fistulas may also develop acutely following biopsy. The majority disappear spontaneously with time, and only the occasional one requires treatment by the interventional radiologist. Macroscopic haematuria occurs in fewer than 10 per cent of patients, and bleeding sufficient to warrant blood transfusion in around 1 per cent. Rarely, severe haemorrhage may require treatment with the insertion of coils or gel foam embolization. Exceptionally, death may occur, usually due to the failure to detect haemorrhage and provide appropriate resuscitation.

Complication rates are increased in patients with both acute and chronic renal failure. Uraemia prolongs the bleeding time, even when the conventional coagulation screening is normal (prothrombin time, activated partial thromboplastin time, and peripheral platelet count). The risk of uraemic haemorrhage can be at least partially reversed prior to biopsy by good dialysis to improve platelet function, correction of the haematocrit and any underlying coagulation defect, and by giving an infusion of deamino-D-arginine vasopressin (**DDAVP**; desmopressin) immediately prior to the procedure (0.3 µg/kg over 30 min).

20.4 Acute renal failure

J. Firth

The clinical approach to the patient with acute renal failure

Introduction

Acute renal failure is defined as a significant decline in renal excretory function occurring over hours or days. This is usually detected clinically by a rise in the plasma concentration of urea or creatinine. Oliguria, defined (arbitrarily) as a urinary volume of less than 400 ml/day, is usually present, but not always. Acute renal failure may arise as an isolated problem, but much more commonly occurs in the setting of circulatory disturbance associated with severe illness, trauma, or surgery; transient renal dysfunction complicates some 5 per cent of medical and surgical admissions. A community-based study conducted during 1993 reported that the incidence of severe acute renal failure in adults (serum creatinine >500 µmol/l) was 172 per million, rising from 17 per million in those under 50 years of age to 949 per million in those aged between 80 and 89 years. A recent (year 2000) study from renal units and intensive care units (ICUs) in a defined geographical area of Scotland found that 131 patients per million per year required renal replacement therapy for acute renal failure. There are many possible causes (Table 1, Table 2, and Table 3), but in any given clinical context few of these are likely to require consideration.

Diagnosis of the presence of acute renal failure

A high index of clinical suspicion is required to diagnose acute renal failure at an early stage of its development. This is because symptoms and signs attributable to the accumulation of fluid, electrolytes, acid or uraemic wastes within the body may not be apparent until the condition is far advanced. Furthermore, the symptoms and signs that may arise are not specific: unsuspected hyperkalaemia is the greatest danger, since this may produce no symptoms whatsoever before causing cardiac arrest.

All patients admitted to hospital with acute illness should be considered at risk of developing acute renal failure. Those who have some pre-existing chronic impairment of renal function are particularly susceptible to acute exacerbations. This group includes all elderly patients, in whom a combination of low muscle mass and low dietary meat consumption may conspire to maintain an apparently 'normal' plasma creatinine level, despite a reduction in glomerular filtration rate to as little as 25 per cent of that expected in a healthy young adult.

To recognize impairment of renal function early, the basic care of all acutely ill patients should include careful monitoring of fluid input and output, daily weighing, lying and standing (or sitting) blood pressure, and regular estimation of plasma creatinine, urea, and electrolytes. Although it might seem to the physician to be a simple matter to monitor fluid input and output, this simplicity is often only present in theory, excepting in patients who are restricted to parenteral fluids and who have a urethral catheter. Drinks may be spilt, extra drinks may be acquired from a variety of sources, urine may be spilt, and vomit and diarrhoea are often found in places where they are difficult to quantitate. These considerations mean that the most likely explanation for fluid balance charts being difficult to interpret is the erroneous recording of input or output. Daily weighing on accurate scales provides a much more reliable picture of net overall fluid balance. Patients who are acutely ill invariably lose flesh weight, commonly at a rate of up to a few hundred grams per day. If weight appears to fall at a rate faster than this, then negative fluid balance is likely: the occurrence of greatly increased 'insensible' losses through the skin and lungs during fever being a common explanation. Aside from weight loss, the development of a postural drop in blood pressure is a reliable sign that a patient has become significantly volume-depleted. If weight rises at any time, then this must be due to positive fluid balance, whatever the input/output charts may suggest. It may not be obvious from clinical examination where the fluid has gone: the possibilities of sequestration in the peritoneal cavity or in the tissue interstitium should be recognized.

Plasma urea, creatinine, and electrolytes should be measured on admission in all acutely ill patients, and repeated daily or on alternate days in those who remain so. These measurements will ensure that advanced acute renal failure does not seem to have occurred 'suddenly' in patients already in hospital. However, many patients will be found to have significant renal impairment on admission, and many more will develop some degree of renal impairment whilst on the ward. In all cases the physician must try to make a precise diagnosis of the cause.

Diagnosis of the cause of acute renal failure

In the initial assessment of a patient who appears to have acute renal failure three questions should be asked.

Question 1: is the renal failure really acute?

The only basis for excluding the possibility of pre-existing chronic renal impairment with absolute confidence is the knowledge of a previous normal measurement of renal function. In cases where there is uncertainty, a diligent search for previous notes and biochemical information may save the patient and the doctor the inconvenience (and occasionally hazard) of unnecessary investigation. The finding of two small kidneys on ultrasound examination indicates the presence of chronic renal disease. Other clinical features are poor discriminators between acute and chronic renal impairment. A history of vague ill health of some months' duration, of nocturia, of pruritus, or the findings of skin pigmentation or anaemia would all suggest chronicity (see Section 20.5). However, anaemia is not invariable in chronic renal failure (for example, in polycystic kidney disease the haemoglobin concentration may be normal), and anaemia can develop over a few days in acute renal failure, as may hypocalcaemia and hyperphosphataemia. Radiological evidence of renal osteodystrophy is only found in patients with obviously long-standing renal failure and never aids the clinical distinction between acute and chronic renal failure.

Question 2: is urinary obstruction a possibility?

One of the merits of the traditional division of the causes of acute renal failure into prerenal, renal, and postrenal is that it encourages consideration of the possibility of urinary obstruction, which in community studies accounts for about 25 per cent of severe acute renal failure cases, mostly due to prostatic obstruction.

It is extremely important that obstruction should not be missed, since most cases are readily treatable and delayed diagnosis may lead to permanent renal damage. Obstruction is particularly likely to cause acute renal failure in those with a single functioning kidney, in those with a history of renal stones or of prostatism, and after pelvic or retroperitoneal surgery, but the possibility of obstruction should be seriously considered in all cases where another positive diagnosis cannot be made. The presence of anuria, or of alternating polyuria and oligoanuria, are helpful clues. However, it is not widely appreciated that a patient may pass normal or elevated volumes of urine despite significant obstruction, although this is extremely rare. The mechanism is poorly understood, but three factors present in obstruction tend to

impair urinary concentrating ability, thereby leading to the preservation of urinary volume despite obstructive depression of the filtration rate. These factors are structural damage to the inner medulla and papilla, functional changes in the distal nephron resulting from increased intraluminal or interstitial pressure, and loss of medullary hypertonicity at low filtration rates.

Ultrasound examination of the kidneys and bladder is the usual first method of investigation for the presence of obstruction. However, it is important to remember that the quality of the image obtained by renal ultrasonography is highly variable, depending on the patient, the equipment, and the operator. Furthermore, ultrasound detects calyceal dilatation, not obstruction, and the test may be 'negative' (because the calyces fail to dilate, or do so only minimally) in about 5 per cent of cases of acute obstructive renal failure. If doubt as to the diagnosis persists in the clinician's mind, then the examination should be repeated, and other investigations pursued if uncertainty still remains. If renal function is adequate (creatinine concentration less than about 250 µmol/l) then **DTPA** (diethylenetriaminepentaacetic acid) or **MAG3** (mercaptoacetyl triglycine) renography with furosemide (frusemide) injection may be helpful, showing delayed excretion and clearance of radionucleide from the obstructed kidney(s). If renal function is severely impaired then imaging modalities that depend upon renal excretion (including intravenous pyelography) are not useful, and percutaneous antegrade nephrostomy/pyelography or cystoscopy with retrograde ureteric catheterization and pyelography should be undertaken. (See Chapter 20.14 for further discussion.)

Obstruction, once diagnosed, must be relieved urgently by bladder catheterization, percutaneous nephrostomy, or cystoscopic insertion of ureteral stents, as a prelude to definitive treatment (where possible) of the underlying obstructive lesion. The most important causes of urinary obstruction are renal calculi, retroperitoneal fibrosis, and malignant diseases of the uterine cervix, prostate, bladder, and rectum (see Chapter 20.14).

Question 3: are glomerulonephritis, interstitial nephritis, vasculitis, or other rarities possible?

To make these diagnoses, which although rare have critically important management implications, stick testing of the urine and microscopy of the urinary sediment is an essential part of the assessment of any patient with unexplained acute renal failure. If stick testing indicates more than + of protein or more than a trace of blood, then a sample of urine should be examined under the microscope. This should be done by centrifuging 10 to 15 ml of urine at 1500 to 2500 r.p.m. (approximately 400 to 1120 g) for 5 min, carefully discarding all but 1 ml of the supernatant, and then resuspending the pellet. Examination should be made under high power, preferably after staining, which makes the cellular elements of casts more obvious. Red cell casts (Fig. 1) are present in acute glomerulonephritis, renal vasculitis, accelerated-phase hypertension, and (sometimes) in interstitial nephritis, but not in other conditions. Their presence indicates the need for urgent specialist renal referral.

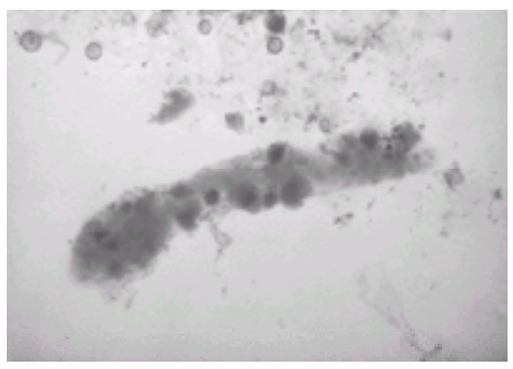

Fig. 1 A red cell cast. The red cells incorporated in the cast, which has a typical cylindrical appearance, look dark in this tone image due to staining with a blue dye.

Clinical features of acute renal failure

In the early stages of acute renal failure there are few warning symptoms. The patient may notice a reduction in urinary volume, but non-oliguric renal failure comprises as many as 50 per cent of cases in some series, and most patients who are unwell do not drink as much as usual and therefore are not concerned if they pass little urine. The clinical picture is likely to be dominated by the primary condition, of which acute renal failure is a complication, and by the effects of intravascular volume depletion, with dizziness caused by postural hypotension a common reason for patients being brought to medical attention.

In the later stages of acute renal failure there are manifestations of uraemia with anorexia, nausea, vomiting (or occasionally diarrhoea), muscular cramps, and signs of encephalopathy—including a 'metabolic' flapping tremor (asterixis), progressing in extreme cases to depressed consciousness and *grand mal* convulsions. Skin bruising and gastrointestinal bleeding may occur. Uraemic haemorrhagic pericarditis is another potentially fatal complication, but this occurs much less frequently in acute renal failure than in (neglected) chronic renal failure.

Biochemical changes

The clinical diagnosis of renal failure, acute or chronic, is made when the plasma urea and creatinine concentrations rise. Other important biochemical changes include the development of hyperkalaemia, metabolic acidosis, hypocalcaemia, and hyperphosphataemia. Hyperkalaemia is due not only to reduced urinary excretion, but also to potassium release from cells—either as a consequence of cell death or as a result of metabolic acidosis. Particularly rapid rises are to be expected when there is extensive tissue damage or hypercatabolism, as in rhabdomyolysis, burns, and sepsis. Transfusion of stored blood is sometimes said to cause dangerous rises in plasma potassium concentration in oliguric patients. However, the transfused blood may not really be to blame, but the circumstances that demand transfusion. Loss of blood into the gastrointestinal tract or body tissues is followed by red cell lysis and the absorption of a considerable potassium load.

Protein catabolism produces sulphuric and phosphoric acids. These are normally buffered by bicarbonate and excreted by the kidney. In acute renal failure these systems fail, leading to the development of acidosis. This is usually modest in degree (plasma pH 7.2–7.35), but can be more severe, manifesting as sighing Kussmaul respiration and/or with circulatory compromise. Acidosis is sometimes the metabolic abnormality most obviously necessitating urgent institution of renal replacement therapy, but overzealous administration of bicarbonate should be avoided (see below).

Calcium malabsorption occurs early in acute renal failure and is probably secondary to disordered vitamin D metabolism. Hypocalcaemia can develop with surprising rapidity. It is usually asymptomatic, but tetany and fits may be provoked by injudicious over-rapid correction of acidosis with resultant depression of ionized calcium. Profound hypocalcaemia and marked hyperphosphataemia, together with hyperuricaemia, is to be expected in rhabdomyolysis. Transient hypercalcaemia is frequently seen during the recovery phase from acute renal failure, and this is particularly common after rhabdomyolysis, probably being caused by secondary hyperparathyroidism related to preceding hypocalcaemia. The hypercalcaemic phase may be prolonged and accompanied by metastatic calcification in patients in whom there has been extensive muscle injury.

The plasma sodium concentration is usually normal in cases of acute renal failure: any deficit of sodium is usually matched by that of water, thus leading to reduction of the extracellular fluid volume but with an unchanged plasma sodium concentration. However, on occasion the intake of water, either drunk in response to thirst or inflicted iatrogenically, may exceed the rate of excretion such that hyponatraemia results.

The retention of uric acid, sulphate, and magnesium occurs in acute renal failure, but these biochemical abnormalities are rarely clinically significant, with the exception of the grossly elevated levels of uric acid that can be seen in rhabdomyolysis and following tumour lysis.

General aspects of medical management

The immediate management of the patient with renal impairment is directed towards three goals. The first is the treatment of any life-threatening complications of acute renal failure. The second is prompt diagnosis and treatment of hypovolaemia. The third is specific treatment of the underlying condition: if this persists untreated then renal function will not improve.

Life-threatening complications

Hyperkalaemia (see also Chapter 20.2.2)

Hyperkalaemia is most commonly dangerous in the context of acute renal failure, and is important because it can cause cardiac arrest. Patients may occasionally notice muscle weakness or paralysis, but the significance of these symptoms is rarely appreciated, and usually there are no symptoms whatsoever. All doctors who work with acutely ill patients should be able to recognize the characteristic electrocardiogram (**ECG**) appearances, which are a better indicator of cardiac toxicity than the serum potassium level. As serum potassium rises, the following changes progressively occur (Fig. 2):

1. 'tenting' of the T wave;
2. reduction in size of P waves, increase in the PR interval, widening of the QRS complex;
3. disappearance of the P wave, further widening of the QRS complex;
4. irregular 'sinusoidal' ECG;
5. asystole.

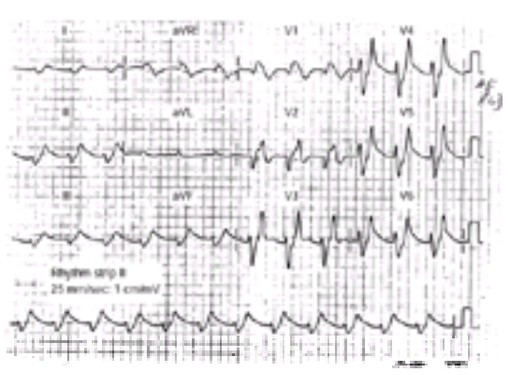

Fig. 2 An electrocardiogram showing severe hyperkalaemic changes in a patient with a serum potassium level of 8.6 mmol/l.

Treatment of hyperkalaemia is described in Table 4.

Pulmonary oedema

The most serious complication of salt and water overload in acute renal failure (usually iatrogenic) is the development of pulmonary oedema. Severe cases are dramatic. The patient is terrified, restless, and confused. Examination reveals cyanosis, tachypnoea, tachycardia, widespread wheeze or crepitations in the chest, and a gallop rhythm (if the heart can be heard). Investigation demonstrates arterial hypoxaemia and widespread interstitial shadowing on the chest radiograph. (See Chapter 15.15.2.2 and Chapter 16.1 for further discussion.)

The patient should be sat up and supported, and given oxygen by face-mask in as high a concentration as possible using a reservoir bag. Furosemide (frusemide) may work as a venodilator but is unlikely to provoke a substantial diuresis in a patient with renal failure. Morphine can relieve symptoms rapidly and should be given in small (2.5 to 5 mg) doses, repeated if necessary and if tolerated, and with the opioid antagonist naloxone to hand in the event of deterioration due to toxicity. An intravenous infusion of a venodilator such as isosorbide dinitrate may be helpful.

The definitive treatment for pulmonary oedema caused by renal failure is the removal of fluid by haemodialysis or haemofiltration. Acute peritoneal dialysis is much less effective in this capacity and should only be considered in circumstances where haemodialysis and haemofiltration are not available. The immediate beneficial effects of venesection of 200 to 400 ml of blood from the patient *in extremis* should not be forgotten.

Recognition and treatment of volume depletion

A key part of the immediate assessment and management of any patient who is very ill, which will include many of those with acute renal failure, is to make a correct assessment of the intravascular volume status and to resuscitate rapidly and effectively. (See Chapter 16.1 for further details.)

Fluid and electrolyte requirements in established acute renal failure

Fluid

Many patients with acute renal failure are volume-depleted at the time of presentation. An urgent priority is to correct such depletion rapidly. Once this has been achieved—as judged by an improvement in peripheral perfusion, a fall in pulse rate, loss of postural drop in blood pressure, and a rise in jugular venous pressure—the perspective changes. In the absence of normal renal function the greatest care must be taken to regulate the intake of fluids and electrolytes to match losses in the urine, from the gastrointestinal tract, and from other 'insensible' sources. As a working rule, fluid intake is limited to the volume of the previous day's urine output and gastrointestinal losses, plus 500 ml, but this allocation may need to be substantially increased in the presence of fever or in hot environments, when insensible losses may be much increased. However, as discussed above, fluid-balance charts are frequently inaccurate and unthinking adherence to the 'output plus 500 ml' rule can lead to grief. There is no substitute for careful, twice-daily clinical examination for signs of intravascular volume depletion or excess, supplemented by accurate daily weighing to gauge the overall net fluid balance, and an intelligent flexible response to the findings.

Sodium

In the patient who is not being dialysed, the intake of sodium must also be matched to output. Requirements are usually very small in those who are oliguric, perhaps only 15 to 30 mmol/day, but if the patient is polyuric the requirements can be considerable, with a danger of volume depletion if these are not met. The urine of a patient with polyuric renal failure will usually contain sodium at a concentration of 50 to 70 mmol/l, hence if urine output is 3 litres/day then over 200 mmol of sodium may be required. On occasion, the urine output in polyuric acute renal failure can be massive (even up to 1 litre/hour)—if the response is to administer an even greater quantity of fluid (output plus insensible losses), then it is possible to contrive a vicious cycle whereby an ever-increasing urinary output is rewarded by ever-increasing fluid infusion. To avoid this situation in the patient with polyuria it is best to limit input to urinary output alone, thus allowing other fluid losses to establish a mild overall negative balance, only increasing fluid input if the patient develops significant postural hypotension, which should be checked for twice daily. For unknown reasons, an excess of sodium and water in patients with tubular necrosis leads to peripheral or pulmonary oedema, whereas in those with glomerulonephritis it tends to produce hypertension.

Potassium

Because hyperkalaemia is one of the most important problems in the management of acute renal failure, it is essential to check plasma potassium levels at least daily, and in those with hypercatabolism or gastrointestinal bleeding, or who require surgery, more frequent estimations are advisable. In oliguric cases, dietary consumption should be limited to the minimum compatible with an adequate intake of protein and amino acids (20–30 mmol/day).

Diuretics that work on the distal tubule (for example, spironolactone, amiloride, and triamterene) promote potassium retention: they should never be used in renal failure, and it is important when reviewing the drug chart to remember that these agents are frequent constituents of tablets containing a combination of diuretic/antihypertensive compounds. Intravenous preparations of antimicrobial agents that contain large amounts of potassium should also be avoided whenever

possible.

Excretion of potassium can sometimes be enhanced in those who are oliguric by the use of high doses of furosemide (0.5–1 g daily). Oral potassium-exchange resins (e.g. Calcium Resonium), prescribed concurrently with a laxative, can be useful in controlling serum potassium for a few days or weeks, but they are not effective treatments for acute severe hyperkalaemia (see Table 4) and are usually found to be unpalatable for long-term use. By contrast, in polyuric acute renal failure substantial losses of potassium can occur and need to be replaced. Measurement of the urinary potassium concentration can be helpful in estimating how much potassium is required.

Renal replacement therapy

Mandatory indications for immediate instigation of renal replacement therapy are:

1. refractory hyperkalaemia;
2. intractable fluid overload;
3. acidosis producing circulatory compromise;
4. overt uraemia manifesting as encephalopathy, pericarditis, or uraemic bleeding.

These indications will be present in some patients on their admission to hospital. However, in most cases renal function will be seen to decline over a period of days or a few weeks despite optimal medical therapy. In this situation here is no hard and fast rule as to when renal replacement therapy should be initiated. There is no level of nitrogenous waste at which the patient suddenly becomes susceptible to overt uraemic sequelae. Nevertheless, it is clearly not sensible to wait until an obvious uraemic complication (which might be fatal) arises. Modern practice is (whenever possible) to begin renal replacement therapy when the blood urea reaches 25 to 30 mmol/l and the serum creatinine 500 to 700 µmol/l, unless there is clear evidence that spontaneous recovery is occurring. There are three basic options for renal replacement therapy: peritoneal dialysis, haemodialysis, and haemofiltration.

Peritoneal dialysis

Peritoneal dialysis is technically the simplest form of renal replacement therapy and is commonly used worldwide, although remarkably little has been published recently about its use in those with acute renal failure. The principle is the same as that described for the long-term treatment of patients with chronic renal failure (see Section 20.5), the major differences being: (1) that catheters are used which can be inserted percutaneously using a metal stylet (although some use the same type of catheter as that used for continuous ambulatory treatment); and (2) that smaller volume exchanges with shorter dwell-times are the norm. The technique requires an intact peritoneum and is therefore precluded in the many patients whose renal failure is associated with abdominal surgery. Other problems include difficulties in maintaining dialysate flow, leakage, peritoneal infection, protein losses, and restricted ability to clear fluid and uraemic wastes. These limitations mean that, particularly in the hypercatabolic patient, peritoneal dialysis is frequently unable to provide good dialysis of the patient with acute renal failure as judged by modern standards. It is fair to say that peritoneal dialysis is virtually never the first choice modality for renal replacement therapy in an adult with acute renal failure in those centres that have a range of techniques at their disposal.

Haemodialysis and haemofiltration

Traditional haemodialysis, which is usually performed on alternate days but may be associated with better outcome when applied daily, can provide good control of uraemia in patients with acute renal failure who do not have severe haemodynamic compromise. The major disadvantage and limitation of the technique (apart from cost) arises from the fact that it is intermittent: in each 4-h treatment at least 2 to 3 litres of fluid must typically be removed to make 'space' either for the infusion of drugs/parenteral fluids or for oral fluid intake during the 24- to 48-h period before the next dialysis. This imposes a substantial haemodynamic stress, which often cannot be tolerated by those who are cardiovascularly unstable, and is the main reason why continuous haemofiltration techniques have largely replaced haemodialysis in intensive care units.

The standard haemofiltration technique works as follows: a mechanical pump (but sometimes the patient's own arterial pressure) drives blood through a haemofilter of high hydraulic conductivity. An ultrafiltrate of plasma is removed, usually at a rate of between 1 and 2 litres per hour. This is replaced, minus the volume of other fluid inputs and the amount of 'negative balance' required, using (most commonly) a lactate/acetate-based substitution fluid. The process is tolerated well, even by patients who are very ill, and the continuous nature of the technique permits continuous fine tuning of the intravascular volume. A large number of technical variations are possible—for example, combination of filtration and dialysis elements (haemodiafiltration), use of differing replacement fluids—but there is nothing to suggest that any one of these is better than another, excepting in those who are unable to metabolize lactate, when bicarbonate-based substitution fluid is essential.

In the same way that there is no evidence on which to make firm recommendations as to when to start renal replacement therapy in those with acute renal failure whose chemistry is gradually 'going off', there is also little information on which to base targets for the clearance of metabolic wastes that should be achieved by treatment. One recent study compared the outcome of patients treated with different doses of venovenous haemofiltration: those randomly assigned to ultrafiltration at a rate of 20 ml/h per kg did less well than those receiving 35 ml/h per kg or 45 ml/h per kg, there being no significant difference between the latter two groups.

Other issues in the management of patients with acute renal failure

Indications for renal biopsy

Most cases of acute renal failure are due to prerenal failure or to the clinical syndrome of acute tubular necrosis. They occur in an appropriate clinical setting and follow a typical time course, with recovery of renal function over a few weeks. In such instances renal biopsy should not be performed, since the information gained is exceedingly unlikely to influence management, and the risks of the procedure are therefore not warranted. There are, however, circumstances in which renal biopsy is essential to establish a correct diagnosis, with important implications for both management and prognosis. Biopsy should be considered when:

1. the history, examination, or laboratory tests suggest a systemic disorder that could cause acute renal failure and could be diagnosed by renal biopsy;
2. the urine sediment contains red cell casts;
3. the case history is atypical; and
4. renal failure is unusually prolonged (say beyond 6 weeks), although in this context cortical necrosis (see below) is better diagnosed by computed tomography (**CT**) scanning or angiography.

Nutrition

Patients with acute renal failure are invariably catabolic and derive a larger fraction of their energy expenditure from protein breakdown than normal. Insulin resistance, metabolic acidosis, the release of proteinases into the circulation, and changes in the metabolism of branched-chain amino acids have all been suggested as possible reasons. If nutrition is neglected, patients with acute renal failure lose weight very rapidly, and those that lose most have the highest mortality. However, it has not been proven in controlled trials that any form of nutritional support can generate a positive nitrogen balance, improve nutritional status, or alter the mortality rate in patients with acute renal failure. Nevertheless, there is a consensus that early institution of nutritional support probably improves prognosis. Despite this, and almost certainly to the patient's detriment, action is frequently delayed or not taken at all, particularly if it is thought that the extra fluid load required will mandate the institution of dialysis or the need for additional dialysis sessions in an already busy unit.

Typical recommended daily adult requirements are total energy 35 kcal/kg body weight, protein 1 g/kg but and nitrogen 0.16 g/kg but there is no good evidence on which to base stipulations and some would advocate more calories and more protein for those who are catabolic. If patients with acute renal failure are oliguric, the nutritional support should be given in a restricted fluid volume, with reduced amounts of sodium, potassium, and phosphate. For practical purposes it is sensible to have enteral and parenteral fluids that satisfy these needs available routinely (a variety of commercial preparations are available): extra water and electrolytes can always be added when required. In the many patients who are too unwell to take adequate food by mouth, commonly those who need it most, tube feeding or parenteral nutrition should be started early. Protein restriction, aimed at moderating the rise of plasma urea, is not appropriate management for the patient with acute renal failure.

Bleeding

In uraemia the bleeding time is prolonged, and in acute renal failure this summates with any abnormality of haemostasis that might be simultaneously induced by the precipitating condition. Better control of uraemia and the routine use of H_2-receptor antagonists have been associated with a greatly reduced risk of upper gastrointestinal bleeding, a previously frequent and grave occurrence. Impairment of haemostasis is not a cause of great clinical concern in most patients, but there are some who bleed—from anywhere and everywhere. Guidelines for the management of such cases are given in Table 5.

Sepsis

Overwhelming septicaemia is a common cause of acute renal failure, and in such instances the diagnosis is often straightforward. However, in many more cases the role of sepsis is insidious and difficult to diagnose with certainty. There is often strong clinical feeling, but little in the way of hard proof, that sepsis underlies the slide towards worsening renal and multiorgan failure in patients who have been apparently successfully resuscitated from major trauma or surgery. Septicaemia is the commonest cause of death in those with acute renal failure. The index of clinical suspicion must therefore be very high: if a patient with acute renal failure appears to be deteriorating in any way, the question must be asked 'is this sepsis?'. Unused intravenous lines and urinary catheters should be removed, and those that are necessary but in any way 'suspicious' should be replaced. The patient should be examined regularly for signs of a septic focus. There should be a low threshold for repeated, thorough microbiological investigation. Proven infection should be treated promptly with appropriate antimicrobial agents (dose modified as required). In many cases, however, it will be necessary to start treatment 'blind', having taken specimens for culture and having made an educated guess as to the likely pathogen, with the possibility of Gram-negative septicaemia high on the list.

In the patient who appears 'obviously septic' or to be 'going off', but in whom no cause can be found, attention should be directed towards the abdomen, this being the most likely place for hidden mischief, either infective or ischaemic. Radiological investigations, in particular CT scanning, can be very useful in searching for abdominal sepsis or dead bowel, but should not be relied upon too faithfully. However, surgical exploration may be required, both to diagnose and to treat, especially in patients whose renal failure follows previous abdominal surgical procedures.

Prescription of drugs

Many drugs are excreted by glomerular filtration or tubular secretion and must be given in reduced dosage or at longer intervals than normal in patients with renal failure (see Chapter 20.16). For patients with acute renal failure the following should not be given without very good reason: non-steroidal anti-inflammatory drugs, angiotensin-converting enzyme inhibitors, angiotensin-II receptor antagonists (all of which have adverse effects on renal perfusion and glomerular filtration), and aminoglycoside antibiotics (these are discussed later in this chapter). A note about two other drugs that may be given to patients with acute renal failure is also appropriate here: both aciclovir and penicillins can cause encephalopathy if given in the doses used to treat severe infection in patients with normal renal function. The dose of aciclovir needs to be reduced from between 5 and 10 mg/kg every 8 h to between 2.5 and 5 mg/kg every 24 h in those receiving renal replacement therapy, and physicians should restrain themselves from prescribing the maximum recommended doses of penicillins. If in doubt, consult the manufacturer's data sheet before prescribing any drug to a patient with acute renal failure.

Prognosis

Acute renal failure of sufficient severity to require renal replacement therapy carries a high mortality. In a series of over 1300 cases, the actuarial 1-year survival of all medical and surgical cases rose from 39 per cent to 58 per cent between 1956 and 1988, despite an increase in the median patient age from 41 to 61 years over this period. The prognosis varies according to the cause of acute renal failure: mortality is between 40 and 60 per cent in patients with renal failure as part of the multiple organ failure syndrome, but less than 10 per cent in those who have renal failure alone. Death should rarely be attributable to a primary sequel of renal failure, for example uraemia or hyperkalaemia, and the incidence of life-threatening gastrointestinal haemorrhage is much reduced: sepsis is the major killer. Patients die *with* but not directly *of* renal failure.

Specific causes of acute renal failure

Prerenal failure and acute tubular necrosis

Introduction

Between 80 and 90 per cent of the cases of acute renal failure seen by physicians will fall into the categories of prerenal failure and acute tubular necrosis (those due to prostatic obstruction usually being managed by others). The term 'prerenal failure' is used when renal dysfunction is entirely attributable to hypoperfusion, and where restoration of renal perfusion leads to rapid recovery. The term 'acute tubular necrosis' does not find favour with all; although necrosis of tubular cells can usually be found by diligent examination, the lesion may be inconspicuous and the pathophysiological implications of such necrosis as might be seen remain uncertain. The glomeruli and vessels are usually normal. In common usage (retained here), the term 'acute tubular necrosis' describes a clinical entity comprising acute renal failure with three main characteristics:

1. it is seen in specific clinical contexts, frequently involving circulatory compromise and/or nephrotoxins;
2. urinary abnormalities usually suggest tubular dysfunction; and
3. essentially complete recovery of renal function is expected within days or weeks in most cases if the patient survives the precipitating insult, with a period of polyuria commonly following oliguria (but see the later section on prognosis).

The syndrome can be seen after virtually any episode of severe circulatory compromise, but not all causes of circulatory derangement are equally devastating to renal function. Primary impairment of cardiac performance, for example following myocardial infarction, may cause plasma creatinine to rise somewhat, but rarely causes renal failure of sufficient severity to require renal replacement therapy. By contrast, an apparently similar haemodynamic upset caused by sepsis frequently does, as demonstrated in Table 2 and Table 3. Multiple insults are the rule rather than the exception. Circumstances associated with a particularly high risk of acute renal failure include repair of a ruptured aortic aneurysm (20 per cent, as opposed to 3 per cent for elective repair), hepatobiliary surgery (10 per cent), pancreatitis (10 per cent), and burns (2 to 38 per cent, depending on the series).

Pathophysiology

The perfusion of the kidney seems to suffer more than that of any other organ when the circulation is compromised. In the face of modest underperfusion, the glomerular filtration rate is relatively preserved by a compensatory increase in the filtration fraction. This increase has repercussions on tubular function which, along with other factors, leads to the increased tubular reabsorption of sodium, water, and urea—a situation rapidly reversed by restoration of renal perfusion. However, following prolonged circulatory shock, renal function frequently deteriorates in a manner that is not immediately reversible, and it is not at all obvious why this should be so. Lack of a clear pathophysiological understanding has bedevilled all attempts at the development of rational therapy. Under normal conditions the kidney enjoys high blood flow, exceeded on a volume/weight basis only by the carotid body, and oxygen tension in the renal venous effluent is high, suggesting that oxygen supply greatly exceeds demand. Such a situation might be expected to confer protection from the effects of circulatory compromise, but no such benefit is observed: indeed the kidney appears to be more susceptible to damage than other organs. Acute renal failure resembling acute tubular necrosis can be produced in animal models by ischaemia, and the condition often arises clinically in the setting of profound haemodynamic disturbance, leading to the supposition that—despite apparently generous blood flow normally—renal ischaemia is the cause of renal failure in such circumstances. Two main hypotheses, not necessarily mutually exclusive, have been proposed to explain this. The first stresses that arteriovenous shunting of oxygen, resulting from the specialized anatomical arrangement of the vasa rectae that is essential for the countercurrent mechanism involved in urinary concentration and dilution, leads to the presence of areas of profound hypoxia within the normal kidney. These areas might therefore be operating on the verge of anoxia in the normal organ and hence be susceptible to ischaemic damage in response to a modest compromise of whole-organ blood flow. The second hypothesis is based on clinical and experimental evidence of intense constriction of renal vessels during shock, and suggests that very severe reduction in renal blood flow (perhaps only transient) may be responsible for the initiation of ischaemic damage. The justification for many of the interventions proposed in the management of patients at risk of acute renal failure, or with established acute renal failure, is that they might preserve renal blood flow and/or reduce renal oxygen consumption, thus rendering the development of ischaemic injury less likely.

Once damage to the kidney has been sustained, a variety of factors may be responsible for the persistence of excretory failure that is characteristic of the clinical

syndrome of acute tubular necrosis. There is evidence from experimental models and in humans that backleak of filtrate can occur from damaged tubules, but reduced renal blood flow and the prevention of fluid flow through tubules by internal blockage or external compression may also contribute to filtration failure. Even in experimental models it is very hard to determine what is happening at any time, and impossible to do so in clinical practice. However, the processes involved are beginning to be dissected, but matters are ferociously complicated and progress is slow. Many of the abnormalities have a structural as well as a functional basis, hence rapid reversal cannot be expected, there being good evidence that recovery from acute tubular necrosis depends upon cellular regeneration.

Diagnosis

The diagnosis of acute tubular necrosis is based on the clinical context, which often involves circulatory compromise, and the exclusion of obstruction or renal inflammatory conditions, usually by ultrasound examination of the kidneys and testing of the urine for blood and protein, respectively.

In prerenal failure the biochemical composition of the urine reflects the response of normal tubules to impaired renal perfusion. There is avid retention of sodium and water, leading to low urinary sodium and high urinary urea and creatinine concentrations, together with a high urinary osmolarity. Restoration of renal perfusion leads to rapid improvement in renal function. By contrast, conventional wisdom holds that in acute tubular necrosis the urinary sodium concentration is elevated and the urinary urea and creatinine concentrations and urinary osmolarity are relatively low, but this is not always so. Biochemical analysis of the urine is rarely useful in clinical practice, as explained in Table 6. From a practical point of view, treatment is begun on exactly the same lines whether the expected diagnosis is of prerenal failure or of acute tubular necrosis. The response to resuscitation retrospectively defines the diagnosis and determines further management.

Circumstances predisposing to prerenal failure are almost invariably associated with raised plasma levels of ADH. This acts on the collecting duct to increase the tubular reabsorption of both water and urea, hence the plasma concentration of urea rises out of proportion to that of creatinine in prerenal failure. Plasma urea may also appear to be disproportionately raised in the presence of sepsis, steroids, tetracycline (catabolic effect), and gastrointestinal haemorrhage (protein meal).

Avoidance

One of the main aims of the basic nursing and medical care provided to all acutely ill patients is to minimize the chances of the development of renal impairment. This can arise despite exemplary treatment, but poor care increases the likelihood. As described above, regular measurement of serum creatinine will permit early recognition of declining renal function, but is not of itself therapeutic. The best way to prevent the development of prerenal failure or acute tubular necrosis is to maintain an optimal intravascular volume (as described above, with further information given in Chapter 16.1), and to avoid or reduce exposure to nephrotoxic agents.

One common clinical situation worthy of specific note is the patient about to undergo a major elective surgical procedure such as repair of an abdominal aortic aneurysm. In the past the risk of acute renal failure following such an operation was substantial, but this has been considerably reduced by recognition of the importance of careful attention to fluid management—with the aim of avoiding episodes of hypovolaemia—both before, during, and after the procedure. It is good practice to maintain a diuresis, which can often be accomplished simply by infusion of crystalloid at moderate rate, since this appears to render the kidney less susceptible to insult. Although the routine use of diuretic agents is advocated by some, they would appear to have no specific advantages over a simple saline diuresis in protecting the kidney. Modest doses of diuretics (furosemide (frusemide) 40–80 mg, mannitol 25 g) given intravenously to a volume-replete patient undergoing a procedure that might compromise renal blood flow (for example, bile duct surgery, resection of aortic aneurysm, cardiac bypass) will increase urinary volume and may afford protection from acute renal failure. This is not proven, but the treatment should do no harm provided that the patient is not volume-depleted. However, the tendency of some to administer very large doses of diuretic agents should be restrained, since these can provoke massive diuresis (urine output >500 ml/h) and thereby lead to considerable difficulties in the control of electrolytes, especially potassium. A multicentre, randomized, double-blind, placebo-controlled trial of the use of dopamine in critically ill patients with evidence of early renal impairment did not show that this treatment was of any benefit.

For high-risk cases the insertion of a central venous pressure line preoperatively is a sensible precaution: the positioning of the patient for surgery and the presence of drapes may prevent proper intraoperative clinical assessment of cardiovascular status, and the risks of elective insertion of a central venous pressure line in the relative calm of the anaesthetic room are considerably less than those incurred if the attempt is made with the patient 'going off' on the operating table.

Clinical findings

There are no specific clinical features of prerenal failure or acute tubular necrosis. There may be symptoms of acute renal failure, as described previously, but these are also not specific and are rarely prominent, hence the clinical picture at presentation is likely to be dominated by signs of volume depletion and those of the precipitating condition.

If the patient does not die of acute renal failure, either because the degree of uraemia is modest or renal replacement therapy is provided, then renal recovery occurs in the vast majority of those who survive the precipitating insult. This may begin at any time from a few days to a few months (median 10–14 days) after the onset of acute renal failure, with a progressive increase in urinary volume typically preceding improvement in the plasma levels of creatinine and urea. Due to a relatively persistent defect in renal tubular sodium reabsorption and concentrating ability, a period of polyuria may ensue, placing the patient at risk of sodium and water depletion. Young patients can be expected to recover clinically normal renal function, but in those over 70 years of age recovery may be delayed, incomplete, and sometimes does not occur at all—leading to lifelong dependence on renal replacement therapy.

Specific treatment

The importance of effective treatment of the underlying condition and of rapid correction of hypovolaemia are above clinical dispute, although neither has been subject to controlled trial as regards the outcome of prerenal failure and acute tubular necrosis. Diuretic agents, in particular loop diuretics such as furosemide (frusemide), and/or 'renal dose' dopamine are often given to the patient who is thought to have acute tubular necrosis and whose urine output is inadequate. Decent trials are very thin on the ground, but there is no compelling evidence that any of these 'specific' remedies are helpful. In established acute tubular necrosis large doses of furosemide (0.5–2 g/day) may substantially increase urinary volume, and this can ease the management of fluid balance and reduce the degree of hyperkalaemia. However, such treatment is most unlikely to lead to improvement in the renal clearance of metabolic wastes, almost certainly does not alter the requirement for renal replacement therapy, and does not affect mortality. The evidence in favour of 'renal dose' dopamine (1–3 μg/kg per min) is generally weak and, although dopamine receptors certainly exist in the renal vasculature and on the renal tubules, it may well be that the effects that are sometimes observed clinically relate to an improvement in cardiac output rather than to any direct effect on the kidneys. However, many nephrologists have seen cases where the administration of a loop diuretic and dopamine has appeared to a have beneficial effect, hence it is not unreasonable to try such treatment, but not to prolong it if it is ineffective in a particular instance. Practical recommendations are given in Fig. 3.

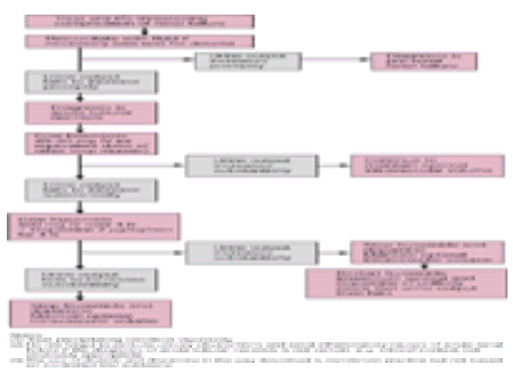

Fig. 3 An algorithm for the practical management of the patient with prerenal failure or acute tubular necrosis.

All other medical treatments should be regarded as experimental and not given except in the context of controlled trials. In experimental models the use of growth factors has been shown to speed renal recovery from acute tubular necrosis, and the possibility that such an approach might be applied clinically has generated the

greatest recent excitement. Unfortunately, the only substantial clinical trial published so far showed no evidence of benefit.

Prognosis

Complete recovery of renal function can be anticipated in those with acute tubular necrosis who survive the precipitating insult, excepting in the elderly (over 70 years) in whom there is a substantial chance (10–20 per cent) that dependence on dialysis will be lifelong.

Nephrotoxic causes of acute renal failure

Exogenous nephrotoxins

A wide variety of exogenous agents, including therapeutically prescribed drugs, can cause acute renal failure. Some of these agents are listed in Table 7. The following are worthy of particular note.

Aminoglycosides

Gentamicin, amikacin, kanamycin, and streptomycin are all potentially nephrotoxic, as are tobramycin and netilmicin to a lesser degree. These drugs are usually prescribed for patients thought to be suffering from potentially fatal infections, hence in clinical practice it is frequently impossible to separate with certainty the harmful effects of aminoglycosides from those of the underlying condition, or of other drugs used in treatment. However, evidence from animal models supports the view that these agents are genuinely nephrotoxic, rather than that their prescription is simply a marker for severe infection, which is itself a potent cause of acute renal failure.

The risk of nephrotoxicity is increased by old age, pre-existing renal insufficiency, high dosage, prolonged treatment, combined treatment with other nephrotoxic drugs, renal ischaemia, and volume depletion. It has been stated that acute renal failure complicates up to 25 per cent of therapeutic courses of gentamicin, even when monitoring optimally controls drug levels. Parenteral administration is not required for the development of toxicity: acute renal failure can occur as a result of systemic absorption when aminoglycosides are used in irrigating or bowel-sterilizing solutions. The typical clinical picture is of relatively mild non-oliguric renal failure coming on 1 to 2 weeks after starting treatment. Tubular proteinuria and impaired ability to concentrate the urine precede a loss of glomerular filtration rate. Proximal tubular damage involves the brush border, reflected by increased urinary excretion of g-glutamyl transferase, alanine aminopeptidase, and of lysosomal enzymes. Recovery may be slow, delayed, or incomplete.

The nephrotoxicity of particular aminoglycosides is related to the strength of their positive charge. They bind to negatively charged membrane phospholipids, particularly in the kidney to parts S1 and S2 of the proximal tubule, where they are delivered to megalin (the Heymann nephritis autoantigen, a member of the low-density lipoprotein (**LDL**) receptor family) in coated pits. The complex is endocytosed and trafficked to the endosome, where gentamicin inhibits fusion *in vivo* and *in vitro*. Polyaspartic acid polymers normalize fusion and ameliorate nephrotoxicity, suggesting that binding of other ligands to megalin may be useful in limiting aminoglycoside uptake and nephrotoxicity, but this possibility has not yet been explored clinically.

Aminoglycosides should only be used in the relatively uncommon circumstance that there is no suitable alternative antibiotic that is not nephrotoxic, and careful monitoring of levels is mandatory to avoid toxicity if gentamicin or similar agents must be used.

Radiographic contrast media

The incidence of acute renal failure associated with the use of radiographic contrast media has been reported to vary between 0 and 50 per cent. This extraordinary variability reflects differences in other risk factors in the populations under examination and in the definition of renal failure used. Recent prospective studies, using non-ionic contrast media and in which careful attention has been paid to the maintenance of adequate hydration, have shown a very low incidence of significant renal impairment—even in groups reported to be at high risk (diabetes, myeloma). When renal impairment does occur it is usually mild.

Endogenous nephrotoxins

Myoglobin

Myoglobinuric acute renal failure, the mechanism of which remains uncertain, is typically associated with crush injury to muscle, but there are a large number of causes of non-traumatic rhabdomyolysis (Table 8). A high index of suspicion is required to diagnose cases that are not obviously associated with muscle injury, since muscular pain, swelling, and tenderness may not be prominent features and can even be absent. The key to making the diagnosis is to detect myoglobin in the urine, or a very high level of enzymes released from muscle in the plasma. The former is recognized by the combination of dark-brown ('coca cola') urine that tests positive for 'blood' on a reagent strip, but which does not contain red cells on microscopy. The muscle enzyme usually measured in plasma is creatine kinase: the normal range of this is up to just below 200 U/l; in rhabdomyolysis values above 10 000 U/l are commonly seen, a value of only 1–2000 U/l not being enough to establish the diagnosis of rhabdomyolytic acute renal failure in the absence of other supporting evidence. Extremely high levels of plasma myoglobin, aldolase, and lactic dehydrogenase are also seen, all being released from damaged muscle.

Rhabdomyolysis can be associated with very high plasma levels of urate (>750 µmol/l), phosphate (>2.5 mmol/l), aspartate and alanine transaminase (**AST** in the many hundreds of U/l, exceptionally in the thousands; **ALT** in the few hundreds of U/l; respectively), and with an unusually low plasma calcium concentration (<1.5 mmol/l). Any of these findings should lead to serious consideration of rhabdomyolysis in any patient with unexplained acute renal failure.

If the diagnosis of rhabdomyolysis is made, then the question of whether to initiate an alkaline diuresis arises, since on theoretical grounds it would be anticipated that alkalinization of the urine would lead to enhanced excretion of the putative toxin and protect against acute renal failure. Victims of crush injury have been treated with infusion of very large volumes of fluid (12 litres/day) and high doses of mannitol (160 g/day) and bicarbonate (240 mmol/day). In comparison with historical (almost certainly volume-depleted) controls the incidence of renal failure has been impressively reduced, but the difficulties of controlling potassium balance in the face of such a massive diuresis should not be underestimated. It may well be that avoidance of hypovolaemia using a less aggressive and more easily managed fluid regimen would be equally efficacious.

Haemoglobin

In several situations, acute renal failure is seen in association with massive haemolysis: malaria, glucose-6-phosphate dehydrogenase deficiency, mismatched blood transfusion, arsine poisoning, copper sulphate poisoning, burns, and as a complication of bladder irrigation with hypotonic solutions. In each circumstance it is possible, but not proven, that the development of acute renal failure might be attributable to, or exacerbated by, the presence of large amounts of free haemoglobin within the circulation.

Urate (see also Chapter 20.10.5)

The tumour lysis syndrome is associated with a rapid rise in plasma uric acid concentration (and almost certainly liberation of other nephrotoxins) as a complication of the treatment of lymphoma, leukaemia, myeloma, or other 'high-turnover' tumours. This can result in the deposition of urate crystals in the distal tubule, which can both cause physical obstruction and initiate an inflammatory response, leading to acute renal failure in which freshly voided urine is heavily laden with urate crystals. Hyperuricaemia and renal failure have been described on rare occasions after recurrent epileptic seizures.

Hyperuricaemic acute renal failure is predictable and hence potentially avoidable in the context of the treatment of malignancy. The most important issue is that dehydration should be avoided at all costs, and a brisk saline diuresis should be initiated at least 24 h before the initiation of chemotherapy if possible. The use of an alkaline diuresis has been advocated, since uric acid is undoubtedly more soluble in alkaline urine, but this may encourage the precipitation of phosphate within the renal tubules and should not be employed if the serum phosphate is high. It is common practice in many centres to give allopurinol, even at a dosage above the usual 300 mg/day, but others would not do so on the grounds that this may encourage xanthine nephrotoxicity, although the risks of this seem to have been overstated.

If hyperuricaemic acute renal failure does develop, then it is unlikely that any of the treatments described above, or diuretics, will reverse the condition. Prompt improvement usually follows reduction of the plasma uric acid concentration, which is best accomplished by haemodialysis. On very rare occasions the ureters can become obstructed by urate crystals—indicated by colic, pelvicalyceal distension, or persistent oliguria—and ureteral catheterization and washout may be required.

Other endogenous nephrotoxins

More uncommon even than intratubular obstruction by urate crystals is similar obstruction by phosphate, also seen in the context of massive cell destruction in the treatment of malignant disease. Urinary alkalinization should be avoided because it may promote intratubular phosphate precipitation.

The possible role of immunoglobulin light chains in causing acute renal failure related to myeloma is discussed in Chapter 20.10.5.

Vascular causes of acute renal failure

Acute cortical necrosis

Acute cortical necrosis is an uncommon cause of acute renal failure, accounting for around 1 per cent of cases in the developed world, but more (3.8 per cent) in the experience of one large centre in the developing world (North India). However, these figures may be an underestimate, given that investigation is not pursued in many patients who fail to recover from what was presumed to be acute tubular necrosis, on the grounds that test results do not reliably predict prognosis or affect management, which is supportive.

Acute cortical necrosis presents in the same context as acute tubular necrosis, which is almost always the diagnosis made initially on clinical grounds. Suspicion should arise immediately if a patient without obstruction is anuric, as was found in 79 per cent of 113 patients in the largest study reported, but cortical necrosis is often considered only when renal function fails to improve.

Most cases of acute cortical necrosis are the result of obstetric disasters, particularly postpartum haemorrhage, abruptio placentae, eclampsia, or septic abortion. Snake bite, haemolytic uraemic syndrome, acute gastroenteritis, pancreatitis, septicaemia (often with disseminated intravascular coagulation), trauma, and drug-induced intravascular haemolysis are risk factors in the non-obstetric population.

The pathological findings are of microvascular thrombosis, mainly affecting interlobular arteries, arterioles, and glomeruli, with complete infarction of affected areas of cortex. The medulla and a rim of juxtamedullary tissue are spared.

The best investigations to establish the diagnosis of acute cortical necrosis are renal angiography and contrast-enhanced CT scanning. The former reveals attenuation of interlobular arteries, an increase in the subcapsular vessels, and a negative outer cortical nephrogram. The latter shows enhancement of the renal medulla, but no enhancement of the renal cortex and no excretion of contrast. Biopsy necessarily samples only a very small piece of tissue and may mislead because of the patchy nature of renal damage. Radiopharmaceutical investigations that depend upon renal excretion (for example, **DMSA** (dimercaptosuccinic acid) scans) are unhelpful in patients with very poor renal function.

In the months or years after an episode of acute cortical necrosis, the kidneys tend to contract: cortical calcification, producing an eggshell or tramline appearance on the abdominal radiograph, is a characteristic sequel, but this is not useful in making the diagnosis acutely.

Return of renal function in cases of acute cortical necrosis occurs very slowly, if at all, and is attributable to the survival of islands of intact cortical tissue. About 50 per cent of patients recover sufficiently to come off dialysis, but the glomerular filtration rate rarely exceeds 10 to 20 ml/min. Hypertension (including accelerated phase) may be a major problem, and a subsequent decline in renal function with the necessity for a return to dialysis/transplantation is not uncommon.

Large-vessel obstruction

Arterial obstruction

Occlusion of the main renal arteries—or of the artery supplying a solitary functioning kidney—by trauma, dissection, thrombosis, or embolism may rarely be the reason for acute renal failure. Loin pain sometimes occurs, and there is usually a low-grade fever, such that the clinical picture may mimic acute pyelonephritis, but symptoms can be notable by their absence. Proteinuria and haematuria may occur.

Diagnosis is important because thrombolysis and/or renovascular surgery can be surprisingly effective in restoring function, even when undertaken a considerable time after arterial occlusion (up to many weeks), in those with atherosclerotic renovascular disease in whom (prior to occlusion) a collateral blood supply to the renal parenchyma has developed. Suspicion should be aroused by complete, sudden anuria in the absence of urinary obstruction, especially if the clinical setting is appropriate, for example atrial fibrillation in an arteriopath. A useful pointer to the diagnosis is the finding of a urinary sodium concentration similar to that of plasma (see Table 6), but DTPA renography and renal angiography are the appropriate diagnostic tests if the diagnosis of renal artery occlusion is suspected. CT scanning may reveal wedge-shaped infarcts when occlusion is incomplete.

Venous obstruction

Renal vein thrombosis can cause acute renal failure, most commonly in adults as a complication of the nephrotic syndrome, but in infants and children as a result of abdominal sepsis or severe dehydration. Renal pain is common, as is increasing proteinuria and haematuria (which can be macroscopic), but there may be no symptoms. If there is clinical suspicion of the diagnosis, for example unexplained deterioration of renal function in a nephrotic patient, then appropriate investigation includes ultrasound/Doppler examination of the renal veins and inferior vena cava, CT/MRI scanning, or renal arteriography with late films taken specifically to look for filling of the renal veins. Treatment by anticoagulation is the usual practice. (See Section 20.3 for further discussion.)

Small-vessel obstruction

Accelerated-phase hypertension (see also Chapter 15.16.3)

'Accelerated-phase' hypertension (a term preferred to 'malignant' hypertension because the implication of malignancy is terrifying for patients) occurs when the blood pressure is elevated sufficiently to cause fibrinoid necrosis of blood vessels, leading to the development of haemorrhages and exudates in the ocular fundi. It may develop as a consequence of pre-existing renal disease, but does not always do so, and is itself a potent cause of renal damage. Acute renal failure is a common complication in those with previously normal renal function, and is associated with proteinuria, haematuria, and the presence of urinary red cell casts. The higher the creatinine at presentation, the poorer the prognosis for both patient survival and renal outcome: in one study only 9 per cent of those with an initial plasma creatinine below 300 µmol/l progressed to need renal replacement therapy, compared with two-thirds of those with a plasma creatinine above this level. The ability of the kidney to autoregulate perfusion is disturbed in accelerated-phase hypertension, hence the therapeutic lowering of arterial pressure may be associated with reduced renal perfusion and an abrupt decline in renal function. Accelerated-phase hypertension is one of the conditions in which renal function sometimes recovers after a lengthy period on dialysis. Renal failure was the cause of two-thirds of the deaths in patients with accelerated-phase hypertension in the days before dialysis was available.

Systemic sclerosis (see also Chapter 18.10.3)

This disease does not usually involve the kidney, but a syndrome resembling accelerated-phase hypertension and termed 'scleroderma renal crisis' is well recognized in patients with diffuse cutaneous systemic sclerosis. It usually occurs within the first 5 years of the disease, may be the presenting feature, and often appears during the winter months. Rapid worsening of skin manifestations may precede the crisis, but frequently there is no warning. The patient may develop headaches, visual disturbance, and convulsions. Arterial pressure is usually grossly elevated, but the renal syndrome can occur without a rise in arterial pressure. Haemorrhages and exudates are often seen in the ocular fundi. Renal failure, with proteinuria and haematuria, develops rapidly. A microangiopathic haemolytic anaemia may complicate the situation. Plasma levels of renin are grossly elevated. There have been a number of case reports of arrest or reversal of the syndrome after treatment with

angiotensin-converting enzyme inhibitors or nifedipine. These agents should be tried, but more in hope than expectation that they will prevent relentless progression to endstage renal failure.

Glomerulonephritic and vasculitic causes of acute renal failure

A large number of glomerulonephritic and vasculitic diseases can cause acute renal failure, sometimes in association with pulmonary haemorrhage (see Table 1 of Chapter 20.10.3). These are discussed in detail in the relevant subsections of Section 20.7, and in Chapter 20.10.3 and Chapter 20.10.4. Together they form only 5 to 10 per cent of cases of acute renal failure, but making the correct diagnosis is of extreme importance because of the management implications. Regrettably, most nephrologists have seen cases where the diagnosis has been much delayed because renal impairment has incorrectly been attributed to acute tubular necrosis, and infiltrates on the chest radiograph to oedema or infection. This error, which can be catastrophic, should be avoided in patients in whom the cause of acute renal failure is not obvious, by:

1. A history and examination specifically directed towards determining whether one of the conditions listed in Table 1 of Chapter 20.10.3 might be present.
2. Microscopy of the urine to look for the presence of red cells and red cell casts.
3. The following blood tests:
   a. measurement of antiglomerular basement membrane (**anti-GBM**) antibodies—positive in Goodpasture's disease (see Chapter 20.7.9);
   b. measurement of antineutrophil cytoplasmic antigen antibodies (**ANCA**)(screening by indirect immunofluorescence test, specific tests for antiproteinase-3 and antimyeloperoxidase antibodies)—positive in microscopic polyangiitis and Wegener's granulomatosis (see Chapter 20.10.3);
   c. estimation of serum complement levels (C3 is depressed in postinfectious glomerulonephritis, mesangiocapillary glomerulonephritis, systemic lupus erythematosus) (see Chapter 20.7.7, Chapter 20.7.8, and Chapter 20.10.4);
   d. measurement of anti-streptolysin O titre (**ASOT**—elevated in poststreptococcal glomerulonephritis) (see Chapter 20.7.7);
   e. serological tests for systemic lupus erythematosus (see Chapter 20.10.4);
   f. cryoglobulins (see Chapter 20.10.5) (tests of serum immunoglobulins and for urinary light chains should also be performed—see below).
4. Considering the possibility that pulmonary infiltrates in a patient with acute renal failure might be due to haemorrhage. The chances of this are increased if there is a history of haemoptysis (associated with several forms of rapidly progressive glomerulonephritis), nasal discharge, or bleeding (associated with Wegener's granulomatosis), or if anaemia is unusually profound and otherwise unexplained. Lung function tests demonstrating an increase in carbon monoxide transfer factor can establish the diagnosis.
5. Performing an urgent renal biopsy. In any patient with acute renal failure and an active urinary sediment, renal biopsy should be performed unless the diagnosis is clear (for example, a classical history of poststreptococcal nephritis, obvious infective endocarditis/shunt nephritis) or there is a strong contraindication, for example a single kidney or serious bleeding disorder.

The possibility of the presence of a rapidly progressive glomerulonephritis/vasculitis constitutes a medical emergency. Anti-GBM disease responds well to immunosuppression with plasma exchange, steroids and cyclophosphamide, but only if treatment is begun before dialysis is required. Immunosuppressive treatment should be given as early as possible in the course of acute renal failure complicating microscopic polyangiitis/idiopathic rapidly progressive (crescentic) glomerulonephritis, Wegener's granulomatosis, and systemic lupus erythematosus. The urgency is such that it may well be appropriate to start these treatments while the results of blood tests and renal biopsy are awaited, and to stop them if the findings do not corroborate the initial clinical diagnosis. The management of these patients is complex and patients benefit from the judgement and expertise of specialists.

Interstitial nephritis as a cause of acute renal failure (see also Chapter 20.9.1)

Drugs

Drugs are the commonest cause of acute interstitial nephritis, the usual culprits being penicillins, non-steroidal anti-inflammatory drugs (**NSAIDs**), and diuretics, but many others have been implicated (see Table 1 of Chapter 20.9.1). The classical clinical picture is that a few days or weeks after taking a drug the patient develops flank pain (sometimes), fever, a skin rash, arthralgias, haematuria, blood eosinophilia and elevated IgE, disturbed liver function (sometimes), interstitial pneumonia (rarely), and renal impairment, but renal failure may be the only manifestation. The urine contains protein and blood, with white and red cell casts. Proteinuria may be in the nephrotic range, particularly in association with NSAIDs. The diagnosis can only be established with certainty by renal biopsy, where typical histological findings are of an interstitial infiltrate of lymphocytes and monocytes/macrophages, together with some eosinophils. Epithelioid granulomas may be seen, strongly supporting the diagnosis of a drug-induced interstitial nephritis, but they are not pathognomonic. When large numbers of cells are present in the renal interstitium the diagnosis is not contentious: more difficult are those cases (not too infrequent) in which the infiltrate is modest—how many cells turn 'acute tubular necrosis' into 'interstitial nephritis'? The importance of making the distinction lies in the belief that, apart from withdrawal of the offending drug, treatment of drug-induced interstitial nephritis with steroids is beneficial. There is some evidence that those given prednisolone (typical dosage 20 to 60 mg/day) have an earlier and more complete recovery of renal function than those left untreated.

Leptospirosis (see also Chapter 7.11.31)

Acute renal failure due to an interstitial nephritis may appear within a few days of the onset of disease, but more commonly in the second week. It occurs in about 10 per cent of cases of leptospirosis and is frequently mild, but may be severe, with the plasma urea level rising rapidly due to hypercatabolism. The diagnosis of leptospirosis should be considered in any patient with unexplained acute renal failure who has myalgias/muscle tenderness, conjunctival infection, and/or haemorrhage or jaundice. Direct enquiry must be made as to whether any such patient has been exposed to rats.

Aside from renal impairment, blood tests commonly reveal a dramatic conjugated hyperbilirubinaemia (often >250 µmol/l) and thrombocytopenia (seen in 40 per cent of cases). There may also be elevation of serum creatine kinase and a slight increase in serum AST. Anaemia may be severe due to intravascular haemolysis. By contrast to most other causes of acute renal failure, serum potassium is often normal or low in cases of leptospirosis. Mild abnormalities of blood clotting tests can be seen, but disseminated intravascular coagulation is not a feature, which is an important point in its distinction from bacterial septicaemia.

The diagnosis is established by culture of *Leptospira* spp. (from blood during the first phase or urine afterwards) or positive serology. Doxycycline prophylaxis is effective at preventing leptospirosis, but antibiotics are not of proven benefit in treating disease. Mild cases are self-limiting; most physicians treat patients who are symptomatic with a 7-day course of oral doxycycline or intravenous benzylpenicillin, on the grounds that this appears to shorten the duration of fever and leptospiruria.

Hantavirus disease (see also Chapter 7.10.15)

In Europe

In Europe the Puumula serotype of hantavirus produces an illness that can have many similarities to that produced by leptospirosis, although serological studies indicate that many patients must have a subclinical infection. In those that are symptomatic, high fever is typically followed within a couple of days by loin/abdominal pain and often by nausea and vomiting; photophobia and signs of meningeal irritation can also occur. Acute renal failure follows when these symptoms have settled and is associated with conjunctival haemorrhage (20 per cent), proteinuria (almost 100 per cent of cases), microscopic haematuria (70 per cent), thrombocytopenia (50 per cent), and a transient mild rise in serum liver enzymes. There may be a small increase in serum bilirubin (maximum 40 µmol/l). Mild abnormalities of blood clotting tests are seen, but disseminated intravascular coagulation is rare.

Renal biopsy, performed for the indication of unexplained acute renal impairment, shows interstitial nephritis. This has no pathognomonic features, leading in this clinical context to the differential diagnosis of leptospirosis and sometimes (depending on exposure) disease induced by NSAIDs. Leptospirosis is much more likely if the serum bilirubin is markedly elevated. NSAID-induced disease does not cause conjunctival haemorrhages or thrombocytopenia. The diagnosis of Puumula hantavirus infection is made on the basis of serological evidence. Prognosis is good: no deaths have been reported and renal function returns to normal.

In some areas of Eastern and Central Europe there is a more severe form of hantavirus infection, which is similar to that seen in Asia.

In Asia

The Hantaan and Seoul viruses cause hantavirus disease in Asia: the former causes more severe illness, but both are considerably more dangerous that the Puumula hantavirus seen in Europe. A total of five phases of disease are recognized, comprising:

1. high fever and myalgias, followed by headache and severe abdominal/loin pain, often with an erythematous rash that may become petechial, also conjunctival haemorrhages;
2. severe hypotension;
3. gradual recovery of blood pressure, but associated with oliguria and renal failure with proteinuria and microscopic haematuria—one-third of patients in this stage have major problems with bleeding: gastrointestinal, intracerebral or massive purpura (hence the terms epidemic or Korean haemorrhagic fever);
4. presence of polyuria;
5. convalescence.

Differential diagnosis is from severe leptospirosis and other causes of haemorrhagic fever found in Asia, including dengue and murine typhus. The diagnosis is made serologically. Treatment is supportive. Mortality is between 3 and 7 per cent; survivors recover completely.

'Haematological' causes of acute renal failure

Haemolytic uraemic syndrome and idiopathic postpartum renal failure (see also Chapter 13.5 and Chapter 20.10.6)

The haemolytic uraemic syndrome (**HUS**) is a condition, or group of conditions, in which acute renal failure, characterized on biopsy by thrombosis and necrosis of intrarenal vessels, occurs together with thrombocytopenia, haemolytic anaemia, and red cell fragmentation. (See Chapter 20.10.6 for further information.) A similar picture developing immediately (or up to several weeks) after an entirely uneventful pregnancy and delivery is termed 'idiopathic postpartum acute renal failure'.

Myeloma (see also Chapter 20.10.5)

Acute renal failure complicates about 7 per cent of cases of myeloma, often being the presenting feature, and subacute progressive renal failure is even commoner, affecting 14 to 61 per cent of cases. The cause of renal failure is often multifactorial, with varying contribution from the reversible factors of dehydration, infection, hypercalcaemia, and hyperuricaemia, and with renal damage caused by free immunoglobulin light chains. The reason why some patients with myeloma develop renal failure and others do not remains a mystery. There has been much speculation as to whether variation in the isoelectric point of light chains, and hence their capacity for reabsorption by the renal tubules, might be responsible. However, individual patients with light chains of very similar physicochemical properties can present totally different clinical pictures, varying from no perceptible renal involvement to irreversible renal failure.

In a patient with acute renal failure, a history of bone pain, the findings of clumping of erythrocytes on the blood film, or of gross and unexpected elevation of the erythrocyte sedimentation rate, are clues that myeloma might be the underlying diagnosis. Such clues may be absent when excess production of monoclonal light chains is the predominant problem, hence all patients with unexplained acute or subacute renal failure should undergo investigation both of serum for a monoclonal immunoglobulin component (with immunoparesis) and of their urine (if available) for free _ or l light chains. The renal biopsy appearances are of tubulointerstitial nephritis, with fractured casts in the tubular lumina, tubular atrophy, interstitial oedema/fibrosis, and an interstitial infiltrate that may contain multinucleate giant cells. However, the definitive test for myeloma is a bone marrow biopsy for immunochemical analysis of the plasma-cell population, and this should be performed whenever myeloma is a likely or possible cause of acute renal failure.

The first priority in management is to deal promptly with those factors that can be reversed— dehydration, infection, hypercalcaemia, and hyperuricaemia. Volume resuscitation should be given as described in Chapter 16.1, along with broad-spectrum antimicrobials (after appropriate cultures have been taken) if there is any suspicion of infection. After the intravascular volume has been restored, then (assuming adequate urine output) hypercalcaemia can be treated rapidly and effectively using a two-pronged approach: a diuresis provoked by infusion of 0.9 per cent saline (1 litre every 4–6 h) and furosemide (40 mg as necessary), and intravenous bisphosphonate (for example, disodium pamidronate, 15–60 mg as a single dose, maximum of 90 mg over 2–4 days). It has been suggested that alkalinization of the urine using intravenous sodium bicarbonate may be advantageous in promoting light-chain excretion, but it is unclear whether this is better than adequate rehydration with saline alone.

If there is a clear precipitant for the decline in renal function, then the prospects for renal recovery in patients with myeloma are good; if not, then the renal outlook is less favourable. Although some report that aggressive treatment with cytotoxic agents and/or plasmapheresis can restore renal function in such cases, this is not everyone's experience, and renal recovery seems to be the exception rather than the rule.

The prognosis for patients with myeloma and established renal failure requiring dialysis is poor: 50 per cent 1-year survival, 30 per cent at 2 years. However, many patients will have few symptoms from their myeloma, excepting renal failure, and these patients should certainly be offered the opportunity of renal replacement therapy. In those with considerable extrarenal manifestations the situation is much more difficult, and it may not be appropriate or kind in such circumstances to offer aggressive haematological regimens, producing considerable side-effects, and/or dialysis. The decisions to be made are rarely straightforward: they will substantially depend on an assessment of the overall burden to the patient of their disease and a realistic appraisal of what benefits treatment might produce.

Hepatorenal syndrome

The hepatorenal syndrome consists of the association of severe and usually progressive liver disease with acute renal failure. The renal failure is characterized by:

1. no evidence of renal parenchymal damage (when kidneys from patients with the hepatorenal syndrome have been transplanted, they function normally in the recipient);
2. characteristic 'prerenal' urine biochemistry, in particular a very low urinary sodium concentration (<10 mmol/l) (Table 6);
3. no sustained response to volume expansion; and
4. exclusion of other causes of acute renal failure.

The mechanism of renal failure is uncertain, but is associated with markedly reduced renal perfusion that may be due to excessive action of the vasoconstrictor endothelin.

One of the aims of the general management of patients with liver disease is prevention of the hepatorenal syndrome, the most important consideration being avoidance of known precipitants (drugs, excessive diuresis, delay in the treatment of sepsis). Nevertheless, the syndrome develops in up to 20 per cent of patients with cirrhosis admitted to hospital. There is no specific treatment and the prognosis is extremely poor. In the presence of potentially reversible liver disease, or with the prospect of liver transplantation, intensive therapy and renal replacement therapy are justified. If these criteria are not met, then aggressive support is almost certainly inappropriate.

Tropical

Acute renal failure in the developing world, as elsewhere, is usually a consequence of acute tubular necrosis. The causes of hospital-acquired acute renal failure are the same as in the developed world, with nephrotoxic drugs, major surgery, and hospital-acquired sepsis the dominant factors. By contrast, the causes of community-acquired acute renal failure are very different.

The Chandigarh study showed that 30 years ago diarrhoeal disease and obstetric complications each accounted for about 25 per cent of cases of acute renal failure in North India, but more recently each has accounted for about 10 per cent. Infections that often cause acute renal failure in the developing world include falciparum malaria, leptospirosis, melioidosis, cholera, salmonellosis, and shigellosis. Intravascular haemolysis is a common feature of many cases, being found in over 20 per cent of 325 patients receiving dialysis for acute renal failure in Chandigarh. This was most frequently seen in those with glucose-6-phosphate dehydrogenase deficiency, with copper sulphate poisoning and snake bite the next commonest causes. Poisoning by deliberate (occasionally accidental) ingestion of paraquat (herbicide) is not uncommon in agricultural communities: aside from renal failure this can lead to inexorably progressive respiratory failure with an extremely high mortality. Treatment with corticosteroids and cyclophosphamide has been used in an attempt to prevent pulmonary fibrosis and may be of benefit. Heatstroke can

cause acute renal failure.

Snake bite

Acute renal failure develops in 5 to 30 per cent of the victims of severe viper poisoning and is the cause of between 2 and 3 per cent of cases of acute renal failure, but a very much higher proportion in some centres at some times of the year. It develops from a few hours to 72 h following the bite, and is non-oliguric in 50 per cent of cases. Hyperkalaemia may be prominent in bites associated with myonecrosis, such as those of sea-snakes. The usual renal pathology is acute tubular necrosis, but acute cortical necrosis can occur (see above). Renal management is supportive. (See Chapter 8.2 for further discussion.)

Copper sulphate poisoning

Copper sulphate is extensively used in the leather industry and is a relatively common (although decreasing) cause of poisoning in India. Symptoms include nausea, vomiting, diarrhoea, epigastric pain, gastrointestinal bleeding, and coma. Signs include jaundice, hypotension, and shock. Investigation reveals intravascular haemolysis, methaemoglobinaemia, haemoglobinuria, haematuria, and renal failure, the latter complicating 11 of 29 cases in one series.

Histological examination of the kidneys shows acute tubular necrosis with luminal haemoglobin casts, rupture of tubular basement membranes, and copper in degenerated tubules.

Aside from gastric lavage, management usually involves the administration (urine output permitting) of intravenous 0.9 per cent saline, mannitol, and/or diuretics to encourage copper elimination, intramuscular dimercaprol (but with extreme caution if renal failure has developed), and dialysis.

20.5.1 Chronic renal failure

C. G. Winearls

Introduction

Chronic renal failure is the clinical syndrome of the metabolic and systemic consequences of a gradual, substantial, and irreversible reduction in the excretory and homeostatic functions of the kidneys. It can be difficult to recognize because the symptoms and clinical manifestations are non-specific. However, if suspected, it is easily diagnosed by simple biochemical measurements. Early and specific diagnosis is worthwhile because this allows the application of effective treatments of both cause (in some cases) and consequences (in all cases), and substitution treatments are readily available for complete kidney failure. An understanding of chronic renal failure is important for doctors in both general and specialty practice: they will have to accommodate its consequences in their own work, for example in surgery, obstetrics, and in prescribing, and they will need to refer patients appropriately for specialist investigation and supervision.

For the patients who suffer it, chronic renal failure is an ever-increasing burden that they carry for the rest of their lives. Eventually, when end-stage renal failure (**ESRF**) is reached, they embark on a career of substitution treatments (dialysis and renal transplantation) referred to as renal replacement therapy. The illness and these treatments intrude on every aspect of their lives—physical, social, vocational, and emotional.

Definition

Chronic renal failure is defined as the state resulting from a permanent (and usually progressive) reduction in renal function, sufficient to have adverse consequences on other systems. The threshold at which these develop is at around 40 per cent of normal excretory capacity. A reduction in renal function below the third centile for age and gender (for example, by removing one of a pair of normal kidneys or limited damage to one or both), does not amount to chronic renal failure: although there is a loss of renal reserve, there are no clinical consequences.

The severity of chronic renal failure is graded according to the fraction of kidney function remaining (Table 1). These are useful descriptions because they give an indication of the likely symptoms and complications that should be anticipated, and provide cues to the key steps in both immediate and future management. Accurate measurement of glomerular filtration rate is not necessary to categorize the degree of renal failure: knowledge of the patient's age, gender, and body-weight applied to the Cockcroft–Gault formula:

$$\text{glomerular filtration rate} = [\,(140 - \text{age in years}) \times \text{weight (kg)}\,] / \text{plasma creatinine } (\mu\text{mol/l}) \times 0.82 \text{ (subtract 15 per cent for females)}$$

will give an acceptable estimate (see Chapter 20.4 for further discussion). However, this grading of the severity of renal failure has limitations: as ESRF approaches there is a poor correlation between the actual glomerular filtration rate and symptoms which are caused by downstream consequences of that reduction: for example, breathlessness by pulmonary oedema or acidosis, fatigue by anaemia, muscle weakness by abnormalities in calcium and phosphate. The decision when to start dialysis should be made after integrating knowledge of the estimated glomerular filtration rate, symptoms, and recognition of complications. Decisions should not be based on estimates of plasma creatinine or urea.

Incidence and prevalence

The only accurate data on the incidence of chronic renal failure is for ESRF that is treated with renal replacement therapy, that is to say the number of patients starting such treatment. This is available from national and other databases, which also provide data on the prevalence of patients receiving renal replacement treatment (Table 2).

The incidence or prevalence of ESRF that is not treated with renal replacement therapy is unknown, nor is such information available for lesser degrees of chronic renal failure (mild, moderate, and severe): many patients are undiagnosed or not yet referred. This is illustrated by the fact that as many as 30 per cent of new patients starting renal replacement therapy meet a nephrologist for the first time less than 3 months before dialysis is begun. Crude estimates suggest there are about

500 to 1000 patients per million population with significant chronic renal impairment. Many of these patients will never require renal replacement therapy and will die with renal failure and not of it, examples include patients with malignant urinary tract obstruction, diabetes mellitus, renovascular disease with widespread cerebro- and cardiovascular disease.

From a workload point of view there are about 500 to 600 per million patients on renal replacement therapy in the United Kingdom and Australia, and over 1000 per million in the United States and Japan. This means that an average British general practitioner with 2000 registered patients will have only one dialysis or transplant patient on their list, and will see one new ESRF patient every 5 years. They will, however, be involved in the care of one or two patients with chronic renal failure. Renal failure is, when compared to chronic cardiovascular and respiratory diseases, a relatively small part of the general practitioner's workload.

The epidemiological study of renal failure has revealed some stark facts. It is a disease of the elderly: the incidence in a population over 75 years of age is 10 times higher at 400 per million population (**pmp**) than it is in those under 40 years of age; 50 per cent of patients now starting on renal replacement therapy are over 65 years of age. The incidence is higher in males (1.3:1), in areas of social deprivation, and in particular ethnic groups. In the United Kingdom it is 3.5 times higher in citizens of Asian or Afro-Caribbean backgrounds. In 1997 in Australia the incidence in Aboriginals was 435 pmp, which was six to seven times higher than in Caucasoids at 68 patients pmp. In New Zealand the incidence in Maoris is three to four times higher than in Caucasoids. These ethnic variations (which are related to the higher prevalence of diabetes and hypertension) can account only for part of the huge difference in the incidence of ESRF between Europe and the United States. There is still no easy explanation for the higher number of ESRF patients in Caucasian Americans than in the same age groups in Europe. Acceptance criteria for renal replacement therapy are much more stringent in the United Kingdom than in the United States, but although patients with terminal illness, dementia, or severe comorbid conditions are not usually started on dialysis, few patients who would benefit (that is, those who would survive independently for longer than 12 months) are excluded.

The prevalence of treated ESRF, in other words the number of patients receiving dialysis or a life-sustaining renal transplant, varies according to the capacity and availability of renal replacement programmes. In countries such as Germany, the United States, and Japan, where there are no constraints on the acceptance of patients for treatment, the prevalence is higher than elsewhere in the world. There are important health economic implications: renal replacement treatment has proved so successful that it is now accepted as a right in most developed countries. Improvements in patient survival and increases in acceptance rates (these have trebled in the United Kingdom in the last decade) mean that the total numbers of patients, and therefore the aggregate cost of maintenance treatment (already 2 per cent of the National Health Service (**NHS**) budget) is still increasing. A steady state has not yet been reached, and until it does the resources allocated will have to be increased too.

Causes of chronic renal failure

End-stage renal failure databases are the usual sources for descriptions of the causes of chronic renal failure. There are flaws in these because the meaning of terms such as 'pyelonephritis' may vary; diagnoses are allocated as best guesses by clinicians; glomerulonephritis is diagnosed without renal biopsy; and hypertension cited when it may be no more than a consequence of whatever caused the renal failure. The most rigorous database is that of the Australia and New Zealand Data (ANZDATA) Registry. The data in Table 3 should be interpreted with these caveats in mind.

Glomerulonephritis

Primary glomerulonephritis and secondary inflammatory glomerular disease (see Section 20.7, and Chapter 20.10.3 and Chapter 20.10.4).

Glomerulonephritis remains the most common cause of chronic renal failure outside the United States, accounting for 34 per cent of new cases in Australia. The patients usually suffer the common chronic glomerulonephritides, especially IgA disease, but including focal sclerosis, membranous nephropathy, and mesangiocapillary nephritis. These patients, more often males, are identified as marked for ESRF by heavy proteinuria, hypertension, interstitial changes in their renal biopsy specimens, and early and progressive renal dysfunction, in other words they have severe disease. Others have glomerular lesions secondary to systemic diseases such as systemic lupus erythematosis, Henoch–Schönlein purpura, systemic vasculitis, and, rarely, antiglomerular basement membrane antibody disease (**anti-GBM** disease). Progression to ESRF can be rapid or gradual after a severe acute nephritic illness has been halted but leaving substantial residual injury.

Diabetes (see Chapter 20.10.1)

This is now the commonest cause of ESRF in the United States (40 per cent of new patients) but is still behind that for glomerulonephritis in the United Kingdom and Australia (21 per cent). The diagnosis of diabetic nephropathy is usually assumed because of proteinuria, usually with concomitant retinopathy, in patients with a history of diabetes for 10 or more years. About half of the patients have type 2 diabetes, meaning that the onset was in middle life and not immediately requiring insulin.

By 40 years from the onset of diabetes, some 30 to 40 per cent of patients with type 1 diabetes have developed nephropathy and some, but not all, of these will survive long enough to develop ESRF. Between 5 and 10 per cent of type 2 diabetics already have nephropathy at the time their diabetes is diagnosed, and by 20 years from diagnosis 25 per cent of these will have overt nephropathy. It is not possible to predict with certainty which diabetics will develop nephropathy, but it is more likely in Blacks, Asians, and males, and in those with a family history of hypertension. There is now persuasive evidence that good glycaemic control reduces the risk of diabetic nephropathy, and that improving control will reduce the risk of progression of patients with microalbuminuria to overt nephropathy. It has not been shown that glycaemic control affects the prognosis of established diabetic nephropathy. Once overt nephropathy (proteinuria above 0.5 g/day) develops, the median time to ESRF is about 7 years for those with type 1 diabetes but it is more variable in type 2.

Young people with type 1 diabetes present the greatest challenges—they often have many additional complications such as blindness from retinopathy and vitreous haemorrhage, peripheral and autonomic neuropathy, precocious cardiovascular disease, and, unfortunately, some scepticism of conventional medical advice. The older diabetics are usually obese and often have severe peripheral vascular and coronary disease. Both these groups need a multidisciplinary team to care for them—nephrologists, diabetologists, ophthalmologists, vascular surgeons, and podiatrists.

When assessing diabetics with renal problems it should be remembered that they are also susceptible to non-diabetic renal disease such as glomerulonephritis and (particularly) renovascular disease. Their renal failure can be exacerbated by papillary necrosis, usually associated with pyelonephritis. They are more susceptible to renal tuberculosis and fungal infections, especially if autonomic neuropathy has affected bladder function.

There is a general and probably appropriate tendency to start dialysis earlier in those with diabetes. In the younger patient one aims for renal transplantation, ideally with whole pancreas transplantation, as early as possible. Islet-cell transplantation may, in the future, prove to be the best option. Dialysis and diabetes seem to have a synergistically adverse effect on the vasculature. Before embarking on transplantation, a vigorous search for silent coronary artery disease is essential. The prognosis for the survival of all diabetics is much worse than for any other cause of renal failure except malignancy.

Hypertension and renal vascular disease (see Chapter 15.16.2.2 and Chapter 20.10.2)

Hypertension is cited as the primary renal disease causing ESRF in 12 per cent of Australian patients and in 25 per cent in the United States. Chronic renal failure is a rare complication of primary essential hypertension, but the large number of patients with hypertension means that it is a relatively common cause. The risk of renal failure is higher in Blacks. Accelerated-phase hypertension was once a frequent cause of ESRF but is now relatively rare, except again in Blacks. Renovascular disease, which is not separately classified, is an increasingly common cause, especially in the elderly. The patients have a history of other vascular diseases—coronary, cerebral, or peripheral—and present with renal impairment, hypertension, and occasionally 'flash' pulmonary oedema. If the arterial stenoses or occlusions are bilateral or the stenosis is in the artery supplying the functionally dominant kidney, angiotensin-converting enzyme (**ACE**) inhibitors or a2-receptor blockers will cause a sharp but usually reversible rise in plasma creatinine. Angioplasty and stenting seldom rescue much renal function but may slow progression or prevent acute occlusion. In atheromatous renal arterial disease, stenting makes relatively little difference to blood pressure control.

Adult polycystic kidney disease (see Chapter 20.11)

The development of renal failure is seldom a surprise in patients with adult polycystic kidney disease whose condition has usually been diagnosed for other reasons (for instance, a family history, hypertension, haematuria, or a loin mass). Once renal impairment is diagnosed, the loss of function is predictable at about 5 to 6 ml/min per year, tending to be more rapid in males than females. Adult polycystic kidney disease accounts for about 6 per cent of those receiving renal replacement therapy

in the United Kingdom and Australia, the median age at which ESRF (which is not inevitable) is reached being 55 years, but with a wide range from 25 to 75 years. ESRF occurs 10 to 15 years later in those with type 2 adult polycystic kidney disease than in those with the commoner type 1 disease.

Reflux nephropathy (see Chapter 20.12)

Reflux nephropathy (a congenital and often inherited abnormality of the vesicoureteric junction) and congenital structural abnormalities of the urinary tract are important causes of chronic renal failure in the young, the mean age of entering renal replacement therapy programmes being 30 years. Once a threshold fraction of nephron mass has been lost, perhaps as a consequence of infection-related scarring, the remaining glomeruli develop segmental hyalinosis and eventually sclerosis, manifesting as proteinuria and hypertension, both heralding a steady decline towards end-stage disease. Antireflux procedures make no difference to the prognosis, and management is medical.

Miscellaneous (Table 4)

Many renal conditions, some primary and others secondary to systemic diseases, can cause chronic renal failure.

Drugs

Analgesic nephropathy is declining in incidence but is still common in Australia and parts of Europe (5 per cent). Ciclosporin toxicity can cause chronic renal failure in patients who have received cardiac, liver, and lung allografts. A few patients on long-term lithium medication for bipolar affective disorder develop chronic renal failure. Long-term, non-steroidal anti-inflammatory drugs (**NSAIDs**) use is also associated with chronic renal failure.

Obstructive uropathy (see Chapter 20.14)

Neglected or unrecognized obstruction, associated sometimes with calculi, infection, or malignancy, accounts for a small but significant number of patients requiring dialysis. Any manoeuvre (for example, ureteric stenting) which relieves obstruction, is worthwhile for the preservation of renal function.

Dysproteinaemias (see Chapter 20.10.5)

Primary amyloid, myeloma kidney, and the other immunoglobulin deposition diseases are relatively rare. The patients, usually elderly, generally have a poor prognosis, having to cope with the consequences and treatment not only of the underlying disease, but also the hazards and inconvenience of dialysis. Survival on dialysis is seldom longer than 2 years.

Pregnancy (see Chapter 13.5)

Irreversible postpartum renal failure is now rare in developed countries but is still a problem in the developing world.

Unknown

In a significant proportion of patients no confident diagnosis of the cause of chronic renal failure can be made. There are no clues in the history, although a renal condition may have been suspected because of long-standing minor urinary abnormalities (such as asymptomatic proteinuria or haematuria). Imaging reveals small echogenic kidneys, which cannot safely be biopsied, and even if tissue does become available it seldom reveals a specific diagnosis. The glomeruli are sclerosed and there is widespread interstitial fibrosis and vascular changes, which are probably secondary. It may be that there are unrecognized renal diseases caused by environmental toxins, but this is speculation. The recent description of the development of renal failure after the consumption of Chinese herbal remedies containing aristocholic acid shows the need to be agnostic on causality. Some patients do probably have unrecognized glomerulonephritis (as shown by the development of IgA nephropathy in subsequent kidney allografts). Others may have silent cholesterol emboli, analgesic nephropathy, or 'burnt out' tuberculosis.

The pattern in developing countries of Asia, Africa, and Latin America is quite different. Chronic glomerulonephritis (especially infection-associated disease, see Chapter 20.7.10) and hypertension are the dominant causes in Africa. In Asia, diabetes mellitus—usually type 2—is almost as common a cause as glomerulonephritis. Obstructive uropathy is a more common cause than in Europe because of the higher incidence of tuberculosis, schistosomiasis, urethral strictures, and renal stone disease. Other diseases more common in these countries, which may cause chronic renal failure, include systemic lupus erythematosus (especially in Asian women), sickle-cell disease, and human immunodeficiency virus (**HIV**) infection.

Pathophysiology of chronic renal failure

In chronic renal failure, compensatory and adaptive mechanisms maintain acceptable health until the glomerular filtration rate is about 10 to 15 ml/min, and life-sustaining renal excretory and homeostatic functions continue until the glomerular filtration rate (**GFR**) is less than 5 ml/min. The favoured explanation for the pathophysiology of this condition centres on the 'intact nephron hypothesis' first proposed by Bricker, which states that despite distortion of renal architecture and a widened range of single nephron GFR in diseased or damaged kidneys, glomerular and tubular function remains closely integrated in all individual nephrons, both normal and damaged. As the GFR of the whole kidney falls, still-functioning nephrons produce an increased volume of filtrate ('hyperfiltration') and their tubules respond appropriately for overall homeostasis by excreting fluid and solutes in amounts that maintain external balance. For sodium and potassium, compensation can occur down to a glomerular filtration rate as low as 5 ml/min and plasma values are commonly normal. For phosphate and urate, adaptation is less precise and plasma concentrations are increased in many patients at a glomerular filtration rate of 20 ml/min and in almost all at 5 to 10 ml/min.

The functional adaptations of individual nephrons that allow homeostasis to be maintained in the face of a substantially reduced GFR do not come without a price, and the 'trade off' hypothesis needs to be considered alongside the intact nephron hypothesis. This describes the concept that adaptations arising in chronic renal failure may control one abnormality, but only in such a way as to produce other changes characteristic of the uraemic syndrome. The best example of 'trade off' is the increase in parathormone secretion essential for the increased fractional excretion of phosphate: as the glomerular filtration rate falls plasma phosphate rises, parathormone secretion increases, and plasma phosphate is lowered by decreased tubular reabsorption. The cost of normal plasma phosphate is then secondary hyperparathyroidism, sometimes leading to metastatic calcification (see Chapter 20.6.1).

Electrolytes and water

Inability to concentrate urine in the presence of dehydration is often the first symptom of chronic renal failure, resulting in polyuria, nocturia, and thirst when GFR is about 30 ml/min, although diseases that predominantly affect the medulla, such as pyelonephritis, interstitial nephritis, and medullary cystic disease, may present with a concentration defect at an earlier stage. Defective urine concentration is due to an increased solute load in surviving nephrons, with minor contributions from decreased tubular function and increased GFR per nephron. Thirst accompanies polyuria and water balance is maintained provided there is free access to fluid. As obligatory water loss is increased, careful attention needs to be paid to fluid balance in the presence of anorexia, fever, surgery, and other sources of extrarenal loss if dehydration, hypotension, and further impairment of renal function are to be avoided.

Diluting capacity is preserved until renal failure is advanced, the asymmetrical narrowing of the range of urinary osmolality eventually producing the fixed (300 mosmol/kg) urinary osmolality of chronic renal failure with its obligatory polyuria (Fig. 1). It should be noted, however, that although urinary dilution is maintained until late in chronic renal failure, large water loads are excreted more slowly than in normal subjects and excessive intake (by drinking or an ill-advised iatrogenic infusion of dextrose-containing solutions) can result in hyponatraemia, mental disturbances, and convulsions.

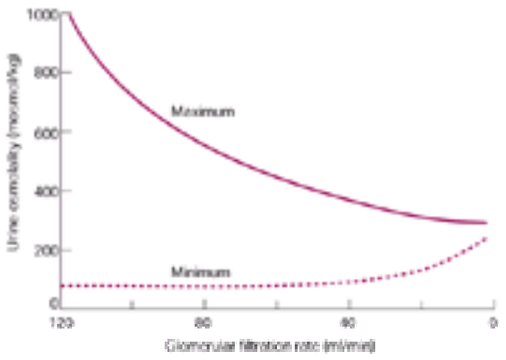

Fig. 1 Progressive loss of flexibility in water handling as renal failure worsens. Concentrating ability is impaired earlier than the ability to excrete a dilute urine.

Sodium excess and hypertension

As renal function decreases, hormonal mechanisms increase the fraction of filtered sodium excreted so that the sodium balance and extracellular fluid volume are maintained until the GFR is less than 10 ml/min. The extent of this adaptation is such that the 1 per cent or less of filtered sodium excreted by normal subjects increases to 30 per cent in those with late chronic renal failure. However, adaptive mechanisms are not unlimited, and in late renal failure increased total body sodium, with water to maintain osmotic equilibrium, presents as fluid overload and hypertension. Initially, excess extracellular fluid does not cause oedema, but in late renal failure an elevated jugular venous pressure, functional incompetence of the mitral valve, and pulmonary and peripheral oedema are often seen. Another major consequence of sodium and fluid excess is hypertension, present in 80 per cent of patients in late chronic renal failure and occasionally presenting in the accelerated phase, although precisely how sodium retention and increased extracellular fluid volume lead to high blood pressure remains uncertain.

Sodium depletion

Patients with chronic renal failure can also be vulnerable to sodium depletion. In the presence of dietary sodium restriction or loss of sodium by various routes, functioning nephrons cannot restrict sodium excretion promptly so that the extracellular fluid, plasma volume, and GFR all decrease. Although this sodium and fluid loss has been attributed to an osmotic diuresis, other mechanisms are involved and may dominate; thus, if sodium restriction is induced slowly over months, patients can reduce their urinary sodium concentration to less than 10 mmol/l without significant reduction in GFR. A few patients with early chronic renal failure, usually with diseases affecting the renal medulla (for example, obstructive uropathy and medullary cystic disease), present with a urinary sodium leak and sodium depletion on a normal sodium diet. Blood pressure in these patients is normal or low, often with a postural drop of arterial pressure. Sodium supplements may be needed.

Potassium

Most patients maintain a normal external potassium balance until their GFR is less than 5 ml/min, but their capacity to excrete potassium is limited and severe hyperkalaemia may follow a sudden reduction in residual GFR, excess dietary intake (chocolate, nuts, instant coffee, some fruits and their juices, wine), potassium-sparing diuretics (spironolactone, amiloride, triamterene), medication with a high potassium content, surgery, and hypercatabolic states. Acidosis raises serum potassium by ion transfer out of cells and interference with renal excretion. Hypoxia causes hyperkalaemia by impaired uptake of potassium from extracellular fluid. In some patients, particularly those with diabetes mellitus and/or interstitial nephritis, and sometimes in early chronic renal failure, hyperkalaemia may be due to selective aldosterone deficiency (hyporeninaemic hypoaldosteronism) or the use of angiotensin-converting enzyme (ACE) inhibitors. Tubular resistance to aldosterone is another rare cause of hyperkalaemia. Complications occur at plasma potassium concentrations above 7.0 mmol/l; a weakness in pelvic and shoulder girdle muscles may be the presenting symptom, but in most patients serious electrocardiographic abnormalities and cardiac arrhythmias are the first sign of hyperkalaemia (see Chapter 20.2.2 and Chapter 20.5.2 for further discussion).

Calcium and phosphate and Vitamin D

The role of the kidney in regulating calcium and phosphate in body fluids and tissues is described in Chapter 20.6.1. Magnesium concentrations are usually high and care must be exercised with the use of magnesium-containing drugs.

Acid–base

The kidney is an essential organ for maintenance of the acid–base balance by reabsorption of filtered bicarbonate, acidification of urinary buffers. and excretion of ammonia. As renal failure progresses, at least until GFR is less than 20 ml/min, intact nephrons increase their excretion of hydrogen ions to prevent acidosis. Increasing acidosis, variable between patients, occurs at a GFR of less than 10 ml/min—when normal net acid production exceeds the excretory capacity of remaining nephrons and diminished tubular function impairs ammonia synthesis and bicarbonate regeneration. Renal diseases that principally affect tubules and interstitial tissues are associated with acidosis quite early in the course of chronic renal failure. Acidosis seldom requires treatment unless the bicarbonate concentration is less than 15 mmol/l and the pH less than 7.30, except in children in whom prevention of severe acidosis with bicarbonate supplements may have a beneficial effect on renal osteodystrophy and growth retardation. Delayed excretion of excess base is also a feature of late chronic renal failure so that metabolic alkalosis may occur more easily and resolve more slowly after, for instance, prolonged gastric aspiration.

Endocrine dysfunction

The endocrine functions of the kidney can be disturbed in kidney disease, for example reduced production of 1,25-dihydroxy vitamin D (see Chapter 20.6.1) and erythropoietin (Fig. 2). There are also diverse abnormalities in the production, control, protein binding, catabolism, and tissue effect of extrarenal hormones in renal failure. Hormone concentrations may be elevated as a result of reduced degradation (insulin) or increased secretion in appropriate response to metabolic alterations (parathormone, **PTH**). Hormone concentrations may be reduced owing to impaired production (oestrogen, testosterone). There may also be disturbances of activation through altered prohormones. Finally, reductions in hormone-binding proteins are most commonly a consequence of protein loss in nephrotic patients or in those on continuous ambulatory peritoneal dialysis.

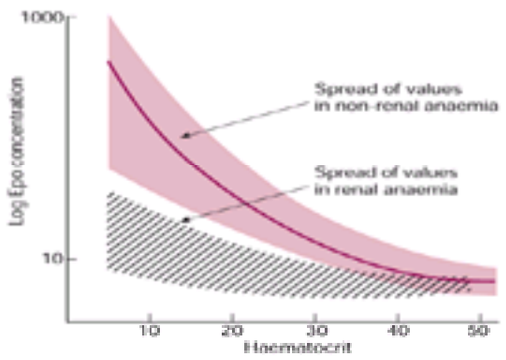

Fig. 2 In renal anaemia the erythropoietin concentration rises in response to anaemia, but to a much lower concentration than in non-renal anaemia. This is a consequence of defective oxygen sensing, reduced synthesis, or both.

Thyroid hormones

Total thyroxine (T_4) may be low with increased reverse tri-iodothyronine (T_3) as a result of impaired conversion of T_4 to T_3. Loss of thyroid-binding globulin (**TBG**) may further lower total circulating T_4 concentrations. However, patients are not clinically hypothyroid and measurements of thyroid-stimulating hormone (**TSH**) remain a reliable diagnostic test for hypothyroidism in patients with renal failure.

Growth hormone

Plasma growth-hormone levels are abnormally high in patients in renal failure because of delayed clearance and alterations in the hypothalamic–pituitary control of growth-hormone release. In adults the clinical implications of these changes are not clear. In children with renal failure and growth retardation, production of insulin-like growth factor-1 (**IGF-1**) in response to growth hormone is impaired; this can be overcome by treatment with exogenous recombinant growth hormone in supraphysiological dosage.

Insulin

Decreased clearance of insulin seems to be balanced by increased peripheral resistance to the effects of insulin, hence there are usually no clinical effects and patients are not prone to hypoglycaemia or diabetes, but there is a reduced requirement for insulin in diabetics as renal function declines.

Sex hormones

Males

Prolactin levels are high in renal failure and may contribute to gynaecomastia and sexual dysfunction in men. Testosterone levels are often low to normal in males, but gonadotrophins are raised, implying testicular failure as the cause.

Females

Raised prolactin levels contribute to infertility. In severe renal failure the pituitary–ovary axis is disturbed: luteinizing hormone is raised, but the normal pulsatile release and preovulation surge are absent, hence cycles are often anovulatory, causing oestrogen deficiency.

Middle molecules and the uraemic syndrome

Although many of the manifestations of the uraemic syndrome are attributable to the derangement in electrolyte concentrations, fluid imbalance, and endocrine deficiencies, there are others that are explained by the actions of substances and metabolites retained because of excretory failure. Examples include encephalopathy, glucose intolerance, platelet dysfunction, anaemia, and leucocyte dysfunction. Knowledge of the nature, mode of action, and contribution of those substances referred to as 'uraemic toxins' or 'middle molecules' to the syndrome is incomplete. The best example of a middle molecule is b $_2$-microglobulin, which is normally excreted by the kidneys, reaches a concentration of 30 times higher than normal in dialysis patients, and accumulates as b $_2$-microglobulin amyloid in joints and bone. It meets fully the criteria of a 'uraemic toxin'. However, because a substance is retained in uraemia and removed by dialysis does not mean that it can be indicted for a particular element of the uraemic syndrome. To be sure that a substance is relevant to the uraemic syndrome, its concentration should be raised in renal failure, should relate to the severity of the particular effect, and the effect should be reproduced by the substance alone and ameliorated by reducing the concentration. The subject of uraemic toxins has been approached by considering: (1) their existence predicted by abnormalities detected in *in vitro* systems; (2) known chemical effects of urea retention; and (3) identifiable substances.

Urea itself has rather modest effects, but it is used as a marker of accumulation of other metabolites. It inhibits cell-membrane electrolyte transport *in vitro* and is thought to have a direct effect on appetite and protein anabolism. It forms isocyanic acid, which reacts with amino groups on amino acids, carbamoylating them or the proteins of which they are constituents. Similarly, modification of lipoproteins may decrease their binding to receptors, thereby delaying their metabolism.

In a manner analogous to reverse genetics, the existence of certain uraemic toxins can be predicted. Examples include insulin resistance, which in uraemia is improved by dialysis, and a number of factors in uraemic plasma that inhibit glucose metabolism have been found but not identified. Similarly, inhibitors of calcitriol binding to its receptor have been found in ultrafiltrates of uraemic plasma.

Some compounds that accumulate in uraemia are thought to have a direct effect, including:

1. homocysteine—raised concentrations of which are thought to be atherogenic by an oxidation effect on lipoproteins;
2. methylguanidine—a neurotoxin that may explain the uraemic peripheral neuropathy;
3. the aminoguanidine **ADMA** (asymmetric dimethylarginine)— is a potent inhibitor of nitric acid synthesis that may have a bearing on hypertension of renal failure;
4. b$_2$-microglobulin—accumulation of which causes b$_2$-microglobulin amyloid;
5. drugs such as morphine—which are metabolized to excretable glucuronides that accumulate in renal failure and cause or exacerbate encephalopathy.

Although incomplete, knowledge of the presence of uraemic toxins is what underpins the perceived benefit of early and adequate dialysis for uraemia.

One of the clearest manifestations of the uraemic syndrome is anaemia. The physiological mechanisms controlling red cell mass are shown in Fig. 3. The maintenance of a normal red cell mass requires a rate of red cell production by a healthy bone marrow, with no substrate limitations and under the influence of an adequate amount of erythropoietin, to balance red cell loss and destruction. In uraemia all components are disturbed. Red cell lifespan is shortened by accelerated destruction, possibly caused by substances within uraemic plasma that alter the red cell membrane. To compensate for a shorter lifespan, a higher than normal production of red cells is required, which is dependent on an increase in the erythropoietin secretion rate. Concentrations do indeed rise, but not enough to set erythropoiesis at a sufficient level (Fig. 2). The classic experiment of providing exogenous erythropoietin to treat anaemia shows that: (1) red cell survival is not altered by erythropoietin; (2) red cell mass is restored; (3) marrow activity has to be maintained at a higher than normal level to achieve this. It is a much-argued point whether the marrow is itself normal. *In vitro* experiments reveal that constituents of uraemic plasma can suppress erythropoiesis. However, the fact that the effects of these constituents can obviously be overridden by exogenous erythropoietin does not exclude the possibility of resistance. It is not possible to say whether the doses of erythropoietin required to reverse anaemia are physiological because the modes of delivery—subcutaneous and intravenous injection—are not.

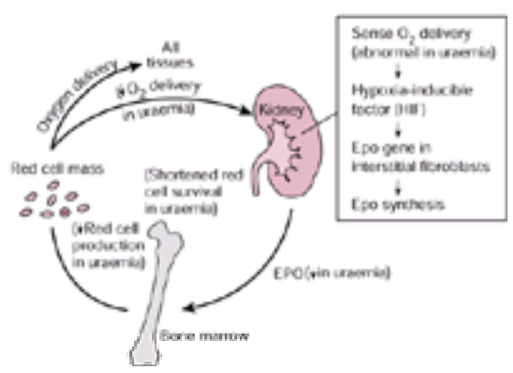

Fig. 3 The relationship between red cell mass, oxygen delivery, anaemia, erythropoietin (Epo) synthesis, and red cell production in the bone marrow. Erythropoietin production is reduced in uraemia, either because of defective sensing or reduced synthesis.

Progression of chronic renal failure

The clinical course of most nephropathies is a progressive decline in renal function. However, the rate of progression varies considerably between patients and diseases, generally being faster in chronic glomerulonephritides than in tubulointerstitial nephritides.

Factors influencing the rate of progression

Proteinuria

The degree of proteinuria correlates with the rate of progression of the underlying nephropathy and is the most reliable prognostic factor in chronic renal failure. In chronic glomerulonephritis, persistent heavy proteinuria (greater than 3 g/24 h) predicts a poor outcome. Conversely, the absence of significant proteinuria or its partial or complete remission indicates a favourable prognosis. In patients with diabetes or tubulointerstitial nephropathy, such as reflux nephropathy, the onset of significant proteinuria (greater than 1 g/24 h) usually predicts a decline in renal function. Proteinuria may be a marker of severe renal disease, but it is possible that the filtration and overloading of the tubules with protein may itself damage the nephron.

Hypertension

The most important factor influencing the rate of progression is systemic hypertension, which appears early in the course of renal diseases and long precedes the onset of ESRF. As with proteinuria, hypertension is a marker of more severe renal disease, but there is good evidence that the raised arterial pressure is itself pathogenetic.

Other factors

Ethnicity and genes

Certain major histocompatibility antigens have been associated with a poor outcome in some forms of glomerulonephritis, for example in membranous nephropathy. In adult polycystic kidney disease, patients with type 1 (abnormal gene on chromosome 16) have an earlier onset and a faster rate of decline compared to those with type 2 (whose abnormal gene is on chromosome 4) (see Chapter 20.11). Afro- and, to a lesser extent, Hispanic Americans suffer a faster rate of progression when compared to Caucasians. Diabetic nephropathy progresses more rapidly in Afro- and native Americans.

Gender

Renal function deteriorates faster in males with adult polycystic kidney disease, mesangial IgA disease, and membranous nephropathy. In Western societies, males tend to have a higher blood pressure than age-matched females, which may explain this difference.

Mechanisms of progression

The loss of filtration rate in chronic renal disorders is a consequence of progressive glomerulosclerosis, tubulointerstitial fibrosis, and vascular sclerosis. Glomerulosclerosis has been attributed to immunological (glomerulonephritis), haemodynamic (hypertension), or metabolic (diabetes mellitus) insults leading to glomerular endothelial injury. In surviving ('remnant') glomeruli, a compensatory increase in intraglomerular capillary pressure (glomerular hypertension) results from a disproportionate afferent arteriolar vasodilatation and the loss of autoregulation, exposing them to systemic hypertension that in turn is associated with endothelial damage. Injury to the glomerular endothelium favours platelet adhesion, aggregation, and the formation of glomerular microthrombi, allowing the transudation of macromolecules, including lipids and growth factors, into the glomerular mesangium. These stimulate mesangial proliferation and the increased synthesis of extracellular collagenous matrix.

Tubulointerstitial scarring

There is a correlation between the severity of tubulointerstitial scarring and GFR. Tubulointerstitial inflammation and widespread interstitial fibrosis are markers of a worse outcome in renal disease: these are characterized by inadequate healing with excessive collagen deposition and involve interactions between renal tubular cells, inflammatory cells, and resident fibroblasts through the release of cytokines and growth promoters.

Vascular sclerosis

The extent and severity of renal vascular changes (arterial and arteriolar) is also relevant to outcome. Although hyalinosis of smaller renal vessels is common in patients of all ages with chronic renal disease, severe arteriolar hyalinosis is often seen in the kidney tissue of patients with chronic nephropathies in the absence of significant systemic hypertension. Moreover, the everity of these vascular changes is greater than that seen in patients with essential hypertension. This arteriolar hyalinosis further jeopardizes the glomerular and tubular blood supply, causing ischaemic injury and further scarring.

Clinical presentation

The presentation of chronic renal failure will depend on the degree of renal dysfunction at the time medical help is sought.

- *Asymptomatic*—At one extreme are asymptomatic patients in whom an abnormal creatinine is noticed on a 'routine' biochemical screen. Such patients may be shocked when it is explained that they have lost what might be a substantial amount of their renal function, and counselling them and persuading them to comply with follow up and medication is sometimes difficult. Patients with illnesses known to cause renal failure, such as adult polycystic kidney disease, are easier to manage because they usually understand the progressive nature of renal failure and the need to introduce various measures in steps.
- *Associated disease*—Much renal failure is picked up in general medical, hypertension, diabetic, cardiac, and urology clinics because clinicians are aware of the effect of other diseases on renal function.
- *Symptomatic presentation*—Relatively few patients are diagnosed because they present with the non-specific symptoms of chronic renal failure, such as lethargy, dyspnoea, and anorexia. Those that are will be relieved that their symptoms have an explanation. At the extreme end of this category are the patients who present with an acute uraemic emergency requiring urgent dialysis, constituting about 5 per cent of patients entering renal replacement treatment programmes. Another 25 per cent are close to end-stage renal failure when they are first seen by a nephrologist and need dialysis within 3 months of the first consultation.

It may at first be difficult to distinguish acute from chronic renal failure, but a systematic history, examination, and appropriate investigations should soon distinguish the two (Table 5). The presentation of ESRF as a uraemic emergency is often the result of missed diagnostic opportunities, but may be the presentation of a rapidly progressive illness such as rapidly progressive nephritis, myeloma, or renal vascular disease.

Assessment

All patients with chronic renal failure should be referred for specialist opinion, although their care can often best be shared with the primary care physician or other specialist, for instance a diabetic physician.

The patient with ESRF

The 5 per cent of patients with chronic renal failure who present as uraemic emergencies may be comatose, may have fitted, and may have asterixis. The skin shows excoriation from pruritus, purpura, and bruising on a sallow yellow-brown background. The blood pressure is raised and examination of the fundi may reveal haemorrhages and exudates. The apex beat is displaced laterally and there is often a pericardial friction rub. There are basal lung crepitations and oedema of the

face, sacrum, and ankles. Blood investigations show a urea concentration above 50 mmol/l, a creatinine concentration above 1000 µmol/l, hypocalcaemia, hyperphosphataemia, hyperkalaemia, and a partially compensated metabolic acidosis. There is a normochromic normocytic anaemia, a normal white blood count, and a platelet count in the low normal range.

The patient may be too ill to give a history, but family and/or friends report a general deterioration in health over the preceding 6 months with dyspnoea, anorexia, pruritus, and nocturia. Such a patient is easy to diagnose, indeed the ammoniacal smell of the breath often alerts the family practitioner. This medical emergency is now infrequently encountered in societies with developed medical services, but the gradual nature of the deterioration is such that it may take some dramatic event like a fit to provoke referral. The morbidity in such patients is high and it is obvious that the opportunity for halting the underlying pathology or slowing progression will have been lost. Most patients present with a much milder combination of symptoms and signs and are often irritated that their non-specific symptoms had not earlier been attributed to chronic renal failure. They should be told that renal failure is rare and that, in the absence of obvious clues, no doctor should be criticized for missing the diagnosis in the early stages.

Many patients will present to hospitals without dialysis facilities. If so, it needs to be established whether there are any immediately life-threatening complications that mandate urgent transfer to a hospital where dialysis can be provided. These include hyperkalaemia, refractory pulmonary oedema, severe hypertension, metabolic acidosis, and encephalopathy. The specific management of these is described in Section 20.5. After dealing with these issues, the next point is to determine whether there are factors which have caused or are causing an acute reduction in chronically impaired renal function. If so, can they be reversed? (Table 6). Examples include:

- *Hypoperfusion*—This can result from dehydration caused by diarrhoea, vomiting, iatrogenic deprivation of fluid (e.g. following surgery), or the overzealous use of diuretics. An occasional cause is the renal loss of salt and water in conditions such as medullary cystic disease. Significant dehydration is associated with a reduction in weight and postural hypotension. Worsening renal arterial stenosis and cholesterol emboli should be sought in arteriopaths.
- *Drugs*—Many drugs, particularly non-steroidal anti-inflammatory drugs (**NSAIDs**), aminoglycosides, and antihypertensive agents, can cause a reduction in GFR, and many others cause acute interstitial nephritis. Tetracyclines cause nausea and vomiting. Clofibrate causes rhabdomyolysis and myoglobinuria. Contrast media in the dehydrated patient are another cause of sudden deterioration in function.
- *Infection*—Systemic infection such as pneumonia can reduce the GFR, and renal parenchymal infections in patients with diabetes, analgesic nephropathy, or adult polycystic kidney disease can damage the remaining functioning renal tissue.
- *Obstruction*—Renal function may worsen substantially in a patient with chronic renal failure if one kidney is obstructed by calculi or papillary necrosis, for example. Sloughed papillae should be sought in those with analgesic nephropathy, diabetes, an obstruction, or sickle-cell disease. Retroperitoneal fibrosis may be occult and is not always detected by ultrasound examination (see Chapter 20.14).
- *Relapse* of the underlying disease—Patients with diseases such as systemic lupus erythematosus, IgA nephropathy, or systemic vasculitic syndromes will deteriorate when the underlying disease relapses, causing further damage to glomeruli. Diagnosis can be difficult because the kidneys are too small to biopsy. Serology and examination of the urine deposit can be helpful. Occasionally, membranous nephropathy and membranoproliferative glomerulonephritis can change in character with the development of extracapillary proliferation (crescent formation), and this is associated with a rapid decline in function. Renal vein thrombosis also causes deterioration in function and should be considered in those with chronic nephrotic syndrome, particularly with underlying membranous nephropathy or focal segmental glomerulosclerosis.
- *Hypertension*—The development of accelerated-phase hypertension may cause a sharp and irreversible reduction in residual renal function. This is most likely in patients with glomerulonephritis.
- *Congestive heart failure*—Independent of the salt and water retention of uraemia, congestive heart failure itself can lead to a reduction in GFR. This can be a result of hypertension, myocardial infarction, or arrhythmias.
- *Hypercalcaemia*—The use of vitamin D analogues such as alfa-calcidol (1a-hydroxycholecalciferol) to prevent hyperparathyroidism often leads to hypercalcaemia. When marked (plasma [Ca^{2+}] >3 mmol/l), this causes a reduction in GFR, usually by causing dehydration.
- *Pregnancy*—Early in pregnancy the plasma creatinine concentration tends to fall, but the course of diseases such as reflux nephropathy or glomerulonephritis may accelerate (see Chapter 13.5).

Once the pressure of the emergency situation is resolved, or if the patient has been referred to the outpatient department with apparently stable chronic renal impairment, the clinician will need to make a thorough assessment of the cause and degree of renal failure and its complications, and institute the appropriate treatments, counsel the patient about the prognosis, and (if appropriate) plan for renal replacement treatment.

History and examination

Questions will be directed towards possible causes, duration of illness. and complications (Table 3, Table 4, and Table 5). Patients with advanced chronic renal failure usually admit to a gradual deterioration in health during the previous 6 months, but some are remarkably uncomplaining, claiming to 'feel fine' despite very abnormal blood tests. This is usually an indication of a very gradual decline towards chronic renal failure. Clues as to the cause may come from all past interactions with doctors: for instance, proteinuria during a medical examination for employment and insurance purposes or during pregnancy, or a urological assessment for microscopic haematuria.

The severity of renal failure will be gauged from the uraemic symptoms of anorexia, vomiting, lassitude, breathlessness, and ankle swelling. The clinician will need to know all about the patient's family as well as their social and employment background to allow advice on the future and to plan treatment.

The examination often provides little extra diagnostic help, but it is important to look for evidence of multisystem disorder, generalized vascular disease (which might indicate a renovascular cause for renal failure), and urinary obstruction. The latter cannot be excluded on physical examination, but if the cause of chronic renal failure is not apparent it is essential to palpate carefully for an enlarged bladder and to perform a rectal examination. Examination also allows an assessment of the consequences of chronic renal failure on blood pressure, left ventricular hypertrophy, and salt and water balance.

Investigations

The work-up of a patient newly diagnosed with chronic renal failure (Table 7) is partly diagnostic and partly for staging and preparation for dialysis and/or transplantation.

Radiological

A minimum set of investigations includes: ultrasonography to determine renal size, echogenicity, and calyceal appearance and to ensure complete emptying of the bladder; and a chest radiograph for heart size (cardiothoracic ratio— **CTR**) and lung fields. Some nephrologists would routinely also take radiographs of the hands and pelvis, looking for renal osteodystrophy and vascular calcification.

Biochemical

Creatinine clearance can be estimated using the Cockcroft–Gault formula (see above). The calcium, phosphate, and parathormone levels will give a pointer to the presence of renal osteodystrophy, and hence to the need for dietary advice and to the scope for prescription of vitamin D analogues and calcium-containing phosphate binders. Measurement of cholesterol and triglyceride concentrations will dictate the use of HMG-CoA (3-hydroxy-3-methylglutaryl coenzyme A) reductase inhibitors (statins). There is now a low threshold for statin prescription to patients with hypertensive renal failure because of their very high risk of cardiovascular events.

Haematological

Most patients will have a normochromic normocytic anaemia; although this will be due mainly to erythropoietin deficiency, it can be exacerbated or caused in some by iron deficiency. The iron status (plasma ferritin, percentage hypochromic red cells) should always be measured so that a trial of intravenous iron can be given before the more expensive option of erythropoietin treatment is initiated, the usual threshold for which is a haemoglobin concentration of less than 11 g/dl. Vitamin B_{12} and folate concentrations are rarely abnormal and should not be part of a routine work-up.

Immunological

These tests are mainly of diagnostic use and are performed only when clinically indicated, that is to say when there is diagnostic uncertainty (Table 7).

Cardiac work-up

An ECG is a routine but insensitive marker of left ventricular hypertrophy or ischaemia, except for previous myocardial infarction. Echocardiography is now the preferred investigation to detect left ventricular hypertrophy. In patients being considered for renal transplantation, exercise testing, radionuclide scanning, or angiography are required if there is any suspicion of asymptomatic ischaemic heart disease, for example in juvenile-onset diabetics or a past history of ischaemic events.

Virological

The presence of the hepatitis B surface antigen (**HepBsAg**) and hepatitis C (**Hep C**) antibodies or RNA will need to be established to decide whether a patient needs to be dialysed in isolation (Hep B), or using a dedicated machine (Hep C). HIV testing in many centres is only performed in high-risk groups, or if renal transplantation is contemplated, but in other centres it is done (after appropriate counselling) as a routine. Knowledge of the patient's immune status for cytomegalovirus (**CMV**), Epstein–Barr virus (**EBV**), and herpes zoster virus (**HZV**) will be useful baseline information if the patient is likely to undergo renal transplantation.

Clinical complications of chronic renal failure

The clinical complications of chronic renal failure are widespread (Fig. 4).

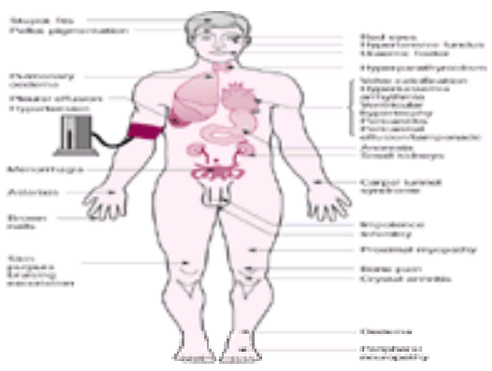

Fig. 4 Symptoms and signs of uraemia.

The cardiovascular system

The single most important complication of chronic renal failure is raised arterial blood pressure, which accelerates atherosclerosis and is the main cause of the left ventricular hypertrophy that is found in 75 per cent of patients. Left ventricular dilatation, coronary atherosclerosis, ventricular dysfunction, and cardiac failure are common, explaining why cardiac disease is the leading cause of death in patients with ESRF, the relative risk being highest in the young. There is a high risk of acute myocardial infarction, but sudden arrhythmic death is the more common fatal cardiac event. Patients are prone to develop pulmonary oedema with relatively small increases in extracellular fluid and tolerate dialytic removal of fluid poorly.

The factors giving rise to this dangerous combination of left ventricular hypertrophy and coronary atherosclerosis operate early in chronic renal failure and include hypertension, dyslipidaemia, anaemia, hyperparathyroidism, and hyperhomocysteinaemia. The combination of these factors has a synergistic effect on the risk of cardiovascular disease.

Pericarditis is a dreaded complication of chronic renal failure because it may lead to tamponade and death. It was more common in the days when dialysis was delayed until the patient was extremely uraemic, but it still occurs in underdialysed, chronically fluid overloaded, and infected patients. Progression to constriction is rare.

Calcific aortic stenosis and mitral valve calcification leading to incompetence occurs in about one-third of patients in dialysis. Endocarditis is not uncommon in haemodialysis patients, but could still be considered as surprisingly rare considering the frequency with which access to the circulation is made. It is usually caused by *Staphylococcus aureus* and leads to destructive valve disease often needing surgery.

Musculoskeletal system

Chronic renal failure causes major problems in the skeleton. Osteitis fibrosa, osteomalacia, and reduced bone turnover are a consequence of hyperparathyroidism, phosphate retention, and deranged vitamin D metabolism. These manifest as bone pain, deformity, pathological fractures, soft tissue and especially vascular calcification, and proximal myopathy. (See Chapter 20.5.2 for further discussion.)

Patients are also prone to develop crystal arthropathy, either from urate or pyrophosphate. Uric acid concentrations are high because of reduced excretion and the effect of diuretics. Long-term dialysis patients develop a specific b $_2$-microglobulin amyloid, deposits of which cause a large joint and spinal arthropathy, and the carpal tunnel syndrome. Large-joint haemarthroses are seen in anticoagulated renal failure patients, probably because of synergy between the use of heparin and uraemia-associated effects on haemostasis. Gout can be prevented with xanthine oxidase inhibitors such as allopurinol (but note the need for a reduced dosage in patients with renal impairment), or uricosuric agents such as probenecid. Initiation of these agents should be covered by colchicine for they can provoke acute attacks. NSAIDs can be used during acute attacks in chronic renal failure for short periods, provided that the effect on salt retention and GFR is acknowledged. Colchicine or corticosteroids are alternatives. The cyclo-oxygenase-2 inhibitors do not have an advantage over conventional agents.

Gastrointestinal system

Anorexia and nausea are almost universal symptoms in uraemia and are accompanied by a blunting of taste. Both lead to decreased caloric intake and malnutrition. If there is poor oral hygiene, mouth bacteria will break down urea in saliva to ammonia, giving an unpleasant taste in the mouth and uriniferous smell to the breath. Patients often suffer early morning vomiting in the late stages of renal failure. These upper gastrointestinal symptoms are aggravated or even caused by opioid analgesics, the metabolites of which accumulate in renal failure. Diverticular disease is a problem in dialysis patients who may become constipated because of a reduction in the fluid and bulk of their diet. Patients on dialysis with primary amyloid are, for the same reasons, more at risk of perforation of the colon.

Clostridium difficile is endemic in renal units. Elderly patients in particular often develop pseudomembranous colitis after treatment with broad-spectrum antibiotics, especially cephalosporins. Treatment is with oral metronidazole or vancomycin, but if a toxic megacolon develops then colectomy is essential to preserve life.

Gastrin levels are higher in patients with chronic renal failure than in controls, but peptic ulceration is not obviously more common than in the general population. However, gastrointestinal haemorrhage, both acute and chronic, is believed to be more common in renal failure and is attributed to angiodysplasia or non-specific gastric ulceration aggravated by the platelet dysfunction of uraemia. The chronic blood loss is more noticeable because the erythroid bone marrow is already near the limit of compensation for shortened red cell survival.

Pancreatitis is only more common in uraemia because it can be provoked by hypercalcaemia, which is a hazard of vitamin D-analogue treatment. Chronic dialysis patients do have a fibrotic pancreas, but this does not seem to have clinically relevant effects on exocrine secretion.

Hepatitis B infection, if contracted in the presence of renal failure, is likely to become chronic. Patients fail to clear the virus because of their depressed cell-mediated immunity, but they seldom develop severe hepatitis or chronic liver disease. Hepatitis C infections are only more common in renal failure because of exposure to blood transfusions and its transmission in haemodialysis units. The natural history does not seem different in patients in renal failure.

The nervous system

Obvious encephalopathy is a very late manifestation of uraemia, typically leading to confusion, myoclonic twitching of distal muscle groups, and impaired consciousness. Seizures are rare unless there is also accelerated-phase hypertension. Before this preterminal state is reached, higher mental function is impaired and patients will complain of difficulty concentrating and of lethargy. It is important to exclude synergic sedation from drugs such as codeine, dextropropoxyphene, carbamazepine, or benzodiazepines. Electroencephalography (**EEG**), although an unnecessary investigation in these circumstances, shows slowing of the background rhythm. Brain computed tomography (**CT**) scans are unhelpful and magnetic resonance imaging (**MRI**) can be frankly misleading. Treatment is with dialysis—frequent, short, and gentle. The myoclonic jerks can be suppressed by benzodiazepines such as clonazepam, 500 to 2500 µg per day.

A specific encephalopathic ('dialysis disequilibrium') syndrome can occur during or after the institution of dialysis in uraemic individuals. From a normal mental state, the patient develops a headache, confusion, involuntary movements, and seizures, all suggesting the development of cerebral oedema. This is attributed to rapid urea removal leading to changes in the water content of brain cells. It is prevented by slow dialysis, avoiding rapid shifts in urea concentration.

Aluminium-induced encephalopathy—dialysis dementia—has disappeared as a clinical problem since dialysis water is properly purified to exclude aluminium, and aluminium-containing phosphate binders are not given for very long periods. Such patients exhibited a gradual deterioration in intellectual performance, progressing to dementia with involuntary movements.

Sensorimotor peripheral polyneuropathy is a late complication of chronic renal failure. This presents as dysaesthesiae, restless legs, and eventually weakness with foot drop, also loss of power in the small muscles of the hand. Nerve conduction studies do not show specific diagnostic features, there being a delay in the conduction velocity and a reduction in the amplitude of the action potential. The neuropathy is thought to be a result of the effect of an unidentified toxic 'middle' molecule. Dialysis results in a slow improvement, but patients are often left with motor disability. Autonomic neuropathy manifests largely as abnormal cardiovascular reflexes, especially during dialysis.

A specific mononeuropathy of renal failure is the carpal tunnel entrapment syndrome caused by b $_2$-microglobulin-derived amyloid deposition. Almost all dialysis patients develop this by 10 years of treatment unrelieved by renal transplantation.

One final comment: although renal failure can lead to many neurological problems, as detailed above, it is important that such problems are not automatically attributed to uraemia—drug accumulation and vascular disorders are common differential diagnoses.

The skin

The effects of uraemia on the skin are obvious and cause much distress to the patients. Yellow-brown pigmentation prominent in sun-exposed areas is a feature of prolonged chronic renal failure. It is attributed to an effect of retained melanocyte-stimulating hormone (**MSH**), retention of vegetable-derived lipochrome and carotenoids, and iron.

Pruritus is the most exasperating symptom for both patient and nephrologist because it is so difficult to treat. It is associated with xerosis (dry skin) and is worse when the skin is warm. A number of explanations are advanced including sensitivity to histamines, a raised calcium phosphate product, and uraemia itself. The itch–scratch cycle can lead to infection and nodular prurigo. Treatment includes starting or increasing dialysis, applying skin emollients, controlling the plasma phosphate level, keeping cool, and the prescription of antihistamines, for example chlorphenamine (chlorpheniramine) 4 mg at night (which is also slightly sedative). Naltrexone, an opioid antagonist, and ultraviolet phototherapy are effective in the short-term.

Cutaneous and subcutaneous calcification (calciphylaxis), a result of small-vessel calcification and occlusion, leads to painful livedo reticulosis and ischaemic ulceration. Once established, it is difficult to treat.

Bullous eruptions in sun-exposed areas, mimicking those of porphyria, are seen in dialysis patients. They are attributed to retained uroporphyrins or other photosensitizing chemicals that inhibit porphyrin breakdown. Iron excess is implicated in the pathogenesis, so phlebotomy and erythropoietin are part of the treatment.

Sexual function

Males

A combination of loss of libido and erectile impotence are experienced by about half the men on dialysis. Loss of libido will be a consequence of ill health and depression and is improved when well being is restored. Impotence has many causes, including pelvic vascular disease, venous leakage because of neuropathy, and drugs (for example, thiazides or a-blockers). Treatment of impotence with vacuum devices, intracavernosal injection of phentolamine, or oral sildanefil may be effective. Low sperm counts and motility that are not improved by hormonal treatment account for the lower fertility of uraemic men. *In vitro* fertilization is an option. Priapism is a rare complication of haemodialysis treatment. Gynaecomastia is common.

Females

Most women with severe renal failure develop amenorrhoea or irregular menses due to hypothalamopituitary dysregulation. Oestrogen levels are low, accounting for atrophic vaginitis and contributing to osteoporosis. Women with severe uraemia are usually infertile and the rare pregnancies almost always end in miscarriage. Patients with mild to moderate renal failure do become pregnant, when the risk of an accelerating decline in function and chance of a successful outcome are related to the severity of preconception renal dysfunction, proteinuria, and blood pressure (see Chapter 13.5).

Haematological effects and host defence

Renal anaemia, which is normochromic and normocytic, accounts for many of the symptoms that previously were attributed to uraemia. These include lethargy, cold intolerance, and loss of stamina. Anaemia increases the cardiac output and therefore contributes to the development of left ventricular hypertrophy and dilatation. The low haematocrit itself has an effect on platelet function as measured by prolonged bleeding times.

Platelet numbers are usually normal but function is impaired at the level of endothelial contact. The coagulation system is not affected. The uraemic bleeding diathesis manifests as occult gastrointestinal blood loss, oozing from any injuries or surgical incision, menorrhagia, and epistaxes. It is aggravated by the consumption of aspirin, a regular component of drug regimens in patients with cardiovascular disease.

T-cell immunity is impaired in renal failure, but the mechanism has not been explained. Evidence for this defect is the higher risk of reactivation of tuberculosis and herpes zoster, a failure to clear hepatitis B, and a poor response to immunization with hepatitis B vaccines. Neutrophil function is abnormal in a number of *in vitro* tests and may explain the high incidence and severity of bacterial infections, especially those associated with vascular access. The defect is attributed to the effects of iron, increased cytosolic calcium, and 'granulocyte inhibitory proteins'.

Metabolic effects

Renal failure causes a degree of glucose intolerance explained by resistance to insulin-mediated glucose uptake in skeletal muscle. There are complex effects on

lipids resulting in an increased concentration of very low-density lipoproteins (**VLDL**) and an increase in high-density lipoproteins (**HDL**). Protein catabolism is enhanced in renal failure, perhaps as a consequence of metabolic acidosis. This has significant effects during periods of malnutrition and infection.

Psychological manifestations

The psychological problems of patients with chronic renal failure, usually anxiety and depression, are the predictable and understandable consequences of loss of health, control, and pleasure. They are most obvious in those with the most to lose—the young and ambitious—and may be relatively minor in the elderly who are grateful that they have a treatable illness and not an immediately lethal one.

The best treatment is good sympathetic symptomatic care from physicians, nurses, and other staff with whom they can build a relationship. In particular, one should try to eliminate fear of the unknown (caused by ignorance and often by gossip in the clinic waiting room) and encourage an optimistic approach. Psychiatrists usually have little to offer unless there is a specific mental illness, but psychotherapists may be able to help with phobias, guilt, and anger. Antidepressants should be used sparingly, but gentle night sedation is frequently helpful.

Medical treatment of chronic renal failure

Patients with chronic renal failure should be managed by nephrologists (or at least physicians with an interest in renal disease) in 'low clearance clinics' or outpatient departments geared to the three issues—conservation of renal function, compensation for the effects of chronic renal failure, and preparation for eventual renal replacement therapy.

Conservation of function and prevention of progression

Measures to conserve renal function may be specific for the cause of renal disease or general, i.e. applicable to all patients. There are a few treatable causes of chronic renal failure diseases for which the pathology can be modified if not actually arrested.

Specific measures

Urinary obstruction

Relief of obstruction is very rewarding, allowing the patient many years of survival without the need for dialysis because 'natural' progression seems to be relatively slower than for other parenchymal diseases. Proof of a persistent obstruction can be difficult in an already dilated renal tract. Isotope renography with furosemide (frusemide) is unreliable when renal function is poor, so if there is doubt, attempts to improve drainage should be made. This may involve an indwelling bladder catheter for high-pressure bladder outflow obstruction, stenting of ureteric strictures, or even antegrade nephrostomy drainage.

Drug-induced renal disease

If analgesic abusers stop taking the drugs, renal function can stabilize. The same may apply to ciclosporin, NSAIDs, and lithium.

Glomerulonephritis—primary and secondary

The progression of most of the common primary glomerulonephritides is relentless. There are no proven treatments of IgA nephropathy, membranoproliferative glomerulonephritis, or focal segmental glomerulosclerosis. Aggressive membranous nephropathy does respond, but not permanently, to regimens of alkylating agents (chlorambucil or cyclophosphamide) with corticosteroids.

Unsuppressed systemic lupus erythematosus and systemic vasculitis can both accelerate the decline in renal function. Proving 'activity' can be difficult and will require knowledge of serological tests, urinary sediment, and other non-specific markers, such as proteinuria, anaemia, and the concentration of acute-phase reactants. Renal biopsy may help, but is not an option when the kidneys are already small and scarred. A trial of increased immunosuppression is often worthwhile.

Ischaemic renal disease

Angioplasty with or without stenting of atheromatous renal artery stenosis seldom reverses renal failure, but it does seem to stabilize or slow progression. It is now a safe undertaking with a low risk of acute occlusion of the renal arteries.

Myeloma

Chemotherapy, which reduces the paraprotein load, improves renal function in patients with myeloma provided the renal failure is not advanced.

Amyloidosis

Treatment of the underlying cause of amyloid A (AA) disease (for example, familial Mediterranean fever (**FMF**) and Still's disease) improves the renal consequences of the process. Chemotherapy of primary amyloidosis (AL amyloid) has been disappointing. Although prednisone and melphalan regimens improve survival, they do not delay the progression of renal failure. It remains to be seen whether marrow ablation and stem-cell rescue will be an effective and applicable treatment for more than a select minority of patients.

Urinary tract infection

Treatment of renal tuberculosis or infection of polycystic kidneys is effective in reducing renal destruction. In reflux nephropathy, suppressing lower urinary tract infections makes relatively little difference, but true pyelonephritis must be treated with the appropriate antibiotics. Antireflux procedures do not alter the natural history.

Stone disease

Measures to reduce stone formation in cystinuria, hypercalciuria, and hyperuricaemia are effective (see Chapter 20.13). Allopurinol is effective in stabilizing renal function in patients with inherited forms of hyperuricaemia.

Diabetes

Control of blood pressure halts or retards diabetic nephropathy, although there is no evidence that better treatment of diabetes (glycaemic control) has a substantial effect (see Chapter 20.10.1).

General (non-specific) measures

Once there has been a loss of more than 50 per cent of renal function the residual nephrons become vulnerable to injury from glomerular hypertension, quite independent of the primary pathology. The clearest example of this phenomenon is the patient who has 1.5 kidneys removed because of cancer and is left with one-quarter of their normal renal mass. Despite the fact that the remaining kidney tissue has no intrinsic pathology, the patient develops hypertension, proteinuria, and progressive glomerulosclerosis leading to renal failure, the mechanisms involved being described above (see ' mechanisms of progression'). Countering the factors that are thought to favour the vicious cycle of nephron loss and autologous injury could stop or delay the process.

Hypertension

There is good evidence relating the presence of systemic hypertension to progression of chronic renal failure and height of the blood pressure to the rate of decline of renal function. Lowering blood pressure is effective in delaying the rate of progression of renal failure, best exemplified in diabetic nephropathy. The optimum target blood pressure is uncertain, but most nephrologists operate on a 'lower the better' principle. Excepting in diabetic nephropathy, it is still unclear whether ACE inhibitors or a2-receptor blockers are superior to other blood pressure-lowering drugs, but the prejudice of most nephrologists is that they should be the first-line agents. The additional benefit of ACE inhibitors is attributed to their effects on glomerular hypertension and the prevention of angiotensin-induced vascular injury.

Dietary protein

Dietary protein restriction slows the progress of glomerulosclerosis in residual nephrons in animal experimental models of chronic renal failure. Trials in humans have evoked much controversy, but the consensus is that there is a modest effect of a 0.2 g/kg per day reduction in protein consumption (from that consumed in a normal Western diet) in patients with GFRs of 13 to 24 ml/min. In practice, nephrologists do no more than advise against high-protein diets. Promotion of low-protein diets has been abandoned in favour of maintaining good nutrition and starting dialysis earlier.

Other

There is no evidence that antiplatelet drugs, anticoagulants, lipid-lowering measures, and low-phosphate diets delay the progression of chronic renal failure.

Compensation for the effects of chronic renal failure

Although there is usually a remarkable adaptation to the loss of as much as 90 per cent of kidney function, a figure which allows the survival of patients with severe chronic renal failure, there is much that should be done to improve health and prevent complications.

Water and electrolyte balance

Only those with oliguric end-stage renal failure need to restrict their fluid intake precisely, when the usual (but seldom complied with) recommendation is that the patient's daily intake should be 500 ml (for insensible losses) plus a volume equivalent to their daily urine output. Patients with chronic renal failure pass normal volumes of urine. However, they do need to be counselled against binge drinking or ignoring extra fluid losses in hot weather and during episodes of diarrhoea or vomiting, because the free-water clearance is blunted and concentration is impaired in renal failure.

Dietary restriction to 60 mmol/day each of sodium and potassium will not exceed the capacity of the failing kidney to maintain balance. Tolerant and flexible advice to provide a safe and tasty diet is more likely to be adhered to than one with absolute and complete exclusions. Sodium balance and blood pressure will be improved by diuretics, usually of the 'loop' type, and in resistant cases in combination with a thiazide such as metolazone.

If the potassium level rises above 7 mmol/l, haemodialysis should be initiated unless there is an otherwise remediable cause. Occasionally this is an isolated finding in an otherwise stable patient, when the ECG should be checked (with emergency treatment as described in Section 20.5 if there are ominous changes) and the measurement repeated. Causes of hyperkalaemia to be considered in those with chronic renal failure—other than a fruit, chocolate, or coffee binge—include gastrointestinal haemorrhage, acidosis, and tissue necrosis, such as a gut infarction or gangrene. Chronic disproportionate hyperkalaemia (for example, when the GFR is still above 10 ml/min) is encountered in diabetics with hyporeninaemic hypoaldosteronism, hypoadrenalism, and as a response to ACE inhibitors.

Calcium, phosphate, and vitamin D

Secondary hyperparathyroidism—so difficult to suppress or reverse when established—starts early in chronic renal failure, when the GFR falls below 40 ml/min. Prevention requires countering the three key stimuli: hyperphosphataemia by diet and phosphate binders; provision of 1,25-dihydroxycholecalciferol, either as calcitriol or 1a-hydroxy-cholecalciferol; and maintaining a normal ionized calcium level. To control phosphate, milk products and fish will be limited; the favoured phosphate binder is calcium acetate taken three times a day with meals. A vitamin D analogue should be started in low dose (e.g. 0.25 µg of alfacalcidol three times/week) as soon as the parathormone is found to be above the normal range. It can be quite difficult to persuade patients to adhere to phosphate restriction or to remember to take binders because the immediate benefit is not obvious. (See Chapter 20.5.1 for further discussion.)

Control of blood pressure

A major focus of the follow-up of patients with chronic renal failure is to achieve and maintain a satisfactory blood pressure: the aim is for less than 140/90 mmHg, but in practice this can be difficult to achieve. It is essential that the patients be engaged as partners in the endeavour: it will help if they understand that good blood pressure control will delay the need for dialysis, prevent left ventricular hypertrophy, which will have an adverse effect on survival, and reduce the risk of cardiovascular events. Patients should be encouraged to measure and record their own blood pressures because readings in hurried clinics and general practitioner surgeries are often unreliable. When there is a disparity between clinic and home readings a 24-h ambulatory recording may provide reassurance that increased doses or extra drugs are not needed. Equally, they will justify such a change for a reluctant patient. The choice of drugs will depend on clinician preference and patient tolerance. There is a move towards the use of ACE inhibitors or angiotensin-receptor blockers as first choice because of the potential added benefits, but most patients will require two to four-drug regimens.

Nutrition

Chronic renal failure causes anorexia, acidosis, and insulin resistance. All three contribute to the subtle malnutrition that may develop in the months during which the decision to start dialysis is procrastinated. The dietician's role here is as much to ensure the prevention of malnutrition as to monitor the excess consumption of the problem items. If anorexia causes a reduction in calorie and protein intake, supplements should be prescribed only as a bridge to the starting of dialysis.

Metabolic acidosis

This frequently goes unnoticed as many laboratories do not routinely report plasma bicarbonate levels and it is unusual to take an arterial blood sample in a low-clearance clinic. Acidosis is more common in patients with interstitial renal disease who have an acquired renal tubular acidosis. The usual symptom is effort dyspnoea not explained by pulmonary oedema or anaemia. A chronic acidosis will aggravate hyperkalaemia, inhibit protein anabolism, and accelerate calcium loss from bone where the excess hydrogen ions are buffered. Sodium bicarbonate 1.2 to 1.8 g thrice daily can be prescribed to patients who can bear this sodium load (for example, those with obstructive uropathy who are acidotic salt wasters).

Anaemia

There is no absolute haemoglobin concentration at which the symptoms of anaemia become manifest, so the decision to treat is a matter of judgement: generally the aim is to maintain the haemoglobin level at or above 11 g/dl. Because chronic anaemia leads to left ventricular hypertrophy, which has adverse effects on patient survival and cardiac function, there is a move towards earlier (and even preventive treatment) of anaemia in patients with chronic renal failure. Whether this will improve survival and reduce cardiac complications is a subject of clinical trials.

For patients not yet on dialysis who have a haemoglobin level under 11 g/dl, one can either start erythropoietin, subcutaneously, at 50 U/kg per week (rounded up to reach 1000 units) in two divided doses, or give a trial of intravenous iron first. This can either be a single dose of iron dextran (1 g), taking precautions against the occurrence of anaphylaxis, or intravenous iron saccharate 200 mg weekly for 5 weeks.. A similar regimen is used for dialysis patients. Patients should learn to inject erythropoietin themselves using the prefilled syringe and pens that are available. Longer acting analogues of erythropoietin are now available and will allow once-weekly administration. Doses can be titrated up, the usual maintenance dose being between 25 and 150 U/kg per week. If patients require higher doses or respond poorly they should be investigated for iron deficiency, sepsis, severe hyperparathyroidism (which causes marrow fibrosis), chronic blood loss, or non-compliance. If no cause is found then a bone marrow examination may be helpful. Recently red cell aplasia caused by autoantibodies to erythropoietin has been

described. Patients on haemodialysis can receive the erythropoietin intravenously, but the dose required will be about 30 per cent higher and they are especially liable to develop iron deficiency, which can be prevented by the intravenous administration of 100 mg iron saccharate every 2 weeks. The ferritin concentration should be monitored and the iron temporarily stopped if it rises above 500 µg/l. A checklist for the management of renal anaemia is shown in Table 8.

The reversal of anaemia increases blood pressure in about 30 per cent of patients. High/normal haematocrits are associated with an increasing risk of vascular access thrombosis and do not appear to alter cardiac prognosis.

Drugs

It is essential that the appropriateness of the prescription of drugs to patients with renal failure be checked and the doses adjusted according to the estimated GFR (see Chapter 20.16).

Preparation for dialysis and transplantation

Once end-stage renal failure is inevitable, the patient must be prepared physically and psychologically for renal replacement treatment. In many patients it is possible to predict approximately when the end-stage will be reached (Fig. 5). This information is useful for the patient and provides a guide for the timing of the creation of vascular access, placement of peritoneal dialysis catheters, or activating the patient on to a transplant waiting list. One should avoid the temptation to delay starting dialysis for as long as possible, for the quality of life and health of a well-dialysed patient is superior to that of a non-dialysed, uraemic malnourished one.

Fig. 5 A reciprocal creatinine plot showing the progressive decline in renal function in a patient with glomerulonephritis. The timing of the need to start dialysis could be predicted sufficiently well to allow planning of treatment.

The absolute indications for dialysis are the development of complications that cannot be contained by conservative and pharmacological means. These are hyperkalaemia, fluid overload, severe hypertension, pericarditis, encephalopathy, and neuropathy. To wait for these is bad practice. Nephrologists generally wait until the patient has some uraemic symptoms such as anorexia, lassitude and pruritus, if only because their relief reinforces the need to adjust to regular dialysis. Apart from potassium concentrations and the degree of acidosis, blood tests such as urea and creatinine do not provide a safe guide to when to start. Nevertheless, it is advisable to start dialysis, in the absence of symptoms, at creatinine clearances of less than 10 ml/min. In small patients with little muscle bulk the urea concentration is often between 30 and 40 mmol/l and the creatinine concentration between 650 and 800 µmol/l; in larger subjects the blood urea concentration is typically 45 to 50 mmol/l and that of creatinine above 1000 µmol/l. Initiation of dialysis at lower blood levels of urea and creatinine is recommended in diabetic patients.

The choice of modality—haemodialysis, continuous ambulatory peritoneal dialysis, or renal transplantation—depends on many factors, not least their availability and the patient's preference (see Section 20.6 for further discussion). If transplantation is appropriate, there is no reason not to perform it before dialysis is mandatory. If haemodialysis is chosen, vascular access should be created 4 to 6 months before it is needed. If continuous ambulatory peritoneal dialysis is to be used, the Tenckhoff catheter should be placed 2 to 3 weeks before dialysis needs to be started to allow it to seal.

Management of terminal uraemia

There will be patients for whom dialysis is inappropriate or who either choose not to start or to discontinue treatment. Because, intuitively, one would predict that instituting dialysis in a patient with renal failure and other comorbid conditions should result in some improvement by ameliorating at least one element of their clinical condition, it is very hard not to start. There are those who argue that there is no harm done by starting because treatment can always be stopped or the patient will die despite dialysis. However, withdrawing dialysis or dying while on treatment are traumatic for both the patient's family and staff. If possible, one should discuss the option of not starting before treatment is actually needed. The patient will need to know what the treatment can achieve and at what cost—access, travel to dialysis, restrictions, and complications. If one takes the view that dialysis is a treatment offered to allow the patient to continue living with a reasonable quality of life as opposed to delaying death in the short term, dialysis will not be offered to patients with other life-limiting conditions. Certainly one could argue that it should not be started when survival beyond 3 months outside of hospital is unlikely, indeed at least 10 per cent of deaths in dialysis programmes follow withdrawal of treatment. The ethical and legal issues are complex and require that the patient makes the decision not to start or to discontinue when fully informed and able to do so.

Properly managed death from uraemia is peaceful and free of suffering. It is important to ensure that the patient has peace of mind, in that they are comfortable with the decision, and that their family members are understanding and supportive. They will be comforted to know that their doctor respects their decision. Several distressing symptoms may need to be controlled. The first is breathlessness from pulmonary oedema and acidosis, best controlled with a morphine infusion. The second is nausea and anorexia, which can be helped with regular chlorpromazine 25 mg four times daily: ondansetron 8 mg twice daily can also be effective. Food and fluid should be offered in small palatable helpings and no pressure to eat exerted on the patient. The mouth can become dry and crusted from mouth breathing and will smell foul from the uraemic saliva. Regular mouth washes and gum care will help. Pruritus is managed by keeping the skin cool, and soft with emollients. The patient may not be aware of myoclonic jerks but these will distress the family, so benzodiazepines, such as clonazepam, should be prescribed.

20.5.2 Bone disease in chronic renal failure

Michael Schömig and Eberhard Ritz

Introduction

Renal bone disease is a major cause of disability in patients with terminal renal failure. It is mainly, but not exclusively, due to secondary hyperparathyroidism. Previously, aluminium-induced bone disease, secondary to high aluminium concentrations in the dialysate or ingestion of aluminium-containing phosphate binders, played an important role, but this iatrogenic complication has virtually been eliminated. With more efficient prevention and treatment of secondary hyperparathyroidism, patients with uraemia with low bone turnover are encountered with increasing frequency, but whether this condition (so-called adynamic bone disease) has any clinical consequences, other than the propensity to hypercalcaemia, remains unresolved.

It is important to recognize that abnormal calcium/phosphate metabolism impacts not only on parathyroid glands and bone, but also on cardiovascular function; for example, it increases the risk of cardiac death, calcific aortic stenosis, and coronary plaque calcification. This adds a new dimension to the importance of returning calcium/phosphate metabolism to normal in patients with renal failure.

Pathogenesis of renal bone disease

The role of phosphate excess

In early renal failure, plasma phosphate concentration is normal or low, but renal phosphate excretion (more precisely the fractional clearance of phosphate) is increased. Hyperphosphataemia develops when the glomerular filtration rate is approximately 30 ml/min. This causes and aggravates secondary hyperparathyroidism due to indirect mechanisms, such as inhibition of the synthesis of the active vitamin D metabolite 1,25-(OH) $_2$vitamin D$_3$ (calcitriol) in tubular epithelial cells, and possibly also by inducing a tendency for hypocalcaemia. More recently, it has been shown that phosphate directly stimulates parathyroid hormone (**PTH**) synthesis and secretion as well as causing parathyroid cell proliferation independent of low 1,25-(OH) $_2$D$_3$ and hypocalcaemia.

The role of 1,25-(OH)$_2$vitamin D$_3$ (calcitriol) deficiency

The hepatic vitamin D metabolite 25-(OH)D$_3$ is transformed in tubular epithelial cells to the active vitamin D metabolite 1,25-(OH) $_2$vitamin D$_3$. Synthesis is stimulated by PTH and inhibited by hyperphosphataemia. Even in early renal failure there is a tendency for 1,25-(OH) $_2$D$_3$ concentration to decrease, although this is very often compensated by increased PTH concentrations. The average concentration of 1,25-(OH) $_2$D$_3$ falls as renal failure progresses (Fig. 1). One specific problem is that vitamin D metabolites bound to plasma-binding protein (DBP) may be lost in the urine in patients with nephrotic-range proteinuria, so that deficiency of active vitamin D may ensue. The renal 1-a-hydroxylase reaction is normally substrate-independent, but becomes dependent on the availability of the substrate 25-(OH)D $_3$ in some patients with renal failure, hence vitamin D deficiency aggravates the deficit in the synthesis of 1,25-(OH) $_2$D$_3$.

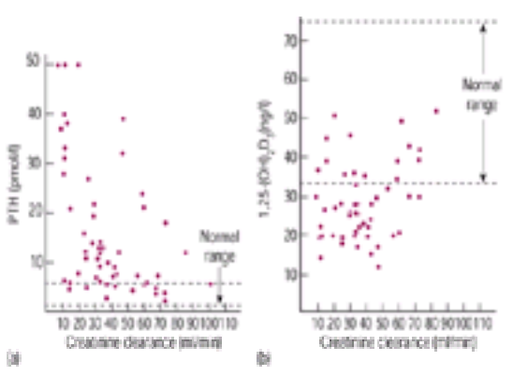

Fig. 1 Intact plasma parathyroid hormone values and serum 1,25-(OH) $_2$D$_3$ levels as a function of the glomerular filtration rate (GFR) in patients with chronic renal failure.

The role of hypocalcaemia

Plasma (total and ionized) calcium concentrations are maintained until the patient reaches pre-endstage renal failure. Nevertheless, the tendency to hypocalcaemia, which is due to a combination of (1) reduced active calcium resorption in the intestine as a result of insufficient active vitamin D, and (2) resistance of the skeleton to release bone mineral and calcium as a result f (partial) resistance to PTH and active vitamin D, may play a more important role in the genesis of secondary hyperparathyroidism than previously thought. The parathyroid gland senses the calcium concentration in the extracellular space via the calcium receptor (CaR) and there are some observations that argue for abnormal sensing of Ca^{2+} even in early renal failure, which may possibly be reversed by agents that improve calcium sensing (calcimimetics).

Clinical manifestations

Pattern of skeletal involvement

The following bone lesions are found in the skeleton of patients with renal failure, in isolation or in combination (Table 1).

Osteitis fibrosa

This is increased osteoclastic bone resorption and increased osteoblastic bone aposition with (1) consecutive intense remodelling of bone trabeculae in the spongiosa, and (2) rarefaction and tunnelization of cortical bone with or without deposition of fibrous tissue (endosteal fibrosis) (Fig. 2).

Osteomalacia

Osteomalacia is a disparity between the rate of bone matrix synthesis and bone matrix mineralization, leading to widening of the seam of unmineralized bone matrix (osteoid), usually associated with signs of diminished numbers and activities of cells at the bone surface. Pure osteomalacia is rarely seen nowadays. In the past it was mainly due to aluminium toxicity and vitamin D (cholecalciferol) deficiency.

Mixed lesions

In many patients with renal failure a combination of osteitis fibrosa and osteomalacia are present.

Adynamic bone disease

In patients with a low serum PTH concentration the number and activity of cells on the bone surface is strikingly reduced and bone turnover is reduced, as evaluated by isotope- or tetracycline-labelling techniques. This condition is relatively frequent in patients with renal failure treated with active vitamin D. It predisposes to hypercalcaemia because the capacity of the skeleton to sequester calcium is reduced, but whether it has more far reaching clinical implications is currently unknown.

Osteopenia or osteoporosis

The problem of diminished bone mass, superimposed upon uraemia-specific bony abnormalities, is very common in patients with renal failure. The most common causes are a history of treatment with steroids and (premature) menopause. It is currently unresolved whether the risk is aggravated by smoking and low calcium diets and whether it can be prevented by substitution of oestrogens/gestagens or selective oestrogen receptor modulators.

Other pathologies

There are several pathologies unrelated to calcium metabolism that have to be taken into consideration in patients with renal failure (Table 1). A dialysis-specific type of amyloidosis with preferential osteoarticular involvement—b $_2$-microglobulin-related amyloidosis—must also be considered in the differential diagnosis of bone pain or bone destruction (see Chapter 20.6.1).

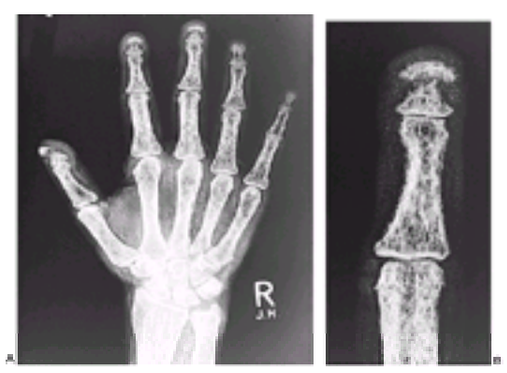

Fig. 2 The radiograph of the hand (a) shows reduced mineral density as well as fluffy and mottled texture of the bones. Note (i) subperiosteal resorption zones at the radial site of the middle phalanges (see also (b)—erosion cavities with overlying areas of calcification (periosteal neostosis), (ii) longitudinal striation of cortical bone (corresponding to enlarged Haversian channels), (iii) thinning of cortical bone by endosteal bone resorption, and (iv) loss of the terminal lamella of the terminal phalanx. The terminal phalanx of the second digit had collapsed, such that the patient presented with 'pseudo-clubbing'. Vascular calcifications are seen above the first digit and along the exterior side of the radius. A detail of the index finger is shown in (b).

The salient differences between osteitis fibrosa and aluminium-related bone disease are summarized in Table 2.

Signs and symptoms

While patients with renal failure left untreated usually have hypocalcaemia and hyperphosphataemia, patients with advanced secondary hyperparathyroidism are characterized by hypercalcaemia and hyperphosphataemia associated with an increase in alkaline phosphatase and its bone isoenzyme.

In the patient with hypercalcaemia it is important to consider causes other than secondary hyperparathyroidism which necessitate specific treatment (Table 3). Similarly, bone pain is not common even in advanced osteitis fibrosa, but bones subjected to mechanical stress (spine, calcaneus, foot) may be painful. Whilst fractures are uncommon, skeletal deformity, leontiasis faciei, and avulsion of the patella may occur. By contrast, osteomalacia, particularly that secondary to aluminium intoxication, may be very painful, especially when Looser zones—fatigue fractures—occur. Again it is important to exclude alternative causes of bone pain (Table 4).

Severe extra-osseous calcifications—periarticular, bursal, or visceral calcifications (see Fig. 2, Fig. 3, and most dramatically, Fig. 4)—are usually the consequence of severe hyperphosphataemia with or without elevated serum PTH concentrations. Tumoral tissue calcification is often triggered by trauma, for instance haematoma. It is favoured by low bone turnover, a situation in which the capacity of the skeleton to sequester calcium phosphate is diminished. Calciphylaxis is a medical emergency where ischaemic skin eschars form secondary to calcification of cutaneous arterial vessels: it usually responds to parathyroidectomy, which may need to be performed as an emergency.

Fig. 3 Calcification of the popliteal artery in a patient with diabetes and severe hyperparathyroidism.

Fig. 4 Tumorous calcification around the left shoulder in a patient on dialysis with aluminium intoxication.

Prophylaxis of secondary hyperparathyroidism

Rationale

Secondary hyperparathyroidism is the combined result of failing excretory function of the kidney (leading to phosphate excess) and failing endocrine function of the kidney (leading to calcitriol deficiency). Consequently, appropriate management requires that both abnormalities must be treated.

Phosphate control

It is usually recommended that phosphate-lowering interventions should begin once plasma phosphate concentrations exceed the upper limit of the normal range—1.45 mmol/l. This is usually the case when the creatinine clearance is approximately 30 ml/min, but the plasma phosphate concentration depends not only on renal clearance, but also on dietary phosphate intake, protein catabolism, and other confounding factors. The problem of phosphate retention persists when patients are on dialysis: the normal dietary intake of phosphate is 50 to 100 mmol/day, of which 50 to 70 per cent is absorbed in the intestine. This exceeds the amount of phosphate that is eliminated by conventional thrice-weekly haemodialysis (33 mmol per session, i.e. 100 mmol/week), such that an average daily positive phosphate balance of 30 mmol ensues.

The risk of precipitation of calcium phosphate is particularly high if hyperphosphataemia is accompanied by hypercalcaemia, reflected by the calcium × phosphate product (desirable range below 5.6 $mmol^2/l^2$, although the practical value of such calculation is limited).

Phosphate is present in virtually all foods, hence reduction of dietary intake is difficult without incurring the risk of malnutrition. Patients should be advised, however, to avoid items with very high phosphate content, for example dairy products and those to which phosphate is added, such as sausages and phosphate-rich soft drinks. A protein-restricted diet is often recommended to patients with renal insufficiency (although there is controversy regarding this, see Section 20.6) and one desirable consequence is that this diet reduces the dietary intake of phosphate.

However, since dietary restriction of phosphate is usually not feasible or sufficient, patients with uraemia remain in positive phosphate balance unless oral phosphate binders are administered. The agents most commonly used are calcium carbonate and calcium acetate: aluminium-containing substances have been widely used in the past, but because of the risk of aluminium intoxication (encephalopathy, osteopathy, anaemia, etc.) they should generally be avoided. These substances trap phosphate in the intestinal lumen by forming insoluble calcium phosphate complexes, hence it follows that they must be taken together with meals because phosphate in the food can only be precipitated within the intestinal lumen when phosphate binders are present. Furthermore, ingestion of calcium-containing phosphate binders without meals increases the risk of hypercalcaemia. If aluminium-containing phosphate binders are used (in cases where hypercalcaemia develops with calcium-containing phosphate binders), then plasma aluminium concentrations must be monitored at regular intervals (relatively safe range: below 60 µg/l). Phosphate binders without calcium or aluminium are currently under investigation.

If hyperphosphataemia does not respond to intervention, one should consider non-compliance, increased phosphate release from the skeleton (e.g. in marked osteitis fibrosa), or insufficient efficacy of dialysis.

Reversal of cholecalciferol deficiency

Deficiency of the parent compound cholecalciferol (vitamin D_3) is common among patients with renal failure as a result of altered lifestyle with insufficient sun exposure, hyperpigmentation of the skin, and loss of protein-bound vitamin D (metabolites) into proteinuric urine or peritoneal dialysis fluid. Vitamin D deficiency can be diagnosed when plasma 25-(OH)D_3 concentrations are low (< 50 nmol/l). In renal failure the synthesis of 1,25-(OH) $_2D_3$ depends on the concentration of the precursor substance 25-(OH)D_3, which explains why administration of 1000 U vitamin D per day (which is two to three times the average daily intake) leads to an increase of calcitriol and decrease of intact PTH (**iPTH**) in many patients with renal failure. Note, however, that treatment with pharmacological doses of native vitamin D is never appropriate in renal failure: these are much less effective than hydroxylated metabolites (see below) and, if they do raise the serum calcium concentration, carry a substantial risk of inducing prolonged hypercalcaemia.

Administration of active vitamin D

Although there is not complete consensus, most authorities advise that prophylactic administration of active vitamin D should be considered when 1,84-iPTH concentrations are elevated in early renal failure, or two- to threefold above the normal range in advanced renal failure despite measures to correct plasma phosphate and plasma calcium concentrations. In advanced chronic renal failure, or when patients are on dialysis, complete return of iPTH concentrations to normal is not desirable, because in patients with renal failure a normal bone turnover is found only if PTH concentrations are slightly above the normal range. It is currently unknown whether this reflects PTH resistance of the skeleton or insufficient specificity of the PTH assay, which also measures some inactive fragments of PTH.

It has emerged that relatively low doses of calcitriol or alternative active vitamin D preparations (e.g. 1-a-calcidol) are necessary to prevent the progressive increase of iPTH in patients with renal failure, for instance 0.125 or 0.25 µg 1,25-(OH) $_2D_3$ per day. The rationale for administration of 1,25-(OH) $_2D_3$ is not only the acute reversal of oversecretion of PTH, but also prevention of parathyroid hyperplasia. This is important because hyperplasia is at least partially irreversible. Administration of active vitamin D preparation is fraught with the risks of hypercalciuria, hypercalcaemia, and accelerated loss of renal function. However, monitoring urinary and plasma calcium can prevent this, and the risk is negligible with very low doses, that is, 0.125 µg/day of 1,25-(OH) $_2D_3$. 1-a-Hydroxy-cholecalciferol is a prodrug, which is hydroxylated in the liver *in vivo* to 1,25-$(OH)_2$vitamin D_3. Biotransformation may be abnormal if hepatic disease is present, but otherwise the two compounds yield comparable therapeutic results. Table 5 provides an algorithm for the prophylaxis of secondary hyperparathyroidism.

Selection of dialysate calcium concentration

Active intestinal calcium transport is impaired in uraemia, hence patients with renal failure without additional calcium intake are in negative calcium balance. On dialysis, calcium may be lost into the dialysate, indeed convective calcium loss is obligatory with ultrafiltration and may amount to up to 200 to 400 mg/week. Loss of calcium into the dialysate also occurs by diffusion if the plasma concentration of diffusible calcium is higher than the dialysate calcium concentration. In the past, a high dialysate calcium concentration of 7 mg/100 ml (1.75 mmol/l) was recommended, so that net uptake of calcium occurs during the dialysis session to compensate for convective loss of calcium via ultrafiltration during, and negative intestinal calcium between, dialysis sessions. If calcium-containing phosphate binders or active vitamin D preparations are administered, intestinal uptake of calcium is high and the patients may develop hypercalcaemia. Lowering of dialysate calcium concentration to 6 mg/100 ml (1.5 mmol/l) (temporarily even to 5 mg/100 ml or 1.25 mmol/l) counteracts this tendency. It is important, however, to verify that patients take their medication when low dialysis calcium concentrations have been selected. If calcium carbonate and/or active vitamin D preparations are not taken, there is a

definite risk that the calcium balance becomes negative and that secondary hyperparathyroidism is exacerbated.

Treatment of advanced hyperparathyroidism

Administration of active vitamin D

In the patient with advanced hyperparathyroidism (i.e. 1,84-iPTH above approximately 50 pmol/l or eightfold above the normal range), higher doses of active vitamin D are required. However, it is important to stress that active vitamin D must only be administered if hyperphosphataemia and hypercalcaemia are not present (or have been reversed) to prevent extra-osseous calcifications and further stimulation of the parathyroid gland in response to hyperphosphataemia, which is aggravated by administration of active vitamin D. Treatment should start with relatively modest doses, for instance 0.5 µg calcitriol per day. If this dose is tolerated without provoking hyperphosphataemia or hypercalcaemia, then it can be gradually increased until plasma 1,84-iPTH concentrations begin to fall. Several schedules of administration of active vitamin D are currently under discussion, but a complete consensus has not yet emerged.

Continuous compared with pulse administration

In experimental studies, continuous (daily) administration is less effective than intermittent (pulse) administration in lowering PTH concentration and preventing parathyroid hyperplasia. So far, there is no good clinical evidence that this effect is sufficiently marked to be of clinical importance.

Oral compared with intravenous administration

It can be shown that intravenous administration causes rapid lowering of 1,84-iPTH concentrations, but head-on comparisons of intravenous and oral administration have failed to show any superiority of the intravenous route.

Alternative vitamin D analogues

The major side-effects of treatment with active vitamin D are hypercalcaemia and hyperphosphataemia. There has therefore been an intense search for vitamin D analogues that suppress the parathyroid gland while having less hypercalcaemic and hyperphosphataemic potential. Several analogues are available (19-nor-1,25-dihydroxyvitamin D_2, namely Paricalcitol; 19-nor-22-oxa-1a,25-dihydroxyvitamin D_3, namely 22-oxacalcitriol), but so far there is no evidence that they are clinically better.

Calcimimetics

Calcimimetic substances—those that stimulate the calcium sensor—cause substantial acute and sustained decrease in the elevated PTH concentration of patients with moderate and advanced hyperparathyroidism. In experimental studies they also prevent further parathyroid hyperplasia, a finding of great importance because advanced parathyroid hyperplasia is irreversible (see below). There is currently only limited clinical experience, and concerns have been raised because the calcium receptor is expressed on numerous tissues other than the parathyroid gland. Anecdotal observations of long-term administration without side-effects in patients with parathyroid carcinoma raise the hope that these compounds will become an important ingredient in the management of the patient with renal failure.

Parathyroidectomy

It has recently been recognized that marked parathyroid hyperplasia is a process that bears many similarities to tumour growth. In patients whose estimated parathyroid mass exceeds 1 to 1.5 g, nodular hyperplasia is usually found. The nodules frequently exhibit monoclonal growth, with microsatellite analysis showing loss of heterozygosity for many alleles, including putative tumour suppressor genes. These nodules also express few vitamin D and calcium receptors, explaining the frequent lack of response to medical management. It appears that continuous stimulation of the parathyroid gland selectively favours cells with higher proliferative potential, so that the gland progressively escapes from growth inhibitory control mechanisms. This is illustrated by the fact that regrowth, including locally invasive regrowth, occurs in a high proportion (approximately one-third, or even more in studies with longer follow-up) of patients after subtotal parathyroidectomy or autotransplantation of parathyroid tissue.

There has recently been a tendency to consider parathyroidectomy early on if patients with marked elevation of 1,84-iPTH (above approximately 50 pmol/l) fail to respond to medical treatment within 4 to 8 weeks by decreasing their PTH concentration and have massive parathyroid enlargement on imaging procedures, with an estimated mass greater than 1 to 1.5 g.

An absolute indication for parathyroidectomy is calciphylaxis—ischaemic skin necrosis secondary to calcification of skin arteries; a relative indication is intractable pruritus associated with high PTH, or biomechanical problems that require urgent stabilization (e.g. rupture of the patella or epiphyseolysis in children with uraemia).

There is a long-standing debate as to whether total parathyroidectomy or subtotal parathyroidectomy (with a remnant left *in situ* or autotransplanted into the subcutaneous abdominal fat or forearm musculature) is preferable. Leaving parathyroid tissue behind is associated with a relatively high risk of recurrence, presumably because of the higher growth potential of the parathyroid. The risk can be reduced if only non-nodular parts of the gland are autotransplanted. As an alternative to surgery, alcohol injection into the enlarged parathyroids under ultrasonographic guidance has been tried successfully, but this procedure is not completely devoid of risk (paresis of the recurrent nerve).

Table 6 summarizes the approach to the management of patients with advanced renal secondary hyperparathyroidism, and Table 7 gives guidelines on how to interpret the common laboratory values used to diagnose abnormal calcium metabolism or follow therapeutic intervention.

Haemodialysis

Ken Farrington and Roger Greenwood

Introduction

The availability of effective renal replacement therapy has transformed the outlook for patients with chronic renal failure over the past 40 years, replacing certain and imminent death with the prospect of long-term survival. Growing numbers of patients worldwide are now dependent on regular dialysis treatment to sustain life, the escalating proportion of older and frailer patients being direct testimony to the durability and flexibility of the treatment. Inevitably this success needs qualification. First, the functions of the kidney are many and diverse and dialysis effects only partial replacement of a few of these, notably the excretion of nitrogenous waste products, and control of water, electrolyte, and acid–base balance. Second, although there is agreement about the general aims of dialysis treatment, to prolong life and prevent or reduce morbidity from the uraemic syndrome, consensus on the way to achieve these aims is still far off. There is still debate about what constitutes adequate dialysis and even about which parameters are appropriate. Third, although dialysis undoubtedly prolongs life in patients with endstage chronic renal failure, mortality still far exceeds that in the general population. This is mainly due to cardiovascular disease, which is endemic and runs an accelerated course in patients on dialysis, whatever the modality employed. This chapter outlines the scope of current practice in haemodialysis stressing those aspects most relevant to clinical management.

The development of haemodialysis

The pioneers

Although dialysis had been known since the mid-nineteenth century as a means of separating dissolved elements by diffusion through a semipermeable membrane, it was not until over 80 years later that haemodialysis was first used clinically to treat acute uraemia. The development of reliable means of vascular access in the 1960s (the Scribner silastic shunt and the Brescia–Cimino arteriovenous fistula) allowed its extension to maintenance treatment for patients with chronic renal failure and Pandora's box was open.

Expanding services

The initial rigid selection criteria for access to dialysis treatment soon bent under the combined strain of ethical concern and patient expectation, eventually giving way to more liberal policies. There were marked geographical variations, largely economically driven, in the rates of the subsequent expansion of dialysis programmes, as well as in the modalities employed and in the patterns of service provision (Fig. 1 and Fig. 2). Renal transplantation has had a limited impact on this expansion, having hit the ceiling of donor organ availability.

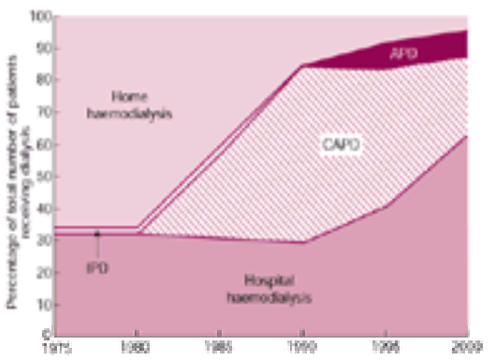

Fig. 1 Dialysis treatment modalities in the United Kingdom. Schematic representation of changes to treatment modality. IPD, intermittent peritoneal dialysis; CAPD, continuous ambulatory peritoneal dialysis; APD, automated peritoneal dialysis.

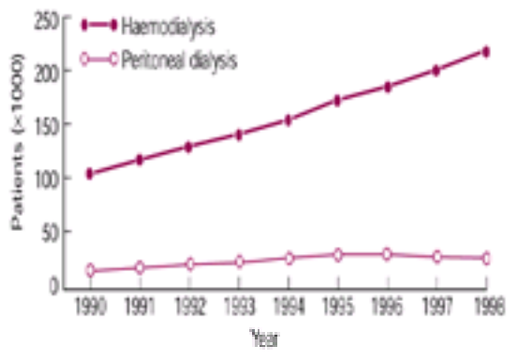

Fig. 2 Dialysis treatment modalities in the United States (United States Renal Data System (USRDS) data).

In the United States and most of Europe, haemodialysis was rapidly decentralized from the pioneering units but remained centre-based in hospitals and free-standing facilities in cities, towns, and rural areas. In the United Kingdom little decentralization occurred, with self-supervised home haemodialysis the chosen means of expansion and selection criteria remaining tight. During the 1980s continuous ambulatory peritoneal dialysis (CAPD) was seized upon as the means to liberalize access to treatment in the United Kingdom. It became the dominant dialysis mode, displacing centre-based haemodialysis to a rescue mode for those in whom CAPD was precluded or had failed. Elsewhere in Europe and in the United States centre-based haemodialysis remained the norm.

The impact of adequacy

Although patients continued to dialyse thrice weekly, there was a general trend to reduce dialysis times below 4 h. This first occurred in the United States as a mechanism to cope with constrained funding. 'Short dialysis' was held responsible for the excess mortality in American patients on haemodialysis during the 1980s, and inadvertently focused attention on the concept of dialysis adequacy, such that most units now prescribe and monitor dialysis dose by urea kinetic methods. Applying the same methods to CAPD, it became apparent that adequacy in this mode was critically dependent on residual renal function. Unless dialysate volumes are increased, adequacy is compromised, sometimes to the point of technique non-viability, when residual renal function has been lost. This has been a major factor in the steady relative decline in the United Kingdom CAPD population during the 1990s (Fig. 1), which has been more than offset by increased centre-based haemodialysis provision. The automated peritoneal dialysis (APD) programme has also grown but remains small. During the last decade, practice in the United Kingdom appears to be converging on United States and European norms.

Changing demographics

The mean age of the dialysis population has increased considerably over the last two decades and is now around 61 years. One-third of all new patients in the United Kingdom are over 70. The elderly, most of whom will not receive transplants, account for most of the increased acceptance and prevalence rates, which now exceed 90 and 300 patients per million population, respectively.

The proportion of patients with non-renal comorbidities, particularly cardiovascular disease, has increased dramatically. Multiple pathologies are common: about 15 per cent of patients on United Kingdom programmes are diabetic, and the United States figure is nearer 50 per cent (see section 20.6). Many such patients have widespread micro- and macrovascular complications at the time of dialysis initiation. These changes have placed increased demands on nephrological and other specialist resources.

Technical aspects

The principles of dialysis

Dialysis is a physicochemical process allowing separation of the components of a complex solution by solute exchange across a semipermeable membrane. Such membranes act as molecular size-selective filters, the size threshold depending on the nature of the membrane. In haemodialysis the membrane is interposed between the patient's bloodstream and a rinsing solution (dialysis fluid). Diffusive and convective mass transfer takes place across the membrane, allowing changes in the composition of body fluid compartments. The rate of diffusive solute transport is dependent on flow rates, concentration gradients, and membrane characteristics. Convection involves the bulk movement of solvent and dissolved solute across the membrane. The driving force is transmembrane hydrostatic pressure, which can be adjusted by application of variable negative pressure to the dialysate side of the membrane. Solute transport (by solvent drag) is independent of diffusion. In general, convection contributes little to the clearance of rapidly diffusible small solutes such as urea (molecular weight 60), but can make a major contribution to the clearance of larger, poorly diffusible molecules such as b $_2$-microglobulin (molecular weight 11 200), provided the membrane is porous to so-called 'middle' molecules. Convective movement of water from blood across the membrane is known as ultrafiltration.

Membranes and dialysers

The original haemodialysis membranes were fashioned from regenerated cellulose, but technology has since proliferated and there are now three classes of membrane, though there is much overlap (Table 1). Membranes are arranged and supported in devices called dialysers to form separate paths for blood and dialysis fluid flow, usually in a hollow-fibre design. Dialysers are classified by design type, membrane composition, surface area, and permeability characteristics defined in terms of dialyser clearance (K_d) for a range of solutes and ultrafiltration coefficient (K_{uf}), which is the water flux per unit of transmembrane pressure. In contrast to cuprophane, high-flux synthetic membranes are highly permeable (high K_{uf} and high K_d for middle molecules), remove b_2-microglobulin and other potentially toxic middle molecules, and tend to be more 'biocompatible', meaning that they cause less activation of inflammatory cells, the complement cascade, and contact pathways, and less cytokine production. High-flux membranes, when employed in countercurrent mode to maximize diffusion, permit 'back-filtration' of dialysis fluid into blood, hence use of ultrapure water to prepare dialysis fluid is mandatory. Many would argue that this improves biocompatibility and is highly desirable anyway. Synthetic membranes are expensive and dialyser reuse is still an economic necessity in most high-flux programmes.

Dialysis water and fluids

Patients on haemodialysis are intimately exposed to huge quantities of water (300 litres in a single week compared with a standard weekly exposure of 15 litres). The potential for poisoning by waterborne impurities is significant. Aluminium and chloramines are examples of proven toxins, which must be removed. Bacterial and endotoxin contamination can produce acute problems. Ultrapurity is crucial in high-flux modes in which dialysis fluid is passively (back-filtration) or actively (on-line haemodiafiltration) infused directly into the patient. A combination of purification techniques are employed that include filtration, activated carbon adsorption, ion-exchange resin perfusion, reverse osmosis, and ultraviolet irradiation. Regular monitoring ensures chemical and microbiological standards are maintained. Acid and bicarbonate concentrates are then mixed with treated water in a single-patient proportionating system to produce dialysis fluid of the desired composition (Table 2). Regulation of dialysis fluid composition is the main tool to achieve a return to normal of electrolyte and mineral content and acid–base balance in body fluid compartments. Although there is great potential for individualization, a programme-standard composition is typically adopted, which may be varied in particular circumstances.

The dialysis machine and the extracorporeal circulation

Dialysis machines control and monitor much of the haemodialysis process and have crucial fail-safe functions. In the standard extracorporeal circuit, arterial blood is withdrawn from the arteriovenous fistula via the 'A' needle by a peristaltic pump (Fig. 3), circulated through the dialyser, through a bubble trap, and returned 'downstream' into the fistula through the 'V' needle. Heparin is infused downstream from the blood pump. The venous pressure monitor (*P*v) protects against blood loss from the circuit to the environment and detects downstream obstruction to flow. The bubble-trap level detector protects against air embolus. The arterial pressure monitor (*P*a) protects the fistula by detecting excessive negative pressure. Fail-safe mode activates the venous clamp and switches off the blood pump.

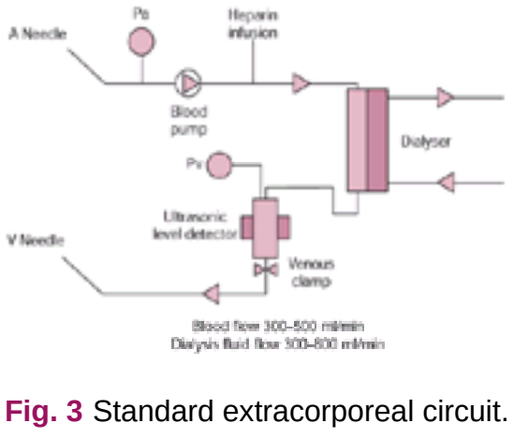

Fig. 3 Standard extracorporeal circuit. *P*a = arterial pressure detector, *P*v = venous pressure detector. A needle, arterial needle; V needle, venous needle.

Control of ultrafiltration

Modern dialysis machines utilize volumetric methods that permit precise control of ultrafiltration. A balancing system regulates dialysis fluid flow rates to and from the dialyser allowing for the removal of the required ultrafiltration volume, which is preset by the operator.

Anticoagulation

Routine anticoagulation with heparin, administered by intravenous bolus and subsequent infusion, is monitored by the whole-blood activated clotting time. Heparin-free dialysis, employing regular saline flushes of the circuit, is possible in high-risk patients. Prostacyclin is an expensive alternative.

Quantification and adequacy of dialysis

Predialysis blood urea and creatinine concentrations are poor indicators of dialysis adequacy. Low levels have been associated with increased mortality, suggesting that they are as (or more) likely to be due to reduced generation resulting from protein malnutrition and muscle wasting than due to increased clearance indicative of adequate dialysis. This was the lesson of the 1980s.

Urea kinetic modelling

The reanalysed data from the National Cooperative Dialysis Study (**NCDS**), still the only completed randomized study of the effect of haemodialysis dose on outcome, defined a new parameter of adequacy—the normalized urea clearance, *Kt*/*V*. This is a dimensionless parameter in which *K* is the urea clearance of the dialyser, *t* is the duration of dialysis in minutes, and *V* is the urea distribution volume, which approximates to total body water volume and is normally estimated from anthropomorphic data. The reanalysis showed that a *Kt*/*V* greater than 0.8 per dialysis was associated with good outcomes provided the patients were adequately nourished as defined by a normalized protein catabolic rate (**NPCR**) greater than 0.8 g/kg/day. NPCR can be calculated from urinary urea excretion in an interdialytic urine collection together with blood urea measurements taken at the start and finish of the collection (see equations in Appendix).

It is important to stress that the NCDS findings defined a minimum adequacy standard. The emerging view is that higher delivered *Kt*/*V*'s produce improved outcomes. It is not yet possible to say whether there is an upper threshold above which no further improvement is obtained. Current guidelines suggest a minimum target *Kt*/*V* of 1.2 to 1.3. The dose of dialysis prescribed can be adjusted to achieve the target *Kt*/*V* by changing the surface area of the membrane, blood flow rate, dialysis fluid flow rate (these influence urea clearance by the dialyser), and dialysis duration. This logic allows adequate dialysis to be delivered in a shorter time using larger dialysers and high flow rates (high-efficiency dialysis). It is important to have a means of monitoring the effectiveness of delivery of the prescribed dose.

Monitoring dialysis delivery using the urea reduction ratio

The simplest measurement of dialysis dose is the urea reduction ratio (**URR**), which is given by:

$$\mathrm{URR} = 100(1 - C_{post}/C_0)$$

where C_0 is the initial blood urea concentration, and C_{post} is the blood urea concentration in a blood sample taken immediately post-dialysis.

URR is a quality assurance tool, and cannot be used to prescribe dialysis dose. It takes no account of urea generation, ultrafiltration, or residual renal function, but does correlate with outcome testifying to its clinical utility. URR can also be converted to *Kt*/*V* (see Appendix).

Monitoring dialysis delivery using urea kinetic modelling

Assuming urea is distributed in a single pool within the body and that the effects of urea generation and ultrafiltration during dialysis are small, the blood urea concentration (C_t) at any time (t) during the dialysis is given by:

$$C_t = C_0 e^{-Kt/V}$$

Hence, the delivered dose of dialysis *Kt*/*V*, can be calculated from the expression:

$$Kt/V = \ln(C_0/C_{post})$$

The expression that corrects for urea generation and ultrafiltration during dialysis is more complex, and the single pool assumption is also an oversimplification. The rapid removal of urea (and other solutes) from the bloodstream during dialysis creates intercompartmental disequilibra. The intracellular concentration of urea exceeds the extracellular, and that in poorly perfused peripheral pools exceeds that in well-perfused body compartments. Urea exchange between these compartments continues after cessation of dialysis and causes a post-dialysis rebound of blood urea concentrations. This rebound can be substantial in high-efficiency treatments and can cause overestimation of *Kt*/*V* delivery by as much as 20 per cent, making the single pool assumption untenable in short high-efficiency treatments. There are a number of ways of dealing with this problem: the most straightforward is to delay the post-dialysis sample until rebound is complete (equilibrated post-dialysis sample), but this can be inconvenient (the patients want to leave the dialysis unit as soon as their treatment is completed). Much more complex is to model the system as two pools, requiring the assumption of a number of physiological parameters and iterative solution by computer. There are a number of less complex approximations, which are usually preferred and have been shown to produce equivalent results. The bottom line is that urea kinetic modelling can be used to prescribe the amount of dialysis necessary to attain the target *Kt*/*V*. The method has the flexibility to take account of residual renal function,

in which case the target *Kt*/*V* (total *Kt*/*V*) has dialysis ($K_d t/V$) and residual renal ($K_R t/V$) components.

Other approaches to adequacy

Urea clearance is the basis of most current methods of assessment of dialysis adequacy, in spite of the fact that urea transfer is not representative of the kinetics of most uraemic toxins. An alternative, the solute removal index (ratio of mass of solute removed by dialysis to the mass present at the start of dialysis) has a theoretical advantage over *Kt*/*V* in that it allows direct comparison of the adequacy of all treatment modalities. Larger molecules such as b $_2$-microglobulin are certainly toxic in dialysed patients but do not figure in our currently accepted notions of adequacy. Broader definitions are required. Urea kinetic modelling needs to be regarded as an essential component of a more global view of adequacy, which includes clinical as well as other laboratory data.

Initiation of dialysis

Blood urea and creatinine concentrations are poor indicators of dialysis adequacy and are subject to the same misinterpretation in the predialysis phase as endstage chronic renal failure is approached. This may lead to delay in dialysis initiation. The National Kidney Foundation Dialysis Outcomes Quality Initiative (**NKF-DOQI**) guidelines for dialysis initiation are thus based on urea kinetic modelling and suggest that dialysis should be started when weekly renal *Kt*/*V* is less than 2.0 unless the patient is asymptomatic, has a stable oedema-free body weight, and a normalized protein equivalent of urea nitrogen appearance (equivalent to NPCR) greater than 0.8. The guidelines have the benefit of aligning the approach to the assessment of severity of uraemia in predialysis and dialysis phases, but still lack a firm evidence base.

Incremental dialysis

This approach recognizes that the target total urea *Kt*/*V* has dialysis ($K_d t/V$) and residual renal ($K_R t/V$) components. As residual renal function declines during the first few years of dialysis, the dialysis component is gradually increased to ensure the target continues to be achieved. This allows a gentler initiation and maximizes the use of scarce resources. It does require regular estimates of residual renal function, and also assumes an equivalence of renal and dialyser clearance which holds for urea, but not necessarily for other solutes, or other renal functions. It is relevant that the viability of CAPD as a renal replacement modality also depends on this assumption.

Dry weight

Regulation of salt and water balance is one of the key functions of the kidney. Renal failure results in salt and water retention, which along with activation of the renin–angiotensin–aldosterone system, contributes to hypertension, left ventricular hypertrophy, and dilatation. These are potent causes of morbidity and mortality. 'Dry weight' is an important concept dating back to the early days of maintenance haemodialysis. It assumes that body weight at any time consists of two components: the dry weight or target weight, at which the patient's fluid compartments are normal in volume, and an excess weight consisting of surplus volume, which expands body fluid compartments and elevates blood pressure. The only way of defining dry weight is trial and error. The protocol requires cessation of antihypertensive agents and weight reduction during successive dialyses during the first few weeks or months after initiation. The dry weight is the point at which the patient is oedema free and below which hypotension occurs on further fluid removal. The implicit assumption is that patients on dialysis have normal cardiovascular responses, which may have been reasonable in the highly selected dialysis population of 1970 but is much less tenable in the older, sicker patients on dialysis today. Applying such principles, most of the early patients on dialysis became normotensive without the need for antihypertensive agents. In most current patients the target weight is likely to be the best achievable weight and hypertension is more likely. Shorter treatment times and less rigorous salt restriction have undoubtedly added to these difficulties.

Vascular access

The creation and maintenance of adequate, dependable, and robust vascular access is of vital importance to the continued well-being of patients on haemodialysis, and has rightly been referred to as their 'lifeline'.

Temporary access

For acute haemodialysis, temporary, non-cuffed, dual-lumen catheters can be inserted into femoral, internal jugular, or subclavian veins. The femoral route is simplest and preferred in the very sick patient, but the infection risk is high if femoral catheters are left *in situ* for more than a few days. Temporary catheters in other sites can remain for weeks, though use of the subclavian route risks stenosis of the vein and potentially compromises future permanent access in the ipsilateral arm.

Permanent access

Fashioning an arteriovenous fistula causes arterialization and expansion of the draining vein allowing its repeated puncturing for haemodialysis. A radiocephalic (Brescia–Cimino) fistula at the wrist is preferred, being less likely to produce distal limb ischaemia than proximal fistulas. Forearm vasculature is extremely vulnerable, especially when the patient is in hospital, and needs protecting in those destined for dialysis. Maturation of distal fistulas is slow, so these should be fashioned 3 to 6 months before planned initiation. It may be necessary to resort to other types of access including, in order of preference, an elbow brachiocephalic fistula, an arteriovenous graft composed of synthetic material (e.g. polytetrafluoroethene—PTFE), and cuffed tunnelled internal jugular venous catheters. Many patients still present late for dialysis and require primary central venous access by default. Tunnelled catheters are also required when other access options have been exhausted. Access failure is a significant cause of morbidity and mortality.

Recirculation

If there is a stenosis in the fistula severe enough to limit fistula blood flow to a level less than that demanded by the blood pump in the extracorporeal circulation, then blood returning from the dialyser to the fistula can be drawn directly from the 'V' needle to the 'A' needle and dialysed again. This is known as access recirculation, an effect that can also be produced by misplacement of fistula needles with the 'A' needle downstream to the 'V' needle. Also during dialysis a proportion of the blood returning through the 'V' needle will pass directly to the 'A' needle after passage through the heart and lungs without traversing a capillary bed to be 'replenished' with solute. This is known as cardiopulmonary recirculation and is an inevitable consequence of having a fistula as the access. The higher the blood pump speed the greater the degree of recirculation in all of these circumstances. Access recirculation is a major cause of underdelivery of prescribed dialysis dose, and unexplained reductions of monitored *Kt*/*V* or urea reduction ratios demand further investigation to exclude this. Significant recirculation (greater than 10 per cent), which can be detected and quantified by a variety of sampling and dilution methods (not described here), may require further investigation by Doppler ultrasonography or fistulography to define the lesion before attempting angioplastic or surgical correction.

Haemodialysis and related techniques

Conventional haemodialysis

'Conventional' refers to the use of low-flux cellulosic dialysers in standard circuits (Fig. 3). A decade ago the definition would also have included the use of acetate as buffer, but bicarbonate dialysis is now the norm.

High-flux haemodialysis

Concerns about the biocompatibility of cuprophane, and its poor clearance of middle molecules, especially b $_2$-microglobulin, have fuelled the increasing use of high-flux membranes, and concomitant investment in the use of ultrapure water for preparation of dialysis fluids.

Haemodiafiltration

Haemofiltration is a purely convective mode of treatment, which involves filtration of uraemic plasma and simultaneous infusion of replacement fluid. This greatly

improves middle molecule clearance. However, small molecule clearance is slow (Fig. 4), so the technique is not suitable for routine treatment of patients with chronic renal failure. It has, however, proved highly successful as a continuous treatment for patients with acute renal failure, particularly in the context of multiple organ failure in the intensive care unit (see Section 16). Adding a greater convective component (haemofiltration) to the diffusive and convective clearances offered by high-flux haemodialysis (a technique referred to as haemodiafiltration) allows the benefits of both these modalities to be maximized. The capacity to utilize dialysis fluid as the infusion fluid, made possible by use of ultrapure water in its preparation, means that the technique is economically viable (on-line haemodiafiltration, Fig. 5).

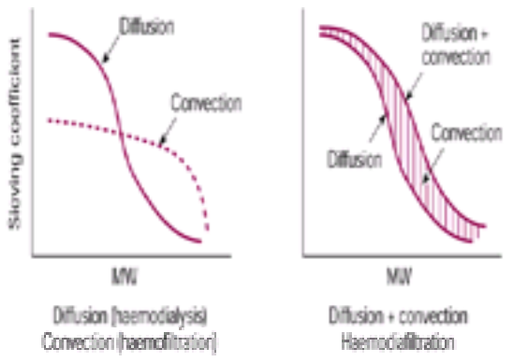

Fig. 4 Comparison of solute removal by diffusion and convection according to molecular weight. Convection has better 'middle molecule' clearance but much poorer clearance of small-molecular-weight solutes than diffusion. Haemodiafiltration combines the strengths of both techniques to broaden the spectrum of solute removal.

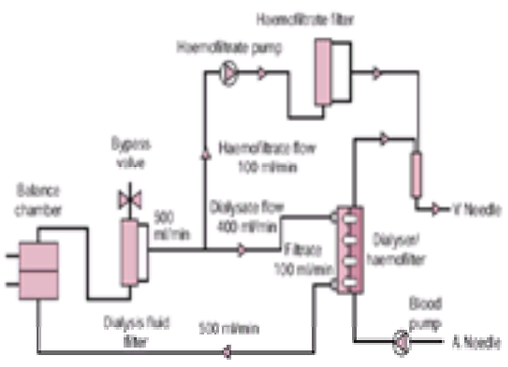

Fig. 5 Circuit for on-line haemodiafiltration. The haemofiltration replacement fluid is haemodialysis fluid pumped through an additional filter before infusion directly into the venous line. HDF, haemodiafiltrate. A needle, arterial needle; V needle, venous needle.

High-efficiency modalities

High-efficiency dialysers have high dialyser urea clearances and large surface areas. Dialysis treatments achieving high urea clearances (usually more than 200 ml/min) are referred to as high-efficiency treatments. Dialysis duration can be shortened by these means, often to below 3 h per session ('short dialysis').

High-efficiency and high-flux relate to different properties of dialysers and dialysis modes, which can be neither, either, or both.

Complications of haemodialysis

Acute complications

Hypotension

Symptomatic hypotension occurs in up to 30 per cent of dialysis sessions. Symptoms include nausea, vomiting, cramps, palpitations, dizziness, and syncope. The major cause is hypovolaemia, resulting from an imbalance between the rate of fluid removal from the circulation by ultrafiltration, and the rate of vascular refilling from the interstitium. Underlying cardiovascular disease, the use of antihypertensive drugs, autonomic dysfunction, and shortened dialysis times, increase the likelihood. The mainstays of management are careful assessment and reassessment of target weight, limited use of antihypertensive agents, reduction of interdialytic weight gain by fluid and sodium restriction, and reduction of ultrafiltration rate. Newer dialysis machines have the capacity to monitor relative blood volume and to profile the sodium concentration of dialysis fluid throughout the dialysis session. These techniques may be useful in particular situations, but neither is yet used routinely. Episodes of hypotension may occasionally have more sinister causes such as primary myocardial events and heparin-induced bleeding.

Disequilibration

The severest forms of disequilibration occur shortly after dialysis initiation (dialysis disequilibrium syndrome). The major predisposing factors are late presentation with severe uraemia and aggressive dialysis initiation with lengthy dialyses and high solute clearance rates. Restlessness, headache, tremors, fits, and coma can result. Dialysis should not be initiated in this way. Cerebral oedema due to fluid shifts induced by intercompartmental differences in urea concentrations and paradoxical cerebrospinal fluid acidosis are among the suggested causes. Post-dialysis headache is a common symptom in patients undergoing regular haemodialysis and may be a minor manifestation of disequilibrium.

Dialyser reactions

Anaphylactic (IgE-mediated) reactions occurring on first use of a dialyser are usually due to ethylene oxide sensitivity, which is used by manufacturers as a sterilizing agent. Reactions with reused dialysers are usually due to disinfectants, such as formaldehyde and peracetic acid, used in reprocessing. Bradykinin-mediated anaphylactoid reactions can occur in patients taking angiotensin-converting enzyme (ACE) inhibitors who are dialysed with polyacrylonitrile synthetic membranes (AN69). All the above occur within the first 20 min of treatment.

Pyrexias

Infected central lines are a potent cause of bacteraemia. Pyrogen reactions due to contaminated water became rare when rebuildable dialysers were replaced by disposable devices in the late 1970s.

Other complications

Use of modern fail-safe dialysis machines and ultrapure water systems has fortunately rendered a number of previously well-described complications exceedingly rare. These include air embolism, severe hypercalcaemia due to dialysis against hard water, and acute haemolysis.

Chronic complications

Hypertension and cardiovascular disease

There are many factors contributing to hypertension in patients on dialysis, including stimulation of the renin–angiotensin–aldosterone system and sympathetic overactivity, but the overriding factor is volume overload. Fluid status varies throughout the dialysis cycle and so does blood pressure. Just what constitutes hypertension in those on dialysis is not well defined, but in most units 60 per cent or more of the patients receive antihypertensive agents, although in other units this is less common. This may be explained by differences in definition and case mix, but other factors are undoubtedly important too, particularly the emphasis placed on the maintenance of optimum sodium balance and adequate ultrafiltration. In some units there may be a tendency to compromise, perhaps too soon, and use drugs, especially in patients with cardiovascular and other comorbidities, making dry weight even more difficult to achieve. Getting this right is crucial since hypertension is an important risk factor for cardiovascular disease, which is the major cause of the excess mortality in the dialysis population.

Volume overload, hypertension, anaemia, hyperparathyroidism, excessive fistula flow rates, and uraemia itself all predispose to left ventricular hypertrophy, which is an independent risk factor for mortality. Correction of anaemia can favourably influence the natural history of left ventricular hypertrophy in patients on dialysis, and early use of erythropoietin in the predialysis period may prevent it. Patients on dialysis also have a variety of lipid abnormalities, hyperhomocysteinaemia, increased oxidative stress, and elevated inflammatory markers, all of which may predispose to cardiovascular disease.

Anaemia

Erythropoietin deficiency is the major cause of anaemia in patients on haemodialysis. The introduction of recombinant erythropoietin in the early 1990s has redefined the uraemic syndrome, in the sense that many debilitating 'uraemic' symptoms can be remedied by successful treatment of anaemia (see Chapter 20.6.2 for further discussion).

A number of additional causes of anaemia may arise from the dialysis process itself. The most common is iron deficiency, which results from the repeated loss of small amounts of blood. Regular iron replacement, preferably given intravenously, is necessary since iron deficiency is a potent cause of resistance to exogenous erythropoietin. Deficiencies of other haematinics can occur, particularly in high-flux treatments and regular supplementation with vitamin B_{12} and folate is recommended. Mechanical and chloramine-induced haemolysis should not occur with modern techniques. There are other causes of erythropoietin resistance, the most potent being infection, often arising from central venous lines in this context, also severe hyperparathyroidism and underlying malignancy.

Bone disease

For discussion of renal bone disease, see Chapter 20.5.2.

Amyloidosis

Dialysis-related amyloidosis is a serious complication of chronic dialysis. The incidence increases with duration of haemodialysis and symptomatic involvement is almost universal after 15 years. Older patients are more susceptible. The syndrome manifests mainly as carpel tunnel syndrome and destructive arthropathy associated with bone cysts, but other organs can be involved. Deposits of amyloid, mainly composed of b_2-microglobulin fibrils, can be found at these and other sites. b_2-Microglobulin is an 11 200-Da protein that is part of the human class 1 major histocompatibility complex. It is 95 per cent eliminated by glomerular filtration, hence levels are elevated in renal failure. Low-flux membranes do not clear b_2-microglobulin but clearance occurs by a combination of convection and adsorption, using high-flux membranes. Elevated plasma levels are the major predisposing factor to amyloid deposition. Other factors may also be important, including modification of b_2-microglobulin by advanced glycation end-products and by oxidative and carbonyl stress. It is also possible that b_2-microglobulin or modified b_2-microglobulin is directly toxic to tissues. Use of high-flux synthetic membranes, especially in haemodiafiltration mode (Fig. 5), reduces plasma levels of b_2-microglobulin, although the level remains about tenfold higher than in those with normal renal function. High-flux dialysis and especially haemodiafiltration may prevent or delay the onset of symptomatic disease. Use of ultrapure water may also be protective. Treatment options are limited for established disease, but renal transplantation may enable slow resorption of deposits.

Patient management

Infection control

Strict adherence to universal precautions is necessary to minimize the risk of cross-infection by bloodborne viruses. Transmission from contaminated external surfaces, rather than through the dialyser membrane, is the major cross-infection threat. Screening of patients about to start dialysis for evidence of prior infection with hepatitis B and C is routine, and should be repeated at least 6 monthly thereafter. Patients negative for hepatitis B surface antigen should be vaccinated: positive patients should be segregated and use a dedicated machine. Patients positive for hepatitis C or HIV should be managed similarly.

Dialysis prescription and monitoring of dialysis delivery

There are a number of elements to the dialysis prescription that should be regularly and systematically reviewed. Target Kt/V is normally 1.2 to 1.3. Patients with intercurrent illness may require more. The value of K is obtained from data sheets from the dialyser manufacturer, taking into account membrane area, and blood and dialyser flow rates. The value of V is obtained empirically from age, sex, weight, and height. If the target Kt/V includes a component for residual renal function then residual urea clearance should be measured monthly and dialysis time readjusted accordingly. Dialysis delivery should be monitored monthly. Prescription and monitoring protocols are now often computer based. Inefficient delivery requires prompt investigation to exclude problems such as access recirculation. Membrane type and flux should be specified. Use of high-flux synthetic membranes is increasingly standard rather than targeted by evidence of amyloid deposition. Setting the dry weight allows the ultrafiltration requirement to be specified for each dialysis. Regular reassessment of dry weight is required, especially during intercurrent illness, when loss of flesh weight predisposes to covert fluid overload. The prescription should also refer to the heparin loading dose and maintenance infusion rate.

Control of hypertension

Predialysis blood pressure measurements may be misleading and cause overdiagnosis and overtreatment of hypertension. Measurements taken 20 min post-dialysis, allowing time for compartmental re-equilibration, are a better reflection of interdialytic ambulatory readings. Target levels have not been defined. We suggest targeting a 20-min post-dialysis reading of 135/85 in patients less than 65 years old. Drug therapy of hypertension is second-line treatment to be deployed after the achievement of optimal fluid status. No class of antihypertensive agent is contraindicated in dialysis patients, although the half-life of renally excreted drugs may be markedly prolonged and care is required with dosing schedules.

Access care and surveillance

Regular clinical examination of fistulas, serial measurement of static and dynamic venous pressures during dialysis, and monitoring of access flow rates by ultrasound dilution may enable access problems to be detected and corrected before the risks of underdialysis supervene.

Diet and nutrition

Malnutrition is common and is usually due to underdialysis. The early signs are subtle and often masked by fluid overload, which can compound the problem. There are no simple, fool-proof laboratory tests. Serum albumin reflects the presence of inflammation as much as it reflects malnutrition. Monitoring of NPCR (normalized protein catabolic rate) may be helpful but cannot replace regular dietetic review. When malnutrition is identified a range of oral nutritional supplements may be deployed. There is a limited role for intradialytic parenteral nutrition. Protein requirements in patients on haemodialysis are not well characterized but have been estimated at 1.2 g/kg ideal body weight/day, which is considerably greater than the non-uraemic requirement. Intakes greatly in excess of this may cause problems unless dialysis dose is correspondingly increased. There is no role for protein restriction. The energy requirement of a moderately active patient on haemodialysis is about 35 kcal/kg body weight/day, which is similar to that of normal subjects.

Attempts should be made to limit interdialytic fluid gains to 1 to 2 litres. This is difficult when residual renal function has been lost. The value of limiting sodium intake (40 to 80 mmol/day) to control thirst is often understated. Potassium restriction (to about 60 mmol/day) is usually required when residual renal function is minimal. The recommended intake of elemental calcium is 1 to 1.5 g/day. Achieving this is seldom difficult given the extensive use of calcium salts as phosphate binders. Phosphate restriction to about 0.8 g/day of elemental phosphorus may reduce the requirement for these agents. There is no consensus on the need to supplement water-soluble vitamins (B and C), but the practice is widespread. Vitamin B_{12} supplements are recommended in high-flux treatments.

Anaemia

Treatment with recombinant erythropoietin has become the mainstay of anaemia management, which is often nurse-led and protocol-driven. Uncertainties remain about the optimal target haemoglobin, recommendations varying between 10 and 12 g/dl. In the dialysis population the use of erythropoietin has unmasked a huge requirement for intravenous iron supplementation. Many patients have a state of absolute or functional iron deficiency, which is difficult to diagnose in those on dialysis. NKF-DOQI recommendations that serum ferritin levels less than 100 ng/ml and transferrin saturation less than 20 per cent are indicative of iron deficiency are reasonably sensitive when taken together, but poorly specific. Other parameters such as the percentage of hypochromic red cells and the reticulocyte haemoglobin content may be useful, but the best test appears to be the pragmatic one of response to intravenous iron. Oral iron is usually ineffective, probably because intestinal iron absorption—already low in endstage chronic renal failure—fails to respond to the stimulus of erythropoiesis, and is further suppressed by high tissue iron stores. Intravenous iron saccharate is used in moderate doses (such as 100 mg on each of 10 successive dialyses) to correct iron deficiency, and as maintenance treatment (such as 50 mg weekly) provided 3-monthly serum ferritin levels remain below about 800 ng/ml. (See Chapter 20.6.2 for further discussion of the use of erythropoietin.)

Bone disease

The goals of treatment are to maintain optimal bone structure and function and prevent metastatic calcification. The short-term surrogate is to maintain biochemical parameters in their target ranges. Serum calcium should be maintained in the normal range. The target range for phosphate is ill-defined and there is confusion about what is desirable and what is achievable. The product of calcium and phosphate (in mmol/l) should be less than 5. Serum parathyroid hormone (**PTH**) levels should be maintained at about two to three times the upper limit of normal. Calcium carbonate and calcium acetate are the phosphate binders in common use. Hypercalcaemia is a real risk. Sevelamer, a new polymeric phosphate binder that does not contan metal ions should be less toxic in this regard. Calcitriol and a-calcidol are used mainly to suppress PTH secretion. When used with calcium salts, the risks of hypercalcaemia are multiplied and careful monitoring is required. Pulsed therapy (usually thrice weekly on dialysis days) may improve the therapeutic ratio, but the benefits of intravenous administration have been overstated. Failure to control hyperparathyroidism still necessitates parathyroidectomy in significant numbers of patients. On the other hand, oversuppression of PTH levels should be avoided, being a risk factor for adynamic bone disease and enhanced metastatic calcification. (See Chapter 20.5.2 for further discussion.)

Other aspects

Selection and preparation of patients on dialysis for transplantation is a crucial aspect of care, which now usually includes rigorous assessment of cardiovascular fitness.

Cardiovascular risk factors such as smoking and lipid disorders should be addressed, and exercise encouraged, both during dialysis sessions and in general. Low-dose aspirin may be beneficial. Folate and vitamin B supplements may reduce elevated homocysteine levels. There is a high incidence of sexual dysfunction, especially in males: some may benefit from androgen replacement, sildenafil may be effective if not contraindicated, skilled counselling may be helpful.

Outcomes

Dialysis undoubtedly prolongs the life of patients with endstage chronic renal failure, but survival remains markedly inferior to that of age-matched peers with normal renal function. Cardiovascular disease is the main cause of death, followed by infection. Comparison of outcome in the different eras of dialysis is fraught with problems, largely because of the dramatic differences in case mix of patients entering programmes. Age, comorbidity, and functional status are independent predictors of morbidity (rate of admission to hospital) and mortality. Late presentation for dialysis has a profound effect on survival; late planned initiation may also have an effect, perhaps mediated through malnutrition; and we have previously alluded to the effects of dialysis adequacy and nutrition on outcome. The relationship between post-dialysis systolic blood pressure and mortality is 'U' shaped, as in the normal population, those with the lowest pressures faring poorly, probably due to coexisting heart failure.

It is difficult to compare the outcome of patients treated with haemodialysis and peritoneal dialysis in any meaningful way. Data from single centres, multicentre studies, and analysis of registry data do not show consistent differences in survival between these modalities. There are a number of confounding factors. Patients initiated on CAPD are younger, have less coexisting non-renal comorbidities, better functional status, and are less likely to have presented late. In addition, technique survival is poor in CAPD, and many patients require transfer to haemodialysis because of peritonitis, inadequate dialysis, or ultrafiltration failure. Haemodialysis can be regarded as the default mode of renal replacement therapy. Quality of life assessments are similar in both groups, but both are inferior to those obtained in patients with successful transplants. It is probably safe to conclude that, in the early years of therapy at least, morbidity and mortality are similar on both modalities if risk-stratified groups are compared.

There are few data to allow comparison of the outcome of conventional haemodialysis and more modern haemodialysis modes. Registry data suggests better survival with more biocompatible membranes, possibly related to enhanced clearance of larger solutes. Evidence is hardening that high-flux modes protect against the development of dialysis-associated amyloidosis.

The future

Haemodialysis is likely to remain centre based for the majority. Technical advances will allow treatments to become more tailored to the specific requirements of the individual. On-line dialysis quantification could guarantee the adequacy of each session. On-line blood volume monitoring coupled with algorithms to control ultrafiltration rate, dialysis fluid temperature, and sodium content, on a minute-to-minute basis, could prevent intradialytic hypotension and allow patients to finish dialysis at their optimal achievable weight. The encouraging results with daily dialysis suggest that this may emerge as a home, self-supervised modality, perhaps for a small proportion of younger, less dependent patients for whom transplantation or retransplantation is not an option. Vascular access will remain the Achilles' heel.

Appendix

$$\mathrm{NPCR} = 148.7(G/V + 0.17),$$

where G is the urea generation rate given by:

$$G/V = [C_{pre2}(V + w_g)/V - C_{post} + (V_u \times U_u)/V]/t_{id}$$

Where C_{pre2} = predialysis blood urea concentration before succeeding dialysis

w_g = interdialytic weight gain

V_u = volume of interdialytic urinary collection

U_u = urinary urea concentration

t_{id} = duration of intradialytic urine collection

$$Kt/V = -\ln(\text{URR} - 0.008t) + (4 - 3.5\text{URR}) \times (W_2 - W_1)/W_2$$

Where t = duration of dialysis

W_1 = predialysis weight

W_2 = post-dialysis weight

20.6.2 The treatment of endstage renal disease by peritoneal dialysis

Paul F. Williams

Introduction

Peritoneal dialysis has been an established treatment modality for acute and chronic renal failure since the early 1960s, but it was not until 1976 with the description of peritoneal equilibration dialysis (later to become known as 'continuous ambulatory peritoneal dialysis'— **CAPD**) by Popovich and Moncrieff that the technique was popularized. By the end of the twentieth century some 15 to 20 per cent of all chronic dialysis patients worldwide were being treated with either CAPD or automated peritoneal dialysis (**APD**). Peritoneal dialysis plays an important role in the integrated care of the patient with endstage renal disease along with haemodialysis and renal transplantation.

Practical aspects of peritoneal dialysis

The process of peritoneal dialysis involves the instillation of dialysis fluid into the peritoneal cavity via a dialysis catheter, thereby allowing the fluid to come into contact with the uraemic blood in the patient's peritoneal capillaries. Dialysis takes place through the diffusion of uraemic toxins down a concentration gradient from capillary blood to dialysis fluid, with fluid removal from the circulation being achieved by varying the concentrations of osmotic agents (usually glucose) in the dialysis fluid. Once the uraemic toxins in the patient's blood have equilibrated with the dialysis fluid then this can be drained out and replaced manually (CAPD) or by machine (APD).

Peritoneal dialysis solutions

The most commonly used dialysis solutions today contain varying concentrations of glucose as the osmotic agent, along with a balanced electrolyte solution using lactate as a buffer to correct uraemic acidosis. Although these solutions have been in widespread use for many years they are recognized to have a number of disadvantages, including low pH and hyperosmolality, which depends on the glucose concentration. These make the dialysis fluids relatively bioincompatible and may be responsible for long-term membrane damage with mesothelial cell loss and glycation of the membrane. A variety of new peritoneal dialysis solutions have been introduced in recent years in an attempt to improve biocompatibility, membrane viability, fluid removal, and malnutrition. These include: (1) solutions using a bicarbonate/lactate mixture instead of lactate alone as the buffer; (2) a glucose polymer-based fluid that allows reduced membrane exposure to glucose and allows slow prolonged ultrafiltration to take place; and (3) an amino acid-based solution which may help to correct hypoalbuminaemia and malnutrition.

Peritoneal dialysis catheters

Access to the peritoneal cavity can be achieved on a semipermanent basis using a silastic Tenckhoff catheter. A variety of modifications on the basic design exist but none has conclusively been shown to be superior. The intraperitoneal portion of the catheter can be straight or coiled and has side and end holes; the subcutaneous portion provides anchorage and a barrier against infection by means of tissue ingrowth into two Dacron cuffs, one placed preperitoneally in the rectus sheath and one subcutaneously.

Insertion techniques also vary: the catheters may be placed percutaneously via a trochar and cannula, via a laparoscope, or with a formal mini-laparotomy. The success or otherwise of the insertion procedure seems to depend on the skill and experience of the operator rather than any intrinsic advantage for one method of insertion, although a formal surgical procedure is warranted in the presence of significant obesity or suspected adhesions after previous surgical operations. Depending on the urgency of starting dialysis, the insertion technique, and local practice, a variable amount of time is usually allowed to elapse prior to starting peritoneal dialysis to allow satisfactory wound healing to take place. The catheters may remain *in situ* for many years if needed, the main reasons for removal being infection, transfer to haemodialysis, or successful renal transplantation.

Peritoneal membrane function

The transport of small molecular weight uraemic toxins across the peritoneal capillary membrane is governed by its permeability to such solutes. This can be assessed by means of the Peritoneal Equilibration Test (PET) introduced by Twardowski. Instilling a 2.27 per cent glucose-based dialysis solution into the peritoneal cavity and taking samples of blood and dialysate for glucose and creatinine measurements over a 4-h period enables the membrane transport characteristics to be classified as low, low-average, high-average, or high with respect to glucose and creatinine concentrations. A high-transporter status will enable rapid equilibration of urea and creatinine, thus enabling adequate solute removal, but the increased membrane permeability prevents the maintenance of the glucose gradient that is essential for adequate fluid removal. Thus patients will achieve satisfactory small-solute clearance, but may have problems with adequate fluid removal. In a similar fashion, patients with a low-transporter membrane will sustain an adequate glucose gradient and achieve adequate ultrafiltration, but poor equilibration of urea and creatinine will leave them at risk of underdialysis. Knowledge of a patient's membrane function soon after starting dialysis can therefore aid in the rational prescription of peritoneal dialysis and may also have prognostic importance, particularly in large patients with declining residual renal function.

Prescription of peritoneal dialysis

CAPD

In the early years of CAPD many patients received so-called standard peritoneal dialysis prescriptions—4 × 1.5- or 2.0-litre exchanges per day—with little or no regard for body weight, membrane function, or level of residual renal function. With increasing experience worldwide and recognition of the need to attain small-solute clearance targets for maximum patient well being and survival, it has become obligatory to provide an individualized dialysis prescription for each patient.

When patients first begin peritoneal dialysis the great majority will have some degree of residual renal function, which may provide some 25 to 30 per cent of the required small-solute clearance. Under these circumstances most will achieve adequate dialysis with standard CAPD or APD prescriptions. Once residual renal function has been lost after 2 to 3 years on dialysis, then it becomes increasingly important to individualize the patients' prescription to enable adequate dialysis to be delivered. In general, patients who have low-transporter membranes will require high-volume exchanges on CAPD to achieve adequate small-solute clearance. As they still maintain adequate glucose gradients they still have adequate ultrafiltration. Patients with high-transporter membranes will often still achieve adequate

small-solute removal, but they will be unable to obtain adequate ultrafiltration to keep them oedema-free unless short frequent exchanges are used. Under these circumstances, if patients do not achieve adequate dialysis in terms of small-solute clearance and ultrafiltration with the above prescription modification, transfer to haemodialysis may be required.

Table 1 summarizes the problems seen with high body-weight anuric patients.

APD

APD makes use of a machine to drain and fill the abdomen with dialysis fluid overnight, usually leaving the patient relatively free from the need to perform any dialysis-related activities during the day. The modality of APD may therefore be particularly suitable for certain groups of patients at the beginning of dialysis, for example the young, or those still at school or work. The increased quality of life achievable with APD is an added benefit in these patient groups, which is partly the reason why APD is the fastest growing renal replacement modality worldwide.

When a patient starts on APD as an initial dialysis modality, the presence of significant residual function may allow the use of relatively low dialysate volumes. However, as the patient's residual renal function declines then the need to reach small-solute and salt and water-removal targets will require the use of larger fill volumes, with the length of overnight dwells matched to peritoneal membrane function. At the other end of the spectrum, APD can also be used to prolong a patient's time on peritoneal dialysis when it is used as a salvage therapy for those no longer adequately dialysed on CAPD. But in some patients with membrane failure or some other reason for inadequate dialysis, then elective transfer to haemodialysis is the appropriate course of action.

Outpatient monitoring of the patient on peritoneal dialysis

Once the patient and their family have been trained to perform peritoneal dialysis in the community, then outpatient review need not be that frequent—perhaps monthly initially, and as time passes and confidence increases the intervals between outpatient visits can be increased up to once every 2 to 3 months. At each clinic visit the patient should be assessed by the nephrologist, dialysis nurse, and dietician, with the aim of ensuring that they are compliant with the dialysis regime and adhering to dietary and fluid balance recommendations.

Adequacy of dialysis

As mentioned previously, the need for individualized dialysis prescriptions is paramount. The CANUSA study, and others, have documented the links between adequacy of dialysis, in terms of small-solute clearances, and patient survival, Hence, it is important to monitor the urea and creatinine clearances achieved by the combination of dialysis and residual renal function on a regular basis—at least yearly. If the clearances fall below recommended targets then changes in the dialysis prescription may be needed to keep the patient healthy. Table 2 shows the targets recommended for urea clearance (*K*t/v urea) and creatinine clearance (Cr Cl) per week.

Nutrition

Malnutrition is a common problem in dialysis patients and may be seen in up to 30 per cent of those on peritoneal dialysis. This may be due to appetite suppression caused by glucose absorption from the dialysate, the presence of dialysis fluid in the abdomen, uraemia secondary to underdialysis, or peritoneal protein losses. If the patient is unable to maintain an adequate protein (1–1.2 g/kg body weight per day) and calorie (30–35 kCal (125–146 joules)/kg body weight per day) intake then malnutrition and hypoproteinaemia will develop with increased risk of death. Dietary advice from an experienced dietician is invaluable under these circumstances.

Cardiovascular status

Up to 50 per cent of all deaths in patients on peritoneal dialysis will be from cardiovascular causes, and therefore attention to the control of risk factors may be of benefit. It is important to encourage patients to stop smoking, take exercise, and to control fluid overload and hypertension by a combination of fluid restriction, fluid removal by dialysis, and the use of antihypertensive drugs where appropriate. Control of hyperlipidaemia by diet and drug therapy is also indicated.

Anaemia

The anaemia of renal failure is readily treatable with recombinant erythropoietin and, providing iron stores are kept at adequate levels, it should be possible to keep the majority of patients at or above target haemoglobin levels. This will improve the quality of life, improve exercise tolerance, and may also reduce cardiovascular mortality.

Infective complications

Exit site infections

Bacterial infection around the catheter exit site is a frequent occurrence, which, if neglected or inadequately treated, may lead to peritonitis and/or the need for catheter removal. The majority of these infections are caused by Gram-positive organisms such as *Staphylococcus aureus* and *S. epidermidis*, with occasional episodes being caused by Gram-negative organisms, for example *Pseudomonas* spp.

Meticulous exit site care, with attention to catheter immobilization locally and regular cleaning of the exit site with antiseptics, may diminish the frequency of such infections. Local application of the antibacterial agent mupirocin on a regular basis may also help eradicate *S. aureus* carriage and consequent infections. However, once erythema, purulent discharge, and pain develop, then broad-spectrum antibiotic therapy is indicated. If this is not successful in eradicating catheter sepsis then it may be necessary to replace the catheter.

Peritonitis

Peritonitis remains the major infective complication of peritoneal dialysis, and either acute or repeated episodes of peritonitis are a common cause of transfer from peritoneal dialysis to haemodialysis.

Common causative organisms include *S. aureus*, *S. epidermidis*, coliforms including *Pseudomonas* spp., and, rarely, fungal organisms. The diagnosis of peritonitis is usually straightforward, being based on the presence of cloudy dialysate fluid with or without abdominal pain. Treatment should be initiated on clinical suspicion, before laboratory culture results are available, and should cover both Gram-positive and Gram-negative organisms. Recommended regimes include intraperitoneal cefazolin or vancomycin (to give Gram-positive cover) with an intraperitoneal aminoglycoside or oral quinolone such as ciprofloxacin (to give Gram-negative cover), with subsequent modification of therapy depending on the culture results. The use of vancomycin has declined over recent years because of worries concerning the development of resistant organisms.

The frequency of episodes of peritonitis in patients on peritoneal dialysis has been falling with increasing experience and technological advances, including the use of disconnect systems and APD machines. It should be possible to reduce the frequency of peritonitis to one episode every 2-patient years or better. If peritonitis does develop then the cure rate without removing the dialysis catheter should exceed 85 per cent, and the majority of patients should be able to continue with peritoneal dialysis after the episode has resolved, unless it was caused by bowel perforation or a fungal peritonitis. A successful continuation of peritoneal dialysis is unlikely in both circumstances.

Transplantation

Patients who are established on peritoneal dialysis may be transplanted safely, and there is evidence that they have a lower incidence of delayed graft function and early rejection. The peritoneal dialysis catheter may be used after transplantation if dialysis is required, provided that the peritoneum has not been breached. It is

usually removed electively some 2 or 3 months later, when the risk of graft failure has diminished.

Survival data

Studies over the years comparing both technique and survival in patients on haemodialysis and peritoneal dialysis have produced conflicting results. In the absence of a randomized controlled trial the differences in the case mix of patients on the two modalities makes interpretation of the data difficult. It seems likely that providing attention is given to monitoring and adjusting dialysis therapy as residual renal function falls, then the two therapies are equivalent and most patients should be allowed to choose the modality that suits them best. There is some evidence that peritoneal dialysis is the more suitable first modality as residual renal function is better preserved with this technique, but once this advantage is lost after 3 to 5 years then patients are more likely to require haemodialysis as a long-term treatment.

The two techniques should be seen as complementary and both should be available to the patient waiting for renal transplantation. The fact that worldwide peritoneal dialysis varies from less than 5 per cent to more than 60 per cent, with a world average of around 15 per cent, probably reflects factors other than patient selection.

Summary

Peritoneal dialysis has been a well-recognized mode of therapy for endstage renal disease since the mid-1970s. Approximately 15 per cent of the world's dialysis population are currently kept alive and healthy by this technique. Patient survival in the short to medium term with peritoneal dialysis is equivalent to that seen with haemodialysis. In the past, the main complications of peritoneal dialysis have been peritonitis, inadequate dialysis, malnutrition, membrane failure, and patient 'burn-out'. With increasing experience, individualized dialysis prescription, and technological advances including new solutions and improved automated peritoneal dialysis machines, the frequency of these complications is diminishing. Peritoneal dialysis should be seen as part of an integrated care package for patients with endstage renal disease, indeed—there being no significant difference between haemodialysis and peritoneal dialysis—the patient should be encouraged to choose the dialysis technique that fits best with their lifestyle. There may be advantages in starting dialysis with peritoneal dialysis and then, as residual renal function declines, moving to haemodialysis while waiting for a renal transplant to become available.

20.6.3 Renal transplantation

P. Sweny

Introduction

Renal transplantation is the preferred option for the treatment of endstage chronic renal failure in patients for whom there are no major medical contraindications. With improvements in immunosuppression and in the equally important general medical support of the immunocompromised patient, the age ranges and permissible comorbidities continue to be extended. In well-selected recipients, both life expectancy and quality of life are superior to long-term dialysis. The two impediments to the extension of transplantation are the shortage of donor organs and the side-effects of the still crude immunosuppressive agents. Xenotransplantation may remove the first of these hurdles, but is likely to increase our dependence on potent immunosuppressive regimes. In humans, immunological tolerance to the graft with preservation of normal immunoresponsiveness to infections and tumours has not yet been achieved.

Supply, demand, and kidney donation

At the beginning of the year 2000 there were approximately 5000 patients waiting for renal transplantation in the United Kingdom. The annual rate of renal transplantation in the United Kingdom is approximately 1300 per year or 24 per million of the population per year and has not altered greatly over the last 5 years. The dialysis population, however, is increasing by 7 to 10 per cent per annum. In most countries the maximum achievable number of cadaver donors is about 35 per million per year against a need of 50 per million per year. The shortage of cadaver donors has been attributed to three main factors: a decline in deaths from road traffic accidents and cerebral haemorrhage, and inadequate numbers of intensive care unit beds. In the United Kingdom living donation represents only 10 to 15 per cent of all transplants (3 to 5 donors per million of the population), whereas in Scandinavia 10 live donors per million of the population has been achieved.

There are currently three possible sources of donor organs for transplantation: cadaveric, living related, and the living unrelated donor. In most countries the last group is restricted to donors that are closely 'emotionally related', for example spouses and partners. Two factors sustain our continued reliance on living donation as a source of kidneys: the first is the shortfall in available cadaver donors, and the second is the superior survival of a well-matched graft from a living related donor. The continuing need for an adequate supply of cadaver organs for transplantation requires an equally continuing education of both the medical and general population. Acceptance of the brainstem death criteria (see Chapter 16.6.3) in many countries has helped greatly in establishing a secure definition of death for both legal and religious purposes. However, given the continuing shortage of organs, many centres are re-exploring the possibility of the rapid procurement of organs for transplantation from non-heart-beating cadavers.

Living donors

Every care must be taken to protect the interests of the donor. Informed consent is crucial. Potential donors must be aware that giving a kidney carries risks, albeit that the mortality rate is only 0.01 to 0.03 per cent, with most deaths attributable to acute pulmonary embolus. The other risks that are involved in a general anaesthetic and an abdominal operation must also be fully explained. Needless to say, the donor should be in good general physical health and have normal kidney function and surgically acceptable renal anatomy. The assessments required are summarized in Table 1. Apart from exceptional circumstances, donors outside the age limits of 18 to 70 years are not considered. It is usual to wait for a young female potential donor to complete her family.

Most studies have shown an increase in life expectancy of donors when compared with age-matched controls. A small proportion of donors will develop hypertension, but at a risk that is similar to that of the general population. A small number develop proteinuria, but this is usually less than 0.5 g per 24 h and does not affect survival. Renal function usually returns to 75 to 80 per cent of the predonation level.

The superior outcome of living related donor kidney transplantation is partly due to better matching, with donor and recipient sharing one or two extended haplotypes in almost all cases. An additional benefit, shared also by kidneys from living unrelated donors, is the physiological state of the organ when recovered under ideal and planned conditions. Rejection is more likely and more severe with cadaver donors: this may be due to the 'cytokine storm' that accompanies the agonal phase of death and ischaemia reperfusion injury. This is thought to increase the expression of HLA antigens and adhesion molecules in the donor organ, making it more visible to the recipient's immune system.

Cadaver donors

In this situation the prime responsibility is to the potential recipient. The kidney should be in as good a physiological state as possible, and there should be no obvious risk of transfer of infection or malignancy by the donor organ. The major contraindications to organ procurement are listed in Table 2. Marginal donors are increasingly being considered, particularly for older recipients and for those with a limited life expectancy. In some situations it may be appropriate to consider organs from hepatitis C (**HCV**)-positive or hepatitis B (**HBV**)-positive donors for positive recipients. Experience in parts of the world where safe long-term dialysis is not available have shown that an acceptable quality of life can be sustained with substandard kidneys, and—given the shortage of organs—marginal donors should not be discarded out of hand without discussion with the local transplant unit.

Recipient assessment

Patients may be transplanted before the need for dialysis (pre-emptive transplantation) or from an established dialysis programme (haemodialysis or peritoneal dialysis). It is essential that all patients are fully assessed by both a transplant surgeon and transplant physician before being placed on the waiting list or offered a kidney, whether it be from a cadaver or a relative. Patients with chronic renal failure develop a multitude of complications that need assessment prior to surgery. Transplantation carries with it the risks of any major surgical procedure together with the added risks of prolonged immunosuppression. An additional consideration is that given the shortage of organs for transplantation, it is important that the best use is made of all organs. Whilst all would agree with this in principle, making decisions in individual cases can be difficult. In some situations the general health and life expectancy of the potential recipient argue strongly against transplantation. In patients with viral hepatitis or cirrhosis there is increasing evidence, particularly for HBV-related disease, that survival will be longer on dialysis. Patients with congenitally abnormal lower urinary tracts can be difficult to transplant and ideally should be managed in centres with urological transplant expertise, some needing complex bladder augmentation or drainage procedures prior to transplantation.

Allocation of kidneys

Fully matched kidneys (zero A, zero B, and zero DR mismatch—denoted 0–0–0 mismatch) and DR identical kidneys do better than less well-matched organs, hence most countries have local or national kidney sharing schemes so that more recipients can receive the benefits of a well-matched organ. Use is increasingly being made of point scoring systems to allocate kidneys fairly, patients accruing points based on the degree of match as well as the length of time they have been waiting for a transplant.

Surgical technique

The new kidney is placed in one or other iliac fossa, usually in an extraperitoneal position that allows ease of repeated biopsy to detect the cause of graft dysfunction. The renal artery is anastomosed end to side to the common iliac artery or end to end to the internal iliac artery. The renal vein is usually anastomosed to the common iliac vein. The transplant ureter only has a short distance to run before it can be implanted into the bladder, which is usually done through a submucosal tunnel to reduce the chances of reflux of urine from the bladder into the transplant. Some surgeons routinely place a vesicoureteric stent to reduce the risks of urine leakage and to promote healing. A drain is usually placed near the renal hilum. Lymphatics in the perihilar region are tied off. A urethral catheter and/or suprapubic bladder catheter is inserted and left *in situ* for about 5 days. The ureteric stent is removed at cystoscopy after a few weeks. Most units use prophylactic heparin routinely.

Note that in the standard renal transplant operation described above the native kidneys are left *in situ*. In some patients one or both may need to be removed (at a separate operation) before the patient can be listed for transplantation: mandatory indications for this include suspicion of renal tumour (usually in those with cystic disease), chronic renal infection, and massive organomegally, when there is literally no space in which to put a new kidney (in patients with adult polycystic kidney disease). Some would also advocate nephrectomy (Table 3) as a prelude to transplantation in those with gross ureteric reflux, renal stone disease, or analgesic nephropathy.

Retransplantation is increasingly being undertaken as the general medical care of patients with renal failure has improved. Second transplants are now not uncommon, and even third and fourth transplants may be occasionally undertaken. Third and fourth transplants are more surgically demanding as vessels available for anastomosis become limited. Aortic and venocaval anastomoses can be performed.

Ischaemia times

Warm ischaemia is defined as the time between circulatory arrest and renal artery cannulation for ice-cold perfusion, together with the time between the removal of the kidney from ice and release of the vascular clamps at implantation. With the beating heart donor, the first component is zero. The maximum permissible warm ischaemia time before irreversable damage occurs is 60 min.

Cold ischaemia time (preservation time) is defined as the time between ice-cold perfusion of the kidney and removal from the ice at the start of the implantation operation. Cold ischaemia times of up to 96 h have resulted in functioning grafts, but times in excess of 30 h are associated with a less favourable outcome. The permissible cold ischaemia time of 30 h allows for organ sharing and equitable operating times for the surgical team.

Postoperative management

Excepting for transplants between identical twins, immunosuppression is required to allow transplantation. The first dose of this is often given pre- or intraoperatively. Details are discussed below.

Following implantation, the function of the new kidney is assiduously monitored. Most units give low-dose dopamine, mannitol, or a loop diuretic, singly or in combination, to ensure good urine flow rate on return from theatre. Hourly urine volumes are closely monitored for the first few days. Fluid balance is usually maintained by a prescription that requires 100 per cent replacement of urine volumes and drain losses with crystalloid, and central venous pressure is monitored and maintained in the high normal range (+10 cmH_2O) with blood or colloid.

Serum creatinine is measured daily. A failure to fall rapidly, or a 15 per cent rise once it has fallen to a plateau, is evidence of graft dysfunction and requires prompt investigations. A kidney that fails to function initially, despite good perfusion on the table when the vascular clamps were removed, is usually suffering from acute tubular necrosis, which is expected to recover. A sudden cessation of urine flow usually means a surgical problem, for example clot obstruction, urinary leak, or vascular catastrophe. A slow tailing-off of the urinary volumes is more suggestive of rejection, hypovolaemia, or developing drug nephrotoxicity. Two of the major immuno-suppressive agents, cyclosporin A and tacrolimus, are nephrotoxic: doses have to be carefully adjusted to maintain the therapeutic range. Blood pressure should be returned to normal, obstruction excluded, and coagulation checked before a biopsy is undertaken. Close and careful monitoring needs to continue for the first 6 months following transplantation as the risk of rejection is at its greatest during this period.

One of the 'holy grails' of transplant medicine is a method of determining the immunological relationship between the recipient and their transplanted organ, since this would allow tailoring of immunosuppression to immunological need. However, immunological monitoring of transplant recipients is still in its infancy: lympocyte T- and B-cell subsets and activation markers can be of value, particularly when antilymphocyte preparations are being used; serial estimation of post-transplant anti-HLA antibodies can help predict patients at risk of chronic rejection. Much work continues to look for better ways of monitoring patients, such as testing for cytokine gene polymorphisms to predict those at highest risk of rejection, and examination of graft biopsies for expression of adhesion molecules, HLA, cytokines, and enzymes (e.g. granzyme, perforin) to characterize better the rejection process. Protocol biopsies may demonstrate subclinical rejection, and some argue that treatment of these may improve outcome, but most units are not convinced and do not perform 'routine' biopsies.

Complications of renal transplantation

Surgical

Table 4 summarizes the main surgical complications, which include those of any general anaesthetic and laparotomy. Extra risk is added because patients on dialysis are immunosuppressed by uraemia *per se* and transplant patients also require immunosuppressive drugs following surgery. Wound healing is significantly delayed in

the early post-transplant period, particularly by steroids. Some patients on dialysis will have a marked bleeding tendency related to defective platelet–endothelial cell interaction. The combination of uraemia, surgical stress, a bleeding tendency, and high-dose steroids produces an increased risk of bleeding peptic ulceration, which the routine use of H_2-blockers has virtually abolished. Many donor organs have small polar arteries that can be lost during or shortly after surgery, in which case the resulting segment of kidney will atrophy. Occasionally a polar infarct can lead to necrosis of a significant segment of renal cortex causing a calyceal fistula and urinary leak. An area of ischaemia around a polar infarct may drive post-transplant hypertension. Perirenal collections of fluid (whether from inadequately tied-off perihilar lymphatics, haemorrhage, or a urinary leak) can become infected: these are best demonstrated by ultrasound, which can guide aspiration for culture and drainage.

Rejection

Rejection can be classified into four main categories (Table 5). These are not mutually exclusive and there is overlap in the pathological processes.

Hyperacute rejection

In the presence of preformed cytotoxic antibodies the new graft infarcts within minutes of insertion. This can occur if transplantation is attempted across ABO incompatibilities. It is a rare event as the lymphocyte crossmatch usually identifies pre-existing anti-HLA antibodies. Transplantation is not undertaken in the presence of a positive lymphocyte crossmatch, but hyperacute rejection can rarely occur in the presence of non-HLA cytotoxic antibodies. There is no treatment save nephrectomy.

Accelerated rejection

A fierce, predominantly T-cell mediated rejection crisis may occur within the first few days of transplantation. This is thought to be due to sensitization of the recipient by a previous pregnancy, blood transfusion, or a failed transplant. Patients present clinically with fever, an acutely swollen tender graft, and a rapidly rising serum creatinine. Salvage usually requires the combination of high-dose intravenous pulse methylprednisolone (10 to 15 mg/kg per day infused over 30 min on 3 successive days) and an antilymphocyte antibody such as antithymocyte (ATG) or antilymphocyte globulin (ALG). The murine monoclonal antibody OKT3 may also be used. It is unusual to be able to reverse fully this type of severe rejection and long-term graft survival is compromised

Acute cellular rejection

In most centres about 25 per cent of patients will experience an acute cellular rejection, usually occurring between days 7 to 21 but up to 3 months following transplantation. Acute cellular rejection is often clinically silent as the inflammatory component of the rejection is masked by immunosuppression. Fluid retention, increasing hypertension, and a sharp rise in creatinine are typical. Assessment of renal perfusion (Doppler ultrasound or renography studies) may show a dramatic reduction in graft perfusion, but these tests are not sensitive or specific enough for a confident diagnosis of rejection. Most centres routinely take kidney biopsies for all episodes of graft dysfunction once infection, toxic levels of the calcineurin blocking drugs (cyclosporin and tacrolimus), and mechanical factors causing obstruction have been excluded. Obtaining a histological diagnosis is very important since several processes can mimic rejection, including drug nephrotoxicity, bacterial pyelonephritis, recurrence of original disease, and post-transplant lymphoproliferative disorder. The hallmark of acute cellular rejection is tubulitis in which the invading lymphocytes have penetrated the tubular epithelial cell basement membrane and directly engage tubule epithelial cells. Late acute rejection episodes usually imply inadequate immunosuppression, sometimes due to poor compliance. Treatment is very effective and usually involves a bolus of intravenous steroid therapy as described above. Long-term graft survival is severely jeopardized if the rejection episode is not completely reversed. With some of the newer, very potent induction regimes, the incidence of acute rejection episodes can be reduced to 10 per cent. Whether this will translate into a higher rate of infection and neoplasia awaits further follow-up.

Chronic rejection

Chronic rejection is a complex pathological process that is difficult to define. At its simplest, it represents the breakthrough of humoral immunity with an antibody-mediated attack on the graft endothelium. The result is an insidious and obliterative endovasculitis with progressive graft dysfunction from ischaemia. Clinically, the features of chronic rejection include difficult hypertension, proteinuria, and a slowly rising serum creatinine. (See the subsection on chronic allograft nephropathy for further discussion.) Chronic rejection is associated with the presence of anti-HLA antibodies in the serum and the deposition of C4d complement in the peritubular capillaries.

Immunosuppression

There is no clear consensus on the best immunosuppressive regime for renal transplantation, and for commercial reasons the large multicentre trials that the community of transplant physicians and surgeons would most like to see performed are unlikely ever to be funded. The choice of agents available is summarized in Table 6.

Most centres worldwide use what is now called standard triple therapy, comprising cyclosporin A, prednisolone, and azathioprine. However, in North America in particular, there is widespread use of additional serotherapy given as induction therapy for the first 10 days after grafting, and azathioprine has been replaced by mycophenolate mofetil in many centres, and cyclosporin by tacrolimus in some.

Agents of established efficacy for induction therapy include polyclonal antibodies such as antithymocyte globulin (ATG) or antilymphocyte globulin (ALG), and the murine monoclonal antibody, OKT3. Two anti-CD25 antibodies, daclizumab and basiliximab, which bind to the a-chain of the interleukin 2 (**IL-2**) receptor, have recently been introduced. Both are heavily engineered antibodies, comprising a murine antigen-binding site and human immunoglobulin. Both are very effective and have been shown to reduce acute rejection episodes by about 30 per cent.

Many centres are now exploring the possibility of tailoring immunosuppression to the needs of the individual recipient, but as described above we are not good at assessing immunological risk. In practice this involves giving immunosuppressants that are perceived to be more powerful—for example tacrolimus instead of cyclosporin, mycophenolate mofetil instead of azathioprine, or adding antibody treatments—to recipients who are thought to be at greatest immunological risk, such as those who are highly sensitized, patients who have rejected a previous transplant, or those who have suffered an acute rejection episode.

The best long-term therapy is equally in doubt. This is partly due to the nephrotoxicity of two of the main agents employed for the prevention of rejection: both cyclosporin A and tacrolimus can produce a nodular arterioleopathy resulting in ischaemic renal damage. It is also clear that the morbidity and mortality from long-term steroid therapy is significant, such that many centres are now attempting steroid-free immunosuppression, reducing and even withdrawing steroids at 3 to 6 months despite the associated risk of rejection, which has been reported to be as high as 30 per cent. Unfortunately, it is not possible to predict who is going to reject on withdrawal of steroids, hence one of the main aims of those developing new immunosuppressive drugs and regimens is to devise agents or protocols that allow less dependence on steroids without increased rates of rejection or other unacceptable toxicities.

The side-effects of immunosuppression

It is important to remember that all currently available immunosuppressive regimen are non-specific in the sense that they suppress not only the immune response to the allograft, but also the immune response to infections and tumours. All the agents used have significant side-effects and toxicities, and to a very large extent the long-term complications of renal transplantation are those of the immunosuppressive agents used. Some side-effects are more related to the total burden of immunosuppression rather than to any specific single agent, for example infections and cancer.

Specific side-effects of particular agents

Steroids

Steroids are responsible for many of the complications of transplantation (Table 7). In recent years the dose of steroids used has been safely reduced, thanks in part to the introduction of the calcineurin-blocking drugs, but attempts to produce totally steroid-free transplantation are only successful in about half of cases. One of the most significant side-effects of steroids is that they mask the inflammatory response so that symptoms develop late, which is particularly important in cases of

intra-abdominal catastrophy such as a perforated hollow viscus.

Calcineurin-blocking drugs

The major drawback of both cyclosporin A and tacrolimus is nephrotoxicity (Table 8), which adds another level of complexity to the differential diagnosis and management of both acute and chronic graft dysfunction. Most consider tacrolimus to be more potent than cyclosporin A, but perhaps more toxic (diabetes mellitus and neurotoxicity). It does, however, have real cosmetic advantages over cyclosporin A, perhaps mediated by lower levels of transforming growth factor-b.

Azathioprine and mycophenolate mofetil

Both agents block purine synthesis. The main side-effects of azathioprine are hepatotoxicity and marrow suppression (Table 9). Mycophenolate mofetil is more potent and more specific than azathioprine, blocking purine synthesis in lymphocytes with a degree of specifity. Its most troublesome side-effect is that of abdominal colic and diarrhoea: about 10 per cent of patients are so badly affected that they are unable to tolerate the drug. A higher incidence of invasive cytomegalovirus disease has been associated with mycophenolate.

Serotherapy

A range of antibodies to lymphocytes is available for clinical use (Table 6). Side-effects vary with the preparation used: it is important to remember that the consequences of augmenting immunosuppression with serological agents may last many months, even though administration is usually limited to 10 to 14 days.

Polyclonal antilymphocyte preparations can cause a marked first-dose effect in which lymphocytes are activated and secrete cytokines. High fever, rigors, and muscle and back pains are common, and hypotension may occur. With successive doses this reaction subsides. The murine anti-CD3 antibody (OKT3) is particularly prone to produce a first-dose effect that can lead to a widespread capillary leak syndrome with non-cardiogenic pulmonary oedema, hypotension, and shock. It should not be given to patients who are fluid overloaded. Aseptic meningitis and encephalitis are also seen occasionally. By contrast, the humanized and chimeric anti-IL2 receptor antibodies that have recently been introduced do not appear to have any short-term side-effects.

General side-effects of immunosuppression

Infectious complications

Introduction

The calcineurin-blocking drugs used for immunosuppression act to inhibit the T-helper cell (CD4) and prevent the elaboration of IL-2 and other cytokines. In some respects this is akin to the effects of HIV infection and it is therefore not surprising that the renal transplant recipient may develop the same range of opportunistic infections and tumours as is seen in patients with AIDS (see Chapter 7.10.21). Clinical features are often dramatic and rapidly evolving, hence prompt and precise microbiological diagnosis is essential. This requires early recourse to invasive techniques, for example biopsy, node aspiration, excision, bronchoalveolar lavage and even lung biopsy. Neurological symptoms and signs may herald central nervous system infection and require urgent CT scanning or MRI and the examination of cerebrospinal fluid whenever possible. Any pyrexial episode in a transplant recipient should prompt a search for infection. Blood and urine cultures should be undertaken routinely.

Figure 1 summarizes the timetable of infections. In the first month, before immunosuppression is fully established, renal transplant recipients may develop the same sort of infection seen after any general anaesthetic, abdominal operation, or urological procedure. From months 1 to 6, immunosuppression is maximal and the risk of opportunistic infections greatest. Thereafter, the risk of infection declines but remains greater than the general population.

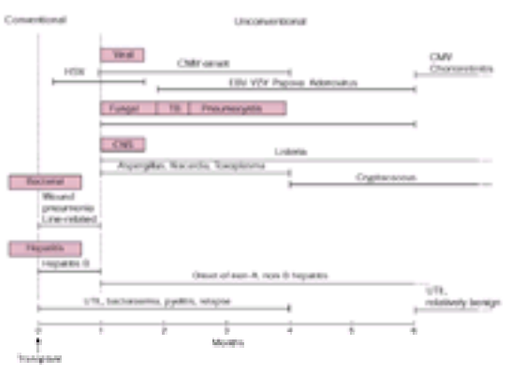

Fig. 1 Timetable of infections (reproduced by permission from Rubin R.H. and Young L.S. (eds) 1994, *Clinical approach to infection in the compromised host*, 3rd edn. Plenum Medical Book Co., New York.)

Viral infections

Not all virus infections prove dangerous to the immunosuppressed renal transplant recipient. Those with particularly important clinical sequelae are summarized in Table 10. The most important group are the DNA viruses of the herpes group: infection with these is immunomodulating in its own right and further immunosuppresses the patient, hence they are not infrequently associated with superinfections, for example *Pneumocystis carinii*, listeria, and bacterial sepsis. Several of the viruses have proven oncogenic potential and are considered later.

Cytomegalovirus

Cytomegalovirus (**CMV**) is the main infectious complication in solid organ transplantation (Table 11), with a primary infection more likely to produce serious disease than either reinfection or reactivation. Viral load, as indicated by quantitative polymerase chain reaction (**PCR**), and the total burden of immunosuppression, are the main determinants of disease. Use of potent serological agents, either for induction or rescue, is strongly associated with CMV disease. As would be expected, the total number of treated rejection episodes is an important risk factor. Diagnosis is usually via PCR for viral DNA or by an antigen assay (pp65) on peripheral blood leucocytes. Monitoring the serological response for diagnostic purposes is obsolete as it is far too insensitive and routine cultures are too slow. A range of effective prophylactic regimes is available: oral valaciclovir is effective and oral valganciclovir is awaited. Another equally valid approach is careful monitoring combined with pre-emptive treatment of infection, where therapy can be given before clinical disease in vulnerable individuals. Two or three weeks of intravenous ganciclovir is usually effective. Foscarnet is a more toxic alternative.

CMV may play a role in triggering or augmenting both acute and chronic rejection. If this is confirmed then more widespread prophylaxis may be indicated.

Epstein–Barr virus (EBV)

EBV-related syndromes (Table 11) are an important cause of morbidity and mortality in renal transplant recipients, the most serious problem being so-called post-transplant lymphoproliferative disorder, which is considered later.

Varicella zoster

Reactivation of latent varicella zoster (**VZV**) produces shingles, which is a common and unpleasant complication of transplantation. Immediate treatment with

intravenous aciclovir can limit spread and reduce post-herpetic pain. Much more dangerous is a primary VZV infection in an immunocompromised individual: this can cause a fulminating disease with hepatitis, pneumonitis, and disseminated intravascular coagulation occurring within a few days. Mortality is high. All patients who are to receive immunosuppression should have their VZV antibody status established. Those who are seronegative should be counselled about exposure to chicken pox and should report any contact immediately. Vaccination is available, but if exposed, susceptible individuals should be given zoster immune globulin (ZIG) and monitored closely. High-dose intravenous aciclovir should be given at the first suggestion of disease.

Herpes simplex

Although the classic herpetic cold sore is common after transplantation, herpes simplex virus (**HSV**) can produce a variety of serious clinical sequelae in the immunocompromised patient (Table 11). Use of prophylactic aciclovir or ganciclovir (primarily for CMV prophylaxis) dramatically reduces the risks of HSV infection. Treatment with aciclovir is very effective.

Human polyomavirus (BK and JC)

Most adult recipients are already seropositive for these viruses, indicating childhood infection that is usually asymptomatic. Primary infection can occur from the allograft. In most cases this is also asymptomatic, but rarely these viruses can cause an acute interstitial nephritis and graft dysfunction. The JC virus has been reported to cause a progressive multifocal leucoencephalopathy in renal transplant recipients, although this is very rare.

Papilloma viruses

Papilloma viruses cause an extensive range of viral warts in renal transplant recipients. Some types have been implicated in the pathogenisis of anogenital carcinomas and squamous cell carcinomas of the skin (see below). The management of viral warts in the immunocompromised patient is difficult when they are very extensive and consideration should be given to reducing immunosuppression. Localized lesions can be treated conventionally with topical agents such as glutaraldehyde or laser therapy, but widespread surgical excision is sometimes required. Local recurrence in scar tissue is common. A combination of oral etidronate (50 mg daily) and topical tretinoin cream (0.05 per cent) can control the lesions in severe cases.

*Human immunodeficiency virus (**HIV**)*

Infection with HIV is considered an absolute contraindication to transplantation. The time to AIDS and death is significantly shortened, particularly if HIV is acquired at or shortly after transplantation. However, the recently introduced intensive antiviral therapy for HIV infection may alter this approach. It is important to remember that HIV infection or behaviour considered to be at risk of contracting HIV or other viruses (lifestyle assessment) excludes such individuals from organ donation.

Bacterial infections

There are a limited number of bacterial infections that are significantly more common and more severe in the transplant population (Table 11). However, there is little doubt that bacteraemias are more common in transplant recipients, usually as a result of urinary tract infections. Metastatic abscesses in joints, skin, muscles, and the brain are also more frequent.

Mycobacterial infections

Reactivation of mycobacterial infection following transplantation is very common in the 'at risk' population, and most United Kingdom units recommend prophylaxis with isoniazid in these groups, although some debate the need for this. Experience in the Indian Subcontinent suggests that pretransplant BCG vaccination is not effective. Mycobacterial infections (both atypical and tuberculosis) can present in many different guises, for example pneumonia, lymphadenopathy, intracranial space-occupying lesions, discharging sinus, pyrexia of unknown origin, and skin ulcers. Tissue biopsy and cultures and smears employing special stains are essential. PCR, particularly of cerebrospinal fluid, is proving helpful. Gallium scanning may identify nodes that can be aspirated under CT guidance. Skin testing is unreliable in the immunocompromised patient.

Treatment is compromised by serious drug interactions between rifampicin and both the calcineurin-blocking drugs and prednisolone. Rifampicin is such a potent inducer of cytochrome P450 that sub-therapeutic levels of the calcineurin-blocking drugs and steroids can develop within weeks. Graft loss from rejection will occur unless doses are increased: that of prednisolone is usually doubled, and the calcineurin blockers may have to be increased still further and given three times daily. Monitoring of drug levels is essential.

In many units a four-drug antituberculous regimen is recommended, comprising rifampicin, ethambutol, isoniazid, and pyrazinamide. When sensitivities become available, this can be reduced. Treatment should be continued for at least a year, particularly in the case of atypical mycobacterial infections. Therapy may be further complicated by hepatotoxicity, for which the differential diagnosis is complex as many other factors can cause deranged liver function tests in renal transplant recipients (for example virus infections—HBV, HCV, CMV, and other drugs)

Nocardia

Nocardia typically produces either a pseudotuberculosis or a pseudostaphylococcal syndrome. Central nervous system infections can occur. Dissemination is common, occurring in 25 to 30 per cent. Diagnosis often requires a biopsy or aspiration, with cultures needing to be pro-longed for at least 3 weeks. Prolonged treatment (at least 6 months) with co-trimoxazole is usually effective, following which long-term co-trimoxazole should continue indefinitely.

Non-typhoid salmonella

Non-typhoid salmonella infections are noteworthy because of their tendency to produce metastatic abscesses following bacteraemia. With control of the acute illness, the continued excretion of the organism may occur in stool or urine. Relapse is common so treatment needs to be prolonged. Suitable antimicrobials include ciprofloxacin, co-trimoxazole, and ampicillin.

Listeria

Listeria has a tendency to localize in the central nervous system following a bacteraemic phase. Neurological syndromes vary from meningitis and meningoencephalitis to space-occupying lesions. It is the commonest cause of post-transplant meningitis. In the absence of evidence of raised intracanial pressure, all patients will require lumbar puncture and examination of cerebrospinal fluid. Delayed or inadequate treatment may result in permanent neurological deficit. Treatment usually includes high-dose ampicillin for at least 6 weeks, combined with gentamicin for the first week. The source of listeria is usually contaminated dairy products, chicken, or uncooked vegetables contaminated by manure.

Fungal infections

Oral candidiasis is a common post-transplant infection. Spread to the oropharynx and lungs may occur. All patients should receive prophylaxis (nystatin mouthwashes or amphotericin lozenges) for at least 6 weeks, but some practitioners would recommend longer courses, or even indefinite treatment in patients with diabetes. Intercurrent courses of antibiotics should be covered with oral prophylaxis against candida.

The spectrum of diseases produced by fungal infections is wide, ranging from mucocutaneous syndromes, severe pneumonias, central nervous system syndromes, to skin or muscle abscesses. This variation in clinical presentation again highlights the need for aggressive invasive investigation. Outbreaks of aspergillus are usually related to hospital building projects and should prompt a search for the source. Deep-seated fungal infections carry a very high mortality. Dissemination is common. Specialist microbiological advice is usually required, but if the fungus is sensitive then liposomal amphotericin is the drug of choice.

Parasitic infections

Some of the parasitic infections listed in Table 10 are geographically restricted and therefore will only be of specific relevance in those areas. Schistosomiasis, for example, can cause ureteric strictures and leaks following transplantation. *Strongyloides stercoralis* is usually found in patients from the West Indies or the Far East: in the immunocompromised it can reactivate, complete its lifecycle in the patient without need for an intermediate host, and produce a hyperinfestation syndrome. A pretransplant eosinophilia is sometimes present. Clinical presentation is with recurrent bouts of Gram-negative septicaemia as the worm penetrates the gut mucosa. Other clinical features include pruritus ani, haemorrhagic enteritis, lava currens, cough, wheeze, and a haemorrhaging bronchopneumonia. Meningitis may also occur. Diagnosis usually requires a duodenal aspirate. Treatment is with thiabendazole, which should be given pretransplant to susceptible patients. Several courses of treatment may be needed to eradicate the infestation.

Scabies may occur in transplant recipients and can produce so-called Norwegian scabies in which there may be many parasitic mites per burrow. In the immunocompromised patient, skin organisms are readily carried into the bloodstream, hence cellulitis and septicaemia are common.

The transplant organ, particularly the heart, can transmit toxoplasmosis. The organism becomes widely disseminated, including the central nervous system. Other clinical features may include low-grade fever, lymphadenopathy, pneumonia, myocarditis, retinopathy, and myositis. It can mimic cytomegalovirus. Treatment is with pyrimethamine and sulphadiazine for at least 4 weeks. Prophylaxis with co-trimoxazole has greatly reduced the incidence of toxoplasmosis following solid organ transplantation.

Pneumocystis carinii

Until the widespread introduction of prophylactic low-dose co-trimoxazole, *Pneumocystis carinii* pneumonia was a dreaded complication of solid organ transplantation. Oral co-trimoxazole or inhaled pentamidine (300 mg monthly) is effective prophylaxis. *Pneumocystis carinii* pneumonia is now most commonly seen in the setting of augmented immunosuppression (additional serotherapy) and in patients who already have developed CMV disease. Presentation is with fever, dry cough, and profound shortness of breath, occurring in the context of few added sounds in the chest and a remarkably clear chest radiograph. By the time the chest radiograph has altered, pulmonary fibrosis is occurring. Successful treatment demands an early diagnosis, such that the renal transplant recipient who complains of shortness of breath on exercise and who desaturates on exercise should be admitted and investigated as a medical emergency. Bronchoalveolar lavage is virtually mandatory under these circumstances. Overall immunsuppression should be reduced in patients with *Pneumocystis carinii* pneumonia, but steroids may need to be increased to cover a stress response (e.g. prednisolone at 20 to 25 mg daily). High-dose intravenous co-trimoxazole is given: 15 to 20 mg of trimethoprim and 75 to 100 mg of sulphamethoxazole per kilogram body weight per day, although these doses may need to be reduced in severe renal failure. Treatment should be continued for at least 2 weeks. It is essential to monitor respiratory effort carefully in the renal transplant recipient with an interstitial pneumonitis and intervene with continuous positive airways pressure or full ventilation if the patient tires or cannot protect his airways. Nutrition should be ensured, using total parenteral nutrition if necessary.

Specific infective problems

Pulmonary disease

Recurrent chest infections are common. Many are viral and will be self-limiting, even in the immunosuppressed transplant recipient. An abrupt clinical onset with fever and a lobar pattern of lung infiltrates is likely to be due to a bacterial infection. A more insidious onset with scattered or diffuse pulmonary infiltrates is more likely to be due to an opportunistic infection. Blood and sputum should be cultured urgently. Sputum samples need careful microscopy and cultures should be set up for mycobacteria, fungi, and legionella. PCR is available for *Mycobacterium tuberculosis*, *Pneumocystis carinii*, and CMV. Antibiotics may be started pending culture results. The regimen that will cover most of the common organisms is penicillin V, clarithromycin (NB drug interactions), and a third-generation cephalosporin.

Failure to respond promptly to therapy or a non-lobar pattern of infiltration is an indication for brochoscopy and bronchoalveolar lavage, the diagnostic accuracy of which is about 80 to 90 per cent. It is essential to examine the fluid thoroughly, which will involve viral and bacterial cultures, special stains, and PCR where available. In clinical practice it is often necessary to start therapy blindly in seriously ill patients. Sometimes this will involve the addition of high-dose co-trimoxazole and ganciclovir to conventional antibiotics. When the results of culture and sensitivity testing become available it may be possible to reduce the antimicrobial regime or change to specific antituberculous or antifungal therapy.

The greatest mimic of a chest infection is pulmonary oedema: measurement of an elevated pulmonary capillary wedge pressure is diagnostic, and a therapeutic test of a potent diuretic sometimes produces a dramatic clearing of the chest radiograph. Other non-infectious causes of acute pulmonary syndromes that may occur in the renal transplant recipient are shown in Table 12.

Urinary tract infection

One-third of renal transplant recipients will develop urinary tract infection. In most this is related to postoperative bladder catheterization and usually resolves with removal of the catheter and a short course of antibiotics. There is an exponential relationship between the incidence of urinary tract infections and the duration of bladder catheterization. Some patients develop numerous recurrent infections, particularly in the first couple of years following transplantation. In some this can be related to a focus of infection in the native kidneys, when bilateral native nephroureterectomy may be indicated if sepsis is severe. A few patients will develop encrustation or even a stone in the bladder as a result of the surgical implantation of the ureter: a plain abdominal radiograph may reveal such calculi, which should be removed cystoscopically.

More worrying is infection ascending into the transplant kidney itself during the intermediate period of post-transplantation immunosuppression when the patient is most immunocompromised. A severe bacterial pyelonephritis can develop in the transplant, presenting as an acute rejection episode with a swollen kidney, low-grade fever, and deteriorating graft function. Such upper tract infections are frequently complicated by septicaemia, and it is always worth remembering that urinary sepsis is the commonest cause of post-transplant bacteraemia. It is essential that episodes of graft dysfunction due to upper tract infection are clearly diagnosed and aggressively treated with appropriate high-dose parental antibiotics. Misdiagnosis resulting in treatment with high-dose intravenous steroids for a presumed rejection episode can be catastrophic.

The advent of technetium-99m labelled DMSA SPECT isotope scanning (single photon emission computed tomography using dimercaptosuccinic acid labelled with technetium-99m) has enabled three-dimensional reconstructions of the grafted kidney to be produced. Progressive scarring can develop in some patients with recurrent infections and reflux to the graft, hence transplant recipients with recurrent urinary tract infections need full investigation and aggressive treatment. Every effort should be made to establish and maintain sterile urine. Long-term prophylactic low-dose antibiotics may be indicated.

Neurological syndromes

The main concerns are those of post-transplant lymphoproliferative disorder or an opportunistic infection producing progressive neurological deterioration due to an increasing space-occupying lesion. Examples of neurological syndromes seen in the renal transplant recipient and their common causes are given in Table 13. The range of infectious micro-organisms that can cause central nervous system lesions is such that a diagnostic aspirate is usually essential. Tuberculosis is common in at-risk patients. Investigation should include a CT scan with contrast or an MRI so that abscesses are not missed. In the absence of evidence of a raised intracranial pressure, cerebrospinal fluid should be examined. As with the processing of bronchoalveolar lavage fluid, close co-operation between clinician and the cytological and microbiological laboratories is essential.

Fits may occur in the early post-transplant period, when the cause is usually multifactorial, including hyponatraemia, hypertension, hypomagnesaemia, hypocalcaemia, and the toxic effects of the calcineurin-blocking drugs. The rejection process itself can cause a rise in intracranial pressure, so-called rejection encephalopathy. Fits occurring after the first month should prompt a search for a serious intracranial space-occupying lesion.

Renal transplantation in the presence of liver dysfunction

The two main liver conditions encountered in patients on transplant waiting lists that give concern in the post-transplant period are hepatitis B (HBV) and hepatitis C (HCV).

Hepatitis B

HBV usually causes persistent infection in patients with chronic renal failure. In many this may be subclinical, but in others a chronic hepatitis and cirrhosis can develop. Serology is of little help in assessing suitability for transplantation, which is contraindicated in the presence of cirrhosis and biopsy evidence of active hepatic inflammation since immunosuppression causes rapid viral replication and progressive liver disease. Death within 5 years of transplantation may occur in up to 50 per cent of patients if wrongly transplanted, usually from extrahepatic sepsis. Long-term therapy with the newer antiviral agents may improve the outlook and allow access to transplantation to those at present denied this.

Hepatitis C

Although HCV is now the most common cause of both pre- and post-transplant liver disease, the effects of immunosuppression on HCV seem much less dramatic than the effects on HBV. Occasional patients do develop a fulminating hepatitis post-transplantation, but overall HCV does not appear to have a major impact on the short- to medium-term outcome after renal transplantation.

Post-transplant liver dysfunction

Abnormal liver function tests following transplantation are common: both drugs and infectious agents may be responsible. Full investigation is required, including imaging of the liver, bile ducts, and gallbladder as well as a liver biopsy. In some instances transient elevation of liver transaminases may herald CMV disease. In other situations raised liver enzymes can represent progressive HCV- or HBV- induced liver disease. It is important to remember that the donor organ can transmit most of the hepatotropic viruses. Treatment clearly depends on the cause. Where possible the offending drug (for instance azathioprine) should be withdrawn and antiviral therapy may be appropriate in the case of HBV and HCV. Interferon therapy is contraindicated as it induces expression of HLA antigens and may provoke acute rejection. In the case of HBV it is often possible to reduce the dosage of immunosuppressive agents significantly without precipitating a rejection episode.

Neoplasia

Post-transplant neoplasia is an important cause of morbidity and mortality. There is some debate as to whether some of the conditions often regarded as neoplastic can truly be classed as cancers, since several are clearly viral related and will regress with reduction of immunosuppression. Table 14 summarizes the tumours seen with increased frequency after transplantation. There is a marked geographical variation: for instance in Japan, renal, thyroid, and uterine cancers as well as lymphoma are common; in Saudi Arabia, Kaposi's sarcoma is the most common; in Australia squamous cell carcinoma of the skin is almost ubiquitous 20 years after transplantation (75 per cent). It is also important to remember than the donor organ can transmit cancer.

Post-transplant lymphoproliferative disorder

Post-transplant lymphoproliferative disorder is driven by Epstein–Barr virus (EBV) present in a latent form (episomal or circular DNA) in B lymphocytes. In non-immunosuppressed individuals a normal T-cytotoxic lymphocyte response terminates infected proliferating B cells. In the presence of effective immunosuppression this does not happen and an unrestricted, increasingly monoclonal B-cell proliferation develops. The more potent the immunosuppressive regime, the earlier post-transplant lymphoproliferative disorder occurs. In most centres, the incidence of this disorder is about 2 per cent. The clinical features are summarized in Table 14. In common with many other infections following transplantation, a primary infection (i.e. the recipient is naive or seronegative for EBV antibodies, while the donor is seropositive) leads more frequently to disease.

Early diagnosis is important as the stepwise reduction of immunsuppression with careful monitoring of graft function can lead to regression of the tumour without graft rejection. Stimulating the patient's immune system with interferon-a or IL-2 may be tried. Conventional cytotoxic therapy should be introduced if post-transplant lymphoproliferative disorder progresses despite the withdrawal of immunosuppression, but this further suppresses the patient's immune system and death from overwhelming infection is all too common. Anti-B-cell antibodies (e.g. rituximab) and infusions of EBV-specific cytotoxic T lymphocytes are promising new avenues of therapy.

It remains to be proved, but seems very likely, that the carefully monitored stepwise reduction of immunosuppression may also be appropriate for other virally induced neoplasms in renal transplant recipients, for example Kaposi's sarcoma and squamous cell carcinoma. A few patients who have lost their grafts in the context of post-transplant lymphoproliferative disorder have been successfully retransplanted.

Kaposi's sarcoma

Kaposi's sarcoma is a vascular tumour composed of proliferating spindle cells (latently infected lymphatic endothelial cells) and thin-walled neovascular formations that is driven by the Kaposi's sarcoma virus (KSV), recently designated HHV8. Aetiological factors are very similar to those of post-transplant lymphoproliferative disorder. Lesions may develop at almost any site on the skin and visceral involvement is common. Prompt diagnosis and early reduction of immunosuppression may result in regression. As with post-transplant lymphoproliferative disorder, the use of cytotoxic agents is associated with a greatly increased risk of death from sepsis. Attempts at retransplantation after regression are associated almost universally with recurrence.

Human papilloma virus related carcinoma

Human papilloma virus (HPV) is responsible for skin, vulval, and anogenital warts, and some types are now clearly associated with carcinoma. Renal transplant recipients should therefore receive full dermatological and gynaecological examinations at regular intervals.

Aetiological factors for skin cancer include exposure to ultraviolet light (which may act by depletion of cutaneous Langerhan's cells as well as direct DNA damage), duration and intensity of immunosuppression, and the HPV virus itself. The prevalence increases progressively with time, such that after 20 years most renal transplant recipients will have cutaneous squamous cell carcinoma. Management should involve cautious dose-reduction of immunosuppressive agents. There is great interest in the role of combined oral and topical retinoids, which are associated with repopulation of the skin with Langerhan's cells and augmentation of natural killer cell activity, and may also act by blocking IL-6 pathways. Some cases of squamous cell carcinoma can metastasize, when reduction of immunosuppression dose, interferon-a therapy, and a willingness to abandon the graft should be considered before recourse to systemic cytotoxic chemotherapy.

Hypertension

The aetiology of post-transplant hypertension is complex (Table 15). Over 75 per cent of renal transplant recipients will need drug therapy for hypertension in addition to lifestyle modification. Most units aim for a systolic blood pressure of less than 145 mmHg and a diastolic pressure of less than 85 mmHg, but there is a lack of clear data regarding the ideal blood pressure. Hypertension plays a crucial role in accelerating vascular disease and chronic allograft nephropathy. Care should be taken with the choice of agents. On theoretical grounds, angiotensin-converting enzyme (**ACE**) inhibitors or angiotensin I (**AT-I**) receptor antagonists appear a rational first choice in view of the multiple proinflammatory, profibrotic, and proproliferative actions of angiotensin II. There are overwhelming data showing reduction of proteinuria and a slowing of progression of renal disease in native kidneys treated with ACE inhibitors, and by implication also by AT-I receptor-blocking drugs. However, the risks of using ACE inhibitors in patients with renal artery stenosis should not be forgotten, transplant renal artery stenosis being most likely to develop between 3 and 12 months after transplantation, sometimes (but not always) associated with a bruit over the kidney. Serum creatinine must be carefully monitored, any substantial rise after ACE inhibition leading to immediate cessation of the drug and consideration of angiography of the transplant renal artery. It is preferable to avoid drugs that exacerbate dyslipidaemia, such as b-blockers and thaizides. Poor blood pressure control with short-acting dihydropyridine calcium-channel blockers may increase proteinuria and cardiovascular mortality. In refractory cases, or those where treatment is problematic, estimation of renin levels in the veins draining the native and transplant kidneys may help in the decision to proceed to a native kidney nephrectomy.

Accelerated atherosclerosis

In common with patients on dialysis, one of the major causes of death following renal transplantation is cardiovascular disease. Indeed, death with a functioning graft is now the major cause of late graft failure. Much of the cardiovascular disease that shortens life expectancy in renal transplant recipients will have developed and be

established pretransplantation. Table 15 summarizes the pre- and post- transplant aetiological factors. Prevention and treatment of established vascular disease is essential. About a third of renal transplant recipients will have hypercholesterolaemia and many will also be hypertensive. Lifestyle modification is important. All renal transplant recipients should be strongly advised not to smoke. Following transplantation, some 10 per cent of transplant recipients become quite grossly obese. It is important to remember that the cardiovascular risk factors multiply rather than summate, hence the long-term management of renal transplant recipients has to address all cardiovascular risk factors.

Electrolyte disorders

Hypophosphataemia

In the presence of inadequately controlled secondary hyperparathyroidism a well functioning transplant will waste phosphate, and in a few cases phosphaturia persists despite resolution of the secondary hyperparathyroidism. In some patients there is steroid-related malabsorption of phosphate. In the first few months following renal transplantation, phosphate wasting can be severe and oral supplements will be required. Untreated chronic hypophosphataemia can lead to bone fractures (hypophosphataemic rickets).

Hyperkalaemia

The calcineurin-blocking drugs cause hyperkalaemia, particularly when levels are toxic. This is thought to be due to type IV renal tubular acidosis in which distal tubular potassium secretion is reduced in response to a fall in renin secretion due to reduced renal prostaglandins. The addition of ACE inhibitors, AT-I receptor-blocking drugs, non-steroidal anti-inflammatory drugs, or potassium-conserving diuretics can produce a brisk rise in serum potassium in renal transplant recipients. Dietary advice and loop diuretics are usually sufficient but a small number of patients may require fludrocortisone (100 to 200 µg daily.)

Hypomagnesaemia

Renal tubular magnesium wasting is a component of the nephrotoxicity of the calcineurin-blocking drugs and can be exacerbated by diuretics and diarrhoea. Hypomagnesaemia may predispose to fits and cardiac arrhythmias in susceptible individuals. Levels should be monitored and oral supplements of magnesium glycerophosphate given if required.

Hypercalcaemia

Hypercalcaemia can develop after grafting if renal osteodystrophy has been poorly controlled and severe secondary hyperparathyroidism is present at the time of transplantation. The transplant kidney produces adequate amounts of 1,25-dihydroxycholecalciferol, which in the presence of high levels of parathyroid hormone will result in hypercalcaemia. Widespread metastatic deposition of calcium can occur if hypercalcaemia is severe. Simple controlling measures include adequate fluids and the use of loop diuretics rather than thiazides. Occasional patients will require regular infusions of pamidronate (15 to 30 mg), which can be combined with intermittent doses of oral a-calcidol to suppress parathyroid hyperplasia. Parathyroidectomy is occasionally required. It may take 12 to 24 months for secondary hyperparathyroidism to resolve following renal transplantation.

Bicarbonate wasting

The transplant kidney may waste bicarbonate as well as phosphate. This may be due to persistent hyperparathyroidism, but can also reflect acute tubule damage from rejection. A chronic metabolic acidosis will contribute to post-transplant osteoporosis and should be treated with bicarbonate supplements.

Hyponatraemia

Hyponatraemia may develop, particularly in the early postoperative period. It is usually due to inappropriate intravenous fluids (excess 5 per cent dextrose or dextrose saline) in the context of deteriorating graft function, and may be an important contributing factor to fits after transplantation.

Musculoskeletal complications

Tendon rupture

Steroids impair collagen synthesis. Tendons and tendon insertions are weakened and avulsions may occur, most commonly in the fingers or Achilles' tendon.

Myopathy

An important complication of steroid therapy is proximal myopathy, which can be incapacitating in some patients. Physiotherapy plus vitamin D supplements and a rapid reduction of steroids (alternate-day prescription or even cessation) can produce improvement. Hypophosphataemia should be corrected. Acute rhabdomyolysis may develop if fibrates or statins are used with the calcineurin-blocking drugs.

Avascular necrosis of bone

Avascular necrosis of bone, particularly of the weight-bearing ends of the long bones, causes an extremely painful joint. When the hips are involved, walking can become impossible and total hip replacement is the only treatment. Prevention may be possible by the careful control of secondary hyperparathyroidism prior to transplantation and the early use of bisphosphonates to minimize post-transplant osteoporosis may be beneficial.

Osteoporosis

Osteoporosis is a common and progressive complication of long-term steroid therapy such that regular bone-density assessment should be part of long-term renal transplant follow-up. The problem is particularly severe in postmenopausal women, in whom hormone replacement therapy is of benefit. Prophylaxis with intravenous pamidronate has been advocated in the first few months after transplantation, but this is not standard practice in most units.

Renal osteodystrophy

In the presence of a poorly functioning graft, control of parathyroid hormone (**PTH**) and the calcium-phosphate product (ideally to be kept at less than 5) is as important as it is in the pretransplant patient with chronic renal failure (see Chapter 20.5.1). PTH levels should be kept at one to two times the upper limit of normal by the careful use of a-calcidol and calcium supplements. Serum phosphate should be kept at 1 to 1.5 mmol/l using calcium carbonate as an oral phosphate binder.

Gout

The calcineurin-blocking drugs impair urate secretion in the proximal tubule, and urate retention is exacerbated by the concomitant use of diuretics, particularly in patients with poorly functioning grafts. Uric acid levels may rise dramatically and be associated with attacks of clinical gout as well as tophi. Management is complicated, both for acute attacks and for prophylaxis. For acute episodes the physician must choose between three treatments, all of which are problematic. Non-steroidal anti-inflammatory drugs are the usual first-line treatment for acute episodes in general medical practice, but in those with renal impairment—including many transplant recipients—they are best avoided, although the recently introduced Cox 2 inhibitors may prove safer. Colchicine can be used for acute attacks, but the transplant recipient tolerates diarrhoea and the attendant hypovolaemia poorly. Oral prednisolone (20 mg daily) can be effective, but will clearly exacerbate steroid side-effects, which are already a problem in many patients. As regards prophylaxis, allopurinol is (relatively) contraindicated if the patient is receiving azathioprine (the dose of azathioprine should be reduced to about 25 per cent of normal) with very careful monitoring for leucopenia. Most uricosuric agents work poorly in the presence of renal impairment, but an important exception to this is benzbromarone (100 to 200 mg daily), which can be safely administered to patients on

azathioprine. In some patients it may be helpful to stop azathioprine altogether and use mycophenolate mofetil in its place so that allopurinol can be used safely.

Haematological complications of renal transplantation

Venous thromboembolism is not uncommon following renal transplantation. The local effects of surgery on the pelvic veins together with immediate postoperative bed rest contribute to the risk. The calcineurin-blocking drugs have an activating and procoagulant effect on endothelial cells and platelets. Nephrotic patients have a profound disturbance of many coagulation factors and represent an extremely high-risk group for perioperative venous thromboembolism. Prophylactic subcutaneous low-molecular-weight heparin (e.g. enoxaparin at 20 mg daily) is standard practice, with higher doses (e.g. enoxaparin at 40 mg daily) in those at highest risk.

A direct endothelial effect of the calcineurin-blocking drugs can result in a *de novo* post-transplant haemolytic uraemic syndrome, and it seems likely that both cyclosporin and tacrolimus may increase the risk of recurrent bouts in patients with this as their primary disease.

Bone marrow suppression may occur as a result of intercurrent viral infection and a variety of drugs. In the context of severe CMV infection it is safe to continue with ganciclovir or aciclovir, but the bone marrow should be stimulated with granulocyte colony-stimulating factor. Profound bone marrow suppression may occur when allopurinol is used with azathioprine if the dose of the latter is not appropriately reduced (see above).

An acute haemolytic anaemia can develop at any time following transplantation. Sometimes this is triggered by an intercurrent infection, but in many cases may be due to antibodies to minor blood antigens. Treatment consists of intravenous immunoglobulin and an increase in steroids.

Patients with a poorly functioning graft will become anaemic just as their predialysis counterparts. Haematinics should be prescribed if patients are deficient, using intravenous iron if iron stores cannot be restored by oral supplements. Erythropoietin may be required.

About 20 per cent of renal transplant recipients develop erythrocytosis. The mechanism is probably multifactorial. The transplant kidney may produce an excess of erythropoietin, occasionally stimulated by renal artery stenosis in the donor kidney. The use of diuretics may produce blood volume contraction. Reduction in erythrocytosis following administration of ACE inhibitors or AT-I receptor-blocking drugs suggests that angiotensin II may contribute to pathogenesis. In most cases the condition is self-limiting, but there is a risk of cerebrovascular occlusion if the haematocrit is grossly elevated and most practitioners recommend regular venesection (or ACE inhibitors) to keep the haemoglobin below 15 or 16 g/dl. A high haematocrit will also exacerbate hypertension.

Cosmetic complications

It is important not to underestimate the psychological importance of the cosmetic disfigurement that can be produced by some of the treatment regimes used in transplantation. They are an important contributing factor to non-compliance, particularly in adolescents, and can even lead to agoraphobia and suicide. With the currently available choices of immunosuppressive agents it should be possible to minimize cosmetic complications when these cause great distress, for example steroid withdrawal, substitution of tacrolimus for cyclosporin A, and use of mycophenolate mofetil to reduce reliance on steroids and calcineurin-blocking drugs. The better cosmetic profile of tacrolimus is thought to be due to lower transforming growth factor-b production, but expense may be a limiting factor in some health-care systems.

Outcome

Graft and patient survival

Figure 2 and Figure 3 summarize the graft survival rates for first cadaver and living related transplants. The highest rate of graft loss is within the first few months. Graft losses due to technical factors should be less than 5 per cent. The major cause of early graft loss continues to be acute rejection. However, it is a matter of concern that the attrition of grafts following the first year has not altered, even with the introduction of newer, more potent immunosuppressive agents. Currently some 4 per cent of grafts fail annually for a variety of causes loosely grouped together as chronic allograft nephropathy (see discussion below). Death with a functioning graft is now the most common cause of late graft failure.

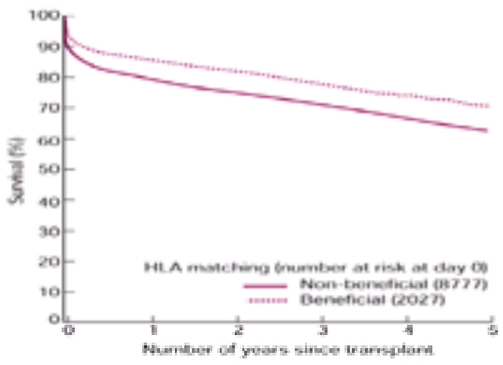

Fig. 2 Graft survival: first cadaver graft (by courtesy of UK Transplant).

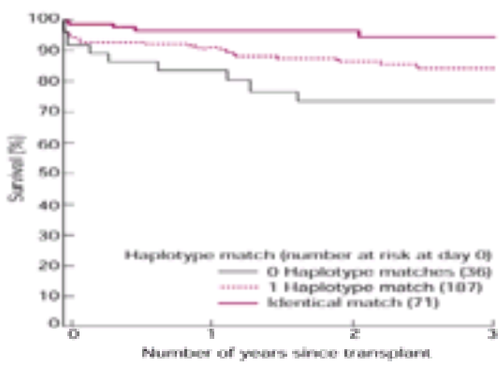

Fig. 3 Graft survival: living related grafts (by courtesy of UK Transplant).

Factors affecting graft survival are summarized in Table 16. Even with potent immunosuppressive regimes, HLA matching remains extremely important, forming the rationale for local and national organ sharing schemes to ensure that the best possible matches can be obtained. Figure 2 indicates that beneficially matched cadaver kidneys (1–0–0 or 0–1–0 mismatch) fare significantly better than non-beneficially matched, and well-matched living related transplants do best of all (Fig. 3).

Early studies indicated that an acute rejection episode had a major impact on long-term graft survival, reducing it by almost a half. If an acute rejection episode is completely reversed the effect on long-term graft survival is markedly reduced. Long-term graft survival can be clearly related to the creatinine level at 1 year. This has led to great emphasis on efforts to reduce the rate of early acute rejection episodes. One crucial observation that predicts those at increased risk is the presence of widely reactive anti-HLA antibodies to potential donors. Those patients who have already rejected a kidney within 6 months of transplantation also do poorly on subsequent transplantation unless immunosuppression is augmented. Increasingly potent induction regimens and combinations of drugs have been introduced, but in the absence of accurate predictors of the risk of rejection this has the effect that a significant number of patients will be grossly over-immunosuppressed, whilst others

remain under-immunosuppressed. Poor long-term graft survival is also related to hypertension, proteinuria, hyperlipidaemia, and a high body-mass index (Table 16).

In the early post-transplant period the major causes of death are related to cardiovascular complications of surgery. However, with good patient selection, mortality in the first year should be very low (less than 1 to 2 per cent), despite the fact that increasingly older patients are being offered transplantation, as are those with significant comorbidities, diabetes mellitus in particular. In the first year the major cause of death is infection (Fig. 4). Later on, death from neoplasia and accelerated vascular disease are more common.

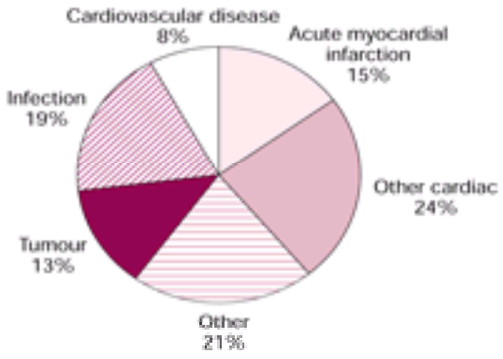

Fig. 4 Causes of death in renal transplant recipients.

Chronic allograft nephropathy

First-year transplant losses from rejection have been dramatically reduced from about 40 per cent in the 1970s to 5 to 10 per cent. Similarly, early rejection rates can be reduced from around 50 per cent to less than 20 per cent. However, as stated above, the rate of chronic graft loss remains at about 4 per cent per year. Some of these graft losses will be due to death with a functioning graft, but many patients present with an insidiously rising creatinine, increasing proteinuria, and worsening hypertension. The causes of this late graft dysfunction are multifactorial and involve many different conditions and several overlapping pathogenic pathways. Histologically, many of these kidneys will show tubular atrophy, interstitial scarring, and an obliterative vasculopathy of the intrarenal arteries and arterioles, but even with a transplant biopsy it may not be possible to define the pathololgical process. Nevertheless, every effort should be made to produce an accurate diagnosis. Obstruction due to ureteric ischaemia must be excluded by renography or ultrasound. A review of past urine cultures and a technetium-99m labelled DMSA SPECT scan may reveal pyelonephritic scarring. Late graft dysfunction due to renal artery stenosis can be demonstrated by angiography. It is possible that the single transplant kidney may have insufficient numbers of nephrons to cope with the work demanded of it, particularly if many nephrons have been lost early from acute rejection, manifest as a raised serum creatinine at 1 year. This situation may also arise if there is a very large size mismatch, with a very large recipient being given a kidney from a smaller donor, leading to the self-perpetuating inherently progressive cycle of hyperperfusion and hyperfiltration of the surviving nephrons (Brenner's hypothesis). Treatment is empirical but must involve control of blood pressure, preferably using an ACE inhibitor or an AT-I receptor-blocking drug to reduce intraglomerular blood pressure.

Some pathogenic aspects of insidious graft loss are akin to atherosclerotic changes, and interventions designed to limit vascular damage may prolong the life of poorly functioning kidneys. The early use of ACE inhibitors (especially if there is proteinuria), aspirin, fish oils, and control of cholesterol may help. Chronic allograft nephropathy may also be due in part to the nephrotoxic effects of the calcineurin-blocking drugs. The newer agent, mycophenolate mofetil, may have a particular role to play in that it has been shown to reduce proliferation of smooth muscle cells, which may ameliorate the obliterative vasculopathy typical of the condition, and permit reduced reliance on long-term calcineurin-blocking agents, but this is yet to be proved.

Recurrence of original disease and *de novo* glomerulonephritis

Most of the primary glomerular diseases can recur in the transplant, but few are associated with graft loss. Overall, histologically demonstrable recurrence occurs in about 60 per cent of patients, but less than 10 per cent will lose their graft as a result. Accurate recurrence rates are difficult to determine, being roughly 2.5 per cent at 2 years, 10 per cent at 5 years, and perhaps as high as 20 per cent by 8 years. Treatment of recurrent glomerulonephritis is not particularly effective but has usually involved intensive plasma exchange or an increase in immunosuppression.

Oxalosis will recur rapidly in the kidney unless a liver transplant is also done to correct the underlying enzyme defect. Transplantation in the presence of circulating antibody to glomerular basement membrane will result in the immediate recurrence of Goodpasture's disease. The dense deposit variety of mesangiocapillary glomerulonephritis, which is usually associated with hypocomplementaemia, predictably recurs and may destroy the graft. In paediatric practice, the nephrotic syndrome associated with focal segmental glomerulosclerosis may recur in the immediate post-transplant period and can be associated with massive proteinuria, hypovolaemia, and thromboembolism. The risk of recurrence should be taken into account when assessing patients for the possibility of a living related transplant.

Membranous glomerulonephritis can develop *de novo* in patients in whom the original disease was demonstrably different (between 2 and 10 per cent).

Other aspects of medical management of transplant recipients

Drug interactions

Care has to be taken when prescribing drugs for renal transplant recipients. Renal function must be considered, as well as the potential for drug interactions between immunosuppressive agents and other pharmaceuticals. Table 17 summarizes the more common interactions. ACE inhibitors, AT-I receptor antagonists, and non-steroidal anti-inflammatory drugs can compromise the perfusion of a single transplanted kidney, particularly if there is a degree of renal artery stenosis. Great care must be taken with potent enzyme inducers such as rifampicin as subtherapeutic levels of steroids and the calcineurin-blocking drugs can occur.

Diet

The help of a renal-trained dietician is essential. Patients may eat voraciously after release from the restrictions of dialysis and, with the euphoric effects of steroids, some gain in excess of 20 kg in the first year. About 5 per cent become grossly obese, which is associated insulin resistance, hyperlipidaemia, sympathetic overactivity, and hypertension. Hypercholesterolaemia is present post-transplant in about 30 per cent of patients and is related to drugs, proteinuria, and diet. Patients should avoid a high intake of saturated fats. Sodium intake—easily gauged from monitoring the 24-h urinary sodium excretion—is often excessive, a desirable intake being less than 100 mmol per day. A high urinary sodium causes urinary calcium wasting and may contribute to post-transplant osteoporosis as well as making hypertension more difficult to control. All patients should spend time with the dietician and be encouraged to adopt healthy eating guidelines. In addition to dietary advice, transplant recipients need education about the risks of contaminated food, for example with listeria, campylobacter, and cryptosporidium.

Additional therapy

The medical complications of renal transplantation are so numerous that many recipients will require many different drugs. The regimen often become intolerable and non-compliance can be a major problem. In the early post-transplant period it is necessary to give prophylaxis with co-trimoxazole, an H_2 antagonist, and possibly a bisphosphonate, as well as an appropriate anti-CMV regime. Patients who are at risk of tuberculosis require isoniazid for the duration of immunosuppression. Hypertension needs aggressive control. In the early post-transplant period there is also the possibility of wasting of magnesium, phosphate, and bicarbonate, each requiring supplements. Uric acid levels may be high and clinical gout may develop requiring either allopurinol or benzbromarone. Long-term management needs to include regular vaccinations (influenza and pneumococcus). To reduce the risks of accelerated vascular disease, aspirins and statins may also be indicated.

In patients with poorly functioning transplants, medical management must include the same measures as would be undertaken in a low clearance clinic for patients

expected to start dialysis. Under these circumstances, treatment may include erythropoietin therapy, iron and vitamin supplementation, a-calcidol, and oral phosphate-binders.

Follow-up

With an uncomplicated transplant operation, patients may only be in hospital for about 7 days. Following discharge, patients will need to be seen two or three times a week for the first month, once or twice a week for the second month, and then weekly for the third month. At each visit blood pressure and graft function is checked. Many units undertake weekly CMV surveillance for at least the first 3 months following transplantation. After 3 months, outpatient visits are gradually reduced with patients eventually being reviewed only every 3 to 4 months. Particular attention has to be paid to cardiovascular risk factors, infections, and neoplasia. Ideally, all patients should have an annual dermatological examination and women should have an annual cervical smear and colposcopy if indicated. Bone density should be monitored regularly. Even in an apparently stable transplant, some units perform a renogram every 1 to 2 years to detect deteriorating renal perfusion or an obstruction from an ischaemic ureteric stenosis. Patients at risk of tuberculosis will require a regular chest radiograph. Vaccinations should be kept up to date. Many centres offer an anniversary clinic when these medical complications can be more fully assessed. Accelerated atherosclerosis will lead to early coronary and peripheral vascular disease. Increasingly, renal transplant recipients are being put forward for coronary revascularization procedures, when it is interesting to note that angioplasty alone is less successful in renal patients and should be combined with stenting.

Pregnancy

A successful renal transplant restores fertility and pregnancy with normal vaginal delivery (unless there are obstetric indications for caesarean section) is possible. Most recommend that pregnancy is not embarked upon in the first year or if the serum creatinine is above 150 µmol/l or proteinuria greater than 2 g/day. Many successful pregnancies have been undertaken with renal function worse than this, but the risks are greater.

There is little evidence that immunosuppression with prednisolone, azathioprine, and cyclosporin A has a significant adverse effect on the fetus. Cyclosporin A may be associated with intrauterine growth retardation and prednisolone may produce neonatal adrenal suppression. Experience with tacrolimus is limited but is probably broadly similar to cyclosporin A. Pregnancy with mycophenolate mofetil is contraindicated. There is an increased risk of hypertension and pre-eclampsia in renal transplant recipients. Care has to be taken with the choice of antihypertensive agent. During delivery, intravenous fluid should be given and great care taken to avoid episodes of hypovolaemia and hypotension. It is usual to give an extra dose of steroid during the delivery, for instance 100 mg of intravenous hydrocortisone, and to increase oral prednisolone for a few days afterwards.

20.7.1 The glomerulus and glomerular injury

John Savill

Introduction

Patients with glomerular injury consequent upon diverse and often poorly understood stimuli present with remarkably stereotyped clinical features (see Section 20.3). Nevertheless, when investigated by percutaneous renal biopsy, clinically similar patients may exhibit an array of histopathological types of glomerular disease that can bewilder all but the most experienced of clinicians. The patterns of glomerular disease that the skilled histopathologist can recognize will continue to be extremely useful to clinicians. However, recent advances in glomerular cell biology point to a complementary approach toward understanding the pathogenesis and present or future treatment of glomerular disorders. Thus, apparently complex histopathological changes can be viewed as the sum of a small number of pathological alterations in the cell biology of the glomerulus. In this scheme, it is apparent that three potentially reversible cellular processes are active to varying degrees in most forms of glomerulonephritis: (1) leucocyte infiltration; (2) changes in the number, size, or phenotype of resident glomerular cells; and (3) changes in the amount and composition of extracellular matrix, which includes the specialized glomerular basement membrane. Furthermore, although three further processes—(4) crescent formation, (5) glomerular capillary thrombosis, and (6) glomerular sclerosis—may be viewed as irreversible events that are best prevented, there is some hope that resolution of such processes and subsequent repair could be encouraged. Consequently, a basic knowledge of the cellular processes that constitute a threat to long-term function in glomerular disease may not only assist in the understanding of complex glomerular pathologies but will also prepare the contemporary clinician for implementing future therapies targeted at key pathological processes.

Key cellular processes in glomerular disease

Leucocyte infiltration

Accumulation of potentially injurious leucocytes is a hallmark of severe inflammatory glomerular injury (Fig. 1).

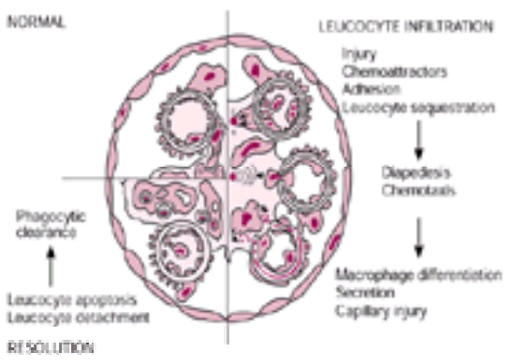

Fig. 1 Leucocyte infiltration in glomerular injury. Generation of chemoattractants and other mediators (consequent upon, for example, immunological injury), causes endothelial cells to express adhesion molecules to which leucocytes bind, these commonly then being sequestered in capillary lumens. However, leucocytes may also migrate towards areas with a high concentration of chemoattractants (chemotaxis), crossing the basement membrane by diapedesis. Monocytes can mature into secretory macrophages, which may further exacerbate capillary injury. Resolution can occur, due to detachment of sequestered leucocytes and apoptosis of leucocytes that have left the bloodstream, the latter leading to anti-inflammatory phagocytic clearance of apoptotic leucocytes.

Granulocytes (usually neutrophils, but sometimes eosinophils) represent the 'rapid response force' of the inflammatory response and are prominent in severe acute inflammatory conditions such as ANCA-positive vasculitis (**ANCA**, antineutrophil cytoplasmic antibody). Granulocytes threaten to exacerbate injury by generating reactive oxygen species and releasing granules yielding toxic cationic proteins, potent degradative enzymes, and monocyte chemoattractants. However, they are also present in self-limited conditions such as poststreptococcal glomerulonephritis, suggesting that their presence does not *per se* direct progressive glomerular injury. Indeed, this shows that granulocytes can be removed safely from inflamed glomeruli. Neutrophils accumulating in the capillary lumen can return to the circulation, while some extravasated cells reaching Bowman's space are flushed out in the urine. Furthermore, neutrophils 'trapped' in the mesangium or in partially occluded glomerular capillaries are cleared away by undergoing constitutive cell death by apoptosis. In turn this leads to anti-inflammatory engulfment of the intact dying cells by phagocytic cells, including macrophages and mesangial cells, with suppression of the phagocyte synthesis of inflammatory mediators by mechanisms involving local release of the anti-inflammatory cytokine transforming growth factor-b1 (**TGF-b1**).

If granulocytes are the 'storm-troopers' of inflammatory responses to tissue injury, then monocyte/macrophages are the 'regimental officers' controlling the attack. Time-course studies in animal models and in human disease emphasize that blood monocytes are recruited within a few hours of neutrophil sequestration in the injured glomerulus. These monocytes mature, by poorly understood mechanisms, into macrophages, which can be very easily overlooked unless detected by specific immunostaining. This confirms abundant macrophage infiltration in many different types of glomerular injury. There is persuasive evidence that macrophages can, depending on circumstances, either exacerbate injury or promote repair. The microenvironment in which macrophages mature, particularly the cytokines present, can irreversibly 'programme' the cells to adopt particular phenotypes. Thus interferon-gamma (**IFN-g**) programmes macrophages to adopt an 'activated/inflammatory' phenotype—which, for example, threatens neighbouring cells with injury or death induced by an enhanced macrophage release of nitric oxide, consequent upon IFN-g-directed induction of the inducible nitric oxide synthase (**iNOS**, also known as **NOS2**). However, if, for example, interleukin-4 (**IL-4**) predominates, macrophages adopt a 'reparative' phenotype in which TGF-b1 secretion will promote extracellular matrix deposition (see below).

T (thymic type) lymphocytes can also infiltrate injured glomeruli, although their presence usually indicates severe damage and a high risk of progression to scarring. T cells have a reciprocal relationship with macrophages—each can tell the other what to do. For example, T cells can summon macrophages to inflamed sites, while macrophage-lineage cells can direct T-cell behaviour by the presentation of antigens on MHC molecules, in the context of other macrophage surface molecules and macrophage-secreted cytokines that help to activate T cells. CD8-positive cytotoxic T cells and their close cousins, the natural killer (**NK**) cells, can injure or kill glomerular cells presenting antigen from infectious or other sources. Helper, CD4-positive T cells are probably important in orchestrating autoimmune glomerular injury, especially where this depends upon autoantibody production by distant B lymphocytes, as in Goodpasture's disease. While T cells may meet their fate by undergoing apoptosis at inflamed sites, these cells are typically 'visitors' circulating through the glomerulus from the blood to the lymphatics, unwanted T cells dying in lymph nodes.

Therapeutic approaches

Glucocorticoids reduce leucocyte infiltration of inflamed tissue by multiple mechanisms, including inhibition of recruitment, promotion of deletion by apoptosis (eosinophils and lymphocytes), and increased phagocyte clearance of dying leucocytes. Immunosuppressive agents such as cyclophosphamide may also reduce leucocyte infiltration, in part by diminishing circulating leucocyte numbers. New therapies in development aim: to inhibit adhesion molecules involved in leucocyte recruitment; to block the action of chemoattractants, such as chemokines or complement fragments; or to inhibit the upregulation of both adhesion molecules and chemoattractants by blocking the action of 'master' proinflammatory cytokines such as tumour necrosis factor-a (**TNF-a**), an approach that has been successful in treating patients with rheumatoid arthritis.

Changes in resident cell number, size, or phenotype

Mesangial cells are smooth muscle-like pericytes of the glomerulus, regulating structure by supporting glomerular capillaries and by modulating the amount or composition of the extracellular matrix (see below). They may also modulate glomerular function, controlling perfusion and filtration by the release of vasoactive mediators and effecting constriction/relaxation. Many glomerular diseases exhibit 'mesangial expansion' or 'mesangial proliferation' in their early stages (Fig. 2), an example being IgA nephropathy. Such pathological features usually reflect an increase in the number of mesangial cells—mesangial hyperplasia, which is due to increased mesangial cell mitosis (true proliferation)—and/or decreased mesangial cell death. Interestingly, however, diabetic nephropathy appears to exhibit a predominant increase in mesangial cell size (hypertrophy) rather than number. Nevertheless, both hyperplasia and hypertrophy involve the activation of intracellular regulatory proteins called cyclin-dependent kinases. In hyperplasia, these cyclin-dependent kinases drive mesangial cells through the cell cycle so that they divide and increase in number, while in hypertrophy such progression does not occur but the cell grows in size. These intracellular controls on mesangial cell number and size are subject to exquisite external controls. Thus, increases in mesangial cell number can be driven by platelet-derived growth factor (**PDGF**) and basic fibroblastic growth factor (**bFGF**). Both mesangial cell hyperplasia and hypertrophy threaten later progression to scarring, this is because these changes in mesangial cell number and size are usually accompanied by the adoption of an abnormal myofibroblast-like phenotype characterized by the expression of a-smooth muscle actin. Such myofibroblast-like mesangial cells are remarkably similar to skin myofibroblasts, which mediate both wound repair and contraction/closure and whose presence is strongly associated with the deposition of excess, abnormal extracellular matrix (see below).

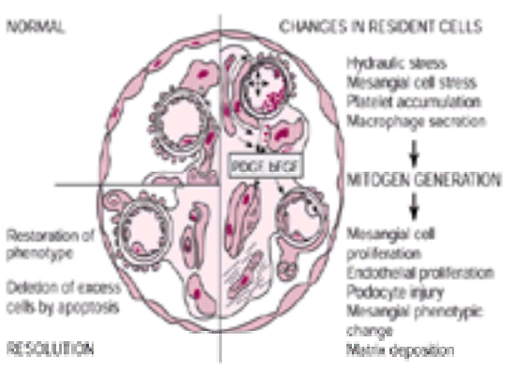

Fig. 2 Resident cell changes in glomerular injury. Hydraulic stress upon mesangial cells (as may occur in glomerular hypertension), secretory macrophages, and recruited blood platelets may all release mitogens such as PDGF (platelet-derived growth factor) or bFGF (basic fibroblastic growth factor). These trigger the proliferation of mesangial and endothelial cells and the phenotypic change seen in these and epithelial cells (podocytes). Such changes are associated with alterations in matrix (see Fig. 3). Resolution involves the deletion of excess resident cells by apoptosis and the restoration of the resident cell phenotype.

Glomerular endothelial cells seem to obey similar 'rules' as mesangial cells. They undergo true proliferation (i.e. hyperplasia) in poststreptococcal and other forms of glomerular injury, although whether this has the ominous implications of a mesangial cell increase is unclear. By contrast, glomerular epithelial cells or podocytes do not readily undergo proliferation in humans after birth: although they can respond to injury by synthesizing DNA and even becoming binucleate, experimental work in rodents emphasizes that adult podocytes rarely divide. Indeed, it is important to emphasize that the number of glomerular resident cells can also decline undesirably, especially when acute glomerular injury progresses to glomerular sclerosis or scarring (see below).

Therapeutic approaches

It has not been established whether any current therapies specifically modulate changes in the resident cell number, size, or phenotype. However, because such changes may be triggered by mechanical cellular stress resulting from an increased glomerular perfusion pressure, some of the beneficial effects of antihypertensive agents, especially angiotensin-converting enzyme (**ACE**) inhibitors and angiotensin II blockers, may prove to be mediated by effects on resident cells. New therapies in development include drugs that specifically inhibit the cyclin-dependent kinases, which may mediate undesirable glomerular cell hyperplasia and/or hypertrophy.

Increased deposition of abnormal extracellular matrix

The normal glomerular extracellular matrix is a network of proteins and proteoglycans (such as heparan sulphate proteoglycan) of critical importance in regulating the survival and properties of glomerular cells, in addition to supporting the glomerular structure. The accumulation of extracellular matrix (**ECM**) is a prominent feature of most glomerular diseases (Fig. 3) and reflects the combined effects of an increased secretion of matrix components and tissue inhibitors of metalloproteinases (**TIMPs**) from glomerular cells. The increased deposition of ECM is thus achieved both by laying down new matrix and preventing the degradation of new or existing ECM. Furthermore, the protein composition of ECM is abnormal in injured glomeruli: there is an accumulation of 'interstitial' type I and type III collagens and of plasma-type fibronectin, alongside an increase in normal constituents such as laminin and type IV collagen. Indeed, there is now a growing body of data to demonstrate that potentially deleterious alterations in glomerular ECM may be dependent upon an excess local secretion (or action) of the cytokine TGF-b1. The propensity of TGF-b1 to promote an undesirable accumulation of ECM is thought to represent the 'dark side' of mechanisms that evolved to promote wound-healing. For example, the accumulation of abnormal ECM is a prominent feature of diabetic nephropathy and may be so exuberant as to form Kimmelstiel–Wilson nodules, constituting a grave threat of progression to scarring. However, in keeping with the dynamic balance between synthesis and degradation that underlies ECM accumulation, abnormal glomerular ECM can be remodelled in self-limited disorders such as some cases of IgA nephropathy.

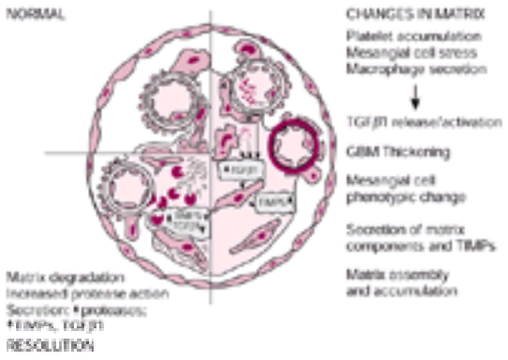

Fig. 3 Extracellular matrix changes in glomerular injury. Mesangial cells (stressed by, for example, hydraulic stimuli), secretory macrophages, and recruited platelets may all release TGF-b1 that is locally activated. In turn, this fibroblastic cytokine causes mesangial cells to adopt a myofibroblastic phenotype, secreting both matrix components and TIMPs, with a net accumulation of abnormal matrix. Similar mechanisms, probably also impinging on endothelial cells, can cause thickening of the glomerular basement membrane (**GBM**). Resolution requires a switch in glomerular cell secretion so that proteases (depicted as 'pacmen') predominate over TIMPs, leading to beneficial matrix degradation.

The general principles of matrix changes in glomerular injury are also evident in the most specialized compartment of the glomerular ECM, the glomerular basement membrane (**GBM**). Thus, thickening of the GBM in cases of diabetic nephropathy largely reflects the accumulation of normal constituents, while grossly similar changes can be caused by the deposition of abnormal proteins, such as amyloid. Examination under polarized light, special stains, immunofluorescence, or electron microscopy may be required to reveal the deposition of abnormal proteins, which can also include immune deposits or fibrils, or intrinsic defects such as those of Alport's syndrome.

Therapeutic approaches

There is no unequivocal evidence that currently available treatments directly and specifically effect changes in the glomerular matrix. New therapies in development include agents to inhibit the profibrotic effects of TGF-b1 (which may be particularly useful in diabetic nephropathy) and drugs that target the control of matrix deposition by antagonizing, for example, TIMPs.

Glomerular crescent formation

Glomerular crescents, abnormal masses of cells filling Bowman's space, are a reflection of severe glomerular injury associated with disorders such as vasculitis, systemic lupus erythematosus (**SLE**), and anti-GBM disease. Indeed, scanning electron microscopy studies of crescentic glomerulonephritis have demonstrated holes in the glomerular basement membrane, consistent with the idea that bleeding into Bowman's space and the deposition of fibrin are crucial pathogenetic factors (Fig. 4). Nevertheless, crescents can be viewed as being a special consequence of the three cellular processes described above. First, monocyte/macrophages and sometimes other leucocytes such as lymphocytes frequently infiltrate them. econd, especially in early crescents, there is prominent evidence of an increase in number and change of phenotype in resident cells, that is to say the 'parietal' epithelial cells of Bowman's capsule, which unlike the 'visceral' glomerular epithelial cells (podocytes) undergo true proliferation in crescentic disease. Third, there is deposition of extracellular matrix, which is obviously abnormal in that it should not be present at all. These cellular processes of glomerular crescent formation are worthy of special consideration because they are widely believed to be incompatible with recovery of function, especially when Bowman's capsule has been breached, potentially allowing ingress of myofibroblasts from the locally injured interstitium.

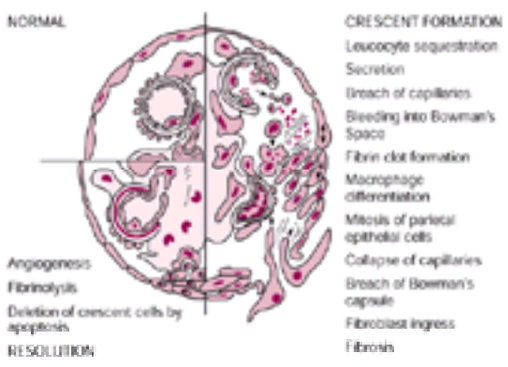

Fig. 4 Crescent formation in severe glomerular injury. Severe glomerular capillary injury, most likely mediated by leucocyte-derived reactive oxygen species and injurious proteins, causes breaches in capillary walls. Bleeding into Bowman's space, with formation of fibrin clot, then ensues. Blood monocytes mature into macrophages and parietal epithelial cells of Bowman's capsule may proliferate. The resultant crescent may compress capillaries, causing their collapse and occlusion, especially when injury is sufficiently severe to allow ingress of fibroblasts from the periglomerular space. It seems that glomerular fibrosis and loss is the rule. However, resolution may occur rarely, for example in poststreptococcal glomerulonephritis. Fibrinolysis, deletion of crescent cells by apoptosis, and repair of damaged capillary networks by angiogenesis may all play a role.

Therapeutic approaches

In some types of crescentic nephritis there is good anecdotal evidence that glucocorticoids/immunosuppressive agents may retard crescent formation by mechanisms likely to include the downregulation of monocyte/macrophage efflux into Bowman's space. Such drugs might also encourage resolution by promoting apoptosis and safe clearance of cells in crescents. Indeed, most nephrologists will have encountered cases of childhood poststreptococcal glomerulonephritis with 100 per cent crescents, which nevertheless exhibit a large degree of resolution, typically in association with immunosuppressive therapy. The fibrin component may be susceptible to anticoagulants/ancrod but new therapies are urgently required. There is active interest in the antagonism of cytokines/chemokines and in the blockade of leucocyte/endothelial adhesion molecules, but new insights into disease mechanisms are needed.

Glomerular capillary thrombosis

Thrombotic occlusion of glomerular capillaries is another manifestation of severe injury, consequent upon disorders such as systemic vasculitis, SLE, malignant hypertension, and radiation nephritis. Formation of platelet thrombi in glomeruli often reflects loss/retraction of glomerular endothelial cells with exposure to blood elements of the glomerular basement membrane (Fig. 5). Indeed, thrombosis often goes hand in hand with segmental necrosis of glomeruli. In such circumstances there would appear to be little prospect of successful repair and scarring of the affected lobule/glomerulus. However, all may not be lost: the astonishing capacity of mesangial cell precursors to repopulate glomeruli completely denuded of mesangial cells by experimental antibody-mediated injury is a testament to the capacity that the glomerulus may have—under suitable circumstances—to 'rebuild' itself. In keeping with such observations, recent data emphasize that angiogenesis, the growth of new blood vessels, can and does occur in the glomerular response to injury, under the direction of cytokines such as vascular endothelial growth factor (**VEGF**). This raises the possibility that such blood vessel growth could replace occluded, destroyed glomerular capillaries.

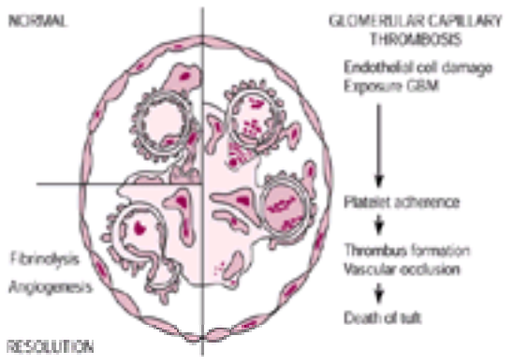

Fig. 5 Glomerular capillary thrombosis. Platelet adherence to the glomerular capillary may reflect mediator generation within the glomerulus, causing endothelial cell activation with adhesion molecule expression, or endothelial cell retraction leading to GBM exposure. Endothelial cells may also be damaged by bloodborne elements or ischaemia–reperfusion injury, as may occur in sickle cell disease. Tufts in which glomerular capillaries are occluded by thrombosis usually die by ischaemic necrosis. However, resolution is possible, since fibrinolysis can result in the recanalization of capillaries, which may be repaired by angiogenesis.

Therapeutic approaches

Clinicians dealing with glomerular capillary thrombosis frequently consider using anticoagulants/antiplatelet drugs, and growing experience of using thrombolytic agents in other vascular territories may lead to their increased use in the hope of recanalizing occluded vessels. New therapies under active consideration are likely

to concentrate on promoting recovery, but selective stimulation of angiogenesis capable of leading to glomerular repair is a distant prospect.

Glomerular scarring/sclerosis

Leucocyte infiltration, increased glomerular resident cell number/size, increased deposition of abnormal extracellular matrix, glomerular crescent formation, and glomerular capillary thrombosis may all be reversible to varying extents. However, all too frequently these cellular pathologies set the scene for glomerular sclerosis (Fig. 6). Nevertheless, although scarred, functionless glomeruli are beyond resurrection. However, recent insights into the pathogenesis of glomerular sclerosis offer some prospect of prevention and are therefore worthy of consideration.

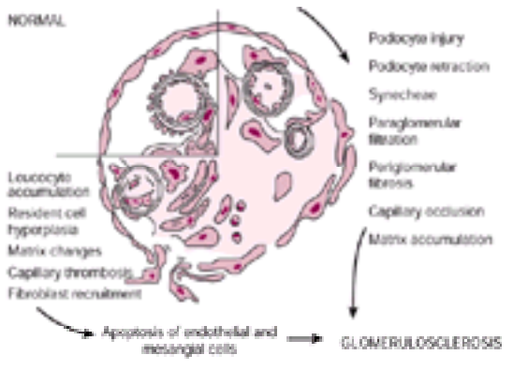

Fig. 6 Two pathways to glomerulosclerosis. At the bottom left, leucocyte accumulation, resident cell hyperplasia, matrix changes, capillary thrombosis, and recruitment of extraglomerular fibroblasts set up a situation in which progressive and unscheduled apoptosis of mesangial and endothelial cells leads to a featureless, non-functioning glomerular scar. This endstage glomerular lesion may also arise because of podocyte injury and retraction (top right), as may occur in HIV infection. 'Naked' GBM then adheres to Bowman's capsule because of local matrix deposition. As the adhesion enlarges, glomerular filtration may occur directly into the paraglomerular space (i.e. 'under' Bowman's capsule) causing gross periglomerular fibrosis and capillary occlusion, with ultimate progression to functionless scarring.

Although an increased number of cells in glomeruli (reflecting leucocyte infiltration and resident cell hyperplasia) characterizes potentially progressive glomerulonephritis, the scarred glomerulus is striking for its lack of cells, being replaced by featureless, acellular matrix. Growing evidence points to the undesirable deletion of resident glomerular cells via unscheduled apoptosis as a final common pathway in glomerular sclerosis. The mechanisms responsible are likely to be complex, since a wide range of possible apoptotic stimuli is likely to occur in injured glomeruli, but the potential consequences of glomerular cell loss are rather easier to appreciate. For example, loss of endothelial cells from glomeruli, as observed in models of progressive glomerular injury, obviously poses a hazard for the disruption of the glomerular blood supply, structure, and function. Such unscheduled loss may be prevented by the antiapoptotic properties of cytokine survival factors. Thus, recent studies suggest that the 165 amino acid isoform of VEGF is of central importance for endothelial cell survival in glomerular injury, while insulin-like growth factor-1 (**IGF-1**) may play a similar role in retarding mesangial cell apoptosis, emphasizing that glomerular cell loss might be preventable.

Recent work, based on elegant morphological studies by Kriz and colleagues, has emphasized the subtle and destabilizing effects of unscheduled glomerular cell loss upon the biomechanics of a delicate multicellular structure, that must contain blood at a much greater pressure than is usual in capillary networks. Loss of supporting mesangial cells is associated with glomerular capillary dilatation, which exerts deleterious mechanical stress upon both glomerular endothelial and epithelial cells, threatening their unscheduled death. Loss of podocytes (see Fig. 6) may be particularly dangerous because of the limited capacity of glomerular epithelial cells for mitosis; rather like precious neurones, if podocytes die they may not be replaced. The consequences of such loss include the formation of tuft adhesions to Bowman's capsule, which may allow abnormal filtration into the interstitium and promote periglomerular fibrosis, the adhesion propagating around an ever-more constricted glomerular tuft. This model may be particularly pertinent to the pathogenesis of focal segmental glomerulosclerosis (**FSGS**). Indeed, the model also predicts the course of the 'collapsing' form of FSGS seen in human immunodeficiency virus (HIV) infection, in which apparent podocyte dedifferentiation seems to deny the glomerulus an essential podocyte-mediated force that counterbalances mesangial cell-mediated constriction of the glomerulus.

Therapeutic approaches

All clinicians employ antihypertensives in the hope of retarding the progression of glomerular scarring, perhaps reducing mechanical stresses that trigger undesirable apoptosis. However, dietary protein restriction has yet to achieve widespread use, despite some encouraging trial evidence and animal data that this reduces potentially harmful glomerular hyperfiltration. New therapies are likely to concentrate on dealing with the cellular pathologies described above in the hope of preventing progression. Nevertheless, the advent of stem-cell therapies and tissue engineering raises the very distant prospect of growing replacement tissue/organs in the laboratory.

Conclusions

When confronted by apparently complex glomerular histopathological changes, it may be helpful to think of the six cellular pathologies described above. Although glomerular histopathology can provide extremely useful prognostic information, considering the cellular pathologies at the root of the problem may help the clinician address the primary concern as to whether the glomerular injury is likely to be amenable to treatment. This will be especially important as new therapies that target pathological cellular processes become available.

20.7.2Iga nephropathy and Henoch–Schönlein purpura

John Feehally

Introduction and definitions

IgA nephropathy

IgA nephropathy (**IgAN**) is the commonest pattern of glomerulonephritis identified in areas of the world where renal biopsy is frequently performed. It was first described by Berger in 1968 and at one time was known as Berger's disease. It is defined by IgA deposition in the glomerular mesangium, accompanied by a mesangial proliferative glomerulonephritis which may vary greatly in severity. Although recurrent macroscopic haematuria is the hallmark of the disease, the old term 'benign recurrent haematuria' is a discredited misnomer since it is now clear that IgAN is an important cause of endstage renal failure (**ESRF**).

Henoch–Schönlein purpura

Henoch–Schönlein purpura (**HSP**) is a somewhat misleading historical term. The purpuric rash is a cutaneous vasculitis (Plate 1), and HSP is a small-vessel systemic vasculitis characterized by IgA deposition in affected blood vessels. The renal lesion (HSP nephritis) is a mesangial proliferative glomerulonephritis, usually indistinguishable from IgAN.

Aetiology and pathogenesis

Mechanism of mesangial IgA deposition

Mesangial proliferative glomerulonephritis, such as is seen in IgAN and HSP nephritis, may be the consequence of immune complex deposition, either due to trapping of circulating IgA immune complexes or the formation of complexes *in situ* by the reaction of IgA with antigen that has already been deposited. No exogenous antigen has consistently been identified in the mesangial deposits in IgAN, which may indicate that the IgA complexes are a common response to different antigens, or that the initiating antigen has disappeared by the time of the renal biopsy. Alternatively, the IgA may be deposited by some mechanism independent of classical antigen–antibody interactions, such as a physicochemical abnormality of the IgA.

The frequent recurrence of both IgAN and HSP nephritis after renal transplantation strongly suggests that the abnormality resides in the host IgA immune system. The mesangial IgA deposits are polymeric IgA1 (pIgA1). Most pIgA is synthesized in the mucosa, and the clinical association of macroscopic haematuria with mucosal infection originally led to the assumption that an exaggerated mucosal IgA response resulted in mesangial IgA deposition. However, IgA production is downregulated in the mucosal immune system and upregulated in the bone marrow, and exaggerated IgA1 responses to immunization in these patients are marrow rather than mucosally derived.

There is increasing evidence of abnormal glycosylation of both serum and mesangial IgA1 in patients with IgAN and HSP nephritis. The glycosylation abnormality may favour the development of immune complexes or may directly provoke mesangial deposition, but these putative mechanisms have not yet been further defined.

Progression of IgA nephropathy

IgA deposition may occur in many patients with mild disease with little mesangial injury. What decides the prognosis in any individual is the extent to which IgA deposition is followed by mesangial proliferation, inflammation, and scarring. There is nothing to suggest that these subsequent mechanisms of damage and scarring are unique to IgAN, rather they are generic to many forms of glomerulonephritis.

Relationship of IgAN and HSP

There is much indirect evidence to suggest a close relationship between IgAN and HSP. Monozygotic twins have been described, one developing IgAN and the other HSP at the same time. HSP developing on a background of proven IgAN has been described in both adults and children. Many abnormalities of the IgA immune system, including abnormal IgA1 glycosylation, have been described in both conditions. IgAN is increasingly thought of as 'HSP without the rash'. Why some individuals get a renal-limited disease (IgAN) and others a systemic disease (HSP) is not known.

Epidemiology

IgAN is the commonest glomerulonephritis in countries where renal biopsy is widely used, typically found in 30 per cent of biopsies with primary glomerular disease, but the apparent prevalence varies markedly around the world. It is commoner in the Pacific Rim and Mediterranean countries, less so in North America and Northern Europe. At least part of this apparent difference is explained by variations in the use of urine testing in health screening and varying attitudes to the value of renal biopsy in individuals with isolated haematuria or other minor clinical evidence of renal disease. In Japan, for example, where there is routine urine testing of schoolchildren and employed adults, the threshold for renal biopsy is low, and the reported prevalence of IgAN is high.

There are also important racial differences in susceptibility. IgAN is uncommon in Afro-Caribbeans. It is also less common in Polynesians than Caucasians in Australasia—a particularly striking finding given the exaggerated susceptibility of Polynesians to most forms of renal disease. Despite many studies of potential immunogenetic associations, the genetic basis for such variations in susceptibility to IgAN has not yet been identified. IgAN is occasionally familial, one very large kindred having been described in Kentucky, in the United States; but the great majority of cases are sporadic.

Clinical features

IgA nephropathy

Macroscopic haematuria

IgAN can occur at any age, but the peak age of onset is in the second and third decades of life (Fig. 1). IgAN is three times more common in males than females.

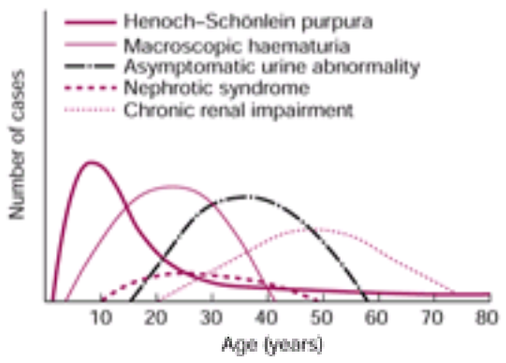

Fig. 1 Clinical presentations of IgA nephropathy (IgAN) and Henoch–Schönlein purpura (HSP) in relation to age at diagnosis. HSP is most common in childhood but may occur at any age. Macroscopic haematuria is very rare in people over the age of 40 years. The importance of an asymptomatic urine abnormality as the presentation of IgAN will depend on attitudes to routine urine testing and renal biopsy. It is uncertain whether those presenting with chronic renal impairment have a disease distinct from that of those presenting at younger ages with macroscopic haematuria. (Reproduced from Johnson RJ, Feehally J. *Comprehensive clinical nephrology*. London: Harcourt Publishers, 1999: 26.3, with permission.)

The characteristic clinical picture of recurrent macroscopic haematuria occurs in about 40 to 50 per cent of cases. A child or young adult develops episodes of painless macroscopic haematuria occurring within a day or so of the onset of an upper respiratory tract infection, or occasionally infections of other mucosal or IgA-secreting surfaces such as the gastrointestinal tract, bladder, or breast. The urine may be frankly bloody, but more often is brown (like 'Coca-Cola' or tea without milk), there are no clots passed and it is usually painless, although there may be dull loin ache. The episodes settle spontaneously after 1 to 5 days and may be recurrent, but rarely for more than a year or two. Serum IgA is moderately elevated in 30 per cent of cases but serum complement C3 and C4 levels are normal. Between episodes there will be persistent microscopic haematuria. This presentation does not occur beyond the age of 40 years (Fig. 1).

Asymptomatic haematuria/proteinuria

Some 30 to 40 per cent of cases of IgAN are identified by urine testing—microscopic haematuria may be combined with proteinuria (usually <2 g/24 h). Since this is glomerular haematuria, dysmorphic red cells may be seen on phase-contrast microscopy, but red cell casts are frequently absent in mild disease.

Nephrotic syndrome

Nephrotic syndrome is the presentation in only 5 per cent of patients with IgAN. Very occasionally in children or young adults this appears to be the consequence of coincidental minimal-change nephrotic syndrome: the proteinuria resolves completely with corticosteroid therapy, but haematuria and IgA deposits persist. More commonly, nephrotic syndrome may develop in cases of IgAN with overt mesangial proliferative glomerulonephritis, or it may be a consequence of glomerular scarring in advanced IgAN.

Acute renal failure

Acute renal failure occurs for two reasons in patients with IgAN. Episodes of macroscopic haematuria may produce acute tubular occlusion by red cells in the face of minor glomerular injury. Alternatively, there can be acute severe necrotizing glomerulonephritis with crescent formation—'crescentic IgA nephropathy', which may be the presenting feature or occur on a background of known milder disease.

Chronic renal failure

Patients with IgAN may also present with hypertension and established renal impairment. This often occurs in older patients (Fig. 1). Too little is yet known about the pathogenesis of IgAN to understand whether this is a distinct disease entity, or simply the same disease presenting much later in the absence of macroscopic haematuria or a urine test to bring it to earlier medical attention.

Clinical associations with IgA nephropathy

The commonest secondary cause of IgAN is chronic liver disease, typically alcoholic liver disease, in which it is probable that IgA deposition is a consequence of impaired IgA clearance from the circulation via the liver. Most hepatic IgAN is asymptomatic, and progression to ESRF is unusual. The other best established associations are with coeliac disease and dermatitis herpetiformis; with rheumatoid arthritis, ankylosing spondylitis and Reiter's disease; and with HIV infection. Many other conditions have been reported occasionally with IgAN, but since IgAN is so common it is difficult to know if these are more than chance associations.

Henoch–Schönlein purpura nephritis

HSP can occur at any age but is commonest in the first decade of life (Fig. 1). There is a slight male preponderance. A palpable purpuric rash caused by cutaneous vasculitis is the presenting feature. It has a characteristic extensor surface distribution, with sparing of the trunk and face. Crops of rash, often provoked by intercurrent infection, may continue for some time, but rarely beyond a year from first presentation. Polyarthralgia is common. Abdominal pain, due to gut vasculitis, is usually mild and transient, but severe pain and bloody diarrhoea may develop due to intussusception.

Apart from intussusception the major sequelae of HSP come from renal involvement. Renal disease in HSP is transient in many cases, asymptomatic haematuria or proteinuria disappearing in a few weeks. Of those with persistent evidence of renal disease, asymptomatic haematuria and proteinuria is the commonest clinical state, but 20 per cent will have nephrotic syndrome. Serum IgA is raised in 50 per cent of patients, but complement C3 and C4 levels are normal. Acute renal failure due to crescentic HSP nephritis usually occurs early and is commoner than crescentic IgAN.

Pathology

Immune deposits

IgAN and HSP nephritis are defined by the presence of mesangial IgA detected by immunofluorescence or immunoperoxidase staining (Plate 2). C3 frequently accompanies IgA in the same mesangial distribution, IgG and IgM are less common. Electron microscopy identifies mesangial electron-dense deposits corresponding to the mesangial IgA (Fig. 2).

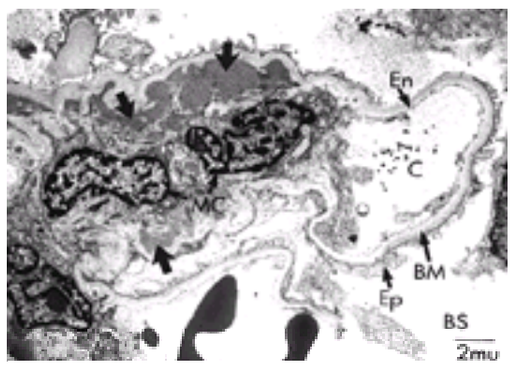

Fig. 2 Electron micrograph of a glomerular capillary loop in IgA nephropathy. Numerous electron-dense deposits representing deposits of IgA (large arrows) are seen within the expanded mesangium (5200 ×). BM, basement membrane; C, capillary lumen; Ep, visceral epithelium; En, fenestrated endothelium; MC, mesangial cell nucleus; BS, Bowman's space.

Light microscopy

Mesangial proliferative glomerulonephritis is the characteristic appearance. Although when haematuria is the only clinical finding, abnormalities seen on light microscopy may be minimal despite florid IgA deposition. Mesangial hypercellularity and matrix expansion are usually global but may be focal and segmental. The hypercellularity is followed by increasing mesangial matrix deposition and eventual sclerosis (Plate 3). In acute renal failure there may be severe glomerular inflammation with crescent formation. In advanced cases there is glomerulosclerosis and corresponding tubular atrophy and interstitial fibrosis, which are entirely non-specific changes of 'endstage kidney'.

Diagnosis and differential diagnosis

IgA nephropathy

By definition, the diagnosis of IgAN requires a renal biopsy: no serological or other laboratory indices provide diagnostic information reliable enough to avoid the need for tissue.

Macroscopic haematuria

Non-glomerular causes of haematuria must always be considered, including renal stones and neoplasia, and excluded where appropriate by urological investigation. While episodic macroscopic haematuria coinciding with an upper respiratory tract infection in children and young adults is the hallmark of IgAN, it is not pathognomonic. Similar episodes can occur with other glomerular diseases, most commonly hereditary nephropathies such as Alport's syndrome and thin membrane nephropathy. The distinction of IgAN from postinfectious (usually post-streptococcal) glomerulonephritis is also important. In post-streptococcal glomerulonephritis there is a 10- to 14-day latency period from the onset of infection and the development of symptomatic renal disease, contrasting with the immediacy of haematuria in IgAN for which the term 'synpharyngitic haematuria' has been coined. The haematuria is usually less heavy in post-streptococcal glomerulonephritis, such that the urine is typically smoky rather than frankly bloody; hypertension, oedema, and other features of the acute nephritic syndrome are usually present. Serological evidence of a recent streptococcal infection (such as antibodies to endostreptosin) and a low C3 level are not found in IgAN.

Nephrotic syndrome

The differential diagnosis when IgAN presents with nephrotic syndrome includes the usual range of glomerular diseases known to cause nephrotic syndrome given the age of the patient.

Chronic renal failure

Advanced IgAN presenting with hypertension, proteinuria, and renal impairment is clinically indistinguishable from many other causes of chronic progressive renal disease. If it is considered important to attempt a precise diagnosis, renal biopsy remains a valuable diagnostic tool since mesangial IgA can often still be identified even when light microscopy shows 'endstage kidney' disease.

Henoch–Schönlein purpura

In children HSP is the commonest form of vasculitis. A clinical diagnosis is often made from the characteristic rash and abdominal pain, but ultimate confirmation requires identification of tissue IgA deposition, which can be found in the vessels of affected skin as well as the kidney. In adults the differential diagnosis is wider, including many other forms of small-vessel vasculitis that must be distinguished on the basis of clinical, serological, and histopathological findings.

Prognosis

IgA nephropathy

Some 30 per cent of children will have a spontaneous clinical remission with complete disappearance of haematuria within 10 years of diagnosis. But IgAN, despite the apparently benign presentation in many cases, is an important cause of endstage renal failure (ESRF). Up to 25 per cent of patients reach ESRF within 20 years of diagnosis. Where a lower risk of ESRF is reported the series will contain larger numbers of patients with mild disease, such as those with isolated microscopic haematuria.

Perhaps unexpectedly, a history of episodic macroscopic haematuria is a favourable prognostic feature. The prognosis for patients who present with microscopic haematuria and minimal proteinuria (<1 g/24 h) is very good, but not perfect. Even in this group up to 5 per cent of patients will develop worsening proteinuria and hypertension during follow-up and are at eventual risk of ESRF. Consequently the long-term follow-up of any patient with biopsy-proven IgAN is mandatory. The risk of progressive renal failure can be predicted by clinical and pathological features at diagnosis (Table 1). These predictive features are not specific to IgAN, but identify the risk of progression in any glomerular disease.

Renal transplantation

Both IgAN and HSP nephritis recur after renal transplantation. Mesangial IgA deposits appear within a few months in 60 per cent of patients with IgAN. Initially this is benign, accompanied by little mesangial injury, but recurrent disease in the long term will contribute to progressive graft loss in a number of patients. However, overall transplant success and graft longevity do not differ in patients with IgAN or HSP from other primary renal disease. The changes in immunosuppressive regimens used to prevent rejection over the last two decades have not altered the recurrence rate or its prognosis.

Treatment

IgA nephropathy

Treatment proposals for IgAN are summarized in Table 2. Only in a small minority of patients with IgAN is there any evidence that drug therapy alters the natural history of the disease. Despite being so common among renal diseases, there is still a dearth of well-conducted, prospective, randomized controlled trials in IgAN on

which to base therapeutic decisions.

Specific treatment for IgAN would either restrict the formation of relevant pathogenic IgA molecules or prevent their deposition in the mesangium. So little is understood about the pathogenesis of the disease that the prospect for such treatment is still remote.

Haematuria

There is no specific treatment for the great majority of patients with IgAN who have isolated haematuria, with or without low-grade proteinuria (<1 g/24 h).

Microscopic haematuria should merely be observed. Recurrent macroscopic haematuria settles without treatment: there is no role for prophylactic antibiotics, and in any case the majority of precipitating infections are viral. Tonsillectomy may reduce the number of episodes of macroscopic haematuria, but there is no evidence that it reduces the risk of progressive renal failure.

Proteinuria

Those with proteinuria above 1 g/24 h in addition to haematuria have a worse prognosis. Immunosuppressive therapies have been tried, although the frequent recurrence of IgAN in transplanted kidneys when patients are receiving immunosuppressive therapy argues against their value. Short-term, randomized controlled trials of corticosteroids have shown no benefit. However, a 6-month controlled trial of treatment with corticosteroids (prednisolone 0.5 mg/kg per day) showed a significant reduction in proteinuria and a reduced risk of developing renal impairment at 5 years' follow-up. This requires further confirmation: corticosteroid treatment is not presently recommended, except in the rare circumstance where the biopsy suggests coincidental minimal-change nephrotic syndrome which may be fully steroid-responsive. All with proteinuria above 1 g/24 h should receive an ACE inhibitor to minimize protein excretion.

Other immune-modulating drugs have been tried in the treatment of IgAN, including cyclophosphamide, azathioprine, ciclosporin, and pooled human intravenous immunoglobulin. However, there are few properly controlled studies, and for none is there consistent evidence of benefit or an acceptable risk–benefit ratio in the great majority of patients who have indolent slowly progressive disease.

Acute renal failure

A renal biopsy is essential when acute renal failure develops in patients with IgAN. If the biopsy shows mild glomerular disease but tubular occlusion with erythrocytes and accompanying acute tubular necrosis, supportive treatment is required while recovery is awaited. If there is crescentic IgAN, a regimen such as that used for renal vasculitis and other forms of crescentic glomerulonephritis should be considered, unless the histological appearances are thought to be advanced and irreversible. Such treatment would typically include oral prednisolone 0.5 mg/kg per day (reducing to a maintenance dose of 5 to 10 mg daily by 3 months), and oral cyclophosphamide 2 to 3 mg/kg per day, the latter being replaced by azathioprine 2 to 3 mg/kg per day after 3 months. There are no randomized controlled trials of these treatments in crescentic IgAN. Although the initial response to treatment is excellent, the medium-term outlook is much less good, and up to 50 per cent of patients may be on long-term dialysis after 12 months.

Progressive renal impairment

Slowly progressive renal impairment due to IgAN requires a management approach common to any form of chronic renal failure. Rigorous control of blood pressure is the one established method of delaying progressive renal failure. Angiotensin-converting enzyme (**ACE**) inhibitors are widely used as first-line therapy for their special role in lessening proteinuria and giving a degree of blood pressure control, although there are no specific prospective studies to prove their additional efficacy in the treatment of IgAN compared to other hypotensive drugs. Fish oil therapy (which provides a supplement of w-3 fatty acids) has effects likely to impact favourably on mechanisms of progressive renal damage and has been used in randomized controlled trials in IgAN, but there is no reason to expect its effects are specific for IgAN, rather than other progressive disease. One such trial has shown a substantial reduction in the risk of progression to ESRF, but other studies have not shown comparable benefit and at present the use of fish oil is not recommended until confirmatory studies are available.

Henoch–Schönlein purpura nephritis

There is very little information to guide the treatment of patients with HSP nephritis. As there are no published randomized controlled trials, and most therapeutic studies in IgAN exclude patients with HSP, it is unclear whether their conclusions can be extrapolated to HSP.

Transient, early nephritis requires no specific treatment. There is no evidence that corticosteroids or other immunosuppressive regimens alter the natural history of the nephrotic syndrome or slowly progressive glomerular damage in Henoch–Schönlein purpura. Crescentic HSP nephritis is more common than crescentic IgAN. Regimens used in the therapy of renal vasculitis have also been applied to crescentic HSP nephritis with apparent benefit, although there are no controlled trials.

20.7.3 Thin membrane nephropathy

John Feehally

Introduction and definition

Thin membrane nephropathy (**TMN**) must always be considered alongside IgA nephropathy (**IgAN**) in the differential diagnosis of glomerular haematuria. TMN is an autosomal dominant condition diagnosed by examination of a renal biopsy by electron microscopy, which shows thin but otherwise morphologically normal glomerular basement membranes (**GBM**). The term 'benign familial haematuria' was used before the GBM abnormality had been identified.

Aetiology and pathogenesis

The genetic basis for TMN has not been defined, although it seems probable that defects in type IV collagen or other GBM proteins will eventually be identified. The gene defects in the a-3 and a-5 chains seen in Alport's syndrome are not found in TMN. A deletion in the gene for the a-4 chain of type IV collagen has been identified in one kindred, but this is not confirmed in other families and it is likely that TMN is genetically heterogeneous.

Pathology

The GBM is diffusely thin but otherwise morphologically normal (Fig. 1). This contrasts with Alport's syndrome in which the GBM is thickened and lamellated and the normal lamina densa of the GBM is disrupted. The normal range for GBM thickness must be determined in each laboratory because of the influence of techniques used for tissue fixation, but typically normal GBM thickness is between 350 and 450 nm. A uniform reduction to less than 250 nm is diagnostic of TMN.

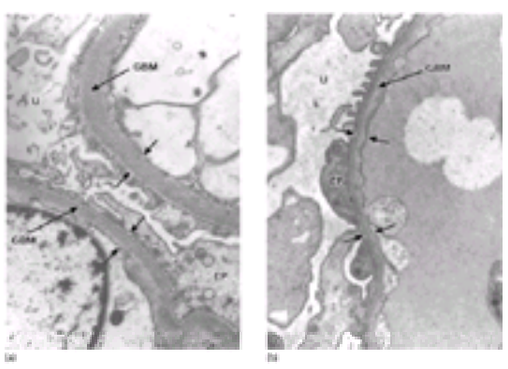

Fig. 1 Thin membrane nephropathy. Electron micrographs contrasting (a) glomerular basement membranes of normal thickness (350–450 nm) with (b) uniform membrane thinning (150–200 nm) in thin membrane nephropathy (both micrographs 20 000 ×). GBM, glomerular basement membrane; Ep, visceral epithelial cells; U, urinary space. (Glutaraldehyde fixation with osmium post-fixation. Ultrathin resin sections stained with uranyl acetate and lead citrate.)

Clinical features

TMN is common and is estimated to be the diagnosis in 20 to 25 per cent of patients presenting to a nephrologist with isolated microscopic haematuria. Autopsy studies suggest it may be present in 5 to 9 per cent of the population. It is an autosomal dominant condition but may also be sporadic. Persistent microscopic haematuria is usually lifelong, and episodic macroscopic haematuria may also occur. Proteinuria is uncommon and progressive renal impairment is rare but has been described in a number of families. Deafness and other extrarenal manifestations seen in Alport's syndrome are absent. There is no specific treatment.

Differential diagnosis

TMN can only be distinguished from IgAN by renal biopsy. Although the coexistence of TMN and IgAN is well recorded, it is a matter of debate whether this merely represents the coincidence of two common glomerular diseases. TMN must be distinguished from Alport's syndrome (hereditary nephritis with deafness), of which the commonest form is X-linked. If there is a clear autosomal dominant pattern of haematuria without renal insufficiency or extrarenal problems a clinical diagnosis of TMN may be established with reasonable confidence, but a renal biopsy in at least one family member is still preferable. Once the diagnosis is established in a kindred, biopsy is not required unless there are unexpected clinical findings. The differentiation from the less common autosomal forms of Alport's syndrome may be less straightforward. Subclinical deafness must be excluded by audiography if necessary. The renal biopsy also requires particularly careful assessment: in TMN there is uniform thinning; early in the course of Alport's syndrome, even if the characteristic structural disruption of the GBM has not yet developed, marked variability in GBM width is typical. Staining of GBM for the a-chains of type IV collagen is highly informative since in Alport's syndrome a-3, a-4, and a-5 are absent, whereas normal a-chain distribution is preserved in TMN.

Prognosis

The prognosis is excellent in the great majority of families with TMN, but there is a small but real risk of developing chronic renal failure, identified by the onset of proteinuria and hypertension. Long-term follow up of those with TMN is therefore required: urinalysis and measurement of blood pressure and renal function is recommended every 1 to 2 years.

20.7.4 Minimal-change nephropathy, focal segmental glomerulosclerosis, and membranous nephropathy

D. Adu

Classification of glomerulonephritis

The most helpful classification of glomerulonephritis is one based on histology. Careful clinical and pathological studies have established the histological patterns of glomerulonephritis in patients with a nephrotic syndrome inhabiting temperate regions of the world (Table 1). The aetiology and patterns of glomerulonephritis in tropical countries differ considerably and are considered elsewhere (see Chapter 20.7.10): discussion in this chapter refers to disease seen in temperate regions. Idiopathic glomerulonephritis accounts for 90 per cent of all childhood cases of the nephrotic syndrome and for approximately 80 per cent in adult patients. Although these histological changes are usually of unknown aetiology, they may also be secondary to well-defined aetiological factors.

General clinical approach

Children

In the original studies of the International Study of Kidney Diseases in Children (**ISKDC**) the diagnosis of minimal-change nephropathy was based on renal biopsies. From these and other studies it was established that for a child aged between 1 and 6 years with nephrotic syndrome and highly selective proteinuria, and who did not have microscopic haematuria, hypertension, or renal impairment, the likely diagnosis was minimal-change nephropathy. When treated with steroids, such children had a greater than 90 per cent chance of going into remission within 4 weeks. Based on these observations, children of this age with the features summarized above are no longer subjected to renal biopsy, but instead are treated with a trial of steroids. This leads to the term 'steroid-responsive nephrotic syndrome of childhood' and most, but not all, of such children will have minimal-change nephropathy. If the proteinuria does not respond to steroids at 1 month then a renal biopsy should be considered to establish the diagnosis. Children over 8 years of age are more likely to have a steroid non-responsive lesion and probably need a renal biopsy. In neonates and in children under 1 year of age there is a high probability of the congenital nephrotic syndrome or diffuse mesangial sclerosis, and therefore renal biopsy should be considered: neither of these lesions respond to steroids.

Adults

Only 20 per cent of adults with a nephrotic syndrome have minimal-change nephropathy and for that reason a renal biopsy is necessary to establish the type of glomerulonephritis. There have been suggestions that renal biopsy is not essential and that all nephrotic adults should be treated with steroids. However, this approach means unnecessary treatment of a large proportion of patients with a toxic drug, also that no assessment would be available of the type of glomerulonephritis or an estimate of the likelihood of a response to treatment and of the prognosis for long-term renal function. In skilled hands the dangers of renal biopsy are small and outweighed by those of steroid treatment.

General aspects of the management of the nephrotic syndrome

Although steroids and immunosuppressants have been widely used in the treatment of the nephrotic syndrome, general measures remain an important part of the treatment of these disorders. Initial treatment of oedema is with salt restriction and if there is hyponatraemia with fluid restriction. Adults are commonly treated with loop diuretics such as furosemide (frusemide), but this must be used with care, particularly in children, because of the risk of volume depletion and consequent renal impairment. Patients with a nephrotic syndrome are at an increased risk of developing thromboemboli but prophylactic anticoagulation is not normally recommended. There is now good experimental and clinical evidence that angiotensin-converting enzyme (**ACE**) inhibitors reduce proteinuria and slow the progression of renal impairment in patients with glomerulonephritis. These agents are recommended in those who are likely to have a prolonged nephrotic syndrome. Such patients are also likely to benefit from lipid-lowering therapy, although this has not been tested by randomized controlled study.

Minimal-change nephropathy

Aetiology

There is a well-recognized association between Hodgkin's lymphoma and minimal-change nephropathy. Rarely, minimal-change nephropathy has been reported in patients with a carcinoma. There are also case reports of minimal-change nephropathy in individuals, often atopic, exposed to bee stings, poison oak, grass pollen, and cow's milk. Non-steroidal anti-inflammatory drugs can cause an interstitial nephritis, which in some cases is accompanied by a nephrotic syndrome with renal histology showing the changes of minimal-change nephropathy.

Pathogenesis

The responsiveness of the nephrotic syndrome of minimal-change nephropathy to steroids, cyclophosphamide, chlorambucil, and ciclosporin A is strong evidence that this disorder is immune-mediated. The pathogenetic mechanisms remain obscure. The low serum IgG and high IgM levels in these patients appear to be a consequence of the nephrotic syndrome and shed no light on pathogenesis. The hypothesis that proteinuria is caused by a lymphokine produced by an abnormal clone of T lymphocytes has been extensively studied: as yet it has neither been proved nor disproved. In Europe an increased incidence of HLA-DR7 is found in patients with minimal-change nephropathy and in Japan the association is with HLA-DR8, thus suggesting a genetic predisposition.

Pathology

The histological features are similar in both children and adults. On light microscopy the glomeruli appear normal or small (Fig. 1 and Plate 1) and on electron microscopy there is effacement of epithelial-cell foot processes over the outer surface of the glomerular basement membrane. Some authors accept a minor degree of mesangial IgM deposition and mesangial proliferation as being consistent with this disorder.

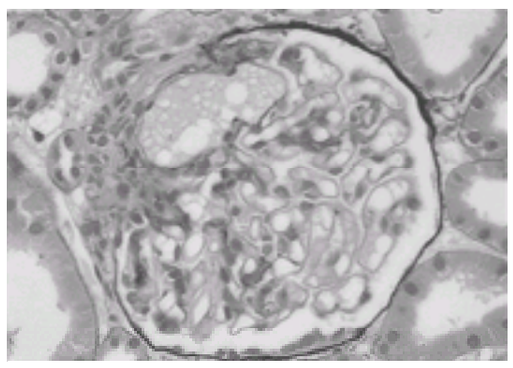

Fig. 1 Minimal-change nephropathy. The glomerulus looks normal on light microscopy. Periodic acid–methenamine silver staining (64 ×). (By courtesy of Dr A. J. Howie.) (See also Plate 1.)

Minimal-change nephropathy in children

Minimal-change nephropathy is found in approximately 76 per cent of children with an idiopathic nephrotic syndrome. Most affected children are under 6 years of age (80 per cent), with a peak age of onset of 2 to 4 years. The condition is responsible for 59 per cent of those aged between 6 and 15 years and about 20 per cent of adults with the nephrotic syndrome. It is more common in boys than in girls, with a male to female childhood ratio of 2:1.

Clinical presentation

The clinical presentation is with a nephrotic syndrome that is characterized by severe hypoalbuminaemia, with a serum albumin level of less than 10 g/l in some 38 per cent of cases. Microscopic haematuria is infrequent (22 per cent), as is hypertension (9 per cent). Renal impairment is infrequent at diagnosis, being found in about 10 per cent of cases, and presentation in acute renal failure is rare. These children are prone to infections, in particular cellulitis and pneumococcal peritonitis.

Diagnosis

The role (or not) of renal biopsy has already been discussed. In 75 per cent of children with minimal-change nephropathy the proteinuria is highly or moderately selective. The concept of protein clearance selectivity was based on the hypothesis that the glomerular basement membrane provided a size-selective barrier to the loss of protein molecules. Although it is now clear that glomerular permselectivity is also based on the charge of molecules, the selectivity test remains useful. A simple version involves dividing the ratio of the urine and plasma concentrations of a large protein (for example, IgG or a $_2$-macroglobulin) by the ratio of the urine and plasma concentrations of a small molecule (for example, albumin or transferrin).

Treatment of minimal-change nephropathy in children

The first-line treatment of minimal-change nephropathy is prednisolone at an initial dose of 60 mg/m ^{2} (maximum dose 80 mg) daily for 4 to 6 weeks, reducing the prednisolone to 40 mg/m^2 (maximum dose 60 mg) on alternate days for a further 4 to 6 weeks. With this treatment 93 per cent of children respond with complete loss of proteinuria within 8 weeks. This duration of treatment is more effective in maintaining a remission than a shorter course of steroids. However, once remission is induced, 66 per cent of children have at least one relapse. The major problem is that between 40 and 55 per cent of children who initially respond to steroids develop multiple relapses when steroids are discontinued, or they become steroid-dependent and relapse when the steroid dosage is reduced. Early, frequent relapses (three or more) in the 6 months following an initial response to steroids predict a frequently relapsing course.

Treatment of relapses

Prednisolone 60 mg/m^2 should be given until the urine is free of protein for 3 days (maximum 4 weeks) then prednisolone 40 mg/m ^{2} on alternate days for 4 weeks. Children's growth should be carefully monitored, using growth curves, during repeated steroid treatment of relapses.

Cyclophosphamide/chlorambucil

Treatment with an immunosuppressant drug should be considered in the following groups of patients: children who are frequent relapsers (two relapses within 6 months of the initial response or four relapses within any 1 year); children who are steroid-dependent (two consecutive relapses occurring during alternate-day treatment for an earlier relapse) or who relapse within 14 days of treatment of an earlier relapse (fast relapse); children in whom two out of four relapses within 6 months were fast relapses; children who are steroid-toxic. There is good evidence that short-term treatment with cyclophosphamide can induce a sustained or even permanent remission in such children. Cyclophosphamide is given in a dose of 2 mg/kg per day (ideally, height for weight) for 8 weeks. Approximately 50 per cent of treated children are in remission at 2 years and 40 per cent at 5 years. One study suggested that the duration of remission was longer with a 12-week course compared with an 8-week course of cyclophosphamide, but this was not subsequently confirmed. Chlorambucil has also been used to treat these patients, but there is no evidence that it is better than cyclophosphamide and it is probably more toxic. Cyclophosphamide has been carefully evaluated in these children and is the drug of choice. Children with the HLA allele HLA-DR7 are less likely to respond to cyclophosphamide.

Toxicity of cyclophosphamide and chlorambucil

The risk of gonadal toxicity is greater in boys than in girls. Gonadal toxicity occurs with chlorambucil at a cumulative dose of 8 to 10 mg/kg. The borderline dose for permanent gonadal toxicity with cyclophosphamide is a cumulative dose of 200 mg/kg. Bone marrow toxicity with both drugs means that the leucocyte count should be regularly measured during treatment. These drugs also increase the long-term risk of developing cancer. Other toxic side-effects of cyclophosphamide include leucopenia, haemorrhagic cystitis, and alopecia. At the doses and duration of treatment outlined above it is relatively safe.

Levamisole

This has been used in children with frequently relapsing or steroid-dependent minimal-change nephropathy and appears to have a steroid-sparing effect. However, the benefits appear marginal and most patients relapse after stopping treatment. Levamisole can cause a reversible neutropenia.

Long-term outcome

The risk of a future relapse is low for those children in whom the nephrotic syndrome goes into remission within 8 weeks of steroid therapy and who do not relapse for 6 months. Early relapse within 6 months is reported to be associated with a risk of relapses for up to 3 years. Some 5.5 per cent of affected children continue to relapse into adult life. All of these children presented with a nephrotic syndrome before the age of 6 years. Children who had persistent proteinuria at 8 weeks had a 21 per cent risk of developing endstage renal failure, and this increased to 35 per cent if they still had proteinuria at 6 months. The long-term mortality rate in children ranges from 2.6 to 7.2 per cent.

Minimal-change nephropathy as part of a spectrum of glomerular disease

In temperate countries, the majority of children with a nephrotic syndrome have minimal-change nephropathy, focal segmental glomerulosclerosis (**FSGS**), or a mesangial proliferative glomerulonephritis (Table 1). Since there is considerable overlap between these conditions, it has been argued that they are all variants of the same disease, termed the 'idiopathic nephrotic syndrome'. In favour of this view is the observation that the histological lesion may evolve with time in a proportion of patients with steroid-responsive nephrotic syndrome. Repeat renal biopsies performed if the character of illness changes—for example, if patients become frequent relapsers, steroid-dependent, or steroid-resistant—sometimes show progression from minimal-change nephropathy or mesangial proliferative glomerulonephritis to focal segmental glomerulonephritis. One study showed that patients with presumed minimal-change nephropathy whose renal biopsies showed large glomeruli were more likely to develop FSGS. In general, those patients with minimal-change nephropathy who develop FSGS but remain steroid-responsive have a good prognosis for renal function, whilst those who are steroid-resistant develop progressive renal failure. The prognosis for renal function is therefore determined by the responsiveness to steroids and not by the histological lesion.

Minimal-change nephropathy in adults

About 20 per cent of adults with a nephrotic syndrome have minimal-change nephropathy. The mean age of onset is 40 years but the condition can occur at any age. The histology is identical to that found in children, with the exception of a higher incidence of globally sclerosed glomeruli that are a feature of ageing.

Clinical presentation

As in children the clinical presentation is with a nephrotic syndrome, although this is not generally as severe. Profound hypoalbuminaemia (serum albumin level under 10 g/l) is rare in adults, being found in only 6 per cent of cases. The disease is slightly more common in men than in women, with a male to female ratio of 1.3:1. More adults than children are hypertensive (30 per cent), have microscopic haematuria (28 per cent), and have renal impairment at diagnosis (60 per cent). These abnormalities are more severe in patients aged over 60 years who are also at particular risk of developing acute renal failure.

Diagnosis

Only 50 per cent of adults with minimal-change nephropathy have highly selective proteinuria, which together with the high incidence of microscopic haematuria and renal impairment makes it impossible to differentiate minimal-change nephropathy from other forms of glomeru-lonephritis on clinical grounds. A renal biopsy is essential to make the diagnosis in adults with a nephrotic syndrome,.

Treatment of minimal-change nephropathy in adults

Treatment is with prednisolone at an initial dose of 60 mg/day: response occurs slightly less often than in children and also more slowly. Some 80 per cent of adults with minimal-change nephropathy do respond, but remission can take up to 16 weeks to occur. Relapse is less frequent in adults (1.7/patient) than in children, and only 21 per cent of adults develop multiple relapses or are steroid-dependent. In adults as in children, cyclophosphamide is effective in inducing a long-lasting remission. In one study 62.5 per cent of patients treated with cyclophosphamide were in remission at 10 years.

Ciclosporin A

There is now good evidence that ciclosporin A is effective in the treatment of minimal-change nephropathy in both adults and children. Patients who are steroid-responsive or multiple relapsers are more likely to respond with complete or partial remissions (70 to 80 per cent) than patients who are resistant to steroids (40 to 50 per cent). The drug should be considered in those patients who develop steroid toxicity because they have multiple relapses or who are steroid-dependent. Ciclosporin A appears to be effective at blood levels of between 100 and 200 ng/ml, and at these levels significant short-term nephrotoxicity and hypertension are uncommon. However, relapses appear to recur with the same frequency after ciclosporin A has been discontinued as before, and for that reason it is still advisable to use cyclophosphamide as the first-choice treatment in patients with a multiple relapsing or steroid-dependent minimal-change nephropathy in the hope of inducing a sustained remission. In this author's view, ciclosporin A can best be viewed as a steroid-sparing agent in patients with minimal-change nephropathy.

Long-term outcome

Some 6 per cent of adult patients are still nephrotic after a mean follow-up of 7.5 years. The survival in patients over 60 years of age has been reported to be 50 per cent at 10 years, and in those aged 15 to 59 it was 90 per cent.

Focal segmental glomerulosclerosis

Focal segmental glomerulosclerosis (FSGS) was first described by Rich in 1957 at autopsy in children who died from a nephrotic syndrome. Fewer terms have generated more disagreement amongst pathologists and nephrologists: it is not a disease entity but a histological lesion that is often of unknown aetiology.

Secondary FSGS

FSGS may be a sequel of glomerular scarring in patients with previous proliferative glomerulonephritis and is seen in biopsies from patients with Alport's syndrome. It is also seen in patients with reflux nephropathy and other conditions leading to a reduced renal mass, and it is likely that the segmental sclerosing lesions in these circumstances are a consequence of glomerular hypertension and hyperfiltration (Table 2). FSGS has also been found late on during the clinical course of patients with a nephrotic syndrome who had an initial renal biopsy showing minimal-change nephropathy.

Pathogenesis

In experimental models, focal segmental sclerosis can develop from different pathogenic mechanisms. These include toxic injury (puromycin nephropathy), immunological injury (anti-GBM nephritis), the lupus-associated nephritis in NZB/NZW F1 mice, and hyperfiltration injury (5/6ths nephrectomy). Some of these models have clinical counterparts, and the diversity of pathogenic mechanisms may explain the variability in the clinical presentation and response to FSGS therapy. As with minimal-change nephropathy there are suggestions that the glomerular injury in FSGS is caused by a lymphokine. The rapid development of heavy proteinuria following renal transplantation in some patients with FSGS indicates that the glomerular injury is caused by a circulating factor.

Primary FSGS

Focal segmental glomerulosclerosis may be apparently idiopathic and found early on during the clinical course of patients with proteinuria or nephrotic syndrome. About 7 per cent of children and 20 per cent of adults with a nephrotic syndrome have FSGS. Even when FSGS is found early on in the course of a nephrotic syndrome there is no evidence to suggest that it represents a homogenous disease.

Pathology

The histological lesions of FSGS comprise segmental areas of glomerular sclerosis with hyalinization of glomerular capillaries, the segmental areas usually being adherent to Bowman's capsule. In childhood FSGS, these lesions predominantly affect juxtamedullary glomeruli. Typically, the areas of segmental sclerosis are randomly distributed within the glomerular tuft with a predilection for the hilar regions, and these patients may be regarded as having classical FSGS (Fig. 2 and Fig. 3 and Plate 2 and Plate 3). In some biopsies the glomerular lesions are located peripherally at the glomerulotubular junction, the so-called glomerular tip lesion. Focal areas of tubular atrophy and interstitial nephritis are prominent. On immunofluorescent microscopy, deposits of IgM and C3 may be seen in the sclerotic areas. Electron microscopy shows diffuse foot-process effacement in apparently unaffected glomeruli.

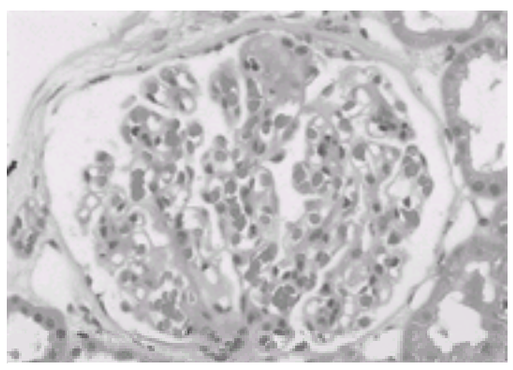

Fig. 2 Classical segmental sclerosing glomerulonephritis at an early stage. The glomerulus shows an erratic increase in mesangium with a segmental area of foamy cells and sclerosis opposite the vascular pole, next to the tubular origin. Haematoxylin and eosin staining (50 ×). (By courtesy of Dr A. J. Howie.) (See also Plate 2.)

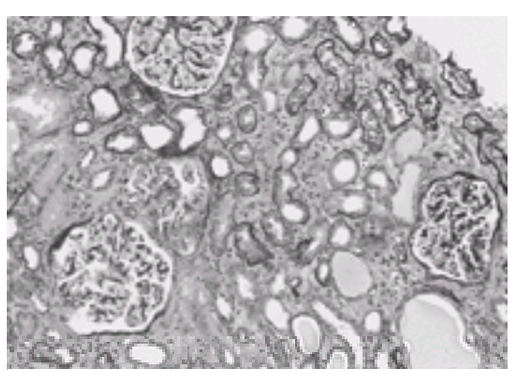

Fig. 3 Classical segmental sclerosing glomerulonephritis at a late stage. Four glomeruli show an erratic increase in mesangium and segmental lesions at various sites. Periodic acid–methenamine silver staining (× 64). (By courtesy of Dr A. J. Howie.) (See also Plate 3.)

Pathogenesis

In approximately 30 per cent of patients with primary FSGS there is a circulating factor that causes an increase in glomerular permeability *in vitro*. This factor appears to be a protein with a molecular weight of between 30 and 50 kDa and is not an immunoglobulin. This factor has also been found in the serum of patients who develop recurrent FSGS postrenal transplantation.

Clinical presentation

Children

Approximately 7 per cent of children presenting with an idiopathic nephrotic syndrome have FSGS. Males and females are equally affected and the peak age at onset is between 6 and 8 years. The majority of patients (75 per cent) present with a nephrotic syndrome, 20 per cent have persistent proteinuria, and 5 per cent haematuria as well as proteinuria. Clinically these patients differ from other children with minimal-change nephropathy, in that two-thirds have microscopic haematuria, half have impaired renal function at diagnosis, and one-third are hypertensive. The proteinuria is usually poorly selective.

Adults

The clinical presentation in adults does not differ in any significant respects from that in children. The mean age at onset is between 20 and 30 years but FSGS has been found in patients aged 70.

Treatment of primary ('classical') FSGS

The prognosis in patients with primary FSGS and proteinuria in the non-nephrotic range is good, and 80 per cent of such patients survive for 10 years without developing endstage renal failure. These patients therefore do not need treatment with either prednisolone or immunosuppressants and should be treated with general measures only.

The main problem is the treatment of patients with FSGS and a nephrotic syndrome. In most studies patients have been given steroids, and approximately 30 per cent of those treated for 8 weeks with prednisolone go into remission. There is now good data from uncontrolled studies that a more prolonged course of steroids, of up to 6 months, is associated with a higher rate of remission. Children are treated with prednisolone at an initial dose of 60 mg/m ^{2} per day and adults with a dose of 60 mg/day. Patients who go into remission have a good prognosis with fewer than 10 per cent developing endstage renal failure. However, the prognosis in patients who do not respond to steroids is poor, with between 30 and 50 per cent developing endstage renal failure over 5 to 10 years. There is no difference in prognosis between adults and children. Adverse prognostic factors include tubulointerstitial fibrosis and a high serum creatinine level.

Other immunosuppressants

The evidence supporting the addition to prednisolone of cyclophosphamide or chlorambucil in the treatment of FSGS is not convincing. Useful remissions have been reported, but in the absence of controlled trials the value of this is difficult to assess.

Several uncontrolled studies have looked at the effects of ciclosporin A: in general, the responsiveness has been poor and paralleled that of steroids. Recent controlled studies in adults suggest that ciclosporin A when added to prednisolone is more effective in inducing remission of the nephrotic syndrome than steroids alone in patients with steroid-resistant FSGS.

Glomerular tip lesion

Some studies suggest that the site of the segmental sclerosing lesions predicted steroid responsiveness. Adult patients with a peripheral segmental sclerosing lesion at the tubular origin, the glomerular tip lesion, have a steroid- or immunosuppressant-responsive nephrotic syndrome and do not progress to endstage renal failure.

Similar observations have been reported in children, although in both children and adults these observations have not been confirmed.

Recurrence after renal transplantation

The nephrotic syndrome recurs in 20 to 40 per cent of patients with primary FSGS, often within days of renal transplantation, and this leads to graft failure in some 50 per cent of cases. After recurrence in a first transplant the rate of recurrence in a subsequent transplant approaches 75 per cent. Plasma exchange and protein immunoadsorption have resulted in a reduction of proteinuria or a remission of the nephrotic syndrome in some patients. These data are not controlled and our experience is that the reduction in proteinuria is transient.

Collapsing glomerulopathy

This is a type of focal segmental sclerosing glomerulonephritis, characterized by segmental or global collapse of glomerular capillaries with basement-membrane wrinkling and crowding of glomerular epithelial cells. These appearances represent a distinct subset of patients with focal segmental glomerulosclerosis, and were initially described in patients with HIV-associated nephropathy in the context of a severe nephrotic syndrome and rapid progression to endstage renal failure. Subsequent reports show that it may also be idiopathic.

Presentation is with a nephrotic syndrome and renal impairment (70 per cent of cases). Treatment with steroids or cytotoxic drugs has been ineffective in inducing remission of the nephrotic syndrome or preventing the development of endstage renal failure. There is a rapid deterioration of renal function and over 70 per cent of patients are in endstage renal failure after a follow up of 5 years.

Membranous nephropathy

Membranous nephropathy accounts for between 20 and 30 per cent of cases of the nephrotic syndrome in adults and about 2 to 5 per cent of those in childhood. Histologically it is defined by the presence of subepithelial immune deposits on the outer surface of the glomerular basement membrane. No cause for this histological lesion is found in most patients living in temperate countries, and it is therefore termed idiopathic membranous nephropathy, but it is unlikely that membranous glomerulonephritis is a homogenous disorder. Its aetiology (where identifiable), genetic basis, frequency as a cause of the nephrotic syndrome, and clinical evolution with or without treatment differ substantially between studies from different countries.

Aetiology

In about 20 to 25 per cent of adults and 35 per cent of children with membranous nephropathy there is an identifiable associated condition (Table 3). The frequency of this varies in different parts of the world. Malignancy, usually a carcinoma and rarely Hodgkin's lymphoma and non-Hodgkin's lymphoma, is found in between 3 and 7 per cent of all cases, rising to 16 per cent in those aged over 60 years. The most common tumours are carcinoma of the bronchus, colon, kidney, breast, stomach, and prostate. Gold and penicillamine are prominent causes of membranous nephropathy and this complication is more common in individuals who carry the *HLA-DR3* gene. There is also some evidence that membranous nephropathy can develop in patients with rheumatoid arthritis who are not taking these drugs. Approximately 3 per cent of all patients with membranous nephropathy have systemic lupus erythematosus; a further 2 per cent of patients have serological features of this disorder or histological changes that are suggestive of it, sometimes predating clinical evidence of the disease by many years. In Northern Europe about 1 per cent of patients with membranous nephropathy have positive hepatitis B serology, but this association is much more common in South-east Asia and in Africa, particularly in children.

Pathogenesis

The immune mechanisms that lead to the development of membranous nephropathy are unknown. In rats, the administration of antibodies against renal tubular epithelial antigen leads to a membranous nephropathy that histologically resembles the human condition. The antibody responsible for this Heymann's nephritis in rats binds to an antigen called gp330, which is found on renal tubular brush border and on glomerular epithelial cells. In glomeruli this leads to the development of subepithelial deposits through the *in situ* formation of immune complexes. Although human renal tubular cells express gp330, this is not found in glomerular epithelial cells, and there is no evidence that a similar mechanism plays a role in human membranous nephropathy. In Europe there is a strong association between membranous nephropathy and the MHC haplotype HLA-A1 B8 DRw3, whilst in Japan the association is with HLA-DR2. By contrast, no such association is seen in the United States.

Pathology

Idiopathic membranous nephropathy is characterized histologically by diffuse thickening of the glomerular basement on light microscopy, usually with argyrophyllic subepithelial spikes (Fig. 4 and Plate 4). On immunofluorescent or immunoperoxidase microscopy this thickening is shown to be due to the presence of immune deposits, usually consisting of IgG and C3, on the subepithelial surface of the glomerular basement membrane (Fig. 5 and Plate 5). The size and extent of incorporation of immune deposits into the glomerular basement membrane on electron microscopy forms the basis of histological classification—stage 1: subepithelial deposits without spikes; stage 2: large subendothelial deposits separated by spikes of basement membrane; stage 3: deposits incorporated into a thickened basement membrane with many spikes; stage 4: a very thick irregular basement membrane with no spikes and resorbed deposits. The presence of mesangial proliferation, mesangial immune deposits, and IgA and C1q on immunofluorescent microscopy raises the possibility that membranous nephropathy is secondary to systemic lupus erythematosus.

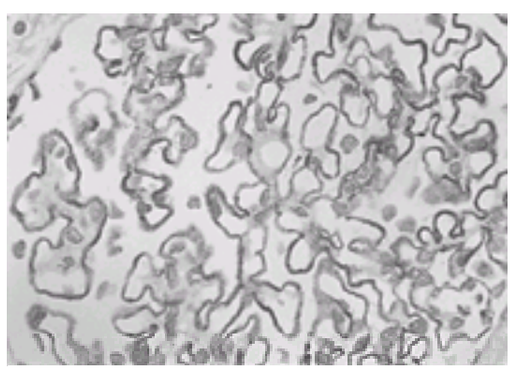

Fig. 5 Membranous nephropathy. Immunoperoxidase staining shows uniform granular deposits of IgG on the epithelial side of glomerular basement membranes (80

×). (By courtesy of Dr A. J. Howie.) (See also Plate 5.)

Clinical presentation

In children, boys are affected three times as often as girls. In adults, most studies report a preponderance of men, with a male to female ratio of 2–3:1. The ajority of patients are aged between 30 and 50, although the condition has been described in patients aged up to 80 years. The clinical presentation is with the nephrotic syndrome in about 75 per cent of cases, with the remainder having proteinuria only. Microscopic haematuria is found in 50 per cent of adults and 90 per cent of children. Macroscopic haematuria is found in about 10 to 20 per cent of children but it is rare in adults. About 25 to 40 per cent of adults and 6 per cent of children are hypertensive at diagnosis, and between 10 per cent and 30 per cent of patients have a raised serum creatinine level.

Renal vein thrombosis

Patients with membranous nephropathy appear to be at particular risk of developing renal vein thrombosis, although this is not as high as originally suggested. Most such patients are asymptomatic, but they may present with pulmonary emboli. Detection is by Doppler ultrasound of the renal veins, computed tomography (**CT**), magnetic resonance (**MRI**) imaging, or using the venous phase of renal arteriography. In practice, a renal vein thrombosis should be looked for if there is a sudden deterioration of renal function in a patient with membranous nephropathy. It is now known that renal vein thrombosis is a consequence of the hypercoagulable state of the nephrotic syndrome and is not a cause of membranous nephropathy.

Membranous nephropathy with a crescentic glomerulonephritis

About 5 per cent of patients with a membranous nephropathy develop a crescentic glomerulonephritis with rapid deterioration of renal function. Most such patients have antibodies to glomerular basement antigen or to neutrophil cytoplasmic antigens. Treatment has been with prednisolone and cyclophosphamide as for other patients with a crescentic glomerulonephritis.

Clinical evolution of untreated membranous nephropathy

In the long-term, untreated membranous nephropathy evolves either to remission or to the development of chronic renal failure. The rate at which either outcome occurs varies in different studies. After a mean follow-up of 4.5 to 6 years, between 9.5 and 22 per cent of patients are in endstage renal failure, 9.5 to 19 per cent have significantly impaired renal function, and 23 to 50 per cent are in remission. The actuarial survival rate shows that about 75 per cent of patients are alive at 10 years and 60 per cent have functioning kidneys. Examination of the control untreated patients in recent treatment trials shows that, of 205 patients followed for between 2 and 5 years, 15 per cent were in complete remission and 9 per cent in endstage renal failure. Any study of treatment in membranous nephropathy must therefore address the difficulty of treating large numbers of patients with toxic drugs who have little risk of developing endstage renal failure.

Treatment

The twin aims of treating membranous nephropathy are first to induce a remission of the nephrotic syndrome and second to prevent the development of endstage renal failure. Despite several careful studies using steroids and immunosuppressants, there is still no agreement that these aims can be achieved.

Steroid treatment

In the 1979 Collaborative study conducted in the United States, 72 adults with membranous nephropathy were randomized to 8-weeks' treatment with either 125 mg prednisolone on alternate days or placebo. The steroid dose was then tapered and stopped over several weeks. Deterioration of renal function, as measured by the glomerular filtration rate (**GFR**), was significantly more rapid in untreated than in treated patients. Further, a significantly lower proportion of treated patients than untreated patients developed renal failure (serum creatinine level over 440 µmol/l).

In the United Kingdom Medical Research Council (**MRC**) study (1990), 107 adult patients with membranous nephropathy were randomized to treatment with either prednisolone 125 mg on alternate days for 8 weeks or placebo. At 36 months there were no significant differences in the plasma creatinine level, creatinine clearance, and 24-h urine protein between treated and untreated patients. In the Canadian study, 158 patients were treated with either prednisolone 45 mg/m ^{2} body surface area per day for 6 months or no specific treatment. No benefits were seen in renal function or proteinuria after a mean follow-up of 48 months. These data indicate that short-term steroids are of no benefit in the treatment of membranous nephropathy.

Steroid and chlorambucil treatment

One study reported that chlorambucil was more effective than azathioprine or placebo in the treatment of membranous nephropathy. This provided the rationale for the Italian multicentre study in which patients were randomized to symptomatic treatment only or treatment with the following alternating regime—month 1: intravenous methylprednisolone, 1 g on each of 3 consecutive days, followed by oral methylprednisolone (0.4 mg/kg per day) or prednisolone (0.5 mg/kg per day) for 27 days; month 2: oral chlorambucil (0.2 mg/kg per day) alone for 1 month, the dose was lowered if the leucocyte count fell below 5×10^{9}/l. Alternating monthly cycles of methylprednisolone and chlorambucil were given for a total of 6 months. After a mean follow-up of 31 to 37 months, significantly more treated than untreated patients were in remission (either total or partial): 23/32 (72 per cent) versus 9/30 (30 per cent). Furthermore, 8 of 30 controls showed a 50 per cent rise in serum creatinine in contrast to none of the treated patients. The side-effects of treatment were minor and consisted of epigastric pain and leucopenia. To answer the question of whether the beneficial effect of this regime was due solely to the steroid component, a further study compared the effect of methylprednisolone alone with methylprednisolone and chlorambucil. Patients treated with the combination were more likely to have an early remission of the nephrotic syndrome, but this benefit was lost after 4 years. There was no difference in the rate of decline of renal function between the two therapies.

Other immunosuppressive regimes

In a recent, randomized controlled study, cyclophosphamide 2.5 mg/kg per day was compared with chlorambucil 0.2 mg/kg per day in the regime described above. The results in terms of remission of the nephrotic syndrome and deterioration of renal function were comparable.

A small, randomized controlled study of 17 patients with a persistent nephrotic syndrome and declining renal function suggested that ciclosporin A slowed the rate of decline of renal function: this requires confirmation in a larger trial.

Meta-analysis of steroid and immunosuppressant treatment of membranous nephropathy

A meta-analysis of four randomized controlled studies comparing treatments of membranous nephropathy showed that regimes comprising chlorambucil or cyclophosphamide, either alone or with steroids, were more effective than symptomatic treatment or treatment with steroids alone in inducing remission of the nephrotic syndrome. These agents increased the relative risk of achieving a complete remission by 4.6 (95 per cent confidence interval of 2.2 to 9.3). The number of patients studied and the design of the clinical trials were such that no conclusion could be drawn on the effects of these treatments on renal function.

Management of the patient with membranous nephropathy and deteriorating renal function

Drug-induced interstitial nephritis, renal vein thrombosis, and crescentic glomerulonephritis should be excluded. In patients with deteriorating renal function due to the progression of membranous nephropathy, several uncontrolled studies have suggested that treatment with intravenous methylprednisolone, or with oral prednisolone and chlorambucil or cyclophosphamide, may reverse the rate of decline in renal function. These studies are difficult to interpret as renal function may stabilize or improve without treatment in some cases.

Prognostic factors

Identifying those patients who at the onset of membranous nephropathy were likely to have a poor outcome for renal function would be helpful in deciding who to treat. Most studies show that adverse risk factors for the development of renal failure include male sex, a nephrotic syndrome, persistent heavy proteinuria, tubulointerstitial fibrosis, renal impairment at diagnosis, and deterioration of renal function in the first 2.5 years after diagnosis. In particular, patients with proteinuria of over 6 g/day for longer than 9 months were found to have a 55 per cent likelihood of progressing to renal failure. Children appear to do better than adults; in one study, 42 per cent of children went into complete remission and only 10 per cent developed endstage renal failure after a mean follow-up of 4 years.

How should membranous nephropathy be treated?

There is still no agreement on how membranous nephropathy should be treated, as up to 40 per cent of patients with this disorder enter spontaneous remission with long-term preservation of renal function. The dilemma is that early treatment of all patients exposes those who were going into remission anyway to the toxicity of drugs, whilst delayed treatment of high-risk patients may be ineffective. The results of current randomized controlled trials into the benefits of treatment with alkylating agents or cyclophosphamide in patients at high risk of progressive renal failure will guide treatment decisions.

20.7.5 Proliferative glomerulonephritis

Peter W. Mathieson

The term proliferative glomerulonephritis covers a variety of conditions (Table 1) where there is increased cellularity of the glomerulus, either due to the proliferation of resident glomerular cells, or infiltration of leucocytes, or both. The proliferative changes may be focal (that is to say, they only affect some glomeruli) and/or segmental (in other words, only affecting parts of each glomerulus). Many of these entities will be considered in other chapters, and only those not covered elsewhere (*****) will be described here.

Mesangial proliferative glomerulonephritis

Patients will typically have haematuria and this may be associated with proteinuria and/or impairment of excretory renal function and/or hypertension. The majority of patients whose renal biopsies show only mesangial proliferation will have IgA nephropathy (see Chapter 20.7.2), but a few will have no IgA deposits and their classification is not straightforward: possibilities include IgM nephropathy and so-called 'idiopathic' mesangial proliferative glomerulonephritis (**GN**).

IgM nephropathy

There is continuing controversy about this diagnostic entity. In patients with nephrotic syndrome, if the only abnormalities on the renal biopsy are in the mesangial region, with proliferation of mesangial cells and deposition of IgM, many authorities would assign a diagnosis of minimal-change nephropathy and advocate treatment with corticosteroids; some would consider that these morphological features are markers for a poorer prognosis and a reduced likelihood of a response to corticosteroids. Others would consider the patient to have a completely different disease entity and give a diagnosis of IgM nephropathy. Some of the confusion may be explained by methodological factors: assessment of the degree of mesangial hypercellularity is subjective, and reagents to detect IgM are notoriously unreliable since they may give high background staining. Mesangial IgM has been found in up to 60 per cent of 'normal' kidneys donated for transplantation; the diagnostic significance of IgM is also cast into doubt by its presence in over 75 per cent of controls as well as in patients with various other forms of glomerulonephritis. The best support for the existence of IgM nephropathy, as an entity distinct from minimal-change nephropathy, comes from the occurrence of a familial form and from the identification of this pattern of glomerular injury in patients who, after lengthy follow-up, have an appreciable risk of developing impaired excretory kidney function.

Idiopathic mesangial proliferative GN

This term may be applied if there is isolated mesangial proliferation without deposition of IgA or IgM. Again there is overlap with minimal-change nephropathy: if the patient presents with nephrotic syndrome, most nephrologists would not allow the presence of mesangial proliferation to deflect them from treating the patient with corticosteroids, although there is evidence that the presence of this histological finding is associated with a poorer response rate. If, however, the patient has haematuria and/or hypertension and/or impaired kidney function, none of which are typical features of minimal-change nephropathy, it is difficult to resist the need for another separate diagnostic category. Unfortunately there are no informative studies to guide treatment or give information on prognosis.

Endocapillary proliferative GN

Patients will often have impaired excretory function, haematuria, proteinuria, and hypertension, sometimes presenting acutely as a 'nephritic syndrome'. On renal biopsy, the glomerular hypercellularity is confined within the glomerular capillary tuft, which is probably due to the combination of a proliferation of intrinsic (endothelial and mesangial) cells together with an infiltration of inflammatory cells. This can occur in systemic lupus erythematosus and as a complication of a variety of infections (see Chapter 20.7.8). Only poststreptococcal GN will be considered here.

Poststreptococcal GN (Plate 1)

Most infection-related GN occurs concurrently with the infection. By contrast, postinfectious GN (of which poststreptococcal GN is the most frequent and best characterized) occurs, as the name implies, after the infection. In poststreptococcal GN the delay between the inciting infection and the onset of the renal complication may be long enough for the infection to have been forgotten, and this may contribute to diagnostic confusion. The typical case follows infection with streptococci of Lancefield group A (b-haemolytic streptococci, *S. pyogenes*), either causing pharyngitis or skin infections such as cellulitis or impetigo. Children are the most common victims. Around 2 weeks later, sometimes longer after skin infections, the patient develops nephritis which may be sufficiently acute and severe to cause a nephritic syndrome with oliguria, hypertension, and oedema. If a renal biopsy is performed, it will show diffuse proliferative GN, with infiltration by neutrophil polymorphs often particularly prominent (Fig. 1). Immunohistology shows deposition of IgG, IgM, and complement in the mesangial and subepithelial areas, and electron microscopy shows large subepithelial deposits ('humps').

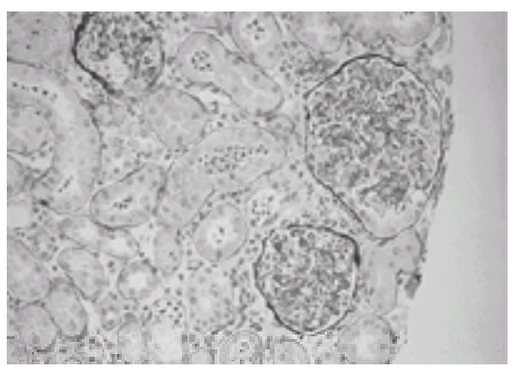

Fig. 1 Poststreptococcal glomerulonephritis.

Serological tests

There are typical serological features which give clues to the pathogenesis: these include antibodies to streptococcal antigens and evidence of activation of the complement cascade. The antibodies are IgG; reactivity with numerous streptococcal antigens has been reported including streptolysin O, deoxyribonuclease B, hyaluronidase, and streptokinase. Anti-streptolysin O is the most useful diagnostic test after pharyngitis, anti-DNAse B is best after skin infections. Hypocomplementaemia (low C3 in the majority of cases, also low C4 in a smaller proportion) reflects activation of both the alternative and the classical pathways (the complement system is discussed in more detail in Chapter 20.7.6. In poststreptococcal GN, the alternative complement pathway may be activated by bacterial antigens and/or by IgG autoantibodies called nephritic factors which resemble those seen in MCGN; the classical pathway may be activated by circulating immune complexes.

Pathogenesis

It is believed that the pathogenesis of poststreptococcal GN can be explained as follows: streptococcal antigens are deposited in glomeruli, by virtue of some aspect of their charge, size, or other physicochemical characteristics, during the early phase of the infection. After the 10 to 14 days necessary for the host to mount an immune response to the bacterial infection, circulating antibody appears and binds to the 'planted' antigens in the glomeruli. Complement is activated, leucocytes are attracted (by complement-activation products C3a and C5a among other chemoattractants) and an inflammatory reaction is provoked, injuring the glomeruli. The precise nature of the streptococcal antigens that act in this nephritogenic manner remains controversial; only certain serological types of streptococci (referred to as M types and serotyped according to cell-wall protein antigens) are capable of inciting GN, but the M proteins themselves are not believed to be nephritogenic. In addition to the planted antigen mechanism, streptococci may lead to GN by their other complex effects on the immune response. These include the direct activation of T cells by a superantigen effect, whereby M proteins can bind to particular Vb regions of the T-cell receptor and activate families of T cells sharing receptors of this 'family'. Antigenic crossreactivity ('molecular mimicry') akin to that thought to be responsible for rheumatic fever may also occur, so that anti-streptococcal antibodies crossreact with, and therefore bind to, renal autoantigens such as laminin and collagen.

Management

Poststreptococcal GN is less common in the developed than in the developing world, possibly influenced by socioeconomic factors. Its general importance lies in the fact that early recognition allows appropriate treatment, with the prognosis often being very good, and also that the immunopathological mechanisms outlined above may be instructive in understanding other forms of GN where the inciting stimulus is not so evident. Treatment of patients with poststreptococcal GN should be directed at eradicating the infection (a 10-day course of penicillin or erythromycin is advised even if the original infection appears to have resolved) and providing symptomatic relief of the consequences of the acute nephritis: aggressive treatment of hypertension, salt, and water restriction with or without diuretics for oedema; and dialysis if necessary (which is uncommon). Recovery is the rule, although haematuria and proteinuria may persist and some authors believe that in the long-term there is a risk of chronic renal failure.

Idiopathic diffuse proliferative GN

A few cases will have no preceding history of infection, no evidence of lupus, and/or atypical features on the renal biopsy: these may be assigned the unsatisfactory 'idiopathic' sobriquet, with the implication that the prognosis and the appropriate treatment are uncertain.

20.7.6 Mesangiocapillary glomerulonephritis

Peter W. Mathieson

Mesangiocapillary glomerulonephritis (**MCGN**) is synonymous with membranoproliferative glomerulonephritis (**MPGN**). The term describes a morphological pattern of glomerular injury in which there is diffuse thickening of the glomerular basement membrane (**GBM**) associated with increased cellularity, giving a characteristic lobular appearance to the glomeruli (Fig. 1 and Plate 1). As with other forms of glomerulonephritis, such as membranous nephropathy (see Chapter 20.7.4), the appearances on light microscopy are indistinguishable whether the lesion occurs as a primary 'idiopathic' renal disease or secondary to an extrarenal/systemic disorder. Extra information is obtained with the use of immunohistology and electron microscopy, which allow further subdivision into three patterns. In type I MCGN there is typically IgG, IgM, and complement C3 in mesangial areas as well as along the glomerular capillary loops in a subendothelial or intramembranous location, and electron microscopy shows discrete electron-dense deposits in these regions. In type II MCGN there is typically no immunoglobulin deposited, but C3 is detected in a linear distribution along the capillary loops and often also in tubular and vascular basement membranes. Electron microscopy shows typical thick, linear, electron-dense material along these basement membranes, giving rise to the other term for type II MCGN which is '(linear) dense-deposit disease' (Fig. 2). Type III MCGN is similar to type I, except that there are subepithelial as well as subendothelial deposits and there may be disruption of the GBM with accumulation of new basement membrane material in layers. Most 'secondary' forms of MCGN are of the type I pattern.

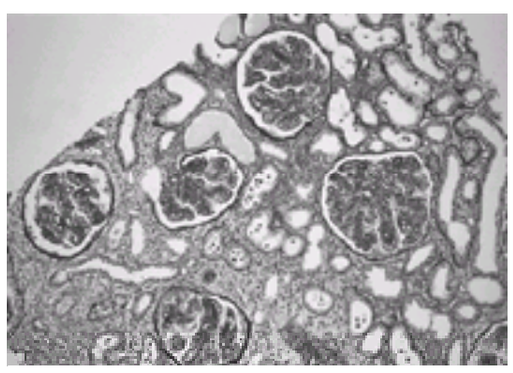

Fig. 1 Mesangiocapillary glomerulonephritis. Note characteristic lobular appearance of expanded glomerulus. (See also Plate 1.)

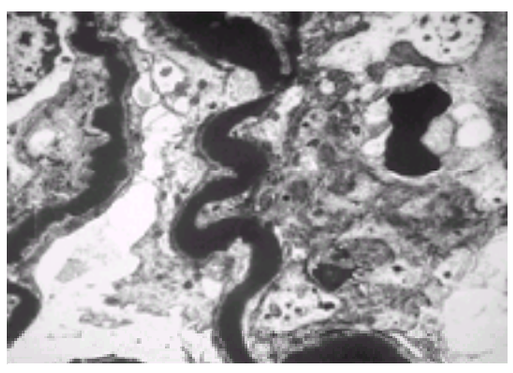

Fig. 2 Electron micrograph of type II MCGN, 'dense deposit disease'. Note linear, electron-dense material along the glomerular basement membrane.

The complement system

The subdivision of MCGN into types I, II, and III is not just of academic importance. MCGN is the type of glomerulonephritis most closely associated with activation of the complement cascade and there is evidence, at least for some types of MCGN, that complement dysregulation may directly cause the renal lesion. The pattern of complement activation differs between the three subtypes of MCGN. Complement activation can occur via two main pathways, the classical and alternative pathways (Fig. 3). A recently described third pathway, the lectin or mannan-binding pathway, yields similar results to classical pathway activation and is of unknown relevance to nephritis. In general, classical pathway activation leads to depletion of plasma C3 and C4, whereas alternative pathway activation leads to a low C3 with normal C4. This is an oversimplification, since both C3 and C4 are acute-phase reactants whose synthesis is upregulated in inflammation. Thus there may be considerable complement activation without depletion of circulating levels, due to increased production. Further complexity is introduced by the fact that genetic deficiencies of C4 are common: there are four C4 genes encoded within the major histocompatibility complex (**MHC**) on chromosome 6, and one or more null alleles are commonly present, which result in no C4 protein production. These result in a reduction of circulating C4 concentrations—it is estimated that only 60 per cent of the normal population has all four normal C4 genes. Thus a single low C4 level must be interpreted with caution unless a previous 'normal' result is available for that individual; serial measurements are helpful since they give an indication of the level of C4 consumption.

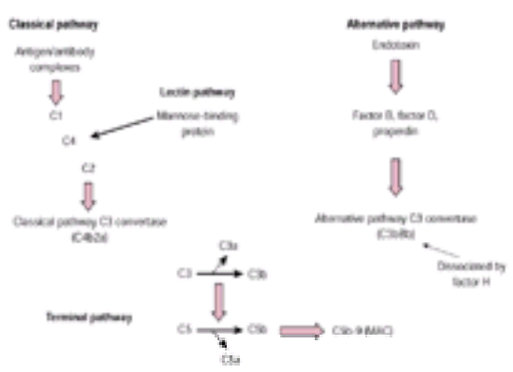

Fig. 3 The complement system.

The classical pathway is activated predominantly by immune complexes: immunoglobulin molecules linked to antigen. The alternative pathway is more concerned with host defence, being activated by bacteria or other foreign surfaces, and existing in a state of constant low-level activity: so-called 'tickover'. This state of constant

activity demands tight regulation to avoid excessive activity, and this is achieved by regulatory proteins factor H and factor I. The classical and alternative pathways converge at the point at which C3 is cleaved. The enzyme formed by classical pathway activation is called the classical pathway C3 convertase, and denoted C4b2a. The enzyme formed by alternative pathway activation is the alternative pathway C3 convertase, denoted C3bBb. Each of these enzymes leads to the cleavage of C3, releasing C3a and leading to the formation of a C5 convertase enzyme which cleaves C5, thereby releasing C5a and leading to the formation of C5b–9, the membrane-attack complex (**MAC**).

Pathogenesis of MCGN

In MCGN, the pattern of complement activation (and therefore possibly the pathogenesis) is different in each of the three forms. In type I, the complement activation predominantly affects the classical pathway (causing low levels of both plasma C3 and C4); in type II it is the alternative pathway which is predominantly affected (low C3 with normal C4); and in type III there is activation of the terminal pathway leading to depletion of C5, sometimes associated with mild depletion of C3 and/or C4. 'Secondary' MCGN may occur in systemic lupus erythematosus (**SLE**); cryoglobulinaemia with or without hepatitis C; infections such as infective endocarditis or other chronic bacteraemic states (for example, 'shunt nephritis', originally described with infected ventriculoatrial shunts); or in association with neoplasms. In each of these situations there is activation of the classical pathway which is presumed to be due to circulating immune complexes, and this is associated with a type I MCGN pattern. In idiopathic type I MCGN, a variety of complement-activating factors have been described: there may be circulating immune complexes, some patients have antibodies to Clq which probably directly activate the classical pathway, and some have other autoantibodies which interfere with the normal regulation of the classical pathway. In type II MCGN, the alternative pathway activation is due to the presence of an IgG autoantibody (known as C3 nephritic factor C3NeF, or more simply as nephritic factor, NeF) which binds to a neoantigen formed when the alternative pathway C3 convertase enzyme, C3bBb, is assembled. The antibody stabilizes this enzyme and protects it from degradation by factor H. Thus the half-life of the enzyme is prolonged, and the normal regulatory mechanism is subverted. This type of nephritic factor has also been described in patients with type I and type III MCGN, but its presence is virtually invariable in type II MCGN. In type III MCGN, the presence of a circulating factor which activates complement slowly in a properdin-dependent manner has been postulated; the reasons for the preferential depletion of terminal pathway components, and whether there is a direct relationship of this activation to the renal injury in type III MCGN, remain unanswered questions.

The best evidence for a causative role of complement activation in MCGN comes in type II disease. As mentioned above, most patients with type II MCGN have the IgG autoantibody known as nephritic factor (**NeF**) which allows unregulated alternative pathway activation. Two other situations in which there is similar overactivity of the alternative pathway, and an associated renal lesion with the appearances of type II MCGN, have recently been characterized. First, genetic deficiency of the regulatory protein known as factor H, which normally serves to degrade the alternative pathway C3 convertase, has been reported in a variety of inbred pigs and also in rare human cases. Second, there is a case report of an individual whose serum contained a monoclonal lambda light chain which interacted with factor H *in vitro* and prevented its action, allowing unregulated alternative pathway activation. Therefore, in these three situations (the presence of NeF, genetic deficiency of factor H, or functional blocking of factor H), there is dysregulated alternative pathway activation, but due to completely different mechanisms. In each case, the renal lesion is type II MCGN, strongly suggesting that it is the complement activation *per se* which leads to the renal injury. Importantly, in the factor H-deficient pigs, replacement of factor H leads to prevention of the excessive alternative pathway activation and an improvement in the MCGN. These observations have clear implications for the therapy of human MCGN (discussed further below).

The NeF autoantibody, and the resultant unregulated alternative pathway activation, have another striking clinical association: with partial lipodystrophy in which there is permanent loss of adipose tissue from the face and neck and sometimes also from the upper trunk (Fig. 4). Such patients may also have type II MCGN, and as with the renal lesion, there is evidence to suggest that the complement activation directly causes the tissue injury: NeF containing IgG can cause complement-mediated lysis of adipocytes *in vitro*. Furthermore, adipocytes are probably susceptible to this injury because they produce complement components: these observations have contributed to the recent appreciation that the complement system plays a previously unsuspected role in the normal physiological regulation of adipose tissue.

Fig. 4 Facial appearance in partial lipodystrophy. This patient has had silicone pads inserted into her cheeks, accounting for the bulges in the regions where adipose tissue has been completely lost.

Clinical presentation

This is with proteinuria, which may be sufficiently severe to cause nephrotic syndrome; and/or haematuria, which, especially in children, may be macroscopic. Hypertension and/or impairment of excretory kidney function may be associated. Acute presentation as a nephritic syndrome is recognized in children. As mentioned above, type II MCGN may be associated with partial lipodystrophy; the loss of adipose tissue can precede the onset of nephritis by many years. Abnormalities in the eye are also recognized in type II MCGN, and may rarely be the presenting feature. Drusen-like deposits and mottled pigmentation are visible in the fundi: retinal neovascularization may occasionally threaten sight and require laser therapy.

Natural history of MCGN

Overall, the renal survival in MCGN at 10 years from diagnosis is about 50 per cent. Children tend to have a more acute presentation and a slower decline in renal function, although with lengthy follow-up the overall renal survival is similar to that in adults. The prognosis differs between the three subtypes of MCGN, with type II carrying the greatest risk of the development of endstage renal failure (**ESRF**): in one recent study the median time to ESRF in types I, II, and III was, respectively, 15.3 years, 8.7 years, and 15.9 years. Since presentation with the nephrotic syndrome carries a substantially increased risk of ESRF compared to other milder clinical syndromes, the adverse prognosis of type II MCGN may simply reflect the greater likelihood of nephrotic presentation with this histological type. As in many other forms of glomerular disease the presence of tubular atrophy and interstitial fibrosis indicate a worse prognosis, as does hypertension at the time of presentation.

Treatment of MCGN

The forms of therapy which have been applied to MCGN are similar to those used in other forms of nephritis: antiplatelet drugs, anticoagulants, corticosteroids, and alkylating agents have been used alone or in various combinations. The studies tend to be small, with varying proportions of children and adults, and of the three subtypes of MCGN. There is a dearth of randomized controlled trials and reviews of the subject have usually concluded that there is no treatment of proven efficacy in MCGN. Nevertheless, there are hints from some of the studies that certain drugs may have useful effects. In particular, high doses of prednisone, usually given on alternate days (especially in children) are favoured by some authors, especially the Cincinnati group who have published most extensively on this subject. However, high corticosteroid dosages are required for prolonged periods and the magnitude of benefit obtained may be too small to justify the risks of such treatment. Possibly by refining the dosage schedule and by applying the treatment only to high-risk groups, such as those with severe nephrotic syndrome, the risk:benefit ratio may be more favourable.

Since complement activation is so prominent in MCGN, therapy aimed at the complement system may be rational: promising anticomplement agents are now becoming available. At present, the best strategy is to try to identify any underlying cause of complement activation and remove it if possible. As in other forms of GN, associated hypertension should be aggressively treated. Patients with proteinuria of any cause have their renal prognosis improved if they are treated with angiotensin-converting enzyme (**ACE**) inhibitors. They are at increased cardiovascular risk, and attention should also be paid to other modifiable risk factors,

especially cigarette smoking and hyperlipidaemia.

Recurrent MCGN in renal transplants

MCGN is one of the types of nephritis that tends to recur in kidney transplants (see Chapter X): type I recurs in around 25 to 30 per cent of grafts and type II recurs even more frequently, possibly in 85 to 90 per cent of cases. Recurrent MCGN only causes graft failure in a minority of cases, presumably because the antirejection immunosuppressive therapy modulates the damage done by the nephritis.

20.7.7 Antiglomerular basement membrane disease

Jeremy Levy and Charles Pusey

Introduction

Antiglomerular basement membrane disease is an autoimmune disease in which patients develop pathogenic autoantibodies against the glomerular basement membrane (**GBM**). Patients typically present with renal failure and pulmonary haemorrhage, but isolated renal disease is well recognized. The triad of anti-GBM antibodies, rapidly progressive glomerulonephritis (**RPGN**), and pulmonary haemorrhage is referred to as Goodpasture's disease in the United Kingdom, whilst the term Goodpasture's syndrome describes patients with RPGN and pulmonary haemorrhage of various aetiologies.

The term 'Goodpasture's syndrome' was first used in 1958 by Stanton and Tange in their report of nine patients with pulmonary–renal syndrome, which referred to a patient with fulminant pulmonary haemorrhage and proliferative glomerulonephritis described by Goodpasture during the influenza pandemic of 1919. In retrospect, this original patient may have had systemic vasculitis, not anti-GBM disease. In recent years much has been learnt about the immune response in Goodpasture's disease, but despite huge advances in our understanding of aetiopathogenesis, the therapy has changed little in the last 20 years.

Aetiology and pathogenesis

The Goodpasture antigen

All patients with Goodpasture's disease have circulating antibodies that bind a glomerular basement membrane antigen, the a3 chain of type IV collagen (a3(IV)). Type IV collagen is found in all basement membranes; but the a3, a4, and a5 chains are restricted in their distribution primarily to the GBM and alveolar basement membranes. The epitope for autoantibodies in Goodpasture's disease is carried at the amino terminus of the 230 amino acid, non-collagenous, carboxy-terminal domain of the a3 chain (a3(IV)NC1), which is normally hidden within the collagen network. The a3(IV)NC1 is also found in the basement membranes of the choroid plexus, the cochlea, Bruch's membrane in the eye, retinal capillaries, and the thymus.

Anti-GBM antibodies and the T-cell-mediated immune response

Transfer of antibodies from patients into squirrel monkeys initially confirmed the pathogenicity of the autoantibodies. Clinical studies report a correlation between antibody levels at presentation and disease activity, and the disease recurs immediately in renal transplants when the recipient still has circulating antibodies. All patients have antibodies against a3(IV)NC1, either circulating or bound to the GBM. A small number of patients develop antibodies against other GBM components, particularly the a1 (15 per cent of patients) or a4 (4 per cent of patients) chains of type IV collagen. However, anti-GBM antibodies are unlikely to be the only cause of glomerular injury, and a cell-mediated immune response is also important in inducing renal damage.

Alveolar haemorrhage generally requires a second insult, either local to the lungs (for example, cigarette smoking or pulmonary oedema), or systemic with activation of cytokines and inflammatory mediators (for example, sepsis).

Genetic predisposition

Goodpasture's disease has been reported in four sibling pairs and two sets of identical twins; however, discordant twin pairs are also documented. More striking is the association with the HLA serotype HLA-DR2, which is carried by more than 85 per cent of patients with Goodpasture's disease, compared with 30 per cent of controls. Molecular analysis of HLA alleles has confirmed the association with HLA-DR15 (DRB1*1501 and -1502), and a weaker association with HLA-DR4 (DRB1*04). A negative association with HLA DR7 (DRB1*07) has been demonstrated. Thus, specific characteristics of the HLA molecules on antigen-presenting cells determine susceptibility to Goodpasture's disease.

Environmental factors

No specific pathogens or toxins have been identified that can initiate Goodpasture's disease; but many case reports have documented exposure to hydrocarbons prior to the development of clinical manifestations, and cigarette smoking undoubtedly precipitates pulmonary haemorrhage. It seems more likely that organic solvents trigger overt pulmonary damage (and possibly renal injury) in the presence of circulating autoantibodies than that hydrocarbons are involved in the initiation of autoimmunity. Several clusters of cases have been reported, but no clear associations with influenza virus or other infectious agents have been proved.

Disease associations

Anti-GBM disease is only rarely associated with other autoimmune disorders, apart from systemic vasculitides. Increasing numbers of patients (up to 30 per cent) have been shown to have circulating antineutrophil cytoplasmic antibodies (**ANCA**), generally P-ANCA, in addition to anti-GBM antibodies. Conversely, only few patients with ANCA-associated vasculitis also have anti-GBM antibodies (2.5–8 per cent). This is an important distinction since the 'double positive' patients tend to behave more like those with 'pure' Goodpasture's disease than systemic vasculitis. Anti-GBM disease has been reported after lithotripsy and urinary tract obstruction, and in some patients with membranous nephropathy. In all these cases it is possible that disruption of the GBM in susceptible individuals can lead to a breakdown in tolerance to the a3 chain of type IV collagen, with the development of autoantibodies and clinical disease.

Epidemiology

Limited epidemiological studies suggest that Goodpasture's disease has an incidence of 0.5 to 1 new case per million of the population per year. It is found in 1 to 2 per cent of renal biopsies. In comparison, systemic vasculitides have an incidence of 15 to 30 new cases per million of the population per year. The disease is less common in Afro-Caribbean and Asian populations. There is a bimodal age distribution, with peak incidence in the third and sixth decades, and a slight excess of males.

Clinical features

Most patients present with RPGN or lung haemorrhage, or both. Some patients have isolated lung haemorrhage and never develop renal failure (although most of

these have haematuria and proteinuria), and a few have mild isolated nephritis. General malaise, fatigue, weight loss, and anaemia are the commonest systemic features, whilst other signs and symptoms are much rarer than in patients with systemic vasculitis.

Pulmonary features

Pulmonary haemorrhage occurs in two-thirds of patients, more commonly in young men, it usually precedes presentation with acute renal failure, and is strongly associated with cigarette smoking. Patients often complain of breathlessness and cough, and there is a poor relationship between overt haemoptysis and the degree of alveolar haemorrhage. Haemoptysis can be triggered by cigarettes, inhaled toxins, fluid overload, and intercurrent infection, either local (pneumonia) or systemic (sepsis). Clinical signs are often indistinguishable from those of pulmonary oedema or infection. The most sensitive indicator is an elevated K_{CO} (diffusing capacity for carbon monoxide), which identifies the presence of haemoglobin in alveolar spaces by increased binding of inhaled carbon monoxide. Radiographic features are not specific, but alveolar shadowing in the central lung fields is typically seen (Fig. 1).

Fig. 1 Chest radiograph from a patient with Goodpasture's disease showing florid pulmonary haemorrhage.

Renal features

Patients can present with isolated haematuria, chronic renal failure, or mild renal insufficiency, but classically present with severe acute renal failure due to rapidly progressive glomerulonephritis. The clinical features of the nephritis are indistinguishable from any other cause of RPGN, with cellular casts in the urine, haematuria, and mild to moderate proteinuria (nephrotic range proteinuria is rare). Hypertension and oliguria are late features. A small number of patients have relatively normal renal function at presentation, but always have abnormal urine findings and evidence of antibody deposition on renal biopsy.

Differential diagnosis

It is crucial to distinguish anti-GBM disease from other cause of RPGN, and especially ANCA-associated vasculitis. There is only a small window of opportunity in which to rescue renal function in patients with anti-GBM disease, by contrast to systemic vasculitis in which renal failure can be reversed at a later stage. All patients with suspected RPGN, acute renal failure of unknown cause, or lung haemorrhage and urinary abnormalities, should have both anti-GBM antibody and ANCA assays performed urgently. Double-positive patients may respond better to therapy at a late stage compared to those with pure anti-GBM disease. Other differential diagnoses to consider include systemic lupus erythematosus (**SLE**), cryoglobulinaemia, haemolytic uraemia syndrome (**HUS**), and other causes of pulmonary renal syndrome (see Table 1).

Pathology

Immunohistology is characteristic (Fig. 2 and Plate 1), with linear deposition of IgG (sometimes with IgA or IgM) and complement C3 along the glomerular basement membranes. Rare patients have been reported with IgM or IgA alone. Less intense linear staining with IgG can occasionally be seen in diabetes, SLE, myeloma, and transplanted kidneys. The most characteristic morphological finding is severe crescentic glomerulonephritis, with almost all the glomeruli exhibiting cellular crescents, usually at the same stage of evolution. Segmental necrosis and cellular proliferation may occur. Blood vessels are usually normal, but rarely vasculitis has been reported even in the absence of detectable ANCA. There is often a prominent interstitial cellular infiltrate.

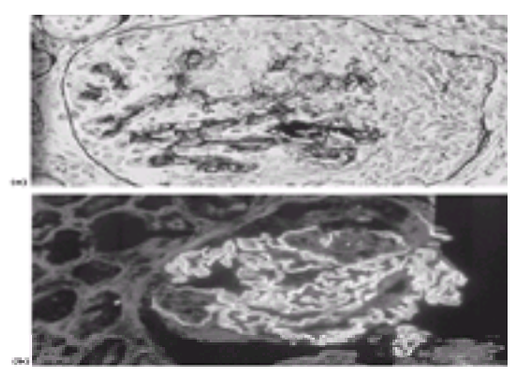

Fig. 2 Renal biopsy from a patient with Goodpasture's disease. (a) Light microscopy showing a single glomerulus with cellular crescent and focal necrosis (silver stain). (b) Immunofluorescence of a single glomerulus with linear deposition of IgG along the GBM. (Figure by courtesy of Dr HT Cook.) (See also Plate 1.)

Histological specimens are rarely obtained from lungs, since transbronchial biopsy does not usually penetrate beyond the bronchial mucosa. Open-lung biopsy can reveal alveoli full of red blood cells, macrophages, and fibrin, interspersed between relatively normal alveoli. Immunofluorescence inconsistently reveals linear deposition of antibody.

Laboratory diagnosis

Serological testing for anti-GBM antibodies and ANCA is crucial for confirming the diagnosis, and a renal biopsy is almost always warranted. Some healthy individuals exposed to inhaled oils, hydrocarbons, or solvents may have borderline raised anti-GBM antibody levels, and anti-GBM antibody has also been detected in HIV-negative patients with pneumocystis pneumonia. Other investigations are detailed in Table 2. Alveolar haemorrhage is an important cause of mortality and must be identified early. All patients should have baseline K_{CO} and chest radiology, repeated as necessary.

Treatment

Untreated anti-GBM disease is usually fatal, and renal function never recovers. In most centres immunosuppressive treatment is given immediately upon diagnosis to those with a serum creatinine concentration below 600 µmol/l at presentation and/or with active pulmonary haemorrhage. Those with a serum creatinine concentration above 600 µmol/l and without active pulmonary haemorrhage need more careful consideration before being treated since they have a small chance of recovery (see below).

Treatment with plasma exchange, cyclophosphamide, and corticosteroids, together with dialysis when required, can allow up to 90 per cent of patients to survive, but

only around 40 per cent of survivors will recover renal function. Daily plasma exchange removes circulating antibodies, whilst cyclophosphamide prevents further antibody synthesis. There has only been one controlled trial of plasma exchange, which utilized a low intensity of exchanges in a small number of patients and showed a non-significant trend towards an improved outcome. However, the dramatic improvement in overall mortality and renal function coincident with the introduction of a treatment regimen of the type described above has led to their widespread use. The regimen we use is shown in Table 3. An alternative to plasma exchange is protein-A immunoadsorption. Ciclosporin has been used in occasional patients unresponsive to other therapies, but is of doubtful benefit. Long-term treatment is unnecessary, and patients can stop taking cyclophosphamide after 2 to 3 months, and withdraw prednisolone over approximately 6 months.

Prognosis

The outcome of patients with Goodpasture's disease in published series is shown in Table 4. Most will now survive the acute illness, but pulmonary haemorrhage and infection remain important causes of death. In those with a serum creatinine concentration below 600 µmol/l at presentation, the creatinine should begin to fall within 1 to 2 weeks of treatment, and the majority will recover renal function. However, patients with a creatinine concentration above 600 µmol/l, or with oligoanuria, less commonly recover renal function. For this reason most centres would not give immunosuppressive agents to this group with the sole intention of trying to restore renal function, although they would for concurrent active pulmonary haemorrhage or if the renal biopsy suggests that tubular necrosis may be contributing to the severity of the renal failure (see above). Crescent scores over 50 per cent, high antibody titres, and a delay in diagnosis are also markers of a poor renal prognosis.

The prognosis in anti-GBM disease is in marked contrast to that of patients with a diagnosis of ANCA-associated RPGN. Renal recovery is to be expected in the latter group with immunosuppression, and around 70 per cent of patients presenting with a creatinine concentration above 600 µmol/l will recover renal function.

Relapses of pulmonary haemorrhage and worsening of renal function can occur early during the course of treatment in the presence of circulating autoantibodies, and can be triggered by smoking, infection, or fluid overload. True late recurrence is very unusual. Transplantation is safe once autoantibodies are no longer detectable, and is best delayed until between 6 and 12 months after the disappearance of anti-GBM antibody.

Anti-GBM disease in Alport's syndrome

Patients with X-linked Alport's syndrome have a mutation in the a5 chain of type IV collagen, but also have undetectable Goodpasture antigen in their kidneys despite a normal a3(IV) gene. Transplantation of a normal kidney into such recipients may allow the development of anti-GBM antibodies as a result of the exposure of the immune system to neoantigens to which tolerance has not developed. These antibodies are usually anti-a5(IV)NC1, but can also be anti-a3(IV)NC1 (classical Goodpasture autoantibodies). Most patients do not develop overt nephritis, but simply deposit antibody along the GBM without recruiting a glomerular inflammatory response. However, a minority develop severe glomerulonephritis. In the absence of lung antigen, pulmonary haemorrhage never occurs.

20.7.8 Infection-associated nephropathies

A. Neil Turner

Introduction

Almost all varieties of renal lesion, particularly glomerular, may be associated with infections. The pathways leading to these are sometimes understood, but sometimes obscure. In the West, infection-associated nephritis was once predominantly recognized during episodes of acute infections in apparently healthy individuals. This is still the pattern in less developed regions; but this could be partly a problem of recognition, as in all populations infections are more common and more severe in malnourished or otherwise debilitated individuals. Improvements in living conditions and healthcare in developed countries have reduced the numbers of healthy people succumbing to complications of infection. By contrast, infections occurring on a background of debilitating illnesses and previous medical interventions have become more common, and are certainly more often diagnosed.

In this chapter, glomerular diseases and interstitial diseases associated with infection are considered in turn. Particular attention is given to those glomerulopathies associated with bacterial endocarditis and other chronic bacterial infections, and to three viral infections of worldwide importance—human immunodeficiency virus (**HIV**), hepatitis B, and hepatitis C.

Pathogenesis

Infection-associated glomerular disease is usually attributed to trapping of circulating antigen–antibody complexes or to immune responses to pathogen-derived antigens that become 'planted' in the glomerulus. The evidence for the deposition of circulating immune complexes is unequivocal for cryoglobulinaemia, and highly plausible for infections occurring within the vascular system such as bacterial endocarditis. In most other infections the evidence is less clear.

Interstitial renal disease is often blamed on direct invasion by micro-organisms, and for some, particularly viruses, there is evidence that this is true. The pathogen may cause injury directly, or indirectly by causing cells to express foreign antigens that generate an immune response. More speculatively, an immune response generated to an organism may crossreact with a remote self-antigen, triggering autoimmunity through molecular mimicry, but there are no unequivocal examples of this.

Infection may also involve the kidney by interfering with the circulation either generally (septic shock) or locally (for instance, by causing thrombotic microangiopathy, as for *Escherichia coli* O157), or *Capnocytophaga canimorsus* (previously DF-2). On occasions, toxins may be released that harm the kidney directly (for example, haemoglobin in malaria). Medically administered toxins include antimicrobial agents that impair renal function by crystallization (aciclovir, indinavir, etc.), or by predictable toxicity (e.g. aminoglycosides and amphotericin), or by idiosyncratic reactions such as acute interstitial nephritis (e.g. penicillins).

Glomerulonephritis associated with chronic and acute bacterial infections

Classic, acute postinfectious glomerulonephritis is considered separately elsewhere. This chapter centres on the more subacute or chronic diseases, although other causes of a 'classical' picture are mentioned.

Shunt nephritis was first recognized in the 1960s and remains the archetype of an immune-complex nephritis. The glomerulonephritis occurring in association with infective endocarditis is very similar. Both are caused by subacute infection within the bloodstream, with constant production and shedding of antigen and the formation of antigen–antibody complexes. Other bacterial infections cause similar pictures, or patterns more similar to acute 'postinfectious' glomerulonephritis.

Shunt nephritis

In shunt nephritis a ventriculoatrial shunt implanted for the treatment of hydrocephalus becomes colonized by bacteria, usually of low pathogenicity. More common modern equivalents of this clinical syndrome are due to infected long-term, indwelling, central vein catheters and other intravascular devices. The syndrome does not occur with ventriculoperitoneal shunts, which are therefore now the preferred neurosurgical option. Although *Staphylococcus epidermidis* has been most commonly implicated, *Propionibacterium acnes* or other organisms are sometimes involved. Typically, the diagnosis is only appreciated after weeks to months of symptoms of mild to moderate pyrexia and malaise associated with haematuria, proteinuria, and progressive renal impairment. Fevers have often been attributed to urinary infection in patients with neurogenic bladders. There may be moderate splenomegaly. Investigations show variable renal impairment, complement consumption, and an acute-phase response with a normochromic normocytic anaemia. The renal lesion is characteristically a type-1 mesangioproliferative glomerulonephritis with deposition of multiple immunoglobulins and complement components beneath the endothelium, the classic appearance of a circulating immune-complex nephritis. Sometimes the picture is more severe, showing a diffuse proliferative lesion, occasionally with crescents. In other cases the histological appearances are less pronounced with focal proliferative changes.

Antibiotic treatment alone is almost never adequate to cure these infections, which require removal of the shunt, followed by its replacement after an interval if drainage is still required. Delayed diagnosis and delayed removal may lead to severe and irreversible renal damage and sometimes to endstage renal failure. Substantial recovery often follows successful treatment.

Infective endocarditis

A similar syndrome occurs in patients with subacute bacterial endocarditis (see Chapter 15.10.2), when minor glomerular involvement is probably extremely common. The majority of signs and symptoms in these circumstances are common to shunt nephritis. Typical streptococcal infections are well represented in case series, but there have been many reports involving 'slow' infections such as Q fever (*Coxiella burnetti*) and more unusual causes including chlamydia and fungi. Infection of prosthetic or native heart valves may be implicated. Right-sided endocarditis occurring in intravenous drug abusers may be particularly likely to present as nephritis, perhaps because the diagnosis is often delayed. Depletion of serum complement is again diagnostically useful, but, as for shunt nephritis, most other serological and

haematological changes are non-specific. Partial treatment with antibiotics makes diagnosis more difficult, as positive blood cultures are usually a key part of proving the diagnosis and planning appropriate therapy.

The pathological lesion is often similar to that of shunt nephritis. A more acute endocarditis (for instance, that associated with *Staphylococcus aureus*) is more likely to cause glomerulonephritis in a diffuse proliferative pattern, sometimes with crescent formation. A third lesion has been increasingly reported in recent literature – focal changes that are indistinguishable from ANCA-associated vasculitis– indeed, in some cases ANCA have been detected. Cutaneous vasculitis may be seen in association with bacterial infection, and this seems particularly likely in endocarditis (Fig. 1 and Plate 1).

Fig. 1 Cutaneous vasculitis in a patient with *Staphylococcus aureus* endocarditis. (See also Plate 1.)

In most cases the outcome depends on the response of the endocarditis to treatment, but renal involvement is a poor prognostic factor for survival, which may be simply because it reflects a long-standing infection. Recovery from dialysis-dependence may occur.

Patients with endocarditis are also prone to two other renal lesions. Interstitial nephritis is frequently due to the prolonged administration of drugs, including high doses of antibiotics. Those with disease on the left side of the heart or with right–left shunts may suffer renal emboli. These are common at autopsies, but glomerulonephritis is probably a more common cause of urinary abnormalities in most patients.

Deep-seated bacterial infections

Amyloidosis is a well-recognized consequence of very chronic bacterial (including mycobacterial) and other infections, and is described in Chapter 11.12.4 and Chapter 20.10.4. As in reactive amyloidosis of other aetiologies, progression of the renal lesion may be prevented or even reversed by treatment of the cause.

Deep-seated infections, particularly abscesses, may also be associated with acute renal pathology. Although the mechanisms involved are presumably similar to those of shunt nephritis and nephritis associated with endocarditis, blood cultures have often been negative in reported cases. *Staphylococcus aureus* is the most frequently implicated organism. A specific type of renal disease in association with methicillin-resistant *Staph. aureus* (**MRSA**) infection has been postulated, but without strong support. A wide variety of renal lesions have been described, usually inflammatory/proliferative and with immunoglobulin deposition. Unsuspected abscesses or other deep-seated infections are occasionally found only after the renal biopsy appearances trigger a search. Such hidden abscesses are more likely to occur in the obese, the elderly, and in those prescribed corticosteroids or who are immunosuppressed by other means or by disease.

Acute glomerulonephritis and other infections

Acute glomerulonephritis resembling poststreptococcal nephritis has been reported in association with a large number of other organisms: including current (as opposed to recent) infection with staphylococci, streptococci, and other bacteria, and with acute viral infections that are usually self-limiting. These include Epstein–Barr virus, cytomegalovirus, coxsackieviruses, and the varicella, measles, and mumps viruses. Some may cause a clinical syndrome that is very similar to poststreptococcal nephritis, while others typically cause a less florid 'nephritic' or mixed 'nephritic/nephrotic' picture.

Diagnostic difficulties in bacterial infection-related glomerulonephritis

Infection-related nephritis may present in a very similar manner to nephritis associated with other systemic diseases, notably microscopic polyangiitis and other small-vessel vasculitides. As both types of disease process may be associated with fever, a systemic illness, and an acute-phase response, it is important to consider the possibility of infection in all patients thought to have systemic vasculitis. Blood cultures should be routine. **ANCA** (antineutrophil cytoplasmic antibody) assays are extremely useful, but it is important to note that ANCA positivity has been recorded in many infections, both by fluorescence and by solid-phase assays: ANCA are not diagnostic of small-vessel vasculitides. Renal biopsy is often the most discriminating investigation: infection-associated glomerulonephritis is usually associated with plentiful immunoglobulin deposition, although the pattern is variable, whereas small-vessel vasculitis is characteristically pauci-immune. Non-glomerular causes of renal impairment (interstitial nephritis, acute tubular necrosis) are also distinguished by renal biopsy.

Interstitial nephritis associated with infections

Bacterial infections

Acute bacterial pyelonephritis is usually a florid and painful disorder associated with symptoms of urinary tract infection, as described in Chapter 20.12. Substantial renal impairment is usual only if a single functioning kidney is affected. Occasionally, however, the diagnosis is masked by immunosuppression (for example, in a transplanted kidney), age, or other factors, and the diagnosis is made by the renal biopsy appearances of neutrophils in the interstitium and in tubules, which are rarely found in any other renal lesions.

Acute interstitial nephritis is a key feature of Weil's disease, a severe form of leptospirosis (see Chapter 7.11.31). Jaundice and renal failure follow a febrile illness caused by infection with *Leptospira interrogans*. The renal lesion comprises interstitial oedema with predominantly mononuclear infiltrates and foci of tubular necrosis. Renal failure is usually oliguric but may be polyuric. Dialysis may be required for days to weeks, and renal recovery may sometimes be incomplete.

Other bacterial infections that may cause a similar pathological picture include Rocky Mountain Spotted Fever (*Rickettsia rickettsii*), in which there may be an interstitial nephritis with foci of haemorrhage, and acute *Yersinia pseudotuberculosis* infection, in which an acute lymphocytic interstitial nephritis has been described in several patients. Legionnaire's disease (*Legionella pneumophila*) has been reported to be associated with renal impairment due to an interstitial nephritis, but in some instances may show a picture of acute tubular necrosis. The same is probably true of other severe pneumonias.

Mycobacteria spp. can cause a chronic granulomatous interstitial nephritis that is discussed below.

Viral infections

Hantaviruses

Hantaviruses are carried by small rodents and have been associated with a range of human syndromes that involve the kidneys with varying severity. 'Haemorrhagic fever with renal syndrome' (**HFRS**) was originally described in Eastern Asia. The usual renal syndrome is of oliguric renal failure, associated histologically with lymphocytic interstitial nephritis that may be haemorrhagic in severe cases, reflecting a systemic bleeding diathesis. Some patients have been reported to have persistent renal impairment after recovery.

HFRS was originally associated with Hantaan strains of hantavirus in Korea, while milder disease, usually with less severe or frequent renal impairment and without haemorrhagic diathesis, was associated with the Seoul strain. The milder disease ('nephropathia epidemica') recognized in Northern Europe, and subsequently more widely, was associated with Puumula strain. However, it has become apparent that there are many more subtypes of hantavirus, and that the association of a serotype with a particular clinical picture is not rigid. Severe disease with shock, variable haemorrhage, and (sometimes) pulmonary impairment has been encountered in patients in the Balkans and Greece. Disease with predominantly pulmonary manifestations and shock has been recognized particularly in North America, although these geographical variations in the clinical picture are no more rigid than the strain variations.

Ribavirin was shown to be effective in treating patients with HFRS in China, but in a smaller trial in North American patients with the pulmonary syndrome it was found to be no better than placebo.

Cytomegalovirus and polyomavirus

Cytomegalovirus (**CMV**) may lie dormant in renal tubular cells, and during new or reactivated infection cause characteristic inclusion bodies. This rarely has significant impact on renal function outside the setting of renal transplantation, where CMV infection commonly occurs concurrently with acute rejection. Although there is evidence that CMV infection may precipitate rejection, it is also clear that the risk of CMV infection is greatly increased by most types of antirejection therapy. CMV may also rarely cause a florid glomerular lesion characterized by gross endothelial-cell damage and swelling, resembling pre-eclampsia. This has again been recognized almost exclusively in renal transplant patients, where some believe that the appearances are due to, or complicated by, vascular rejection.

Human polyomaviruses (BK and JC) were previously believed to be benign passenger viruses that replicated without causing damage during immunosuppression. However, BK virus was recently recognized as a cause of impaired renal transplant function, generally months after transplantation. The histological changes of tubulitis had usually suggested acute cellular rejection, leading to further immunosuppression and favouring further infective damage, but inclusion bodies and immunohistochemical or *in situ* hybridization studies provided evidence for active virus replication—one report described an improvement of renal function in several patients after the reduction of immunosuppressive agents. Similar manifestations have not yet been described in other immunosuppressive settings.

Other viruses

A wide range of other viruses and micro-organisms have been less regularly associated with interstitial lesions. HIV may cause an interstitial nephritis and is considered separately below. Another condition that is likely to be infective in origin, Kawasaki disease (see Chapter 18.10.8), is associated with interstitial nephritis, although glomerular lesions have also been described occasionally.

HIV and renal disease

Renal impairment is commonly encountered at some stage of HIV infection, the largest single cause of serious renal disease being the distinct entity of HIV nephropathy. However, this generalization is misleading since this specific diagnosis is largely restricted to Black patients, and there are many other causes of renal disease in patients with HIV infection.

Focal segmental glomerulosclerosis associated with HIV infection (HIV nephropathy)

HIV nephropathy is characterized by heavy proteinuria and renal impairment. It has become the third most frequent cause of endstage renal failure (**ESRF**) in Black adults of working age in the United States. Although it has often been described as the initial manifestation of HIV infection, detailed analyses suggest that even in these cases the infection is advanced and CD4 counts are usually low. The histological appearances are of focal segmental glomerulosclerosis (**FSGS**) of the 'collapsing' form, with injury and hypertrophy of glomerular epithelial cells accompanied by variable interstitial inflammation with oedema and microtubular dilatation. It typically progresses to ESRF very rapidly, over weeks to months. Perhaps because of its association with low CD4 counts, the medium-term prognosis is usually poor despite renal replacement therapy. Highly active antiretroviral therapy is likely to have improved the outlook, and there are isolated reports of responses of nephropathy to such treatment, but at the time of writing no clear picture has emerged. Renal function in some patients has been reported to improve dramatically in response to treatment with corticosteroids, but this is not predictable and carries significant risk. It has been suggested that any improvement may be due to responses of interstitial nephritis rather than the glomerular lesion, as evidenced by the lack of reduction in proteinuria in one study.

Non-FSGS nephropathy in HIV infection

The large proportion of patients with HIV infection and nephropathy of other causes (a majority in most populations) can rarely be reliably distinguished by clinical criteria. Renal biopsies in this group have shown a very wide range of diagnoses encompassing almost all types of glomerular lesion, interstitial nephritis, cryoglobulinaemia, and thrombotic microangiopathy. Some of these lesions may be related to concurrent infections with other micro-organisms. Others may be related to therapy. Aciclovir and indinivar have replaced sulphonamides as common causes of crystal nephropathy. Idiosyncratic reactions to drugs may be more frequent in patients with HIV infection, but they also receive many drugs with predictable nephrotoxicity. The occurrence of autoimmune phenomena in patients with HIV infection may also be accompanied by an increase in immune-mediated primary glomerular diseases.

Nephropathy associated with hepatitis B virus

Chronic infection with hepatitis B virus (**HBV**) is strongly associated with membranous nephropathy and is an important secondary cause of the lesion, with a frequency that depends on the population. A less clear relationship holds with membranoproliferative nephropathy, while for hepatitis C virus (**HCV**) the converse is true.

Chronic HBV infection is much more common in some regions and racial groups, and the distribution of HBV-related nephropathy closely follows this distribution. The clinical picture may be complicated by the concurrence of HBV infection with infection by HCV or other organisms, or by coincidental significant renal and hepatic disease. HBV membranous nephropathy has a close relationship with virus multiplication, so affected individuals are **HBeAg**- and **HBsAg**-positive (hepatitis B e antigen, hepatitis B surface antigen, respectively) and hepatitis usually coexists, although it may be minor and subclinical. Membranous nephropathy is a more common complication of HBV infection in children, but it is also more benign in this group. The lesion may be static or in some cases (particularly in adults) associated with progressive deterioration to ESRF.

The histopathological appearances are typical of membranous nephropathy (see Section 20.8.6), and HBV antigens may be detectable in glomerular deposits. Whether this is relevant to pathogenesis is debatable. Animal models suggest that antibodies to podocyte surface molecules are a more likely way of producing the membranous lesion than trapping of preformed antigen–antibody complexes.

Seroconversion from HBeAg-positive to HBeAb-positive status is associated with remission of the renal lesion, whether the conversion occurs naturally or is induced by treatment. Spontaneous remission of the renal lesion is more likely in children. Antiviral treatment is the appropriate therapy when required, as immunosuppression may increase the viral burden. Unfortunately this is least likely to be successful in those populations in which the problem is greatest.

HBV infection has been associated with classic polyarteritis nodosa (**PAN**) in some populations, such as in France and North America, but even in these areas HBV–PAN is uncommon and apparently decreasing in incidence. Furthermore, the association of the two diseases is rare in some countries with both low (for example, the United Kingdom) and high (for example, Thailand) rates of HBV carriage. Usually the infection has been acquired within months of the onset of arteritic manifestations. Clinically the disease is typical of PAN, affecting medium and somewhat smaller vessels but not capillaries, and therefore not usually associated with focal necrotizing or crescentic nephritis. ANCA are not usually detected. Treatment is difficult as immunosuppression favours viral replication and exacerbation of liver disease, while remission is associated with seroconversion from HBeAg- to HBeAb-positivity.

Nephropathy associated with hepatitis C virus

Chronic hepatitis C virus (**HCV**) infection is the major cause of mixed essential (type II) cryoglobulinaemia in most populations. The mechanism is unknown, but the cryoglobulinaemia associated with HCV infection is entirely typical (see Chapter 20.10.5). The clinical picture includes cutaneous vasculitis, glomerular pathology

(membranoproliferative glomerulonephritis), and other manifestations. The cryoglobulins contain quantities of HCV antigens and bound antibody, in addition to monoclonal IgM rheumatoid factors.

HCV may also be associated with mesangioproliferative glomerulonephritis in the absence of detectable cryoglobulins. A relationship with membranous nephropathy has been suggested but is not proven.

As for HBV, reduction of viral replication has been associated with disease remission, but this is harder to achieve for HCV than for HBV with current therapies. Immunosuppression with corticosteroids and sometimes other agents may be required to control disease manifestations caused by vasculitis.

Renal sequelae of other chronic infections

Amyloidosis may be a consequence of all sorts of chronic infection, but of the 'tropical' infections is most frequently associated with schistosomiasis, filariasis, or leishmaniasis.

Mycobacteria

Mycobacterial infections cause a chronic granulomatous interstitial nephritis that is characteristically associated with inflammatory and fibrotic abnormalities in the ureters and lower urinary tract. Symptoms often relate to this lower tract involvement; however, the disease may be asymptomatic and in the earliest stages involvement is presumed to be restricted to the kidneys, with subsequent spread to the lower tract. Sterile pyuria is the rule. Impaired renal function is common at presentation. Intravenous urography will show blunting of the calyces, progressing to changes typical of pyelonephritis or papillary necrosis, along with lower tract abnormalities such as ureteric strictures and scarring and contraction of the bladder. Amyloidosis is a well-recognized secondary complication of mycobacterial infections. Idiosyncratic reactions to antituberculous drugs are the other common cause of late renal dysfunction.

Syphilis

Congenital syphilis may cause severe nephrotic syndrome with the histological pattern of membranous nephropathy. This is also the usual pattern in the rare instances when secondary syphilis causes a nephrotic syndrome. Both respond to antispirochaetal treatment.

Malaria

Plasmodium falciparum infections may cause acute renal disease, but chronic lesions are usually associated with chronic *P. malariae* infection, as described in Chapter 20.7.10.

Schistosomiasis

In renal/urological practice, schistosomiasis is best recognized for causing disease of the lower urinary tract, but chronic infections associated with hepatosplenomegaly may be associated many years later with glomerular disease. In *Schistosoma haematobium* infection this is often due to secondary infections with *Salmonella* species rather than directly associated with schistosomal infection. In *S. mansoni* infection the usual relationship is directly causal, producing a mesangiocapillary or mesangioproliferative picture.

Filariasis

Long-standing filariasis may also be associated with glomerular lesions. An acute syndrome with tubulointerstitial nephritis has also been described in association with the presence of microfilariae in renal capillaries.

20.7.9 Malignancy-associated renal disease

A. Neil Turner

Malignant disease may affect the kidneys and urinary tract by five broad mechanisms (Table 1).

Direct involvement of the urinary tract

Solitary kidney tumours in adults are usually caused by renal-cell carcinoma (hypernephroma). Bilateral tumours may occur, but multicentric tumours should lead to the suspicion of an inherited disorder—the least rare of these are von Hippel–Lindau syndrome (see Chapter 20.11; cystic and solid lesions, some malignant), or tuberous sclerosis (see Chapter 20.11; benign lesions), both having an autosomal dominant mode of inheritance. Lymphoma and leukaemia may occasionally invade the renal substance on a sufficient scale to cause renal impairment, but it is rare for other umours to do so.

A rare and aggressive renal medullary tumour has recently been described in young Blacks with sickle-cell trait or disease: these are easily confused with tumours of the collecting system; all reported cases have been rapidly fatal.

The collecting system and lower urinary tract may be affected by transitional-cell tumours or by invasive malignancies. Transitional-cell tumours affecting the bladder are common, and sometimes cause urinary obstruction if they are extensive or if they block one or both ureters or bladder outflow. Lesions in the ureters and collecting system are less common. They occur multifocally in association with analgesic nephropathy and Balkan nephropathy (see Chapter 20.9.2). Multifocal premalignant or malignant changes have also been described in patients with 'Chinese herb nephropathy', an epidemic of renal interstitial fibrosis associated with the ingestion of a herbal slimming aid in Europe during the early 1990s.

Metabolic effects

Hypercalcaemia is a feature of many malignancies, both with and without metastasis. Its renal effects are discussed in Chapter 20.10.5. Hypokalaemia may be a consequence of acute leukaemias or rectal tumours, and occasionally may be severe enough to cause renal dysfunction (see Chapter 20.2.2).

Hyperuricaemia and tumour lysis syndrome

Severe hyperuricaemia (>900 µmol/l) is characteristically associated with the occurrence of massive cell death following chemotherapy for haematological or solid tumours (tumour lysis syndrome), when it is usually accompanied by hyperphosphataemia and often hypocalcaemia. High serum lactate dehydrogenase (**LDH**) levels may also be diagnostically useful. Similar gross hyperuricaemia may also be seen following radiotherapy of radiosensitive tumours; sometimes this also occurs in untreated patients who have haematological or other malignancies with a very high rate of cell turnover. Levels this high can lead to precipitation within renal tubules and acute renal failure. Allopurinol should therefore be given prophylactically before commencing any chemotherapeutic regimen where such a response might occur.

Allopurinol therapy is still appropriate once hyperuricaemia has developed, and maintenance of high urinary output, and possibly urinary alkalinization, should theoretically be beneficial. If oliguric renal failure has developed then prolonged haemodialysis treatment may remove enough urate to permit renal recovery. Urate oxidase (uricase) has also been used in these circumstances to convert urate to the more soluble compound allantoin, but the enzyme is not widely available.

Remote effects of malignant tumours on the kidney

Thrombotic microangiopathy

Thrombotic microangiopathy occurring in association with malignant disease (also known as malignancy-associated thrombotic thrombocytopenic purpura, see Section 22). is often attributed to chemotherapy: although this is particularly associated with some agents (for example, bleomycin, mitomycin), isolated reports do implicate other drugs. However, in some instances the classic presentation with thrombocytopenia, microangiopathic haemolytic anaemia, and renal failure occurs in association with primary tumours. This has been particularly reported for malignancies of the stomach, pancreas, and prostate when occasionally it is the presenting sign, but it more often occurs in the setting of a known tumour.

In the absence of specific evidence, tumour-related thrombotic microangiopathy is usually treated in the same way as thrombotic microangiopathy of other types, by plasma exchange with fresh-frozen plasma. Microangiopathy generally subsides if the tumour is responsive to treatment. Renal function may be recoverable if the process is halted rapidly, an outcome most likely to be achieved in patients with prostatic carcinoma.

Other tumour products

The protean effects of the monoclonal overproduction of immunoglobulins, or their component parts, are considered elsewhere in this section. The tubulotoxic effects of light chains may be amplified by hypercalcaemia in patients with myeloma, or by the concurrent administration of other nephrotoxins—notably intravenous contrast media. Although amyloidosis was reported in older series as a consequence of lymphomas, it is now very rarely encountered as a consequence of malignancy.

Immune reactions

Malignant disease is common, so cancer will be associated with nephropathy by chance on occasion. There are therefore many case reports in the literature, but some associations have been reported consistently and are beyond doubt. The best evidence for a linkage between malignancies and intrinsic renal diseases is in minimal-change disease and membranous nephropathy (see Chapter 20.7.4). There is also substantial evidence for an association of malignancy with various types of vasculitis.

Some malignancies are particularly likely to be associated with renal disease. Chronic lymphocytic leukaemia and similar low-grade, B-cell tumours are associated with a variety of types of glomerulopathy. Thymomas have frequently been associated with glomerular lesions, usually causing nephrotic syndrome exhibiting a variety of histological patterns. There is little evidence, by contrast, for a common association of malignancies with primary interstitial renal diseases.

Minimal-change nephrotic syndrome

Lymphomas, usually Hodgkin's disease, are rarely associated with minimal-change nephropathy; this may be the presenting sign of the lymphoma, and it may also herald relapses. More so than with other renal lesions that are putatively associated with malignancy, it has often been possible to show a close temporal relationship between the occurrence of nephrotic syndrome and the presentation of the tumour. However, there is no way of proving the association in an individual patient, or of

suspecting an underlying lymphoma in patients who present with nephrotic syndrome without systemic symptoms. As the association is very rare in comparison to the number of young patients with minimal-change disease, screening other than by clinical examination and simple investigations does not seem justified. The renal lesion is typical in its pathological characteristics, and usually also in response to corticosteroid treatment.

Less commonly, minimal-change disease has been associated with solid tumours, and particularly with malignant and benign thymomas.

Membranous nephropathy

Membranous nephropathy is sometimes associated with malignancy, especially in the elderly. Series have reported rates of malignancy ranging from 5 to 11 per cent, with the risk being greatest in those at the upper end of the age range. However, different inclusion criteria have sometimes been used to assess risk: for example, some series have included tumours recognized long after a diagnosis of renal disease has been made, when the association may be coincidental. Most reported tumours have been of solid organs but haematological malignancies are also implicated. Very often the disease is advanced and obvious by the time that nephrotic syndrome or a heavy proteinuria is recognized. In some cases, effective treatment of the malignancy has led to an improvement in the nephrotic syndrome or proteinuria. The use of alkylating agents or corticosteroids to treat membranous nephropathy is not recommended in this setting, unless it would be appropriate for treatment of the malignancy itself.

In patients presenting with membranous nephropathy, controversy surrounds the value of screening for malignancy when this is not apparent from initial investigations. However, palpation of the breasts, faecal occult blood testing, and rectal examination should not be neglected. Routine haematological and biochemical investigations are appropriate for all patients, as is chest radiography and renal ultrasound. In older patients there should be a low threshold for investigating gastrointestinal or other symptoms/signs: for example, with upper gastrointestinal endoscopy, sigmoidoscopy/colonoscopy, or mammography. However, in clinical practice the number of treatable and otherwise subclinical tumours uncovered in this way is low, hence an exhaustive series of investigations is not indicated in the absence of clear and specific clinical indications.

Systemic vasculitis

Focal necrotizing and crescentic nephritis (rapidly progressive glomerulonephritis, RPGN), with or without evidence of small-vessel vasculitis affecting other organs, may occur in association with malignancy. Small-vessel vasculitis is more common in the elderly, so that some of the associations will be chance associations. However, there are sufficient reports of unusual associations to strongly suggest a causal relationship in some cases.

As well as true vasculitis, cancer-related thrombotic microangiopathy and thrombotic events complicating disseminated intravascular coagulation in association with cancer may resemble systemic vasculitis and lead to diagnostic confusion. Recent evidence suggests that thrombotic thrombocytopenic purpura itself may be an autoimmune condition caused by autoantibodies to von Willebrand factor protease, but it is not yet clear whether this association also applies to cases associated with malignancy.

The commonest type of vasculitis to be associated with malignancy is small-vessel cutaneous vasculitis. In other cases, the presence of a small-to-medium vessel systemic vasculitis, not usually associated with autoantibodies to neutrophil granule proteins (**ANCA**, antineutrophil cytoplasmic antibody), has been reported in the bowel and other organs, including the kidney. More typical ANCA-associated vasculitis has also been associated with malignancy, and there may be a particular relationship between Wegener's granulomatosis and renal-cell carcinoma. Usually the kidney is not involved in cancer-associated systemic vasculitis, but when it is the appearances are indistinguishable from those of small-vessel vasculitides of other aetiologies. Immune deposits are not usually found in the glomeruli (pauci-immune). Atrial myomas have been associated with lesions of larger and smaller vessels, and it appears that embolization is not always the explanation for this.

Effects of treatment

These include the tumour-lysis syndrome (discussed above), as well as idiosyncratic or predictable reactions to therapeutic agents. On occasions, minimal-change disease or other lesions have been associated with interferon therapy.

20.7.10 Glomerular disease in the tropics

Kirpal S. Chugh and Vivekanand Jha

Introduction

Glomerulonephritis continues to be the commonest cause of endstage renal failure in tropical countries. Reliable statistics on the various types of glomerular diseases encountered in different geographical regions are not available: the published data is mostly based on individual experiences, and suggests a significant difference in the epidemiology, aetiology, and natural history of glomerulonephritis between populations living in countries with tropical and temperate climates. The most important factor that appears to account for this difference is the high prevalence of infection-related glomerulonephritis in tropical regions. Furthermore, the impact of glomerulonephritis on the individual is often more severe: a lower degree of protein loss leads to more severe peripheral oedema and serous effusions in a malnourished individual, and the condition often remains undiagnosed and untreated for long periods due to the lack of uniform access to healthcare, culminating in a higher morbidity and mortality. Because of enormous variation in the prevalence of various endemic infections in different countries, the pattern of glomerulonephritis is different throughout the tropical region.

The overall prevalence of glomerulonephritis appears to be 60 to 100 times higher in tropical countries than in temperate regions. Hospital-based surveys from South Africa, Zimbabwe, Senegal, Uganda, Nigeria, Yemen, and Papua New Guinea show that nephrotic syndrome accounts for between 0.2 and 4 per cent of all hospital admissions. Primary glomerular diseases account for the majority of cases, but secondary causes are responsible for nephrotic syndrome in 40 to 55 per cent of patients in some countries like Zimbabwe and Jamaica.

Primary glomerular diseases

The relative frequencies of the various primary glomerulonephritides in the tropical countries and the rest of the world are shown in Fig. 1 and Fig. 2. Minimal-change disease is as prevalent in Asian countries as in the developed world, but is seen less frequently in Africa. In a study from South Africa, minimal-change disease was responsible for nephrotic syndrome in 75 per cent of children of Indian ancestry, whereas only 13.5 per cent of Black children showed this lesion. The frequency of membranous nephropathy is high in countries with a high hepatitis B carrier rate. A variant of membranous nephropathy associated with hypocomplementaemia has been described in Senegal.

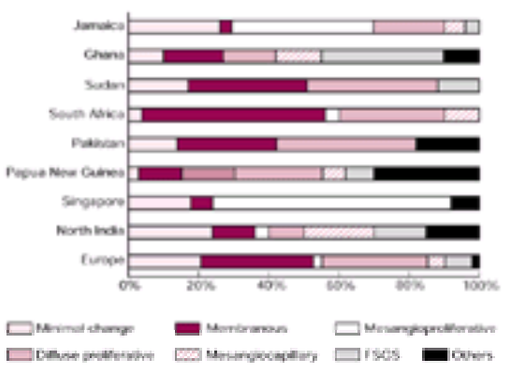

Fig. 1 Prevalence of primary glomerular disease in adults with nephrotic syndrome.

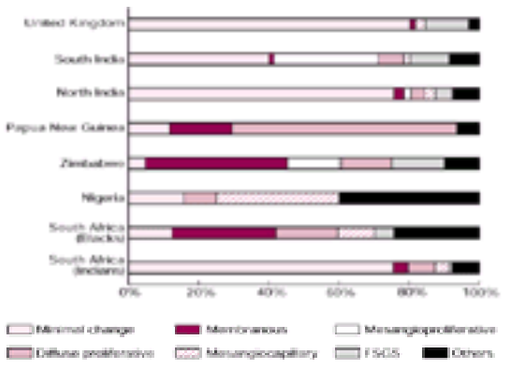

Fig. 2 Prevalence of primary glomerular diseases in nephrotic children.

IgA nephropathy (incorporated under the heading mesangioproliferative nephropathy in Fig. 1 and Fig. 2) has emerged as the commonest primary glomerular disease in many parts of the world, including Far Eastern tropical countries where it accounts for between 30 and 50 per cent of all cases of primary glomerulonephritis. By contrast, its frequency is estimated to be 5 to 15 per cent in countries of the Indian subcontinent and South America, and less than 1 per cent amongst the Black population in Africa. However, the reported differences in prevalence may be partly related to the lack of facilities for performing immunofluorescence studies in many centres in the tropical regions. High dietary fibre intake has been suggested to protect Black people from IgA nephropathy.

Postinfectious glomerulonephritis, due to both streptococcal and non-streptococcal organisms, continues to be encountered in a significant proportion of patients in tropical countries.

Glomerular diseases specific to the tropics

In addition to the well-recognized bacterial and viral infections with worldwide distribution that can cause glomerular disease (see Chapter 20.7.8), several other pathogens have been recognized to be associated with glomerular lesions in the kidneys in tropical countries, leading to a significantly different profile of infection-related glomerular disease. Causal relationships are initially suggested by epidemiological studies and then established by demonstrating the resolution of renal lesions following treatment of the infection. More recently, improved diagnostic techniques and well-designed experimental studies have provided more concrete evidence in favour of a cause-and-effect relationship. Direct confirmatory evidence has been obtained by the demonstration of specific antigens (using monoclonal antibodies), immunoglobulins, and complement within the lesions, pointing to the immunological origin of glomerular disease. The infections that cause glomerular

lesions specifically in the tropics are listed in Table 1.

Malarial nephropathy

Malaria, caused by members of the protozoan *Plasmodium* genus, is endemic in the Indian subcontinent, Middle and Far Eastern Asia, sub-Saharan Africa, and Central America where the hot and humid tropical climate is conducive to multiplication of the disease vector, the Anopheles mosquito. Of the four species that are pathogenic in humans, *P. vivax*, *P. ovale*, *P. malariae*, and *P. falciparum*, only the latter two are associated with clinically significant renal disease. Acute renal failure is the chief complication in falciparum malaria infection. Glomerulonephritis is observed with *P. malariae* infection (quartan malarial nephropathy) and less commonly with *P. falciparum*.

Quartan malaria

Although the first record of quartan malarial nephropathy in the medical literature dates back to 1884, a definite cause-and-effect relationship between *P. malariae* and the nephrotic syndrome was established in 1930 by Giglioli in the surveys carried out in British Guyana. A number of reports subsequently supported his observations, most notable being that by Gilles and Hendrickse who recorded an increased prevalence of *P. malariae* parasitaemia amongst nephrotic children in western Nigeria. The condition has also been reported from Uganda, Kenya, Ivory Coast, Sumatra, New Guinea, and Yemen.

The exact incidence of glomerulonephritis associated with quartan malaria is unknown, but the frequency of nephrotic syndrome in areas endemic for this infection is between 20 and 60 times higher than in non-endemic areas. The prevalence has shown a consistent decline with the eradication of malaria in many areas, most notably in Uganda.

Clinical features

Quartan malarial nephropathy is rare during the first 2 years of life, with the peak incidence being between 5 and 8 years of age. The prevalence declines thereafter, although sporadic cases are reported in adult life. Most patients are poor and malnourished. The most frequent presentation is with a nephrotic syndrome developing several weeks after the onset of quartan fever. Oedema is prominent and accentuated by concomitant protein energy malnutrition. Proteinuria is non-selective in 80 per cent of cases. Gross haematuria is not seen, but microscopic haematuria is noted in some cases. The blood pressure is normal at the onset of disease, but increases once renal failure sets in. Anaemia is a universal feature and enlargement of the liver and/or spleen is noted in over 75 per cent cases. Hypoalbuminaemia is usually profound, with values commonly under 1 g/dl. By contrast with other causes of nephrotic syndrome, the serum cholesterol level tends to be normal or low, reflecting low dietary intake. Serum creatinine is usually normal at presentation. Serum complement (C3) is within the normal range. In the early stages, *P. malariae* parasitaemia is detected in about 75 per cent cases.

Pathology

The predominant light microscopic abnormality is segmental thickening of glomerular capillary walls. This is focal in the early stages, but the number of affected glomeruli increases as the disease progresses. The thickening is due to the subendothelial deposition of Periodic acid–Schiff (**PAS**)- and silver stain-positive fibrils arranged in a plexiform manner. Laying down of new basement membrane material on the opposite side gives rise to the classical 'double contouring'. Eventually the capillary lumina are obliterated and mesangial sclerosis extends to involve all components. Proliferative lesions, including mesangial hypercellularity and small fibroepithelial crescents, have been described in adults.

Immunofluorescence shows deposits of IgG (usually subclass 3), IgM, and C3. Three patterns have been described. The commonest is a coarse, granular deposition along the capillary walls; a minority show diffuse, homogeneously distributed IgG2 deposits; and a mixed pattern is observed in the remaining cases. *P. malariae* antigen is detected in about one-third of patients. Electron microscopy chiefly reveals subendothelial deposits of basement membrane-like material. Intramembranous deposits may also be seen.

Pathogenesis

Demonstration of malarial antigen in the deposits and binding of specific antibody to circulating malarial antigens suggest an immunological basis for the condition. The Rhesus monkey (*Macaca mulatta*) when infected with *P. inui* develops an immune complex glomerulonephritis, and so has been proposed as an experimental model for quartan malarial nephropathy. Subendothelial location of the deposits indicates formation of immune complexes in the circulation rather than *in situ*. The permissive role of environmental factors, such as malnutrition or co-infection with Epstein–Barr virus, has been speculated to explain the development of lesions in some but not all cases of *P. malariae* infection. It has been suggested that the liver may act as a source of continuous antigen supply by harbouring the parasite.

Management

Treatment of quartan malarial nephropathy is highly unsatisfactory. Once established, the disease follows an inexorably progressive course, culminating in renal failure within 2 to 4 years. Antimalarial drugs such as chloroquine and pyrimethamine have been ineffective in controlled trials. Prednisolone is ineffective in inducing remissions and may lead to infections and worsening of hypertension, although some workers have reported a 50 per cent response rate to steroids in those with highly selective proteinuria. Remission of nephrotic syndrome has been reported occasionally with cyclophosphamide in patients with mild histological lesions, but there is no improvement in overall survival. Azathioprine is associated with increased mortality and is contraindicated in this condition.

Falciparum malaria

The incidence of glomerulonephritis associated with falciparum malaria is difficult to estimate as the disease is mild, transient, and overshadowed by other complications. Autopsy studies reveal glomerular lesions in about 18 per cent of cases, but urinary abnormalities including non-selective proteinuria, microhaematuria and casts are noted in 20 to 50 per cent. Full-blown nephrotic and acute nephritic syndromes are seen occasionally. By contrast to quartan malarial nephropathy, glomerulonephritis associated with falciparum malaria resolves within 4 to 6 weeks of eradication of infection.

Pathology

The histological lesions are characterized by mesangial hypercellularity and a modest increase in the mesangial matrix. Basement membrane changes are usually absent. An eosinophilic granular material is present in capillary walls, mesangium, and Bowman's capsule, along with pigment-laden macrophages in the capillary lumina. Immunofluorescence shows finely granular IgG3, IgM, and C3. Malarial antigen can be demonstrated in some cases. Electron microscopy reveals subendothelial and mesangial deposits.

Pathogenesis

Transient glomerular lesions akin to those in falciparum malaria can be induced in BALB/c mice and Sprague–Dawley rats infected with *P. berghei*, also in *P. falciparum*-infected squirrel monkeys, the latter model showing endocapillary proliferation in addition to mesangial hypercellularity. Recent studies have suggested that CD4 cell subpopulations, in particular TH2 cells, may be playing a significant role in the genesis of these glomerular lesions, with renal cytokine expression strongly correlated with the severity of proteinuria in C57BL/6J mice infected with *P. berghei*. The role of concomitant infection, especially with the hepatitis B virus, is under investigation.

Schistosomal nephropathy

Schistosomiasis is a chronic infection caused by trematodes (blood flukes) and affects over 300 million people in Asia, Africa, and South America. Of the seven species pathogenic to man, the most prevalent are *Shistosoma haematobium* (Africa and the Middle East), *S. mansoni* (South America and Africa) and *S. japonicum* (China and the Far East). *S. haematobium* primarily involves the lower urinary tract, whereas *S. mansoni* involves the gastrointestinal tract and portal system, leading to hepatic fibrosis and portal hypertension.

Glomerulonephritis has been described most frequently in association with hepatosplenic schistosomiasis produced by *S. mansoni*. The first reports came from autopsy series in Brazil during 1964. Several clinical observations from endemic areas of Africa, Saudi Arabia, Aden, and Yemen and experimental studies have since confirmed the cause-and-effect relationship of *S. mansoni* infection with glomerulonephritis. *S. japonicum* is known to cause glomerulonephritis only in experimental animals.

In clinical studies, overt proteinuria has been reported in 1 to 20 per cent of patients infected with *S. mansoni* and 2 to 5 per cent with *S. haematobium* infection; microalbuminuria is found in about 22 per cent of patients with hepatosplenic schistosomiasis. Histological studies have documented subclinical glomerular lesions in a much higher proportion of patients, with glomerular abnormalities detected on renal biopsy in 40 per cent of patients who underwent splenectomy in one study, none of whom had clinical evidence of renal disease, hence the true extent of subclinical glomerular involvement remains unknown.

Clinical features

Though described at all ages, glomerulonephritis is seen most commonly in young adults with overt hepatosplenic disease. Males are affected twice as frequently as females. Peripheral oedema and ascites are the hallmarks of clinical glomerular involvement. Hypertension is seen in 50 per cent of cases, appearing late in the disease. Proteinuria is poorly selective and haematuria is uncommon in the absence of lower urinary tract involvement. About 30 per cent of patients exhibit hypergammaglobulinaemia; the serum cholesterol is not elevated in an equal proportion; serum complement (C3) levels are usually low. Non-specific antibody production is demonstrated by false-positive rheumatoid factor or the **VDRL** (Venereal Disease Research Laboratory) test, especially in those with concomitant salmonella infection. Demonstrating viable eggs in the stool or egg-containing granulomas in a rectal or liver biopsy makes the diagnosis of schistosomiasis. It is important to exclude other causes of nephrotic syndrome before attributing the lesions to schistosomiasis. Some patients with schistosomiasis and proteinuria have been shown to have a coexistent salmonella infection.

Pathology

Several patterns of glomerular pathology have been described (Table 2). The Class I lesion is the earliest and most frequent, all three types of mesangioproliferative lesion being seen with equal frequency (see Table 2). It is also the principal lesion in renal allografts with recurrent schistosomal nephropathy. Class II lesions are more frequent in patients with concomitant salmonella infection. The frequency of Class III lesions varies from 20 per cent in asymptomatic patients to over 80 per cent in those with overt renal disease, over 90 per cent of Class III cases belonging to Class III A. Immunofluorescence shows IgG and C3, less commonly IgM and IgA. Schistosomal antigen is detected in a minority of cases. Electron microscopy shows subendothelial and epimembranous deposits in Class IIIA and IIIB, respectively. The Class IV lesion, seen in 15 to 40 per cent of cases, cannot be distinguished from idiopathic focal segmental glomerulosclerosis (**FSGS**) on the basis of light microscopy, but immunofluorescence reveals IgA deposition in most cases. Class III and IV lesions are seen in patients with fibrotic livers. Class V prevalence varies from 15 to 40 per cent, with a higher frequency in African patients. This form is not usually affected by hepatic fibrosis.

Pathogenesis

Schistosomal glomerulopathy is caused by the immunological reaction to specific parasitic antigens. Out of over 100 immunological constituents extracted from adult worms, Cercariae and Schistosomulae, only a few have been identified *in vivo*. The pathogenic antigens originate in the gut of the adult worm, are regurgitated into the host's bloodstream and find their way to the glomeruli. Schistosoma antigens unaccompanied by any immunoglobulin have been demonstrated in the glomeruli of Kenyan baboons infected with *S. mansoni*, suggesting a role for the kidneys in the disposal of circulating antigens. Circulating immune complexes have been documented in humans and experimental animals, with the highest titres in those with hepatosplenic disease. The complexes usually localize in the mesangial region. An additional component of *in situ* immune complex formation is suggested by the extramembranous location of deposits. Interspecies antigenic variation could be responsible for the differential expression of glomerular injury.

Portocaval shunting secondary to hepatic fibrosis is critical in the genesis of an immune reaction to such antigens. Diversion of portal blood carrying the primary load of worm antigen directly into the systemic circulation prevents their normal processing and degradation by hepatic macrophages. This hypothesis is supported by the low frequency of glomerular disease in cases of *S. haematobium* infection that do not show hepatic involvement. Baboons with *S. mansoni* infection develop neither portal fibrosis nor glomerular disease despite heavy infestation. IgA antibodies predominate in the circulation of patients with schistosomal glomerulonephritis, whereas those with hepatosplenic schistosomiasis without glomerular involvement show IgM antibodies. Impaired clearance by the liver and increased production secondary to immunoglobulin isotype 'switching' from IgM- to IgA-producing B cells are postulated to be responsible for this alteration. The number of circulating mononuclear IgA-bearing cells is also increased in these patients.

Elevated immunoglobulin levels and false-positive rheumatoid factor and VDRL tests suggest the presence of an autoimmune disorder. Antinuclear antibodies, specific against the public anti-DNA idiotype 16/6 ID, have been found in the sera and glomerular deposits of humans and experimental animals.

The role of salmonella infection in the genesis of schistosomal nephropathy is unclear. Epidemiological studies have shown that urinary abnormalities disappear following therapy for salmonella alone, suggesting that these abnormalities could be purely due to salmonella infection in some cases.

Management

Treatment of schistosomal glomerulopathy is disappointing. Antischistosomal drugs like oxamniquine, hycanthone, or praziquantel are unsuccessful in altering the clinical course, which is one of inexorable progression to renal failure. Steroids or cytotoxic agents, alone or in combination, are ineffective in inducing remission. Isolated reports of response to these agents have not been evaluated in controlled trials. Salmonella infection should be looked for and treated in all patients.

Filarial nephropathy

Filarial worms are nematodes that dwell in the subcutaneous tissues and lymphatics. These are transmitted to humans through arthropod bites. Clinical manifestations depend upon the location of microfilariae and adult worms in the tissues. Of the eight filarial species that infect humans, *Loa loa*, *Onchocerca volvulus*, *Wuchereria bacrofti*, and *Brugia malayi* are associated with glomerular disease.

Loiasis is prevalent in West and Central Africa and characteristically manifests with localized areas of allergic inflammation and calabar swellings. Onchocerciasis (river blindness) is characterized by subcutaneous nodules, a pruritic skin rash, sclerosing lymphadenitis, and ocular lesions. Bancroftian and brugia infections cause febrile episodes associated with acute lymphangitis and lymphadenitis, leading ultimately to lymphoedema manifesting as hydrocele and elephantiasis. This form of filariasis is endemic in Africa and SE Asia.

The frequency of glomerular involvement in filariasis is difficult to estimate. Urinary abnormalities have been described in 11 to 25 per cent of cases of loiasis and onchocerciasis, with a nephrotic syndrome in 3 to 5 per cent. Nephrotic syndrome is more common in those with polyarthritis and chorioretinitis, and impaired creatinine clearance is more frequent with onchocerciasis than loiasis. Regarding wuchererian and bancroftian filariasis, early studies indicated an increased incidence of proteinuria in patients infected with *B. malayi* compared to controls, but there was no correlation with the severity of filariasis. In a recent survey in an endemic area, proteinuria was detected in over 50 per cent of patients with filariasis, with 25 per cent showing glomerular proteinuria. The frequency of proteinuria, also of microhaematuria and hypertension, is significantly higher in patients with chronic sclerosing filariasis than in those with an acute febrile illness or microfilaraemia. False-positive rheumatoid factor, both of IgG and IgM type, and anti-DNA and antiphospholipid antibodies and autoantibodies against a variety of cytoplasmic proteins may be noted in some cases.

Pathology

Light microscopy reveals a gamut of lesions, including mesangial proliferative, mesangiocapillary, minimal-change disease, chronic sclerosing glomerulonephritis, and the collapsing variant of focal segmental glom-erulosclerosis. A diffuse basement membrane thickening with a mild increase in the number of endocapillary cells is the commonest finding. Mononuclear interstitial infiltration and microinfarcts around blood vessels have been demonstrated in patients with loiasis. Microfilariae may be found in the glomerular capillary lumina, tubules, and interstitium. Electron microscopy shows widely spaced subepithelial, subendothelial, and intramembranous deposits and spikes. *O. volvulus* and *B. malayi* antigens along with IgM, IgG, and C3 have been demonstrated in the deposits. Biopsies from patients with loiasis

exhibit reactivity with hyperimmune anti-Onchocerca serum, raising the possibility of a shared antigen.

Pathogenesis

Filarial glomerulonephritis appears to be immune complex-mediated. Circulating immune complex levels correlate with the adult worm burden. Dogs infected with *Dirofilaria immitis* develop glomerular lesions similar to human filariasis. Immune complexes can also form *in situ*, as suggested by one experimental study that showed the development of glomerular lesions in kidneys after selective catheterization and infusion of *D. immitis* into the renal arteries. The contralateral kidneys either remained uninvolved or showed very minor lesions. Diethylcarbamazine treatment, by killing the parasite, may lead to antigen release into the circulation, thus exacerbating the immune process. A temporal relationship between the administration of this agent and the development of proteinuria has been noted.

Treatment

A good response to antifilarial therapy with diethylcarbamazine is observed in patients with non-nephrotic proteinuria and/or haematuria. The response is inconsistent in those with nephritic syndrome, and deterioration of renal function may continue despite clearance of microfilariae with treatment.

Mycobacterial infections

Leprosy

Leprosy is a chronic granulomatous disorder caused by the acid-fast bacillus *Mycobacterium leprae*. Nephritis in patients with leprosy was recognized by Hansen and Looft in 1894, and continued to be an important cause of death until the 1950s. The two major glomerular lesions encountered in leprosy include glomerulonephritis and secondary amyloidosis.

Glomerulonephritis

The incidence of glomerulonephritis varies from under 2 per cent on clinical evaluation to over 50 per cent on histology. Interpretation of various studies is confounded by bias in patient selection, with specialized centres reporting high figures. Glomerulonephritis is seen in both lepromatous and non-lepromatous forms of leprosy and is more common during episodes of erythema nodosum leprosum.

Clinical features

Most patients present with asymptomatic urinary abnormalities but nephrotic syndrome, acute nephritic syndrome, and rapidly progressive renal failure have all been described in a small number of patients. Hypertension is uncommon. Reduced creatinine clearance is noted in patients with erythema nodosum leprosum, and impaired urinary acidification and concentration may be demonstrated. Hypocomplementaemia is common, and circulating cryoglobulins are present in many cases.

Pathology

The histological picture is varied. The most frequent light microscopic lesions are those of mesangial proliferative and diffuse proliferative glomerulonephritis, although other morphological lesions have been reported. Acid-fast bacilli are seen rarely. Electron microscopy reveals electron-dense deposits in the mesangial and subendothelial regions, focal foot-process widening, glomerular capillary basement membrane reduplication with mesangial interposition, and endothelial cytoplasmic vacuolation. Immunofluorescence reveals granular deposits of IgG and C3, and less frequently IgM, IgA, and fibrin in the mesangium and along capillary walls.

Pathogenesis

The lesions are manifestations of an immune complex process. Circulating immune complexes can be detected in about one-third of those with lepromatous disease and over 75 per cent of patients with active erythema nodosum leprosum. The antigen is thought to be derived from *M. leprae*, but there is also speculation about the role of a non-mycobacterial antigen derived from co-infecting micro-organisms or dapsone:antidapsone antibodies. Alternate-pathway complement activation by cryoprecipitates can exacerbate the glomerular injury.

Management

In general, steroids or antileprosy drugs have no effect on the course of glomerular disease. Prednisolone may hasten the recovery of renal function in patients with renal failure during episodes of erythema nodosum leprosum.

Amyloidosis

The incidence of renal amyloidosis in leprosy ranges from 2 to 55 per cent in different geographical regions. Amyloid was documented in 55 per cent cases in older autopsy and biopsy studies from the United States, but reports from Mexico, Africa, and India found the incidence to be less than 10 per cent. The amyloid is of AA type and is far more frequent in lepromatous compared to non-lepromatous leprosy: erythema nodosum leprosum further increases the risk as each episode is associated with a marked and persistent elevation of serum amyloid A protein. Patients with tuberculoid leprosy who have long-standing and infected trophic ulcers can also develop this complication.

Amyloidosis can be prevented by early and aggressive antileprosy treatment, with particular attention to preventing erythema nodosum leprosum.

Tuberculosis

Renal involvement in patients with tuberculosis takes the form of granuloma formation, interstitial nephritis, and caseous destruction. An association of glomerulonephritis with tuberculosis was postulated in the preantibiotic era, but only stray reports have described immune complex glomerulonephritis and dense-deposit disease in tuberculosis in recent times. The cause-and-effect relationship remains speculative, and a chance association cannot be excluded. A well-known complication, however, is amyloidosis, which is still seen in a significant proportion of patients in poor countries where the disease often remains untreated for long periods. Once established, the course of amyloidosis is unaffected by treatment of the underlying tuberculosis.

Other infections

Variable degrees of glomerular involvement are seen with a variety of infections encountered in the tropical countries. These include: bacterial infections such as typhoid and pneumococcal infection; viral infections including dengue haemorrhagic fever; protozoal infections such as toxoplasmosis, kala-azar, and trypanosomiasis; and parasitic infestations like trichinosis. In most cases, the glomerulonephritis is mild and transient and resolves with treatment of the primary illness. In general, the frequency of glomerular involvement is falling with the reduction in incidence of these infections.

20.8.1 Renal tubular disorders

J. Cunningham

Renal glycosuria

Definition and pathophysiology

Renal glycosuria occurs when there is failure of tubular mechanisms to reabsorb the entire filtered load of glucose under conditions of normoglycaemia. In health, the volume of the glomerular filtrate is approximately 180 litres/day, containing approximately 800 mmol of glucose. The average daily urinary excretion of glucose is approximately 1 mmol, implying that some 99.9 per cent of the filtered load of glucose is normally reabsorbed, mostly in the proximal tubule. The primary event at this site is the reabsorption of very large amounts of Na+. Glucose reabsorption is a two-step process in which a carrier-mediated Na+-glucose cotransporter moves both sodium and glucose passively across the brush border (apical) membrane and thereby into the proximal tubular cell. The active extrusion of sodium across the basolateral membrane of the cell is subsequently linked with diffusion of glucose facilitated by specific glucose transporters, such that glucose is transported, in a manner tightly linked to sodium transport, from the tubular lumen to the peritubular capillaries. The molecular mechanisms by which cotransported solutes such as glucose are moved across the tubular epithelium are not fully understood, although it is likely that the binding of the cotransported solute (in this case glucose) leads to conformational changes in the transport protein and the opening of a sodium gate. Sodium thus moves down a concentration gradient (from lumen to cell), with secondary active transport linking the movement of glucose to that of Na+. These disturbances can be identified functionally, either as a reduction of the tubular maximum capacity for glucose reabsorption or a reduction of the tubular threshold for glucose.

Clinical features

The isolated form of renal glycosuria is familial with a mixed inheritance pattern, suggesting that the condition results from any one of several mutations affecting the glucose transport processes described above. Isolated renal glycosuria has no clinical sequelae and is easily distinguished from diabetes mellitus by the fact that the patient is normoglycaemic. Isolated renal glycosuria is frequently seen in otherwise normal pregnancies, where it results from the increased glomerular filtration rate (**GFR**) taking the filtered glucose load to a level that exceeds the renal tubular maximum capacity for reabsorption. By contrast with the glycosuria of uncontrolled diabetes mellitus, renal glycosuria is never of sufficient magnitude to drive a clinically significant osmotic diuresis.

Abnormalities of glucose transport may be seen in association with other defects of proximal tubular transport. Collectively these are designated as Fanconi's syndrome, in which renal glycosuria is found as part of a generalized disorder of proximal tubular function with aminoaciduria, renal tubular acidosis, and phosphaturia. It is important to distinguish forms of isolated glycosuria from multiple tubular defects, including the Fanconi syndrome, in which there may be important clinical consequences, albeit not directly in relation to the glycosuria itself.

Many patients with chronic renal insufficiency of mild to moderate degree exhibit renal glycosuria, usually in combination with other disorders of tubular function. These are frequently subtle and of little or no clinical significance. They reflect tubular damage as part of the general renal parenchymal pathology, or the consequences of the high filtered solute load per nephron in patients with reduced numbers and mass of functioning nephrons.

Phosphate-handling disorders

Physiology and pathophysiology

The renal handling of inorganic phosphate is the major determinant of extracellular phosphate concentration. In health, the kidney shows a powerful adaptive capacity that is capable of maintaining a normal phosphate concentration in the face of wide fluctuations in dietary phosphate intake. Between 80 and 95 per cent of the filtered load of phosphate is normally reabsorbed, mostly in the proximal tubule, but up to 20 per cent of phosphate reabsorption occurs at more distal sites, namely the distal convoluted tubule and cortical collecting duct. The initial process is the movement of filtered phosphate into proximal tubular cells via a number of specific Na+–phosphate cotransporters that are located in the luminal membrane and have a 3Na+:1HPO_4^{2-}stoichiometry. This linkage allows the movement of sodium ions down their electrochemical gradient to drive the movement of phosphate up its electrochemical gradient even as the tubular phosphate concentration falls. In the later parts of the proximal tubule other higher affinity phosphate transporters retrieve much of the residual phosphate. The final step, namely the exit of phosphate across the basolateral membrane and into the peritubular capillaries, appears to be passive.

As indicated above, the kidney provides not only the principal means for phosphate excretion, but also acts as the principal regulator of phosphate homeostasis. This regulation takes place over a wide range: the kidneys excrete virtually all the typical dietary phosphate intake of approximately 30 to 40 mmol/day, but phosphate deprivation or hypophosphataemia leads to such effective renal phosphate conservation that renal phosphate excretion virtually ceases. These adjustments are mediated by the cotransporter activity described above.

Parathyroid hormone (**PTH**) is an important hormonal regulator of phosphate excretion, stimulating phosphaturia by acting directly on proximal tubular cells to inhibit sodium-dependent phosphate transport by mechanisms that operate through both the cAMP protein kinase-A and the protein kinase-C phosphoinositide pathways. There are receptors for PTH on both the apical and basolateral membranes of the proximal tubular cells, the functional effect of PTH being to decrease the *V*max of both the more-proximal, high-capacity, low-affinity cotransporter and the more-distal, low-capacity, high-affinity cotransporter systems, both resulting in phosphaturia.

Other hormones influencing proximal phosphate transport include growth hormone, insulin-like growth factor-1 (**IGF-1**), insulin, thyroid hormone, and 1,25-dihydroxyvitamin D, all of which augment phosphate reabsorption. By contrast, in addition to PTH itself, phosphate excretion is augmented by PTH-related peptide, calcitonin, glucocorticoids, and atrial natriuretic peptide (**ANP**).

In addition to the above, it appears that the tubular phosphate transport mechanism can respond to changes in dietary phosphate intake, even when the plasma phosphate level changes little or not at all. The nature of this dietary signal is unclear. In parallel with the antiphosphaturic effect of reduced dietary phosphate, there is an increase in bone resorption leading to mobilization of skeletal phosphate (and calcium). Both the renal and skeletal responses to low dietary phosphate are unimpaired by parathyroidectomy and are therefore not mediated by PTH.

Disorders associated with increased urinary phosphate excretion

There are various types of phosphate transport defect, but all cause hypophosphataemia with inappropriate phosphaturia (Table 1). The fractional excretion of phosphate (the percentage of filtered phosphate that appears in the final urine) is increased and the tubular transport maximum for phosphate (*TmP*/GFR) is decreased. The clinical disturbances that result from such disorders may be very severe, important ones being rickets (in children) and osteomalacia (in adults). The development of these depends on the severity and chronicity of the hypophosphataemia, also on the presence or absence of any associated non-renal abnormalities.

Hereditary hypophosphataemic rickets

The terminology is potentially confusing. Vitamin D-resistant rickets (**VDRR**) originally described a syndrome of hypophosphataemia and metabolic bone disease (rickets or osteomalacia) that in many ways resembled that of vitamin D deficiency but which did not respond to treatment with vitamin D. This condition is now more properly called hereditary hypophosphataemic rickets, a designation more consistent with the phosphate-wasting aetiology. That these patients do not respond to vitamin D is undeniable, but true vitamin D resistance (that is, resistance even to 1,25-dihydroxyvitamin D) appears to exist only in patients with functional defects (usually inherited) of the vitamin D receptor.

X-linked hypophosphataemic rickets

This is the most important type of renal phosphate-handling disorder. Presentation is generally with poor growth and rickets in early childhood. The inheritance pattern is consistently of X-linked dominant type. There is a defect in proximal tubular phosphate transport that results in persistent hypophosphataemia and inappropriate phosphaturia. Females (heterozygotes) are less severely affected than males (hemizygotes). There also appears to be a subtle disturbance of vitamin D metabolism, such that the plasma 1,25-dihydroxyvitamin D concentration does not show the increase during hypophosphataemia that is seen in otherwise normal subjects.

Understanding of the pathogenesis and molecular biology of X-linked hypophosphataemic rickets has been greatly assisted by the existence of a murine model, the *hyp* mouse. It is clear that the defect of phosphate transport has nothing to do with the normal PTH modulatory control system. Cross-circulation and kidney transplant experiments in *hyp* mice have shown that the defect can be transferred from affected to non-affected animals. This, together with the observation that cultured proximal tubular cells from *hyp* mice exhibit normal phosphate transport, points strongly to mediation by an extrarenal humoral factor termed phosphotonin. The *hyp* gene is called PHEX (Phosphate regulating gene Homologous to Endopeptidases on the X chromosome). It is expressed in bone and not in kidney, a distribution compatible with the extrarenal origin of X-linked hypophosphataemic rickets.

The diagnosis is made on the basis of characteristic clinical features coupled with persistent hypophosphataemia and a reduced *TmP*/GFR, indicating an inappropriate reduction of the tubular reasborptive capacity for phosphate.

Because the bone disease in X-linked hypophosphataemic rickets is at least partly a consequence of the hypophosphataemia, treatment attempts to normalize plasma phosphate—a difficult task in practice. The administration of oral phosphate supplements increases phosphaturia, hence large oral doses have to be taken at frequent intervals, thereby presenting a substantial compliance problem in these patients, many of whom are young children. Additionally, the administration of large doses of phosphate reduces the plasma 1,25-dihydroxyvitamin D concentration, slightly lowers the ionized calcium concentration in plasma, and thereby triggers secondary hyperparathyroidism. This in turn may compound the skeletal disease and also further increase phosphaturia. These troublesome compensations can be attenuated by the addition of calcitriol (1,25-dihydroxyvitamin D) therapy to the phosphate supplement, with substantially improved clinical outcomes. However, treatment must be monitored extremely closely, there being a constant risk of calcitriol-induced hypercalciuria, hypercalcaemia and nephrocalcinosis. If this occurs, the degree of tubular calcium phosphate deposition appears to be largely determined by the oral phosphate dose: the presence of large amounts of phosphate in the gut lumen prevents the normal association of luminal calcium with oxalate, thereby increasing oxalate availability and absorption. Thus the stage is set for enteric hyperoxaluria, another potent risk factor for nephrocalcinosis and stone formation (see Chapter 20.13).

Oncogenic rickets/osteomalacia

A disturbance similar to X-linked hypophosphataemic rickets is rarely acquired in association with certain mesenchymal tumours, especially giant-cell tumours of bone, neurofibromas, and cavernous haemangiomata. Removal of the tumour is followed by complete normalization of renal phosphate handling, an observation that strongly favours the involvement of a tumour-generated humoral factor in the pathogenesis of the hypophosphataemia. Extracts of these tumours have been found to inhibit phosphate transport in renal tubular cells and to initiate phosphaturia in experimental animals. The humoral factor has been named 'phosphatonin' and it is likely that 'phosphatonin' is the same in X-linked hypophosphataemia and in oncogenic rickets/osteomalacia. It affects only phosphate transport and has no direct effects on calcium metabolism, PTH, or the PTH receptor.

Other phosphate-wasting disorders

Autosomal recessive and autosomal dominant phosphaturic disorders have rarely been reported. Common to these disorders is impaired proximal tubular phosphate transport (low *TmP*/GFR) with inappropriate phosphate wasting and variable metabolic bone disease. The clinical presentations are variable: some present during adolescence or even adulthood, while others present in early life, with some cases resolving spontaneously at puberty.

Syndromes of hereditary hypophosphataemia with hypercalciuria are described below in the section on calcium-handling disorders.

Disorders associated with reduced urinary phosphate excretion

Excessive tubular phosphate reabsorption (high *T*mP/GFR) with resulting hyperphosphataemia is seen in conditions where PTH is lacking or there is renal resistance to PTH (Table 1). In these patients hyperphosphataemia coexists with hypocalcaemia. The hyperphosphataemia is the result of an inappropriately raised *T*mP/GFR. The hypocalcaemia is largely the result of the failure of adequate 1,25-dihydroxyvitamin D (calcitriol) production by the PTH-deprived kidney, arising because the renal 25-hydroxyvitamin D la-hydroxylase is downregulated in the absence of PTH or its receptor.

Hypoparathyroidism

In hypoparathyroidism the renal tubular response to PTH is normal when tested by the administration of exogenous PTH. The metabolic abnormalities merely reflect the lack of PTH. The diagnosis depends on a low or undetectable PTH concentration in plasma, despite a prevailing hypocalcaemia that would normally trigger secondary hyperparathyroidism. For a detailed discussion of hypoparathyroid disorders, see Chapter 12.4.

Pseudohypoparathyroidism

There are two main types of pseudohypoparathyroidism, renal resistance to PTH being a feature of both. In these disorders the resulting hypocalcaemia evokes an appropriate PTH response. Type 1 pseudohypoparathyroidism is associated with a G-protein defect, with failure of coupling between the PTH receptor itself and adenylate cyclase. As a result, PTH (whether endogenous or exogenous) evokes neither a urinary cAMP nor a phosphaturic response. Despite plasma PTH being elevated, the *T*mP/GFR is high with associated phosphate retention. In the type 2 variant, G-protein activity is normal and PTH induces a cAMP response but no phosphaturia, implying a defect of cAMP-dependent protein kinase C.

Clinically, hypocalcaemia and hyperphosphataemia dominate the metabolic picture. There are also somatic features comprising short stature, short fourth and fifth metacarpals, and a variable degree of mental deficiency.

All types of hypoparathyroidism can be treated effectively using oral calcitriol or alfacalcidol. Pharmacological doses of these agents are needed to bring calcium into the normal range: it is frequently helpful to incorporate a calcium supplement into each meal, principally to reduce the intestinal absorption of dietary phosphate in these hyperphosphataemic individuals.

Calcium-handling disorders

Disorders of urinary calcium output (hypercalciuria and, to a lesser extent, hypocalciuria) are quite common and have important sequelae, particularly in regard to

hypercalciuric renal stone disease (see Chapter 20.13). Whilst it is important to recognize that such abnormalities of urinary calcium excretion may reflect intrinsic abnormalities of calcium handling within the kidney, it is also the case that primary disorders remote from the kidneys can also be responsible for disturbances of the calcium excretion rate. For example, hypercalcaemia—as seen in vitamin D intoxication, excessive dietary calcium intake, and osteolytic metastases—is associated with marked hypercalciuria, albeit in circumstances where the kidneys are responding appropriately to the high plasma calcium concentration. Many factors influence the handling of calcium by the renal tubule (Table 2).

Physiology and pathophysiology

In health, between 200 and 250 mmol of calcium appear in the glomerular filtrate each day, assuming an ultrafiltrable blood calcium concentration of 1.3 mmol/l out of the total blood calcium concentration of 2.5 mmol/l. About 70 per cent of filtered calcium is reabsorbed in the proximal convoluted tubule and the rest in the thick ascending limb of Henle's loop (20 per cent), the distal convoluted tubule (5 to 10 per cent), and the collecting tubule (less than 5 per cent). These reabsorptive processes reclaim nearly all the filtered calcium, such that only about 3 to 5 mmol of calcium appears in the urine each day. Assuming constancy of the total-body calcium content, this urinary calcium loss is equal to the net intestinal calcium absorption.

Calcium reabsorption in the proximal tubule and in the loop of Henle occurs passively down the electrochemical gradient generated by sodium and water reasbsorption at these sites. Regulation of calcium transport occurs at more distal sites where both parathyroid hormone and 1,25-dihydroxyvitamin D augment calcium reabsorption, the former by activation of adenylate cyclase via the PTH receptor and the latter by upregulation of calcium binding proteins – calbindins. Thus, parathyroid hormone itself, and also parathyroid hormone-related peptide (**PTHrp**), acts in an anticalciuric fashion, thereby contributing to the hypercalcaemia of primary hyperparathyroidism and the humoral hypercalcaemia of malignancy, respectively.

The extracellular calcium-sensing receptor (CaR)

It is now clear that the extracellular calcium-sensing receptor plays a central role in regulating the renal handling of calcium. It does this by both indirect and direct mechanisms. Indirectly, the CaR in the parathyroid gland senses extracellular calcium and adjusts the output of parathyroid hormone appropriately. This in turn regulates the renal handling of calcium in the distal nephron, with a fall of plasma calcium concentration triggering PTH secretion and thereby renal calcium retention—an appropriate response. Directly, the CaR in renal epithelial cells (most heavily expressed in the cortical thick ascending limb and also present in the proximal tubule, medullary thick ascending limb of Henle's loop, the distal convoluted tubule, and the collecting duct) regulates the handling of both calcium and water. Binding of calcium to the CaR in Henle's loop is thought to diminish the reabsorption of calcium (and magnesium). Thus, conditions of high calcium delivery to the loop of Henle lead to an appropriate increase in calciuria. In addition, it appears that the CaR in the kidney provides a link between distal tubular calcium delivery and the rate of ADH-stimulated water reabsorption at that site. This mechanism would explain the observed nephrogenic diabetes insipidus that accompanies significant hypercalcaemia and which reduces the likelihood of urinary supersaturation of calcium in circumstances of hypercalciuria.

Action of diuretics

Loop diuretics (furosemide (frusemide) and bumetanide), thiazide diuretics, and amiloride all affect renal tubular calcium transport and, as experimental probes, have been extremely useful in the elucidation of the mechanisms of renal calcium handling, as well as in the therapy of hypercalcaemic and hypercalciuric disorders. Loop diuretics inhibit sodium chloride reabsorption in the thick ascending limb of the loop of Henle and with it the passive reabsorption of various cations, including calcium. The resulting increase in the calcium excretion rate can be beneficial (as in the treatment of hypercalcaemia), or deleterious (increased risk of osteopenia or stone formation in chronic drug-induced hypercalciuria). Conversely, thiazide diuretics substantially reduce the urinary calcium excretion rate. Two mechanisms appear to underlie this effect. First, the mild volume depletion arising from the natriuretic and diuretic actions of the thiazide serves to accelerate proximal sodium and water reabsorption, and with it passive calcium reabsorption in this part of the nephron. Second, thiazides appear to increase distal calcium reabsorption directly, although the mechanism is unclear. These actions of thiazide diuretics are extremely useful in the treatment of hypercalciuric stone disease. In addition, there is evidence that thiazides can reduce the negative calcium balance in elderly people, which may translate to a reduction in the incidence of fractures in this age group. Thiazide diuretics slightly elevate the plasma calcium concentration, although usually to a trivial extent only, but this may become clinically significant in patients who have a tendency to hypercalcaemia, such as those with very mild hyperparathyroidism, Paget's disease, or who are immobilized. Amiloride also exerts a hypocalciuric action, probably at the cortical connecting segment, although the precise mechanism is uncertain. The hypocalciuric effect of thiazides and amiloride are, therefore, exerted at different sites of the renal tubule and in clinical practice are additive. Thus combinations of thiazides and amiloride are useful treatments for patients with hypercalciuric stone disease (see Chapter 20.13).

Disorders associated with increased urinary calcium excretion

Idiopathic hypercalciuria

This is an extremely important metabolic disturbance because of the high associated risk of calcium stone formation. 'Idiopathic' in this context implies hypercalciuria without hypercalcaemia and in the absence of other factors known to accelerate bone resorption (for instance, acromegaly, hyperthyroidism, hyperparathyroidism, osteolytic metastases, immobilization, metabolic acidosis) or reduced tubular calcium reabsorption (such as loop diuretics, chronic metabolic acidosis).

In most cases, the hypercalciuria is driven by calcium hyperabsorption by the intestine, and the hypercalciuria is thus of the 'overspill' type. This usually results from an initial defect of renal phosphate handling (reduction of *T*mP/GFR and consequent renal phosphate leak), which stimulates the production of 1,25-dihydroxyvitamin D. In a minority of cases the primary defect is of renal tubular calcium reabsorption ('renal leak' hypercalciuria), with a secondary increase of parathyroid hormone, calcitriol, and intestinal calcium absorption.

The assessment and management of these patients has benefited greatly from an increased understanding of the underlying defects. For example, 'absorptive' hypercalciuria is logically managed initially by measures to reduce intestinal calcium absorption, namely avoidance of excessive dietary calcium intake and, in those with evidence of 1,25-dihydroxyvitamin D excess driven by hypophosphataemia, oral phosphate therapy as well. Thiazides and amiloride are added if these initial measures are inadequate. Conversely, the management of 'renal leak' hypercalciuria requires an increase in tubular calcium reabsorption by reducing the dietary sodium and protein intake (acid load) and giving thiazide diuretics and amiloride.

Hereditary hypercalciuric nephrolithiasis

Recent studies have identified four rare disorders, all characterized by low molecular weight proteinuria, hypercalciuria, nephrocalcinosis, renal stone formation, and (in many cases) renal failure. In some, there are also defects of proximal tubular function with aminoaciduria, phosphaturia, renal glycosuria, and uricosuria (Fanconi's syndrome), as well as impairment of urinary acidification (renal tubular acidosis). These four disorders are Dent's disease, X-linked recessive nephrolithiasis, X-linked recessive hypophosphataemic rickets, and idiopathic low molecular weight proteinuria in Japanese children. The underlying defect appears to be the result of a mutation of a chloride-channel gene (*CLCN5*), the functional loss of which results in a widespread defect of proximal tubular transport.

Disorders associated with reduced urinary calcium excretion

Most patients exhibiting hypocalciuria do so in association with hypocalcaemia and a reduced filtered load of calcium. This is seen in patients with secondary hyperparathyroidism as a response to an underlying vitamin D and/or calcium deficiency, when a reduced filtered load of calcium is combined with accelerated tubular calcium reabsorption driven by increased levels of PTH. Most patients with advanced renal failure also exhibit hypocalciuria.

Familial hypocalciuric hypercalcaemia

These conditions reflect functional aberrations of the extracellular calcium-sensing receptor (**CaR**). In familial hypocalciuric hypercalcaemia (**FHH**, also known as familial benign hypercalcaemia) there is an inactivating mutation in the calcium-sensing receptor gene. Several different mutations are known, most appearing to result in receptors that are truncated or have an abnormal amino acid sequence. These render the receptor less sensitive to calcium which, at the level of the parathyroid gland, makes the parathyroid attempt to set calcium at a supraphysiological concentration. At the level of the kidney, the defect leads to increased tubular calcium and magnesium reabsorption. The resulting metabolic disturbance is characterized by hypercalcaemia, hypocalciuria, and hypermagnesaemia. The PTH hormone concentration is within the 'normal range', but this is inappropriately elevated with regard to the serum calcium concentration. The inheritance pattern is

autosomal dominant with high penetrance.

Most patients tolerate the hypercalcaemia well and the characteristic symptoms of hypercalcaemia (polyuria, constipation, neuropsychiatric disturbance) are conspicuously absent. The disorder may be distinguished from primary hyperparathyroidism by the presence of a family history, the reduction in urinary calcium excretion rate, and the normal urinary excretion rate of cyclic AMP (increased in conditions of parathyroid hormone excess). It is important to distinguish these patients from those with mild primary hyperparathyroidism: the benign natural history and the poor response to subtotal parathyroidectomy means that parathyroid surgery should not be undertaken in these individuals.

Autosomal dominant hypocalcaemia

By contrast to familial hypocalciuric hypercalcaemia, autosomal dominant hypocalcaemia results from an activating mutation in the calcium-sensing receptor that renders it overly sensitive to extracellular calcium. This leads to a downward setting of the normal parathyroid hormone and calcium relationship with resulting hypocalcaemia. Because the mutation also affects the calcium receptor in the renal tubular cells, urinary calcium excretion is inappropriately high. Principal clinical sequelae are the result of the hypercalciuria that predisposes to stone formation, nephrocalcinosis, and renal insufficiency. The hypocalcaemia is generally well tolerated. Treatment with thiazide–amiloride combinations to reduce hypercalciuria is logical but not of established benefit. Hypocalcaemia is generally asymptomatic and treatment of this with vitamin D or calcitriol is generally inappropriate, serving only to increase the degree of hypercalciuria and the risk of nephrocalcinosis and stone formation.

The Fanconi syndrome and aminoaciduria

Physiology and pathophysiology

Filtered amino acids are subject to very rapid proximal tubular reabsorption, at least 95 per cent having been cleared from the glomerular filtrate by the time it reaches the end of the proximal tubule. The transport of organic solute at this site is a two-step process that is both carrier-mediated and sodium-coupled; amino acids enter the proximal tubular cell via the brush border membrane against an electrochemical gradient, and exit via another transporter at the basolateral membrane. Movement in this fashion is accomplished by secondary active mechanisms, whereby coupling to sodium transport allows the movement of amino acids to be driven indirectly by the basolateral membrane Na+/K+-ATPase.

Based on loose structural similarities, the amino acids segregate into four groups, each with a group-specific carrier system (Table 3). Common to many defects of amino acid transport is a reduction of the electrochemical sodium gradient across the proximal tubular cells, leading to the impaired linked transport of glucose, amino acids, phosphate, and a range of other solutes. Some of the amino acid transporters are also expressed in the intestine; in which case defects may be evident at both sites, and clinical disease can result from the intestinal defect, the renal defect, or both.

The Fanconi syndrome

This syndrome comprises a disturbance of proximal tubular functions with generalized aminoaciduria, phosphate wasting (hypophosphataemic rickets and osteomalacia), renal tubular acidosis type-2 (proximal **RTA**), and renal glycosuria. The terms 'juvenile-' and 'adult Fanconi's syndrome' are widely used, but refer only to the age of onset and serve no additional classification purpose. More helpful is to classify, as far as possible, the many causes of the Fanconi syndrome on the basis of aetiology and pathogenesis (Table 4).

Clinical presentations of the Fanconi syndrome usually depend more on the associated underlying abnormality than on the renal tubular defect *per se*. However, the diagnosis ultimately depends on the demonstration of characteristic multiple tubular defects. These may not all be present in all patients and may even fluctuate in an individual patient, hence it is often best to define the specific defects that are present rather than to use the catch-all Fanconi eponym.

Treatment focuses on two issues. First, the cause of the Fanconi syndrome: for example, fructose avoidance in hereditary fructose intolerance, galactose avoidance in galactosaemia, copper chelation therapy in Wilson's disease. Second, the consequences of the Fanconi syndrome: for example, alkali and potassium for RTA type-2, oral phosphate and calcitriol for phosphate wasting.

Specific aminoacidurias

These are classified according to four principal carrier defects (see Table 3).

Neutral aminoacidurias

Hartnup disease

This rare (1:16 000 births), autosomal recessive disorder comprises three features:

1. intestinal tryptophan malabsorption;
2. a pellagra-like syndrome with photosensitive skin lesions, ataxia, and neuropsychiatric disturbances; and
3. neutral aminoaciduria with increased renal clearance of alanine, asparagine, glutamine, histidine, isoleucine, leucine, phenylalanine, serine, threonine, tyrosine, valine, and tryptophan.

The clinical manifestations of Hartnup disease result from the tryptophan malabsorption that leads to nutritional deficiency, which is exacerbated by the accelerated urinary losses of tryptophan. It presents much like pellagra, although is usually less severe and tends to fluctuate in its course. Analysis of the urine distinguishes the two disorders. Hartnup disease responds well to oral nicotinamide therapy (40–200 mg daily).

Dibasic aminoacidurias

These comprise cystinuria, lysinuric protein intolerance, and lysinuria, of which cystinuria is the most common and the most important.

Cystinuria

The group-specific carrier protein for the dibasic amino acids is located on the brush border membrane of the proximal tubular cells and is thought to be the product of a single pair of allelic genes. So far, three potential mutant alleles have been identified that appear to be capable of causing both homozygous and heterozygous forms of cystinuria. When expressed, this transport defect is found in both the kidney and in intestinal epithelium.

Cystinuria occurs in 1 in 7000 births and has serious clinical manifestations. Inheritance is autosomal recessive. Presentation is usually during childhood or adolescence, the syndrome of nephrolithiasis presenting with pain, infection, and, in some cases, renal impairment and hypertension. The stones are radio-opaque (although less so than calcium-containing stones), smooth, and sometimes staghorn-shaped. The diagnosis is confirmed by a positive nitroprusside test, the presence of typical hexagonal crystals in morning urine specimens, and the quantitative measurement of urinary cystine output.

Treatment requires reduction of the cystine concentration in the urine combined with measures to increase its solubility. Typical regimens comprise a high fluid intake, alkalinization of the urine to over pH 7.5 (usually with large quantities of potassium citrate and sodium bicarbonate), and penicillamine. Cystine solubility changes little across the acidic range of pH but increases rapidly above pH 7. At 37 °C and pH 7, the solubility is only 1.66 mmol/l, but this increases to between about 3.3 and 3.5 mmol/l at pH 7.8. However, pushing the pH to even more alkaline levels may be counterproductive since alkalinization decreases the solubility of calcium phosphate, which may be deposited on the cystine stones. Poor compliance is a frequent and unsurprising practical problem with this demanding regimen, particularly in regard to maintenance of a high fluid intake. To be fully effective this requires oral fluids to be taken at least once during the night. Nevertheless, at least 50 per cent of patients respond to these measures if they are rigorously applied and adhered to, and in some cases the stones regress significantly.

Sulphydryl-containing drugs, such as penicillamine, react with cystine to form penicillamine–cysteine, which is much more soluble. In the past this treatment was often reserved for those who failed on the fluid/alkali regimen. However, penicillamine is now used much earlier and often forms part of the initial therapy. Although potentially toxic (cutaneous reactions, marrow suppression, and glomerulopathy), serious reactions are rare, and penicillamine is currently the most effective therapy known. It is given at doses of 1 to 2 g daily, the aim being to reduce the free-cystine concentration in urine to below 1.66 mmol/l, when stone formation is prevented and existing stones can be dissolved.

In cystinuria other basic amino acids (lysine, arginine, and ornithine) are also present in increased amounts in the urine, but only cystine—by virtue of its low solubility—is of clinical importance.

Lysinuric protein intolerance

This is a rare autosomal recessive disorder that results from widespread defects of dibasic amino acid transport, involving particularly the intestine, proximal renal tubule, and liver. Cystine transport is normal. The renal tubular defect plays no part in the pathogenesis of the disease.

Mental retardation, growth failure, and osteopenia are prominent, and are thought to result from reduced activity of the urea cycle with a low plasma urea concentration and hyperammonaemia after food. Treatment with citrulline is sometimes effective, probably by regenerating the deficient urea cycle intermediates, arginine and ornithine.

Imino acids and glycine

Familial iminoglycinuria

This is a relatively common condition, arising in approximately 1 in 15 000 births. Clinically, the inheritance appears to be autosomal recessive, but there are multiple alleles and gene loci for the transport of imino acids and glycine. Proximal tubular transport of proline, hydroxyproline, and glycine is impaired, accompanied in some, but not all, cases with defects in intestinal transport.

Few if any clinical sequelae result from isolated imminoglycinuria, although it was once thought that the abnormality was associated with mental retardation and seizures.

Acidic aminoaciduria

These disturbances are exceedingly rare, involving the dicarboxylic amino acids (aspartic acid and glutamic acid). They are not well understood. The possibility of accelerated renal production and/or failure to transfer these amino acids into the renal circulation is suggested by the observation of renal clearance in excess of the GFR. There are no clinical sequelae.

20.9.1 Acute interstitial nephritis

Dominique Droz and Dominique Chauveau

Introduction

Acute interstitial nephritis has a clinicopathological definition: acute renal failure with prominent inflammation of the renal interstitium, composed mainly of lymphocytes and more rarely of polymorphonuclear cells or granulomas. Since a variable degree of tubular-cell damage is consistently found, the term 'tubulointerstitial nephritis' is preferred by some authors. Because the clinical presentation of acute renal failure is devoid of specific findings, renal biopsy is required in all cases both to establish the diagnosis of acute interstitial nephritis and to allow appropriate management.

Epidemiology and incidence

Although its precise incidence is difficult to determine, acute interstitial nephritis (**AIN**) is a rare disease, found in 1 to 3 per cent of specimens in unselected series of renal biopsy material. In patients presenting with acute renal failure, the proportion with acute interstitial nephritis varies from 6.5 to 15 per cent. Values at the lower end of this range are found in paediatric series. Higher values are found in studies containing larger numbers of elderly patients, where the increased likelihood of drug ingestion is paralleled by an increase in drug-induced hypersensitivity. Overall, acute interstitial nephritis is the third leading cause of acute drug-induced nephropathy, following haemodynamically mediated and direct tubular injuries.

Pathophysiology of acute interstitial nephritis (AIN)

The pathogenesis of AIN is not completely elucidated, and what we know has been extrapolated from animal models. These include spontaneous T cell-mediated interstitial nephritis in kd/kd mice, interstitial nephritis related to antitubular basement antibodies, interstitial nephritis associated with autoimmune systemic disease, and tubulointerstitial damage associated with glomerular diseases and severe proteinuria. Although in rodents these models induce tubulointerstitial damage, very few reproduce the human picture of AIN.

Experimental evidence implicates both humoral and cell-mediated mechanisms, and both antigen-specific and antigen-nonspecific pathways of T-cell activation, but the relevant antigen responsible for T-cell activation is unknown in the vast majority of cases of human AIN. However, in drug-related acute interstitial nephritis the offending drug or one of its metabolic products could function as a hapten, binding to membrane or cellular proteins and being presented in the context of MHC molecules to T-helper cells. Sensitized activated T-helper cells could then produce cytokines, activate macrophages, induce the differentiation and proliferation of B cells producing specific antibodies, and activate other T cells, either cytotoxic cells or those responsible for the delayed-type hypersensitivity reaction. As a consequence, this cascade of reactions could ultimately result in a variable mixture of specific antibody production, death of the target tubular cells, and development of parenchymal granulomas. This cascade-type response could be modified by a variety of mechanisms such as removal of the antigen (for example, the offending drug) or production of inhibitory cytokines.

Aetiology

The causes of acute interstitial nephritis fall into four main categories: (1) drug hypersensitivity reactions; (2) infections; (3) systemic immune-mediated diseases; and (4) idiopathic (Table 1). A drug hypersensitivity reaction is the most common cause of acute interstitial nephritis, accounting for 40 to 60 per cent of the cases, while infections—of bacterial or viral origin—account for less than 5 per cent of cases today. Table 1 provides a detailed list of drugs and infectious agents repeatedly associated with AIN. Although more than 100 drugs have been implicated in acute interstitial nephritis, only a few are repeatedly incriminated, while most reports remain anecdotal. In the presence of acute interstitial nephritis, this should not distract from considering any drug currently or recently consumed by the patient as a potential culprit.

Clinical and pathological features

Most clinical features are non-specific, but the history may point to AIN when renal failure develops in the context of a systemic infection, typical drug reaction, sarcoidosis, Sjögren's syndrome, or uveitis. Blood pressure remains unchanged. Urinary output is variable with mild or moderate proteinuria (<1–2 g/day). Nephrotic syndrome is only found in cases induced by non-steroidal anti-inflammatory drugs. There is no haematuria except in cases related to b-lactam hypersensitivity. Leucocyte casts are common. Fractional excretion of sodium is often high.

Eosinophilia and eosinophiluria are not always present, but argue in favour of an adverse drug reaction. Eosinophils can be detected in the urine using Wright or Hansel stains, the latter being more sensitive. However, eosinophiluria is not specific for drug-induced acute interstitial nephritis and is therefore of poor predictive value.

Kidney size is typically normal or enlarged. Increased cortical echogenicity shown by ultrasound imaging correlates with the degree of interstitial inflammation. Computed tomography (**CT**) scanning is of limited value in the diagnosis of acute interstitial nephritis and other diffuse renal parenchymal diseases.

Renal biopsy remains the sole means of unequivocally establishing the diagnosis of acute interstitial nephritis. The characteristic lesion is the presence of numerous mononuclear cells in the renal interstitium (Fig. 1 and Plate 1). Tubular changes of focal cell necrosis and tubulitis, together with interstitial oedema, are commonly found. Since a discrete interstitial cell infiltrate may be present in primary acute tubular necrosis (either of ischaemic or toxic origin), the assessment of primary acute interstitial nephritis requires careful evaluation of the abundance of the cell infiltrate in comparison with the degree of tubular damage. In addition, the biopsy must be scrutinized for the presence of glomerular pathology, significant immune complex deposition, and vasculitic lesions. If these coexist with a prominent interstitial-cell infiltrate, then diagnoses such as lupus glomerulonephritis, mixed cryoglobulinaemia, and systemic vasculitis need to be considered. Lymphomas or leukaemias may invade the renal parenchyma and cause acute renal failure. The tumoral (clonal) nature of the infiltrating cells is usually obvious, but needs to be distinguished from acute interstitial nephritis.

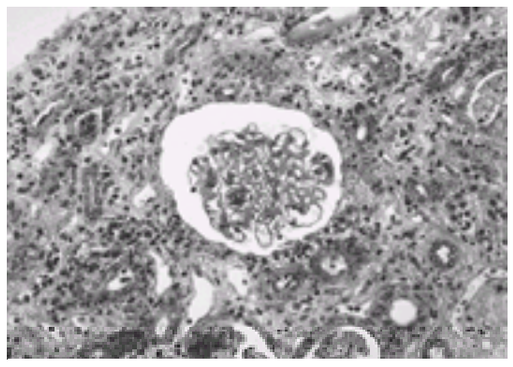

Fig. 1 Acute interstitial nephritis. The renal interstitium is invaded by numerous mononuclear cells. The glomerulus is normal. Mason's trichrome 250 ×. (See also Plate 1.)

In acute interstitial nephritis, the degree of interstitial inflammation is variable and predominates in the cortex. Whatever the cause, T lymphocytes (with an equal proportion of CD4+ and CD8+ cells) and macrophages (CD14+ and CD68+) expressing cell-activation markers, comprise 80 per cent of the infiltrate. Natural killer cells are rare, while polyclonal plasma cells are often observed. Polymorphonuclear cells constitute only a minor part of the cell infiltrate, even in the early phases of the disease, and in cases related to bacterial infection. Eosinophils are rare, even in drug-induced acute interstitial nephritis. Tubular cells express MHC class II antigens. Of note, some interstitial epithelioid and non-caseating granulomas are present in nearly 20 per cent of cases, but they are more common (25 to 45 per cent of cases) in drug-induced acute interstitial nephritis.

In the vast majority of cases (90 per cent), staining for immunofluorescence shows no significant immunoglobulin deposits in the renal parenchyma. However, in rare cases mainly related to systemic lupus erythematosus, granular deposits of immunoglobulin and complement are observed along the tubular basement and in the interstitium. In less than 5 per cent of the cases, linear IgG and C3 deposits are present along the tubular basement membrane, corresponding to the presence of antitubular basement membrane antibodies. Such findings are observed only in cases related to antibiotic use (b-lactams or ciprofloxacin).

Little is known about the long-term histopathological consequences of AIN: most patients recover and serial biopsies have rarely been performed. However, in severe cases, especially those with severe tubule destruction, irreversible lesions with fibrous scars ultimately develop. Late chronic interstitial nephritis is also more frequent when the initial biopsy reveals granulomas, but overall the most reliable histological parameter for prognosis is the extent of interstitial fibrosis on the initial biopsy. The mechanism of fibrogenesis is thought to be that interstitial infiltrating cells and damaged tubular cells release cytokines and growth factors, promoting fibroblast and myofibroblast proliferation and the production of collagen.

Distinctive features of particular causes of acute interstitial nephritis

According to the cause, clinical and laboratory features characterize certain forms of AIN.

Drug-induced acute interstitial nephritis

The most common drugs implicated in acute interstitial nephritis are b-lactam antibiotics and non-steroidal anti-inflammatory drugs (Table 1), but their clinical presentation differs. The *b*-lactams (and especially methicillin, which is no longer used) give the most characteristic picture of drug-related acute interstitial nephritis. The symptoms occur 2 to 60 days after the beginning of treatment and comprise fever, skin rash (usually maculopapular), arthralgias, liver involvement, abundant haematuria (often macroscopic), blood eosinophilia, and a variable degree of renal failure, requiring dialysis in one-third of the cases. Skin tests or *in vitro* evaluation of hypersensitivity reaction are not valuable for implicating a given drug.

Non-steroidal anti-inflammatory drug-associated acute interstitial nephritis usually affects the elderly, is particularly likely to occur when the drug is taken discontinuously, and evolves with a more progressive course. Renal failure develops several months to years after the initiation of the offending therapy; extrarenal signs of drug sensitization are often lacking. Abundant proteinuria and nephrotic syndrome are found in more than 80 per cent of patients (versus 1 per cent in *b*-lactam-induced acute interstitial nephritis). In addition to the interstitial lesions, renal biopsy shows minimal glomerular changes with diffuse podocyte foot-process fusion.

How can the physician recognize a drug as being responsible for the onset of acute interstitial nephritis? Given the variability of clinical course, as exemplified for *b*-lactams and non-steroidal anti-inflammatory drugs, the clinician should first establish an exhaustive list of the drugs used by the patient, including over-the-counter medications, and the date of exposure. This is often a difficult task. In a very few cases, re-challenge with the same drug has mistakenly been performed. When such exposure is elicited and associated with recurrence of the renal and systemic manifestations, then the drug can definitely be regarded as the culprit, but in clinical practice re-challenge should never be recommended. In decreasing order of importance, clues for considering a drug as being responsible for AIN include: (1) appropriate timing, (2) well-documented knowledge of similar nephrotoxicity, and (3) exclusion of other causes (see below).

Infectious acute interstitial nephritis

In children, infections remain the main cause of acute interstitial nephritis. In adults, predisposing factors include old age, diabetes, cytotoxic drug administration, and prolonged corticosteroid therapy. Septicaemia due to various micro-organisms such as *Escherichia coli*, *Proteus* spp., *Staphylococcus* spp., and *Candida albicans* can be associated with direct invasion of the renal parenchyma and acute interstitial nephritis. The clinical picture is that of acute pyelonephritis with a biopsy revealing renal microabscesses.

Haemorrhagic fevers due to Hantaviruses are recognized in Europe with increasing frequency. In these cases, the renal biopsy shows interstitial oedema and medullary haemorrhage, whilst interstitial inflammation remains discrete.

An acute interstitial nephritis with an infiltrate predominantly of CD8+ lymphocytes may be seen in patients with human immunodeficiency viral (HIV) disease, with or without glomerular involvement. Enlargement of the liver and salivary glands with hypergammaglobulinaemia and lymphocytic infiltration of these organs is often found, as well as lymphocytic pneumonitis.

Acute interstitial nephritis in systemic immune-mediated diseases

Lupus erythematosus and Sjögren's syndrome are rare causes of AIN. By contrast, sarcoidosis can present with acute renal failure, with typical sarcoid granulomas found in the renal interstitium. Concomitant hypercalcaemia and/or extrarenal manifestation make the diagnosis of sarcoidosis easy in most cases, but renal involvement can be isolated. In such instances, CT-scanning of the lung may disclose asymptomatic chest involvement. It is conceivable that a localized form of sarcoidosis might be restricted to isolated granulomatous interstitial nephritis, but it is impossible to distinguish between this possibility and that of 'idiopathic' acute interstitial nephritis.

Idiopathic forms of acute interstitial nephritis

Since its description in 1975, an increasing number of cases of acute interstitial nephritis associated with anterior uveitis (or iritis) have been reported. Such an association—referred to as tubulointerstitial nephritis and uveitis, or the **TINU** syndrome—affects mainly young women and adolescent girls. It is characterized by fever, weight loss, blood eosinophilia, hypergammaglobulinaemia, and renal failure. Uveitis may precede the appearance of renal failure by several weeks. An identical clinical picture lacking uveitis has also been described. In the TINU syndrome the biopsy shows diffuse interstitial inflammation, but some granulomas may be present. Whether this association is a manifestation of a limited form of sarcoidosis is still unclear.

Treatment

Treatment of AIN should be first directed against its cause: withdrawal of any drug that might be involved, or prompt treatment of infection. Prednisone improves the renal failure of sarcoidosis and the TINU syndrome, although persistent dysfunction is not uncommon when diagnosis is delayed. Whether or not to use steroids in drug-related AIN remains a matter of debate. Uncontrolled studies suggest that a short course of high-dose prednisone promotes an earlier and more complete decline of serum creatinine toward baseline than in patients left untreated. Some advocate its use when renal failure persists for more than 1 week after withdrawal of the drug or if granulomas are found in the renal biopsy.

In patients with drug-related AIN, the physician should inform the patient that they should not be treated with the presumed culprit or related compounds. More specifically, all b-lactam antibiotics should be avoided in patients who have suffered acute interstitial nephritis attributed to a penicillin compound or a cephalosporin, even though cross-sensitization between the two classes of drugs is not consistent. In those who have recovered from non-steroidal anti-inflammatory-related AIN, acute renal failure may or may not recur after resuming therapy with a non-steroidal anti-inflammatory drug belonging to another family of this class. In some countries, severe drug-induced side-effects, including AIN, should be reported to the health authorities.

20.9.2 Chronic tubulointerstitial nephritis

Marc E. De Broe, Patrick C. D'Haese, and Monique M. Elseviers

Autoimmune

Sarcoidosis

Sarcoidosis is a multisystem disorder of unknown aetiology characterized by the accumulation in many tissues of T lymphocytes, mononuclear phagocytes, and non-caseating granulomas. The pathogenesis and clinical features of the condition are discussed in Chapter 17.11.6.

Clinically important renal involvement is an occasional problem—hypercalciuria and hypercalcaemia are most often responsible, although granulomatous interstitial disease, glomerular disease, obstructive uropathy, and (rarely) endstage renal disease may also occur. The true incidence of renal involvement in sarcoidosis remains unknown, but several small series of renal biopsies suggest that some degree of renal involvement occurs in approximately 35 per cent of patients with sarcoidosis.

Clinical features

Hypercalciuria, hypercalcaemia, nephrolithiasis, granulomatous interstitial nephritis, glomerular disease, and urinary tract disorders can all be observed in patients with sarcoidosis. Macrophages in a sarcoid granulomas contain a 1a-hydroxylase enzyme, but not a 24-hydroxylase enzyme, capable of converting vitamin D to its active form. The resultant increase in the absorption of calcium from the gut, which occurs in up to 50 per cent of those with sarcoidosis, leads to hypercalciuria and, in roughly 2.5 to 20 per cent of cases, to hypercalcaemia. Most patients remain asymptomatic, but nephrolithiasis, nephrocalcinosis, renal insufficiency, and polyuria are potential complications. Nephrolithiasis occurs in approximately 1 to 14 per cent of patients with sarcoidosis and may be the presenting feature. Nephrocalcinosis, observed in over half of those with renal insufficiency, is the most common cause of chronic renal failure in sarcoidosis. The increase in urine output associated with hypercalcaemia and hypercalciuria is due to a reduced responsiveness to antidiuretic hormone.

An interstitial nephritis with granuloma formation is common in sarcoidosis, but the development of clinical disease manifested by renal insufficiency is unusual. A survey of all renal biopsies over a 6-year period at three general hospitals found clinically significant sarcoid granulomatous interstitial nephritis in only four cases. Most affected patients have clear evidence of diffuse active sarcoidosis, although some present with an isolated elevation in the plasma creatinine concentration and no or only minimal renal manifestations. Renal biopsy reveals normal glomeruli, interstitial infiltration mostly with mononuclear cells, non-caseating granulomas in the interstitium, tubular injury, and—with more chronic disease—interstitial fibrosis. Granulomatosis interstitial nephritis is also seen in other diseases, including allergic interstitial nephritis (mainly drug-induced, caused by non-steroidal anti-inflammatory drugs (**NSAIDs**) and 5-aminosalicylic acid), Wegener's granulomatosis, berrylliosis, and tuberculosis. The urinary manifestations of granulomatous interstitial nephritis are relatively non-specific, with urinalysis typical of other chronic tubulointerstitial diseases, being normal or showing only sterile pyuria or mild proteinuria.

Glomerular involvement is rare in sarcoidosis. A variety of different lesions have been described in isolated cases, including membranous nephropathy, a proliferative or crescentic glomerulonephritis, and focal glomerulosclerosis. The presence of heavy proteinuria or red cell casts tends to differentiate these glomerulopathies from interstitial nephritis.

Occasionally, retroperitoneal lymph node involvement, retroperitoneal fibrosis, or renal stones may produce ureteral obstruction.

Diagnosis and treatment

Sarcoid nephropathy should be considered in any patient with unexplained renal failure and hypercalcaemia, nephrocalcinosis, renal tubular defect, or increased immunoglobulins. These patients often have signs and symptoms of pulmonary, ocular, and/or dermal involvement with sarcoidosis. The presence of granulomas on renal biopsy, while not specific to sarcoidosis, should strongly suggest this diagnosis in an appropriate setting. In patients with known sarcoidosis, sarcoid nephropathy should be considered in the presence of renal failure, hypercalcaemia, nephrolithiasis, nephrocalcinosis, or renal tubular defects.

Granulomatous interstitial nephritis can be treated effectively with glucocorticoids, typically prednisolone 1 to 1.5 mg/kg initially, tapered off following signs and symptoms of disease activity. Patients often respond quickly with an improvement in renal function, but this depends greatly on the extent and severity of inflammation and fibrosis before treatment was initiated. There are no controlled trials regarding the dose or length of the treatment.

The hypercalcaemia/hypercalciuric syndrome also responds quickly to corticosteroids: in general the dose needed to treat this complication is significantly lower than that required to treat granulomatous interstitial nephritis, and can be as low as 35 mg of prednisolone daily. Chloroquine, by decreasing the level of 1,25-dihydroxycholecalciferol, is an effective therapy for the hypercalcaemic/hypercalciuric syndrome. Ketoconazole, an inhibitor of steroidogenesis, has been used in a single patient who could not tolerate corticosteroids and was effective in decreasing the level of active vitamin D as well as serum and urinary calcium.

Although uncommon in patients with sarcoidosis, endstage renal failure (**ESRF**) requiring renal replacement therapy is most often due to hypercalcaemic nephropathy rather than granulomatous nephritis. Graft loss due to disease recurrence has not been reported.

Drug-induced nephropathy (Table 1)

Analgesics

Analgesic nephropathy is characterized by renal papillary necrosis and chronic interstitial nephritis caused by the prolonged and excessive consumption of analgesics. It is invariably caused by compound analgesic mixtures containing aspirin or other antipyretic agent in combination with phenacetin, paracetamol, or

salicylamide and caffeine or codeine in popular 'over-the-counter' proprietary medicines.

In the recent past, analgesic nephropathy has been one of the commoner causes of chronic renal failure, particularly in Australia and parts of Europe. Estimates made before phenacetin was removed from over-the-counter analgesics and prior to the enactment of legislation making combined analgesic preparations only available by prescription (in Sweden, Canada, and Australia), suggested that analgesic nephropathy was responsible for 1 to 3 per cent of cases of endstage renal disease in the United States as a whole: up to 10 per cent in areas of North Carolina, and 13 to 20 per cent in Australia and some countries in Europe (such as Belgium and Switzerland). During the 1990s, there was a clear decrease in the prevalence and incidence of the condition among patients undergoing dialysis in several European countries and Australia. Some authors have associated this decrease with the removal of phenacetin from analgesic mixtures. However, it is impossible to draw definitive conclusions from the epidemiological observations since other factors, such as eligibility criteria for dialysis treatment and the availability of analgesic mixtures, may also have had an influence.

Pathogenesis and pathology

The aetiology of analgesic nephropathy remains a controversial issue and the question of which kinds of analgesic are nephrotoxic is still a matter of debate. Since 1955 experimental studies on the nephrotoxicity of analgesics have been performed, mainly using rats fed with large amounts of drugs, sometimes aggravating the renal effects by dehydration or by introducing bacteria into the blood, peritoneum, or bladder. The results have been difficult to interpret, but it could be concluded that renal papillary necrosis was most frequently observed after the administration of aspirin in combination with phenacetin or paracetamol.

In humans, the long-standing excessive use of analgesics observed in patients with analgesic nephropathy is preferentially that of analgesic mixtures rather than single agents, abusers taking these products for their mood-altering effects rather than for the relief of physical complaints. Hence, all these mixtures contain caffeine and/or codeine, substances that can create a psychological dependence. In most of the early analgesic nephropathy reports, nearly all patients had taken large amounts of analgesic mixtures containing phenacetin. There is strong evidence that phenacetin-containing analgesic mixtures showed a high nephrotoxic potency in the past, and several case-control studies, as well as the prospective controlled longitudinal epidemiological study of Dubach *et al*., demonstrated a high increased risk associated with the regular consumption of analgesic mixtures containing phenacetin.

However, the withdrawal of phenacetin from analgesic mixtures in western Europe, Australia, and the United States gives rise to the question of the nephrotoxic potency of different kinds of products. Clinical observations in countries where analgesics without phenacetin have been on the market for more than 20 years (for example, Australia, Belgium, Germany) have shown that identical renal pathology is observed in patients abusing analgesic mixtures that have never contained phenacetin. We observed a cohort of 226 patients with analgesic nephropathy diagnosed according to objective renal imaging criteria: abuse of analgesic mixtures was documented in all except seven cases, and in 46 patients nephrotoxicity was found in the absence of any previous phenacetin consumption. These patients abused the combinations of: aspirin and paracetamol; aspirin and pyrazolones; paracetamol and pyrazolones; and two pyrazolones.

The mechanisms responsible for the renal injury are incompletely understood. Phenacetin is metabolized to acetaminophen and to reactive intermediates that can injure cells, in part by lipid peroxidation. These metabolites tend to accumulate in the medulla along the medullary osmotic gradient created by the countercurrent system. As a result, the highest concentrations are seen at the papillary tip, the site of the initial vascular lesions. The potentiating effect of aspirin with both phenacetin and acetaminophen may be related to two factors. First, acetaminophen undergoes oxidative metabolism by prostaglandin H synthase to reactive quinoneimine that is conjugated to glutathione. If acetaminophen is present alone, there is sufficient glutathione generated in the papillae to detoxify the reactive intermediate. However, if acetaminophen is ingested with aspirin, the aspirin is converted to salicylate, which becomes highly concentrated and depletes glutathione in both the cortex and papillae of the kidney. With the cellular glutathione depleted, the reactive metabolite of acetaminophen then produces lipid peroxides and arylation of tissue proteins, ultimately resulting in necrosis of the papillae (Fig. 1). Second, aspirin (and other NSAIDs) suppress prostaglandin production by inhibiting cyclooxygenase enzymes. Renal blood flow, particularly within the renal medulla that normally exists on the verge of hypoxia, is highly dependent upon the systemic and local production of vasodilatory prostaglandins. The final injury is therefore due to both the haemodynamic and cytotoxic effects of these drugs resulting in papillary necrosis and interstitial fibrosis.

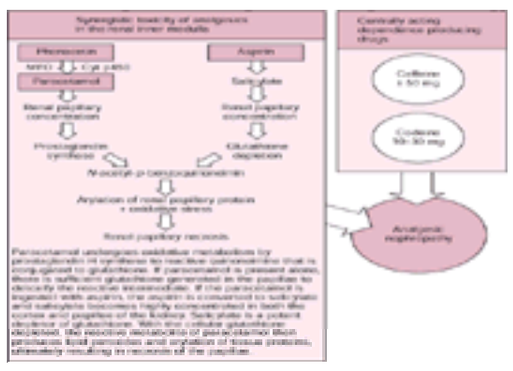

Fig. 1 Synergistic toxicity of analgesics in the renal inner medulla and centrally acting dependence-producing drugs leading to analgesic nephropathy. (Reproduced with permission from Kincaid-Smith P, Nanra RS (1993). In: Schrier RW, Gottschalk CW, eds. *Diseases of the kidney*, pp 1099–129. Little, Brown and Company, Boston, MA, and Duggin G (1996). *American Journal of Kidney Diseases* **28/1** (Suppl. 1), S39–S47.)

The renal damage induced by analgesics is most prominent in the medulla. The earliest changes consist of prominent thickening of the vasa recta capillaries (capillary sclerosis) and patchy areas of tubular necrosis; similar vascular lesions can be found in the renal pelvis and ureter, suggesting that the primary effect is damage to the vascular endothelial cells. Later changes include areas of papillary necrosis and secondary cortical injury with focal and segmental glomerulosclerosis and interstitial infiltration and fibrosis.

Clinical features

The renal manifestations of analgesic nephropathy are usually non-specific: normal renal function or slowly progressive chronic renal failure, and urinalysis that may be normal or may reveal sterile pyuria and mild proteinuria (less than 1.5 g/day). Hypertension and anaemia are commonly seen with moderate to advanced disease; more prominent proteinuria that can exceed 3.5 g/day can also occur at this time, a probable reflection of secondary haemodynamically mediated glomerular injury. Most patients have no symptoms referable to the urinary tract, although flank pain or macroscopic/microscopic haematuria from a sloughed or obstructing papilla may occur or as a result of a transitional-cell carcinoma. Urinary tract infection is also somewhat more common in women with this disorder.

Despite the non-specific nature of the renal presentation, there are frequently other findings that point toward the presence of analgesic nephropathy. Most patients are between the ages of 30 and 70 years, and careful questioning often reveals a history of chronic headaches or low back pain that leads to the analgesic use. Also common are other somatic complaints (such as malaise and weakness), and ulcer-like symptoms or a history of peptic ulcer disease due in part of chronic aspirin ingestion.

The decline in renal function can be expected to progress if analgesics are continued, whereas renal function stabilizes or mildly improves in most patients if analgesic consumption is discontinued. However, if the renal disease is already advanced, then progression may occur in the absence of drug intake, presumably due to secondary haemodynamic and metabolic changes associated with nephron loss. The late course of analgesic nephropathy may also be complicated by two additional problems: malignancy and atherosclerotic disease. Urinary tract malignancy will develop in as many as 8 to 10 per cent of patients with analgesic nephropathy, but in well under 1 per cent of phenacetin-containing analgesic users without kidney disease. In women under the age of 50, for example, analgesic abuse is the most common cause of bladder cancer, an otherwise unusual disorder in young women. The potential magnitude of this problem has also been illustrated by histological examination of nephrectomy specimens obtained prior to renal transplantation, when the incidence of urothelial atypia approaches 50 per cent. The tumours generally become apparent after 15 to 25 years of analgesic abuse, usually but not always in patients with clinically evident analgesic nephropathy. Most patients are still taking the drug at the time of diagnosis, but clinically evident disease can first become apparent several years after cessation of analgesic intake and even after renal transplantation. It is presumed that the induction of malignancy results from the intrarenal accumulation of *N*-hydroxylated phenacetin metabolites that

have potent alkylating action. The highest concentration of these metabolites will be in the renal medulla, ureters, and bladder (as described above), possibly explaining the predisposition to carcinogenesis at these sites. The pathogenetic importance of phenacetin metabolites is suggested indirectly from the observation that the prolonged ingestion of other analgesics that can cause papillary necrosis, but do not form the same metabolites, such as acetaminophen and the NSAIDs, is not associated with tumour formation. The main presenting symptom of urinary tract malignancy in patients with analgesic nephropathy is microscopic or gross haematuria, hence continued monitoring is essential, and new haematuria should be evaluated by urinary cytology, and—if indicated—cystoscopy with retrograde pyelography. The incidence of urothelial carcinoma after renal transplantation in patients with analgesic nephropathy is comparable to the general incidence, of up to 10 per cent, of urothelial carcinomas in ESRF patients with analgesic nephropathy. Removal of the native kidneys prior to renal transplantation has also been suggested, but the efficacy of this regimen has not been proven.

Diagnosis and treatment

The lack of reliable criteria and the high prevalence of analgesic nephropathy during the 1980s in Belgium (17.9 per cent in 1984) led us to perform a series of prospective, multicentre, controlled studies to define and validate the diagnostic criteria for this disease. We could provide strong evidence that specific anatomical changes, best seen by non-contrast computed tomography (**CT** scan), have much greater sensitivity and specificity than other clinical signs and symptoms in the diagnosis of endstage renal disease due to analgesic nephropathy. These changes are: (1) decrease in renal volume; (2) bumpy renal contours; and (3) papillary calcifications. In a more recent study, these observations were validated in a representative sample of patients with analgesic abuse with endstage renal disease and extended to patients with moderate renal failure. In patients with ESRF, decreased renal volume had the greatest sensitivity at 95 per cent, whilst papillary calcification had the highest specificity, and contour or papillary necrosis had a sensitivity and specificity of 90 per cent. In patients with moderate renal failure, papillary calcification was most sensitive at 92 per cent and specific at 100 per cent. The combination of papillary necrosis with either a bumpy renal contour or small kidneys did not improve sensitivity or specificity. In clinical practice, however, it is important to remember that the predictive value of this test, like any other diagnostic test, is very much dependent on the prevalence of the disease in the population under study. This test should therefore be utilized in patients with a reasonable risk for analgesic nephropathy and not as a general screening test.

As indicated above, patients with normal or only mildly/moderately impaired renal function should be strongly encouraged to stop taking analgesics, in the hope that further deterioration in renal function can be avoided. Those with severe or endstage renal failure are unlikely to recover renal function, although there may be other valid medical reasons for recommending that they stop ingesting large quantities of analgesics. The medical management of chronic renal failure is along conventional lines, as is provision of renal replacement therapy.

Non-steroidal anti-inflammatory drugs (NSAIDs)

NSAIDs are popular for treating a wide range of clinical conditions, available both over-the-counter and on prescription. Despite their usefulness, there is substantial evidence from experimental and clinical studies that NSAIDs have a variety of effects on the kidney. The most common renal disorder associated with NSAIDs is acute, largely reversible, insufficiency due to the inhibition of renal vasodilatory prostaglandins in the clinical setting of a stimulated renin–angiotensin system. Older age, hypertension, concomitant use of diuretics or aspirin, pre-existing renal failure, diabetes, and plasma-volume contraction are known risk factors for renal failure after the ingestion of NSAIDs. Rarely, NSAIDs may cause acute interstitial nephritis with proteinuria. These effects appear to be common to all NSAIDs, and are likely to be observed with cyclooxygenase-2 inhibitors as well as cyclooxygenase-1 inhibitors because both have been identified in adult and fetal human kidneys, suggesting a role for both enzymes in normal renal physiology.

By contrast to the well-characterized acute effects of NSAIDs on the kidney, the chronic effects are less well documented. However, a recent report demonstrated that NSAIDs are the most frequent cause of permanent renal insufficiency after acute interstitial nephritis. Risk factors for irreversible failure are pre-existing renal damage, long-standing intake of the causative drug, slow oligosymptomatic disease development, and histological signs of chronicity with those of acute interstitial nephritis. Although renal papillary necrosis and chronic renal failure can occur after the prolonged use of NSAIDs, the actual risk of these serious complications is unknown. Furthermore, the frequency of renal papillary necrosis as a primary or contributing cause of endstage renal disease remains unknown.

5-Aminosalicylic acid

Over the past few years an association between the use of 5-aminosalicylic (**5-ASA**) in patients with chronic inflammatory bowel disease and the development of a particular type of chronic tubulointerstitial nephritis has been suggested.

For many years, sulfasalazine, an azo-compound derived from sulphapyridine and 5-ASA, the latter being the pharmacologically active moiety, was the only valuable non-corticosteroid drug in the treatment of inflammatory bowel disease. Since the therapeutically inactive sulphapyridine moiety was largely responsible for the mainly haematological side-effects of sulfasalazine, this stimulated the development of a number of new 5-ASA formulations (mesalazine, olsalazine, balsalazine) for topical and oral use. In the last decade, these new 5-ASA products replaced sulfasalazine as the first-line therapy for mildly to moderately active inflammatory bowel disease. However, a literature search revealed 17 published cases of renal impairment associated with 5-ASA therapy in patients with inflammatory bowel disease, and in several it was shown that this did not recover completely upon stopping the drug, even after a follow-up period of several years. In a retrospective study, nephrologists reported 40 patients with inflammatory bowel disease showing renal impairment, including 15 cases with interstitial nephritis and previous use of 5-ASA. Stimulated by these findings we started a European prospective registration study aiming to register all patients with inflammatory bowel disease and renal impairment and to control for a possible association with 5-ASA therapy. A cohort of 1449 patients with inflammatory bowel disease seen during 1 year in the outpatient clinics of 28 European gastroenterology departments was investigated: preliminary results showed 30 patients (2 per cent) with decreased renal function, and a possible association with 5-ASA therapy was found in half of them.

However, determining the cause of renal disease in those with inflammatory bowel disease is not straightforward. The most frequent renal complications are oxalate stones and their consequences, such as pyelonephritis, hydronephrosis, and (in the long-term) amyloidosis. Chronic inflammatory bowel disease is also associated with glomerulonephritis: minimal-change glomerulonephritis, membranous, membranoproliferative, focal glomerulosclerosis, and proliferative crescentic glomerulonephritis have all been reported. As for many drugs, reversible, acute interstitial nephritis has been described with the use of 5-ASA compounds. In view of this complexity, the association of 5-ASA and chronic interstitial nephritis in patients with inflammatory bowel disease can be difficult to interpret, since renal involvement may be an extraintestinal manifestation of the underlying disease. However, the particular form of chronic tubulointerstitial nephritis in patients with inflammatory bowel disease treated with 5-ASA is characterized by an important cellular infiltration of the interstitium with macrophages, T cells, and also B cells (Fig. 2).

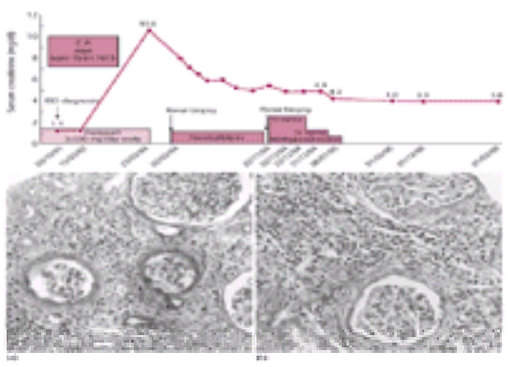

Fig. 2 5-ASA. A 36-year-old male patient suffering from Crohn's disease presented with severe renal failure after 23 months of 5-aminosalicylic acid (Pentasa®) treatment. A first renal biopsy showed widening and massive cellular infiltration of the interstitium, tubular atrophy, and relative spacing of glomeruli. The cellular infiltration was identified using appropriate monoclonal antibodies and consisted not only of T cells and macrophages, but also B cells. A second renal biopsy performed after the drug had been stopped for 8 months, when there was a modest improvement in renal function, again showed a significant cellular infiltration of the interstitium, tubular atrophy, and fibrosis. (a) First renal biopsy, (b) second renal biopsy.

Pathogenesis and pathology

That 5-ASA causes renal disease is supported by the number of case reports appearing in the recent literature of patients with inflammatory bowel disease using 5-ASA as their only medication, the improvement (at least partially) of impaired renal function upon stopping the drug, and a worsening after resuming 5-ASA use. Furthermore, the molecular structure of 5-ASA is very close to that of salicylic acid, phenacetin, and aminophenol, drugs with well-documented nephrotoxic potential (Fig. 1). Calder *et al*. found that necrosis of the proximal convoluted tubules and papillary necrosis developed in rats after a single intravenous injection of 5-ASA at doses of 1.4, 2.8, and 5.7 mmol/kg body weight (high pharmacological doses). The mechanism of renal damage, possibly caused by 5-ASA itself, may be analogous to that of salicylates by inducing hypoxia of renal tissues, either by uncoupling oxidative phosphorylation in renal mitochondria, by inhibiting the synthesis of renal prostaglandins, or by rendering the kidney susceptible to oxidative damage by a reducing renal glutathione concentration after inhibition of the pentose phosphate shunt.

Clinical features

A typical case is shown in Fig. 2. An intriguing aspect of this type of toxic nephropathy is the documented persistence of the renal interstitium inflammation even several months/years after first taking the drug. The disease is more prevalent in men, with a male:female ratio of 15:2. The age of reported cases ranges from 14 to 45 years. By contrast with analgesic nephropathy, where renal lesions are only observed after several years of analgesic abuse, interstitial nephritis associated to 5-ASA was already observed during the first year of treatment in 7 out of 17 reported cases, most of whom had started 5-ASA therapy with documented normal renal function. In several cases, particularly those in which there was a delayed diagnosis of renal damage, recovery of renal function did not occur, and some needed renal replacement therapy.

Diagnosis and treatment

Since this type of chronic tubulointerstitial nephritis produces few if any symptoms, and if diagnosed at a late stage progresses to irreversible chronic endstage renal disease, serum creatinine levels should be measured in any patient with inflammatory bowel disease treated with 5-ASA at the start of the treatment, every 3 months for the remainder of the first year, and annually thereafter. The use of concurrent immunosuppressive therapy, as is the case in severe forms of chronic inflammatory bowel disease, may necessitate extension to the period of intensive renal function monitoring. If serum creatinine increases, a renal biopsy is the only way to demonstrate the cause.

Chinese herbs

In 1992, physicians in Belgium noted an increasing number of women presenting with renal failure, often near end stage, following their exposure to a slimming regimen containing Chinese herbs. An initial survey of seven nephrology centres in Brussels identified 14 women under the age of 50 who had presented with advanced renal failure due to biopsy-proven, chronic tubulointerstitial nephritis over a 3-year period; nine of whom had been exposed to the same slimming regimen. As of early 2000, a total of more than 120 cases had been identified. The epidemiology is unknown, as is the risk for the development of severe renal damage, but the recent publication of case reports from several countries in Europe and Asia would seem to indicate that the incidence of herbal medicine-induced nephrotoxicity is more common than previously thought.

Pathogenesis and pathology

The aetiology of Chinese herbal nephropathy is not fully understood. A plant nephrotoxin, aristolochic acid, was proposed as a possible aetiological agent, but this compound was not part of the herbal preparations used by all the patients. Furthermore, aristolochic acid (0.15 mg/tablet) has been used as an immunomodulatory drug for 20 years in Germany by thousands of patients, sometimes in doses comparable to the Chinese herb slimming regimen; despite this exposure, there is no report relating chronic tubulointerstitial nephritis to aristolochic acid.

In addition to aristolochic acid, patients with Chinese herb nephropathy also received the appetite suppressants fenfluramine and diethylpropion, which have vasoconstrictive properties, and acetazolamide, which alkalinizes the urine, thereby potentially enhancing the nephrotoxic effect of aristolochic acid. Another uncertain factor is why only some patients exposed to the same herbal preparations develop renal disease. Women appear to be at greater risk than men: other factors that might be important include toxin dose, batch-to-batch variability in toxin content, individual differences in toxin metabolism, and a genetically determined predisposition toward nephrotoxicity and/or carcinogenesis.

At one centre in Belgium, 19 native kidneys and ureters were removed in a series of 10 patients during and/or after renal transplantation: multifocal, high-grade, flat, transitional-cell carcinoma (carcinoma *in situ*) was observed in four (40 per cent), whilst all had multifocal moderate atypia. Tissue samples revealed aristolochic acid-related DNA adducts, indicating a possible mechanism underlying the development of malignancy. In another study of 39 patients with Chinese herbal nephropathy and endstage renal disease who underwent prophylactic removal of the native kidneys and ureters, urothelial carcinoma was discovered in 18 and mild-to-moderate urothelial dysplasia in 19. All atypical cells were found to overexpress a p53 protein, suggesting the presence of a mutation in the gene.

The main histological lesion, which is located principally in the cortex, is extensive interstitial fibrosis with atrophy and loss of the tubules (Fig. 3). Cellular infiltration of the interstitium is scarce. Thickening of the walls of the interlobular and afferent arterioles result from endothelial cells swelling. The glomeruli are relatively spared and immune deposits are not observed. These findings suggest that the primary lesions may be centred in the vessel walls, thereby leading to ischaemia and interstitial fibrosis.

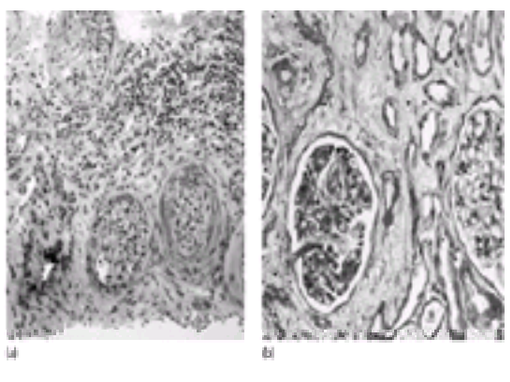

Fig. 3 Renal biopsy showing tubular atrophy, widening of the interstitium, cellular infiltration, and fibrosis, with glomeruli surrounded by a fibrotic ring, in a case of Chinese herb nephropathy. (a) Masson staining, (b) haematoxylin–eosin staining.

Clinical features

Patients present with renal insufficiency and other features indicating a tubulointerstitial disease. Blood pressure is either normal or only mildly elevated, and the urinary sediment reveals only a few red and white cells. The urine contains protein (less than 1.5 g/day), consisting of both albumin and low molecular weight proteins that are normally reabsorbed by the proximal tubules, hence tubular dysfunction—also marked by glycosuria—contributes to the proteinuria. The plasma creatinine concentration at presentation has ranged from 1.4 to 12.7 mg/dl (123 to 1122 µmol/l). Follow-up studies have revealed relatively stable renal function in most patients, with an initial plasma creatinine concentration below 2 mg/dl (176 µmol/l). However, progressive renal failure resulting in eventual dialysis or transplantation may ensue in patients with more severe disease, even if further exposure to Chinese herbs is prevented.

An extremely similar clinical and pathological process has been reported in a group of patients from Taiwan who had ingested a selection of uncontrolled traditional

Chinese herbs that differed from those of the slimming regimen. Despite discontinuation of these remedies, progressive renal failure was common.

Diagnosis and treatment

There are no specific criteria for the diagnosis of this type of renal disease. The condition should be suspected in any patient with unexplained relatively rapidly progressive renal disease who is using/abusing herbal remedies. The presence of tubular proteinuria may be a clue to the diagnosis, particularly in the early stages. The histological appearances are not specific, but renal biopsy is necessary to exclude other conditions in this clinical context.

There is no proven effective therapy for this disorder, which typically presents with marked interstitial fibrosis without prominent inflammation. An uncontrolled study suggested that corticosteroids may slow the rate of loss of renal function. The high incidence of cellular atypia of the genitourinary tract suggests that, as a minimum, these patients should undergo regular surveillance for abnormal urinary cytology. Whether more aggressive management strategies, such as bilateral native nephrouterectomies (particularly in those undergoing renal transplantation), are required is unclear. Findings from a recent report support the more aggressive option. Renal transplantation is an effective modality for those who progress to endstage renal disease, one report noting no recurrence in five patients.

Lithium

Lithium is used extensively in the treatment of patients with manic-depressive psychosis. Different forms of renal effects/injury have been described: most frequently nephrogenic diabetes insipidus, but also renal tubular acidosis, chronic interstitial nephritis, nephrotic syndrome, and focal segmental glomerular sclerosis/global glomerular sclerosis. Hyperparathyroidism is observed in patients treated with lithium.

Pathogenesis and pathology

Lithium is eliminated from the body almost entirely by the kidney, being filtered at the glomerulus and reabsorbed in the proximal tubule, resulting in a clearance of one-third of the normal creatinine clearance. It moves in and out of cells only slowly and accumulates in the kidney, particularly in the collecting tubule, entering these cells through sodium channels in the luminal membrane. Hence, its principal toxicity relates to distal tubular function, where inhibition of adenylate cyclase and generation of cyclic AMP result in downregulation of aquaporin-2, the collecting tubule water channel, and a decrease in ADH receptor density, leading to resistance to antidiuretic hormone. Further effects compound this. A low intracellular level of cyclic AMP leads to the increased cellular levels of glycogen observed in kidney biopsy specimens from patients taking lithium, as does the fact that lithium also directly inhibits enzymes involved in glycogen breakdown. The ensuing increased glycogen storage may interfere with distal tubular function and be responsible for the observation that polyuria and polydipsia in lithium-treated patients is due to nephrogenic diabetes insipidus.

The tubular defect in the distal nephron can also impair the ability to maximally acidify the urine. A lithium-induced decrease in the activity of the H+-ATPase pump in the collecting tubule may be responsible for this defect.

Lithium treatment has been aetiologically related to parathyroid hypertrophy and hyperfunction, the latter seeming to be due to an upward resetting of the level at which the plasma calcium concentration depresses parathyroid hormone (**PTH**) release. Persistent hypercalcaemia (in 5–10 per cent of the patients) may exacerbate both the concentrating defect and the interstitial nephritis seen in lithium-treated patients.

Renal biopsies from patients taking lithium show a specific histological lesion in the distal tubule and collecting duct. On light microscopy there is swelling and vacuolization in cells associated with a considerable accumulation of Periodic acid–Schiff (**PAS**)-positive glycogen. This is present in all renal biopsies from patients taking lithium, it appears within days after the administration of lithium and disappears when lithium ingestion is ceased.

Hestbech *et al*. were the first to suggest that progressive chronic interstitial lesions occurred in the kidneys of patients receiving lithium. However, a controlled study showed no difference between biopsies from patients taking lithium and those from a group of patients who had affective disorders but were not doing so. Specifically, there was no difference in the incidence of glomerular sclerosis, interstitial fibrosis, tubular atrophy, cast formation, or interstitial volume, but there was a significant increase in the number of microcysts in the lithium-treated patients. One reason why it has been difficult to determine the nature of lithium-induced chronic renal damage has been the lack, until recently, of an animal model in which lesions similar to those noted in human biopsies could be demonstrated. However, a recent study on lithium nephrotoxicity carried out in the rabbit showed clear-cut evidence of progressive histological and functional impairment, with the development of significant interstitial fibrosis, tubular atrophy, glomerular sclerosis, and cystic tubular lesions. A recent publication by Markowitz *et al*. revealed a chronic tubulointerstitial nephropathy in 100 per cent of 24 patients having received lithium for several years, associated with cortical and medullary tubular cysts or dilatation. There was also a surprisingly high prevalence of focal segmental glomerulosclerosis and global glomerulosclerosis, sometimes of equivalent severity to the chronic tubulointerstitial disease. Despite discontinuing lithium treatment, seven of nine patients with initial serum creatinine values above 2.5 mg/dl progressed to endstage renal disease. Nevertheless, an answer to the question as to whether or not chronic lithium therapy causes chronic interstitial nephritis still needs more hard data.

Clinical features

Apart from acute lithium intoxication, chronic poisoning can occur in patients whose lithium dosage has been increased or in those with a decreased effective circulating volume, decreased sodium intake, diabetes mellitus, gastroenteritis, and renal failure, thereby resulting in an increase in serum lithium levels. Symptoms associated with poisoning include lethargy, drowsiness, coarse hand tremor, muscle weakness, nausea, vomiting, weight loss, polyuria, and polydipsia. Severe toxicity is associated with increased deep tendon reflexes, seizures, syncope, renal insufficiency, and coma. The commonest manifestation is altered mental status.

Chronic lithium poisoning is frequently associated with electrocardiogram changes, including ST-segment depression and inverted T waves in the lateral precordial leads. Lithium is concentrated within the thyroid and inhibits the synthesis and release of thyroxine, which can lead to hypothyroidism and hypothermia. It may also cause thyrotoxicosis and hyperthermia. Symptoms of hypercalcaemia may also be present, exacerbating the urinary concentrating defect already present in these patients.

In patients with glomerular lesions such as minimal-change or focal glomerular sclerosis, proteinuria generally begins within 1.5 to 10 months after the onset of therapy, completely or partially resolving in most patients within 4 weeks after lithium is discontinued. Reinstitution of lithium has led to recurrent nephrosis in some cases.

The hyperparathyroidism observed in patients receiving lithium treatment is characterized by elevated parathyroid hormone levels, hypercalcaemia, hypocalciuria, and normal serum phosphate levels, by contrast to primary hyperparathyroidism in which hypophosphataemia and hypercalciuria are seen.

Diagnosis and treatment

The severity of chronic lithium intoxication correlates directly with the serum lithium concentration and may be categorized as mild (1.5–2.0 mEq/l), moderate (2.0–2.5 mEq/l), or severe (>2.5 mEq.l).

Polyuria and polydipsia due to nephrogenic diabetes insipidus and other acute manifestations of the effect of lithium on the kidney usually disappear rapidly if lithium is withdrawn. The decision about management, however, usually revolves around the relative benefit of the lithium in controlling and preventing the manifestation of manic-depressive psychosis, and the disadvantage to the patient of the major side-effect of lithium, namely polyuria. In most cases the lithium is so clearly beneficial that the polyuria is accepted as a side-effect and treatment continued. It is likely that the serum concentration of lithium is important, and that renal damage is more likely to occur if the serum concentration is consistently high or if repeated episodes of lithium toxicity occur. The serum lithium concentration should therefore be monitored carefully (at least every 3 months) and maintained at the lowest level that will provide adequate control of the manic depressive psychosis.

Much more difficult to handle is the situation where a patient on long-term lithium therapy is found to have impaired renal function for which there is no obvious alternative cause. As stated above, renal failure may progress even if lithium therapy is withdrawn, and in some patients the discontinuation of lithium can lead to a devastating deterioration in their psychiatric condition. The decision as to whether or not to discontinue lithium should therefore be made after frank and open discussion, admitting all uncertainties, with the patient, psychiatric colleagues, and (if appropriate) relatives/carers.

Endemic Balkan nephropathy

Endemic Balkan nephropathy (**EBN**) is a chronic, familial, non-inflammatory tubulointerstitial disease of the kidneys. A high frequency of urothelial atypia, occasionally culminating in tumours of the renal pelvis and urethra, is associated with this disorder.

As the name suggests, EBN is most commonly seen in South-Eastern Europe, including the areas traditionally considered to comprise the 'Balkans': Serbia, Bosnia and Herzegovina, Croatia, Romania, and Bulgaria. It is most likely to occur among those living along the confluence of the Danube river, a region in which the plains and low hills generally have a high humidity and rainfall (Fig. 4). There is a very high prevalence in endemic areas, with rates ranging between approximately 0.5 and 4.4 per cent, increasing to as high as 20 per cent if the disorder is suspected and carefully screened for among an at-risk population. A striking observation is that nearly all affected patients are farmers.

Fig. 4 Foci of endemic Balkan nephropathy.

Pathogenesis and pathology

Although the aetiology of EBN is unknown, many environmental and genetic factors have been evaluated as possible underlying causes.

Environmental factors

Given that it is endemic to a specific geographic area, toxins and/or environmental exposures that are unique to the Balkans have been investigated. However, no agent and/or general group of compounds or organisms, including trace elements (lead, cadmium, silica, selenium), viruses, fungus, and/or plant toxin, has yet been successfully identified.

One intriguing possibility is that aristolochic acid, a mutagenic and nephrotoxic alkaloid found in the plant *Aristolochia clematis*, may underlie both Chinese herbal nephropathy (see above) and EBN (see Table 1). There are striking pathological and clinical similarities between the progressive interstitial fibrosis observed in young women who have been on a slimming regimen containing Chinese herbs (as well as other agents) and EBN, but this putative association between EBN and aristolochic acid remains speculative.

Genetic factors

Support for a genetic aetiology includes observations that the disease clearly affects particular families, and that some ethnic populations who have lived in endemic areas for generations do not suffer from EBN. The mode of inheritance has not yet been established and possible causative gene(s) have not been identified, but a locus in the region between 3q25 and 3q26 has been incriminated.

By contrast, some observations are inconsistent with a genetic basis. First, EBN is observed in individuals who have immigrated into the 'Balkan' area from regions without the disorder, and in previously unaffected families who have lived for at least 15 years in endemic areas. Second, EBN does not develop in members from previously affected families who have left endemic areas early in life or who spent less than 15 years in these areas.

A unifying hypothesis may be that the disease most likely occurs in genetically predisposed individuals who are chronically exposed to a causative, as yet unidentified agent.

In the early stages of disease, renal histology reveals focal cortical tubular atrophy, interstitial oedema, and peritubuloglomerular sclerosis with limited mononuclear-cell infiltration. Narrowing and endothelial swelling of interstitial capillaries (e.g. capillarosclerosis) is also described. In advanced cases, marked tubular atrophy and interstitial fibrosis develop along with focal segmental glomerular changes and global sclerosis. There is an extremely high incidence of cellular atypia and urothelial carcinoma of the genitourinary tract.

Clinical features

EBN is a slowly progressive tubulointerstitial disease that may culminate in endstage renal disease. Clinical manifestations first appear between 30 and 50 years of age, with findings prior to the age of 20 being extremely rare. One of the first signs is tubular dysfunction, which is characterized by an increased excretion of low molecular weight proteins (such as b2-microglobulin). Early tubular injury can also lead to renal glycosuria, aminoaciduria, and diminished ability to handle an acid (NH_4Cl) load. Over a period of more than 20 years there is a progressive decrease in concentrating ability (resulting in polyuria) and in the glomerular filtration rate (resulting in endstage renal disease). Patients are usually without oedema and are normotensive, hypertension only developing with endstage disease. A normochromic normocytic anaemia occurs with early disease, which becomes increasingly pronounced as the disorder progresses. Urinary tract infection is rarely observed. Kidneys are of normal size early in the course of the disease. A symmetrical reduction of kidney size with a smooth outline and normal pelvicaliceal system is subsequently observed in patients with late-stage disease. Intrarenal calcifications are not observed.

EBN is also associated with the development of transitional-cell carcinoma of the renal pelvis or ureter, with studies noting a wide range in incidence (2 to nearly 50 per cent). These tumours are generally superficial and slow-growing.

Diagnosis and treatment

The diagnosis of EBN is based upon the presence of some combination of the following findings:

- symmetrically shrunken kidneys with absence of intrarenal calcifications;
- farmers living in the endangered villages;
- familial history positive for endemic Balkan nephropathy;
- mild tubular proteinuria, hyposthenuria; and
- normochromic hypochromic anaemia occurring in patients with only slightly impaired renal function.

As with many other chronic tubulointerstitial diseases of unclear origin, there is no specific prevention or treatment. Therapy is therefore supportive, with renal replacement therapy being initiated in patients with endstage renal disease.

The high incidence of cellular atypia in the genitourinary tract suggests that regular surveillance should be performed for abnormal urinary cytologies. Whether

bilateral native nephroureterectomies are required, particularly in those undergoing renal transplantation, is unclear.

Radiation nephropathy

Radiation nephropathy is a renal disorder caused by ionizing radiation. The kidney may be injured by radiation administered to tumours within the kidney or nearby tissues (testis, ovary, retroperitoneum). Clinicians were aware of the potential adverse effects of X-rays on renal function from the beginning of the twentieth century, and between 1940 and 1960 a significant number of cases were reported. In 1953 Luxton established the clinical features of the condition and defined the tolerance of the kidney to irradiation, leading to preventive shielding of the kidneys in patients receiving radiation therapy and to a marked decline in the frequency of radiation nephropathy. In the last decade, however, total-body irradiation preceding bone marrow transplantation has resulted in an increasing incidence of radiation nephropathy, with late chronic renal failure developing in 20 per cent of patients who receive this treatment.

Pathogenesis and pathology

The radiation doses traditionally associated with radiation nephropathy were above 2000 rad (20 Gy) (less in children). By contrast, in patients receiving total-body irradiation preceding bone marrow transplantation, renal impairment was observed after doses of 1000 to 1400 rad (10–14 Gy). Fractionation, time, and effects of cytotoxic chemotherapy can probably explain the differences. In laboratory rodents, fractionation of the total dose into multiple separated doses decreases the risk, probably due to repair of sublethal radiation damage during the time between the fractionated doses. Total-body irradiation before bone marrow transplantation is usually administered over a short period, which does not allow sufficient time for the repair of radiation injury to the kidney. Moreover, the additional cytotoxic chemotherapy given to these patients potentiates the effects of ionizing radiation.

The precise pathogenesis of radiation nephropathy remains to be determined. The initial target of ionizing radiation within the kidney appears to be the endothelial cell. Radiation kills cells by damaging DNA, so that cell death after radiation is delayed until the cell divides. After the initial glomerular endothelial injury, vascular occlusion subsequently develops, leading to tubular atrophy. Because inflammatory cells are not seen in the renal parenchyma, the previously used terminology of 'radiation nephritis' is a misnomer.

The pathological features of radiation nephropathy comprise a continuous spectrum of changes that vary in relation to the dose of irradiation administered and the time elapsed after exposure. Large doses are followed by complete atrophy, thickening of basement membranes, and interstitial fibrosis.

Clinical features

Radiation nephropathy can take several forms. Acute radiation nephropathy occurs between 6 and 12 months after radiation therapy and presents with hypertension, anaemia, and oedema. The severity of hypertension ranges from mild to malignant, and more than half of the patients progress to chronic renal failure. Radiation nephropathy after total-body irradiation before bone marrow transplantation most closely corresponds to this acute form of radiation nephropathy. A more insidious chronic form of radiation nephropathy develops over a period of several years and presents primarily with diminished glomerular filtration rate, hypertension, and (occasionally) proteinuria. Another subset of patients may develop hypertension within a few years of irradiation, evolving in some to malignant hypertension with accelerated loss of renal function. Isolated persistent or intermittent proteinuria may also occur, frequently developing more than a decade after radiation exposure.

Diagnosis and treatment

Radiographic studies may help in the diagnosis of acute radiation nephropathy. CT scans with contrast demonstrate sharply demarcated, dense, persistent nephrograms corresponding to the irradiated areas.

The treatment of radiation nephropathy is supportive. Aggressive treatment of hypertension may slow the progression of renal disease. Hypertension due to unilateral disease may respond to nephrectomy. Additionally, the use of ACE inhibitors may have its classical renoprotective effect independent of antihypertensive action.

Since radiation nephropathy is an irreversible process, preventive measures should be taken during the administration of radiation. This includes selective shielding of the kidneys and the use of fractionated doses. Patients exposed to additional nephrotoxins remain at an increased risk of toxic effects.

Toxins

Lead

Lead toxicity affects many organs, resulting in encephalopathy, anaemia, peripheral neuropathy, gout, and renal failure. It was the epidemic of lead nephropathy in Queensland (Australia) that provided the strongest link between lead and chronic tubulointerstitial nephritis. Henderson noted an excess mortality due to chronic interstitial nephritis in Queensland but not in other parts of Australia, and correlated the incidence of granular contracted kidneys at autopsy with the lead content of the skull in people from Queensland and Sydney, showing that this correlated closely with the incidence of renal failure. Exposure was due to the lead-based paints used between 1890 and 1930, but recently the source of lead is industrial exposure. This type of exposure is often insidious, occurring over a very long period. Two studies have shown an inverse relationship between low-level lead exposure and renal function in the general population. Recent studies have failed to show any effect on renal function 17 to 50 years after an episode of acute childhood plumbism, the difference with Henderson's findings reflecting the greater lead burden in his study compared to the recent ones. Although low-level lead exposure in the general population is associated with mild but significant depression of renal function, its role in the development of endstage renal disease is unclear.

Pathogenesis and pathology

The pathogenesis of renal disease seen in the context of lead exposure may be related to proximal tubule reabsorption of filtered lead, with subsequent accumulation in proximal tubule cells. Aminoaciduria, glycosuria, and phosphaturia representing the Fanconi syndrome are observed after lead exposure, and thought to be related to an effect of lead on mitochondrial respiration and phosphorylation. Since lead is also capable of reducing 1,25-dihydroxyvitamin D synthesis, prolonged hyperphosphaturia and hypophosphataemia caused by lead poisoning in children could result in bone demineralization and rickets. Chronic lead poisoning can affect glomerular function: after an initial period of hyperfiltration the glomerular filtration rate is reduced and nephrosclerosis and chronic renal failure may ensue. Protracted lead exposure also interferes with the distal tubular secretion of urate, leading to hyperuricaemia and gout.

Renal biopsies in patients with subclinical lead nephropathy and a mild to moderate decrease in glomerular filtration rate primarily show focal tubular atrophy and interstitial fibrosis with minimal cellular infiltration. Electron microscopy shows mitochondrial swelling, loss of cristae, loss of basal infoldings, and a lysosomal-like structure containing dense bodies in the proximal tubules. In Australian patients who died as a result of severe lead exposure, their kidneys were fibrotic and shrunken, the interstitium showed variable degree of fibrosis with tubular dilatation, and the vessels had thickened muscular walls with subintimal hyaline deposition in afferent arterioles, but these findings in patients with endstage renal failure were non-specific.

Clinical features

Renal failure becomes apparent years after exposure and is associated with gout in most, if not all, cases. Hypertension is a very common feature of lead nephropathy, and an association between hypertension without renal failure and low-level lead exposure has gained increasing recognition over the past two decades. Although hyperuricaemia is common in renal failure, gout is unusual and its presence should raise the possibility of lead nephropathy.

However, whether chronic lead nephropathy exists as a clinical entity has been questioned. Many studies of occupational lead poisoning have not taken into account the coexposure to other toxins such as cadmium. Additionally, the relationship between early markers of renal tubular dysfunction, such as the urinary excretion of low molecular weight proteins or *N*-acetyl b-D-glucosaminidase, to the subsequent development of renal failure remains to be determined.

Diagnosis and treatment

As the blood lead level only reflects recent lead exposure, and is usually normal in patients with chronic renal failure due to their previously sustained low-level lead

exposure, the diagnosis has to be based on measurement of the body lead burden. The test of choice is the **EDTA** (ethylenediaminetetraacetic acid) mobilization test: this involves the administration of 2 g of EDTA intramuscularly in two divided doses 8 to 12 h apart, and collection of three consecutive 24-hour urine samples. A cumulative excretion of more than 600 µg is suggestive for a high lead body burden. Renal failure in itself does not increase body lead load but it does delay the excretion of lead. The diagnosis of lead nephropathy should be considered in any patient with progressive renal failure, mild to moderate proteinuria, significant hypertension, history of gout, and an appropriate history of exposure.

There is very little experience of the therapeutic use of EDTA in patients with chronic renal failure. Wedeen *et al*. treated eight industrially exposed patients with EDTA injections thrice weekly for 6 to 15 months, all having mild renal failure with GFRs of around 50 ml/min before treatment—four patients improved with a 20 per cent increase in their GFR.

Cadmium

Cadmium is a cumulative environmental pollutant and accumulates in the human body after inhalation or gastrointestinal absorption. Due to its various applications and increased industrial production, this element's release into the environment increased considerably from the 1950s onwards, particularly in Belgium and Japan, which are among the most important cadmium-producing countries worldwide. However, the atmospheric emissions of cadmium from zinc smelters have been reduced since the 1970s. At the present, normal cadmium values are set at 0.1 to 0.8 µg/l (non-smokers) in blood and 0.02 to 0.7 µg/g creatinine in urine.

Cadmium is a highly toxic metal. The kidney is the element's most important target organ and it has long been recognized that high-level exposure to cadmium after inhalation or ingestion can give rise to nephrotoxicity in humans, and that this effect is usually considered to be the earliest and most important feature from the point of view of health. Cadmium induces a tubular proteinuria (of low molecular weight plasma proteins). Hence, when exposed to high levels of cadmium (cadmium in renal cortex >100–400 µg/kg wet weight) in the workplace, workers have developed tubular proteinuria, renal glycosuria, aminoaciduria, hypercalciuria, phosphaturia, and polyuria, and in a few severe cases (long-standing high exposure and urinary excretion >20 µg/g creatinine and b $_2$-microglobulin >1500 µg/g creatinine) renal damage may progress to an irreversible reduction in glomerular filtration. Signs of distal tubular damage such as a cadmium-induced inhibition of ADH-stimulated ion transport have also been reported.

The extent to which chronic low-level environmental exposure to cadmium affects renal function is much less clear. The Cadmibel study, in which a random sample of 1699 subjects was recruited from four areas of Belgium with varying degrees of cadmium pollution, showed that (after standardization for several confounding factors) five markers of renal dysfunction (retinol binding protein, *N*-acetyl-b-glucosaminidase, b $_2$-microglobulin, amino acids, and calcium) were significantly associated with urinary cadmium excretion. There was a 10 per cent probability of these variables being abnormal when urinary cadmium levels exceeded 2 to 4 µg/24 h. However, in a 5-year follow-up of a subcohort from the Cadmibel study, the so-called Pheecad study, in which 593 individuals with the highest urinary cadmium excretion were re-examined on average 5 years later, it was demonstrated that the subclinical tubular effects previously documented were not associated with a deterioration in glomerular function. Hence, in the environmentally cadmium-exposed population, the renal effects due to cadmium appear to be weak, stable, and even reversible. These findings in environmentally exposed subjects may reasonably be extrapolated to the current, moderately exposed, occupational population, where, in various epidemiological studies, increased cadmium levels/exposure have repeatedly been associated with disturbed levels of markers of early renal dysfunction, but without evidence for accelerated progression towards chronic renal failure.

Metabolic disorders

Chronic hypokalaemia

Several renal abnormalities, most of which are reversible with potassium repletion, can be induced by hypokalaemia. Vasopressin-resistant impairment of the ability to concentrate the urine, increased renal ammonia production, enhanced bicarbonate reabsorption, altered sodium reabsorption, and hyperkalaemic nephropathy have all been described.

Persistent hypokalaemia can induce a variety of changes in renal function, impairing tubular transport, and possibly inducing chronic tubulointerstitial disease and cyst formation. Hypokalaemic nephropathy in humans produces characteristic vacuolar lesions in the epithelial cells of the proximal tubule and (occasionally) the distal tubule. This abnormality probably requires about 1 month to develop. More severe changes, including interstitial fibrosis, tubular atrophy, and cyst formation that is most prominent in the renal medulla, occur if prolonged hypokalaemia is maintained. The pathogenesis of these changes is not well understood.

Renal growth accelerates when rats are placed on a potassium-deficient diet, and within 8 days there is a 25 per cent increase in kidney mass. The changes are most prominent in the outer medulla, especially the inner stripe, where hyperplastic, enlarged, collecting-duct cells form cellular outgrowths that project into the lumen causing partial obstruction. If the potassium-deficient state persists, then cellular infiltrates appear in the renal interstitial compartment and tubulointerstitial fibrosis develops. It has been proposed that some of these pathological changes may be initiated by the high levels of ammonia generated in potassium-deficiency states and may be mediated through the activation of the alternate complement pathway. In support of this hypothesis is the finding that bicarbonate supplementation sufficient to suppress renal ammoniagenesis attenuates the renal enlargement and tubulointerstitial disease: against it are reports that increased renal ammoniagenesis induced by acid loading causes renal enlargement without cellular proliferation or interstitial disease. A recent paper provides results consistent with a sustained role for insulin-like growth factor-1 (**IGF-1**) in promoting the marked tubular epithelial-cell hypertrophy and hyperplasia that occurs in the inner stripe of the outer medulla of the kidney with chronic potassium depletion. The same study also showed that potassium depletion causes a selective increase in the renal expression of transforming growth factor-b (**TGF-b**) in the hypertrophied, non-hyperplastic, thick ascending limb, but—unlike IGF-1—it is absent from the hyperplastic collecting-duct cells. This might be responsible for preventing the conversion of the mitogenic stimulus of IGF-1 into a hypertrophic one. It is possible that TGF-b causes the prominent interstitial infiltrate that develops in chronic hypokalaemia, since this 'growth factor' is a well-known chemoattractant for macrophages.

Hyperoxaluria

Hyperoxaluria may be primary or acquired. The primary form is a rare inherited disorder due to an enzymatic abnormality in the metabolism of glyoxylic acid. The acquired forms of hyperoxaluria are more common and result either from the ingestion of oxalate precursors, such as ethylene glycol and ascorbic acid, and exposure to methoxyflurane anaesthesia, or from increased absorption from the intestinal tract in those with inflammatory bowel disease or who have undergone small-bowel resection.

The microcrystallization of calcium oxalate first occurs in the proximal tubules where oxalate secretion occurs. However, the lesions that develop are more severe in the renal medulla, where the increasing concentration of the tubular fluid and its acidification promote the precipitation of calcium oxalate. If the overload is insidious and chronic, inflammatory-cell infiltration, oedema, interstitial fibrosis, tubular atrophy, and dilatation result in a chronic tubulointerstitial nephritis with progressive renal failure.

Hypercalcaemia

Prolonged elevation of urinary and serum calcium levels may result in the deposition of calcium in the kidney (nephrocalcinosis, see Chapter 20.13). This also occurs in some clinical conditions not associated with hypercalcaemia. Increased intestinal absorption of calcium occurs with vitamin D intoxication, sarcoidosis, and the milk alkali syndrome. Skeletal deossification due to neoplasms, hyperparathyroidism, and multiple myeloma can also produce nephrocalcinosis, stones, and functional abnormalities.

Calcium is most concentrated in the medulla, where degeneration and tubular necrosis begins due to intracellular overload with damage to mitochondria and other critical organelles. Reactive inflammatory changes occur in the adjacent interstitium, and necrotic cells may cause intratubular obstruction and tubular atrophy. The final results of these changes are focal areas of tubular atrophy, interstitial fibrosis, and a mononuclear-cell infiltrate.

Hyperuricaemia/hyperuricosuria

There are three different types of renal disease induced by abnormal uric acid metabolism: acute uric acid nephropathy; chronic urate nephropathy; and uric-acid stone disease—the latter being discussed in Chapter 20.13.

The kidneys are the major organs for the excretion of uric acid and a primary target organ affected in disorders of urate metabolism. Renal lesions result from the crystallization of uric acid either in the urinary outflow tract or in the renal parenchyma. The determinants of uric acid solubility are its concentration and the pH of the medium in which it is dissolved. Hence the supersaturation of fluid within the renal tubules as excreted uric acid becomes concentrated in the medulla, and the acidification of the urine in the distal tubule, are both conducive to the precipitation of uric acid. The major sites of urate deposition are the renal medulla, the collecting tubules, and the urinary tract. The p*K*a of uric acid is 5.7, and at the acid pH of the fluid in the distal tubule the bulk of filtered urate will be present in its non-ionized form as uric acid, whereas at the more alkaline pH of the blood and interstitium it is in its ionized form as urate salts.

Acute uric acid nephropathy

Acute uric acid nephropathy is an uncommon condition caused by the precipitation of birefringent uric acid crystals in the collecting tubules, with consequent tubular obstruction, dilatation, and inflammation. This can occur in disorders associated with an increased production of uric acid, for example myeloproliferative or lymphoproliferative disorders, tumour lysis syndrome (see Chapter 20.10.5), chronic haemolytic anaemia, psoriasis, or the Lesch–Nyhan syndrome, or when there is increased renal clearance of uric acid, for example inherited or acquired defects of tubular urate transport, uricosuric drugs.

In those prone to acute uric acid nephropathy, management centres on prophylaxis with a plentiful fluid intake, with or without alkalinization of the urine, and pretreatment with allopurinol, although the latter can increase the risk of xanthine nephropathy. Presentation of acute uric acid nephropathy is with acute renal failure, with urine microscopy revealing plentiful birefringent crystals. Management is supportive. If allopurinol is prescribed, then the dose must be substantially reduced in renal failure.

Chronic urate nephropathy

The principal lesion in chronic hyperuricaemia is the deposition of microtophi of amorphous urate crystals in the interstitium, with a surrounding giant-cell reaction. This results in a secondary chronic inflammatory response similar to that seen with microtophus formation elsewhere in the body, potentially leading to interstitial fibrosis and chronic renal failure.

Evidence linking chronic renal failure to gout is weak, and the long-standing notion that chronic renal disease is common in patients with hyperuricaemia has been questioned in the light of prolonged follow-up studies of renal function in people with this condition. Renal dysfunction could be documented only when the serum urate concentration was more than 10 mg/dl (600 µmol/l) in women and more than 13 mg/dl (780 µmol/l) in men for prolonged periods. Furthermore, the deterioration of renal function in those with hyperuricaemia of a lower magnitude has been attributed to the higher-than-expected occurrence of hypertension, diabetes mellitus, abnormal lipid metabolism, and nephrosclerosis. Nonetheless, it seems reasonable to prescribe allopurinol (in a dose appropriate to the level of renal function) to those very rare patients with biopsy evidence of 'gouty nephropathy', and possibly to patients with chronic renal failure who have a grossly elevated serum urate.

There is an association between severe lead intoxication, chronic renal failure, and gout (saturnine gout) (see above). It has also been suggested that there might be an association between renal disease and hyperuricaemia in those with a past history of exposure to lead and consequent subclinical lead toxicity (saturnine nephropathy). Evidence for this association is not clear-cut, nor is the mechanism whereby lead exposure might aggravate hyperuricaemia and renal failure.

20.10.1 Diabetes mellitus and the kidney

R. W. Bilous

Introduction

Diabetic nephropathy is the commonest single cause of endstage renal failure (**ESRF**) requiring renal replacement therapy in the United States, and the second most common in Europe and Japan. The incidence is increasing, largely because the incidence of diabetes itself is reaching what some have termed epidemic proportions, this growth being greatest in the developing world.

Definition

Nephropathy is a clinical diagnosis based upon the finding of proteinuria in a patient with diabetes and in whom there is no evidence of urinary infection. Conventionally, the level of proteinuria for a diagnosis of 'clinical nephropathy' or 'overt nephropathy' is 0.5 g/day, which is roughly equivalent to a urinary albumin excretion rate (**UAER**) of 300 mg/day. Patients with a UAER between 30 and 300 mg/day are defined as having 'microalbuminuria' or 'incipient nephropathy'. In this chapter, the terms 'incipient' and 'clinical nephropathy' will be used.

Although timed urine collections remain the 'gold standard' for diagnosis, they are cumbersome to use in routine clinical practice and most definitions of clinical or incipient nephropathy depend upon a 'spot' urine sample and thus a test of albumin concentration. Results in excess of 300 mg/l and more than 50 mg/l define clinical and incipient nephropathy, respectively. Sensitivity and specificity can be improved by using an early morning, first-voided specimen and correcting the albumin level for creatinine concentration (albumin:creatinine ratio (**ACR**)). Defining levels are shown in Table 1.

Pathology

Patients with newly diagnosed type 1 disease have large kidneys. Studies in experimental animals suggest that this enlargement is due to tubular hypertrophy and hyperplasia and an expansion of the tubulointerstitium. These changes are probably in response to the increased filtration of glucose and can be reversed in animals, but not man, by glycaemic correction. Otherwise, glomerular and tubular structure is normal at diagnosis in patients with type 1 diabetes.

The pathological hallmarks of diabetic nephropathy are thickening of the glomerular basement membrane (**GBM**) and mesangial expansion with or without nodule formation. GBM thickening can be detected in nearly all patients with diabetes of more than 10 years' duration, irrespective of the UAER. Those with clinical nephropathy almost invariably have GBM widths two to three times the upper limit of normal (350 nm). Mesangial volume remains in the normal range in patients who have a normal UAER. Nodule formation, although virtually pathognomonic, is not invariable. A combination of mesangial expansion and afferent arteriolar hyalinosis with ischaemia leads to eventual total glomerulosclerosis and subsequent loss of filtration capacity, ultimately leading to ESRF.

Patients with type 2 diabetes have been much less well studied, but the pathological appearances of subjects with clinical nephropathy are very similar to those with type 1. However, the pattern of changes in incipient nephropathy is more heterogeneous and a significant prevalence of non-diabetic pathology (around 10 per cent) has been reported in some biopsy series.

Clinical course

The pathological lesions underpinning nephropathy have been recognized since 1936. However, clinical progression is usually defined in terms of changes in the UAER, glomerular filtration rate (**GFR**), and blood pressure. There are few long-term prospective studies of individual patients, and much of our current understanding is based upon cross-sectional data. Albuminuria is clearly a continuous variable and any separation into stages must be regarded as somewhat artificial. However, the distinction between incipient and clinical nephropathy is a useful one for practical purposes.

Urinary albumin excretion rate (UAER)

UAER may increase at diagnosis of type 1 diabetes and during acute hyperglycaemia, but it rapidly returns to normal with glycaemic correction. Thereafter the majority of patients (>60 per cent) will have a normal UAER throughout their diabetic life. The remainder will develop incipient nephropathy at incidence rates of between 1 and 2 per cent per annum, usually preceded by intermittently positive tests for microalbuminuria. The rate of increase of UAER in patients with incipient nephropathy is around 20 per cent per annum, although these rates will be less in those treated with antihypertensive therapy or intensified insulin regimens (see later).

It is unusual to develop incipient nephropathy within the first 5 years of diabetes onset, but it can develop at any time thereafter, even after 40 years. Most patients with type 1 disease and incipient nephropathy will progress to clinical nephropathy unless treated. The average rate of progression is 20 per cent over 5 years, but those with longer durations of diabetes prior to incipient nephropathy tend to progress more slowly. Once the UAER exceeds 300 mg/day there tends to be a relentless increase, sometimes into the nephrotic range, although the rate of change varies between patients and is very dependent upon systemic blood pressure. Historically, the incidence of clinical nephropathy peaks after diabetes of 15 to 17 years' duration, but these figures were obtained before the availability of effective antihypertensive therapy.

Because the onset of type 2 diabetes is more difficult to define, the precise incidence of incipient nephropathy is difficult to estimate. Up to 7 per cent of patients in the United Kingdom have incipient nephropathy and 1 per cent clinical nephropathy at diagnosis of diabetes. As in type 1 diabetes, the UAER will reduce with glycaemic

correction, but usually only in a minority of patients, therefore implying an established nephropathology. The United Kingdom Prospective Diabetes Study (**UKPDS**) in newly diagnosed patients reports rates of transition from normal to incipient nephropathy of 2 per cent per annum and from incipient to clinical nephropathy of 3 per cent per annum, which are very similar to those seen in patients with type 1 diabetes.

Glomerular filtration rate (GFR)

At diagnosis, the GFR is increased in a proportion of patients with type 1 and type 2 diabetes, a phenomenon termed hyperfiltration. The precise prevalence depends upon the definition of 'normal GFR', which varies with methodology and age, but a raised GFR has been described in up to 40 per cent of patients with untreated, non-ketotic type 1 diabetes and in 45 per cent of those newly diagnosed as type 2.

The GFR returns to normal in most patients with treatment, although a significant minority maintain persistent hyperfiltration. In normal people, the GFR declines by 1 per cent per annum beyond 40 years of age, a rate that is no different in normotensive diabetic patients with a normal UAER. Patients with type 1 and type 2 disease with incipient nephropathy also tend to have a stable GFR. However, as the UAER approaches and exceeds the clinical nephropathy threshold there is a steady decline. The rate of loss of GFR is very dependent on systemic blood pressure, and also varies considerably between individuals. In historical series of hypertensive type 1 and type 2 patients, the average decline was 10 ml/min per year, thus leading to ESRF within 7 to 10 years. In patients with well-controlled blood pressure, the rates are around 4 ml/min per year, effectively delaying ESRF by more than 10 years (Table 2).

Blood pressure

In patients with type 1 diabetes, their blood pressure is virtually always normal at diagnosis. In newly diagnosed type 2 patients, over one-third will have hypertension, as conventionally defined (>160/95 mmHg). Type 1 patients who go on to develop incipient nephropathy have significantly higher blood pressures than those who remain with a normal UAER, although the averages remain within the 'normal' range. Patients with newly developed incipient nephropathy show a steady increase thereafter, such that over 45 per cent have a blood pressure of more than 140/90 mmHg within 4 years. Cross-sectional studies also consistently show higher blood pressures with increasing UAER, most type 1 and type 2 patients with clinical nephropathy will be hypertensive.

Clinical concomitants of nephropathy

Most patients with nephropathy will also have retinopathy and neuropathy (the so-called 'triopathy' of microvascular complications), which will also tend to progress along with nephropathy.

However, the most serious comorbid complication of nephropathy is macrovascular disease. The reported relative mortality for European 40-year-old, type 1 patients with clinical nephropathy in Denmark was between 80 and 100 times that of the non-diabetic population, whereas the World Health Organization (**WHO**) study revealed a three- to fourfold excess for patients with type 2 disease. Most of these deaths are due to stroke or myocardial infarction, and in Finland type 1 patients with nephropathy have a 10-fold relative risk for both compared to non-diabetic controls. Similar increases, but of lower magnitude, are seen in type 1 and 2 patients with incipient nephropathy. The reasons are unclear, but increasing blood pressure is certainly a factor, together with the unfavourable blood lipid profile found in patients with an increased UAER.

Non-nephropathic renal disease in diabetes

It is important to remember that not all renal or urinary tract disease in diabetic patients is due to 'diabetic nephropathy'. Urinary tract infection is more common in diabetic women, many of whom are asymptomatic. Urine culture should always be performed in patients with an isolated positive urinalysis for protein. Papillary necrosis is also more common in women with longstanding type 1 diabetes, and is a recognized complication of hyperosmolar coma in patients with type 1 and type 2 disease. Atheromatous vascular disease is common in diabetics and can cause renal artery stenosis, but the prevalence of functionally significant stenosis is not known.

Epidemiology

The incidence of diabetes is increasing worldwide, most rapidly in developing countries. It is estimated that by 2010 there will be a near-doubling of people with the condition to 221 million (5 million with type 1 and 216 million with type 2 disease).

Some of the wide variation in the reported prevalence of incipient and clinical nephropathy can be explained by different selection of the population under study, and by the use of different defining levels of UAER. However, selecting only population-based cohorts with good patient ascertainment, gives prevalence rates for incipient nephropathy of between 5 and 21 per cent for type 1 and 11 to 42 per cent for type 2 disease. Annual incidence rates are similar at around 2 per cent for both type 1 and type 2 patients.

For clinical nephropathy, the prevalence is 6.4 per cent in type 1 patients in the United Kingdom, with a range from 5 to 33 per cent reported worldwide for type 2. A cumulative incidence of approximately 20 per cent after 20 years' duration was found in the type 1 diabetic cohorts of the Steno Hospital in Denmark and Joslin Clinic in the United States, and similar figures have been reported for patients with type 2 diabetes in the United States (25 per cent) and Germany (27 per cent). Although reported annual incidence rates vary from 0.4 to 3.6 per cent, these are highly dependent upon the duration of diabetes in the population under study.

The Steno and Joslin cohorts have shown a 20 to 30 per cent lower incidence of clinical nephropathy in those type 1 patients diagnosed with diabetes in the 1950s and 1960s, compared to those diagnosed 20 years earlier. A single clinic in Sweden reports no patients with clinical nephropathy after 15 years' disease duration in patients diagnosed between 1976 and 1980, compared to 15 per cent and 5 per cent in patients with diabetes onset from 1961 to 1965 and 1966 to 1975, respectively. This reduction has not been seen in other clinics such as the Steno Hospital, for example. There are fewer data in patients with type 2 diabetes, but a recent study from the United States suggests that proteinuria is less common at diagnosis of diabetes, but that its incidence thereafter has not changed in the last 20 years.

Many countries now have registers of patients entering renal replacement therapy and all have shown a dramatic increase in the numbers with diabetic nephropathy. It is not clear, however, whether this is a true increase in the numbers of diabetic patients developing ESRF or a reflection of a change in acceptance policy. Either way, there is going to be a continuing increase in the number of patients with diabetes presenting for renal replacement, particularly from ethnic minorities (Afro-Caribbean and South African), who will make up around 50 per cent of such patients in the United Kingdom by 2001. The reasons for the excess risk of ECRF in these groups is unclear but may be genetic, related to hypertension, or the result of fetal programming. Although patients with type 2 disease have always been thought to develop ESRF less frequently than those with type 1, this may have been because such patients were not referred, or that they died of cardiovascular disease before entering renal failure. In 1997, 71 per cent of all diabetic patients on dialysis in the United States were classified as having type 2 disease.

Pathogenesis

Glycaemia

Observational studies have shown that sustained poor glycaemic control is associated with a greater risk for the development of nephropathy in both type 1 and type 2 diabetes. There are several potential mechanisms by which hyperglycaemia may cause nephropathy. These are common to all the microvascular complications of diabetes and are reviewed in Section 12.11.

Haemodynamic factors

Studies of experimental diabetes in the rat suggested that hyperfiltration alone could cause glomerulosclerosis. The evidence in humans is conflicting, and not helped by differing definitions of an abnormally high GFR. It appears that the rate of decline of GFR in hyperfiltering type 1 patients with a normal UAER is greater than that seen in age- and duration-matched normal GFR controls, but the numbers that go on to develop incipient nephropathy are similar in both groups. In Pima Indians with type 2 diabetes, their baseline GFR is not linked to the subsequent development of incipient or clinical nephropathy.

Growth factors

In experimental animals, the initial increase in kidney size is preceded by an increase in renal production of insulin-like growth-factor 1, and there are reports of increased circulating and urinary levels in diabetic people. However, there is no conclusive link between the initial kidney size or the renal expression of growth factors and the subsequent development of nephropathy in humans.

Hypertension

Systemic blood pressure is higher in patients with type 1 diabetes who subsequently develop incipient nephropathy. In Japanese people and Pima Indians, a prediabetic mean arterial pressure higher than 97 mmHg (>130/80 mmHg) strongly predicts the development of proteinuria. A family history of hypertension has been found in one study of type 1 patients with nephropathy, but not by another.

The situation in Europid type 2 diabetes may be different. In the UKPDS, hypertension (defined as above 160/90 mmHg or above 150/85 on treatment) was present in over 30 per cent of newly diagnosed patients, only a third of whom had increased albuminuria. Cohorts of normotensive (below 140/90 mmHg) type 2 patients with incipient nephropathy from Israel, Japan, and India showed little change in blood pressure over 7, 4, and 5 years, respectively, despite an increase in their UAER over this time.

It is not clear whether the observed changes in blood pressure initiate the nephropathic process or occur as a result of it. What is certain is that progression of nephropathy is much faster in patients with higher systemic blood pressures.

Genetics

There is a greater than 80 per cent concordance for nephropathy and a more than 73 per cent concordance for normal UAER in siblings of patients with type 1 diabetes. In Pima Indians, the prevalence of nephropathy is 14 per cent in the offspring of parents neither of whom have nephropathy, compared to 46 per cent of offspring when both parents have the condition. These observations have led to many studies looking for a possible genetic cause of nephropathy, most of which have used the candidate-gene approach. The most intensively studied genetic abnormality has been the insertion/deletion polymorphism in the angiotensin-converting enzyme (**ACE**) gene, but the results are inconsistent. Other candidate genes that have been studied include polymorphisms of the angiotensinogen, angiotensin-II type 1 receptor, collagen type IV, and aldose reductase genes: results have been variable.

Alterations in cell-membrane ion transporters have been described in patients with nephropathy, notably the red cell sodium–lithium exchanger and the sodium–hydrogen antiporter. Increased activity of the sodium–lithium exchanger is linked to increased blood pressure in non-diabetic subjects, and the sodium–hydrogen antiporter is closely linked to cell responses to growth factors, both of which have a degree of heritability. There is continuing controversy about the importance of these abnormalities in diabetic nephropathy.

Mechanical and structural factors

In experimental diabetes, intraglomerular capillary pressure is closely linked to the development of glomerulosclerosis. It is not possible to measure intraglomerular pressure directly in humans, but mathematical modelling suggests an increase in early nephropathy.

Glomerular volume is increased at diagnosis of type 1 diabetes and is a feature of clinical nephropathy in both type 1 and type 2 disease. A link between baseline glomerular size and subsequent progression to sclerosis has been described in patients with minimal-change disease, but the connection in diabetes is not proven.

Reductions of heparan sulphate proteoglycan in the intercellular matrix of diabetic patients and the GBM of those with incipient and clinical nephropathy have been reported. Workers at the Steno Hospital in Denmark suggested that this might relate to increased tissue damage in the micro- and macrovasculature, but this interesting hypothesis remains unproven.

Fetal programming

The low birth weight-thrifty phenotype hypothesis proposes intrauterine malnutrition as a possible cause of adult hypertension and diabetes, perhaps mediated via reduced numbers of renal glomeruli or islets of Langerhans, respectively. Studies have failed to find lower glomerular numbers in diabetic patients with nephropathy compared to those without, and no consistent correlation between birth weight and adult glomerular number has been found.

Other factors

Smoking rates are higher in diabetic patients with nephropathy, although a plausible mechanism of effect has yet to be defined. A link between raised blood lipids and the causation and progression of renal disease is still hotly debated. Both cross-sectional and prospective studies have shown an association between plasma total cholesterol and triglyceride levels and the UAER, but not between plasma lipids and a change in GFR.

In experimental diabetes, dietary protein restriction can prevent glomerulosclerosis. The cross-sectional EURODIAB study of patients with type 1 diabetes found that the UAER increased in patients with a protein intake of more than 20 per cent of their total food energy, whilst in the Hoorn Study of type 2 diabetic and normal subjects, a 0.1 g/kg body weight per day increase in protein intake was associated with a greater risk of developing microalbuminuria.

Finally, abnormalities of endothelial function, assessed by increases in plasma von Willebrand factor and homocysteine levels, have been described in diabetic patients with initially normal albuminuria who go on to develop incipient nephropathy, as well as in those with a persistently increased UAER at baseline. The EURODIAB investigators suggest that endothelial dysfunction provides a unifying hypothesis of micro- and macrovascular disease in diabetes.

Investigation

The diagnostic criteria for incipient and clinical nephropathy have already been discussed: the choice of urine sample (either timed or spot) and test (either absolute concentration or corrected for creatinine) depend largely upon local factors and patient acceptability. A diagnostic cascade is shown for a single (spot) urine sample in Fig. 1.

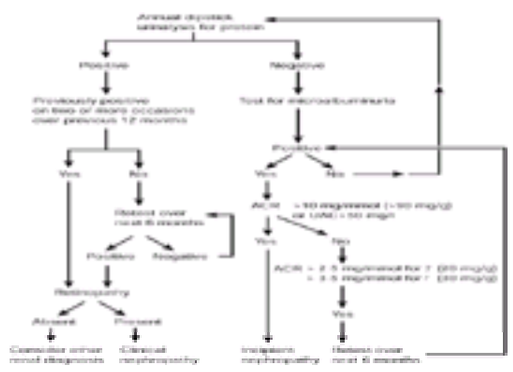

Fig. 1 Flowchart for the diagnosis of incipient and clinical nephropathy. (NB Assumes sterile urine throughout. Exclude infection when proteinuria is first detected and at any time thereafter if there is a history of a urinary tract infection.) ACR, albumin:creatinine ratio; UAC, urine albumin concentration.

Because diabetes is so common, particularly in the elderly, other common nephropathies and uropathies must be excluded if the clinical picture is atypical (for example, renal impairment in the absence of significant proteinuria). In addition, non-diabetic glomerular disease should be considered in proteinuric patients without retinopathy, and in those with an unexpectedly rapid deterioration in renal function, or in whom there are features of other systemic disease. Renovascular disease should be considered whenever an acute increase in plasma creatinine follows initiation of ACE inhibitor therapy, or in those with hypertension that is refractory to treatment.

Treatment

Most studies of treatments for diabetic nephropathy have used surrogate endpoints of efficacy such as a reduction in the UAER. Few have had sufficient statistical power to determine whether the therapy under investigation prevents death, reduces the number of patients entering ESRF, slows the rate of decline of GFR, or slows or reverses the progression of the pathological lesions underpinning nephropathy.

Glycaemic control

Up until 1993, there had been several well-planned, but relatively small, studies of the impact of intensified glycaemic control on the development of nephropathy in type 1 diabetes, with meta-analysis confirming significant benefit. Later that year the definitive Diabetes Control and Complications Trial (**DCCT**) showed that 9 years of intensive (mean Hb A_{1c} 7.2 per cent (normal <6.05 per cent)) compared to conventional insulin therapy (Hb A_{1c} 9.1 per cent) produced a 44 per cent reduction of development of incipient nephropathy (UAER >40 mg/day) in patients with no retinopathy, and 35 per cent reduction in patients with early retinopathy at entry (Table 3). However, the cumulative incidence of incipient nephropathy was still 15 and 27 per cent in the intensively treated patients in the two cohorts.

In patients with type 2 diabetes, there has been one small study from Japan (*n* = 110) and the much larger UKPDS cohort of 3867 newly diagnosed patients of mixed ethnicity. The Japanese study used an almost identical protocol to that of the DCCT, and showed a reduction in incipient nephropathy (UAER >30 mg/day) in the intensively treated group from 28.0 to 7.7 per cent (*p* = 0.032) in those without and 32.0 to 11.5 per cent (*p* = 0.044) in those with retinopathy at entry. In the UKPDS, the percentage of patients developing incipient nephropathy (urinary albumin concentration >50 mg/l) was lower at 19.2 versus 25.4 per cent (*p* <0.001) in the intensively treated cohort after 9 years, representing a risk reduction of 24 per cent (Table 3).

There is continuing controversy as to whether intensive glucose control alone can prevent the progression of incipient to clinical nephropathy. Careful analysis shows that of the 73 patients with a UAER over 40 mg/day at entry into the DCCT, equal numbers developed clinical nephropathy in both the intensive and conventional groups. The UKPDS also found no impact of intensive therapy on the development of a urinary albumin concentration above 300 mg/l (4.4 versus 6.5 per cent at 9 years, relative risk (99 per cent confidence interval (**CI**)) 0.67 (0.42 to 1.07). It therefore seems that once the UAER exceeds 30 to 40 mg/day, other factors (such as blood pressure control) are of more importance for progression.

There are no conclusive data on the impact of improved glycaemic control on the development of endstage renal disease, GFR progression, or death in patients with type 1 diabetes. The UKPDS did show a positive benefit of intensive therapy on the rate of doubling of serum creatinine at 12 years (0.91 versus 3.52 per cent, *p* <0.003) in patients with type 2 diabetes. Pancreas transplantation in type 1 patients has demonstrated that long-term (10 years) glycaemic normalization can reverse established pathological changes in glomeruli. Thus glomerulopathy may take as long to reverse as it does to develop. Notwithstanding this, it is important to remember that good glycaemic control is of proven benefit for retinopathy and therefore still an important goal of treatment in patients with nephropathy.

Blood pressure control

There have been many more studies of antihypertensive therapy than of improved glycaemic control in diabetic nephropathy. For clarity, these will be dealt with under three headings: primary prevention (of incipient nephropathy); secondary prevention (of clinical nephropathy); and tertiary prevention (of endstage renal disease and death).

Primary prevention

The EUCLID study showed that a UAER between 5 and 20 µg/min could be reduced by 2 years' treatment with the ACE inhibitor lisinopril in normotensive (systolic blood pressure <155, diastolic 75–90 mmHg) type 1 patients. There are no comparable studies in patients with type 2 diabetes, but short-term reductions in the UAER have been demonstrated. In the blood pressure control arm of the UKPDS, the percentage of hypertensive patients developing incipient nephropathy at 6 years was 2.3 per cent in the tight (average blood pressure 144/82 mmHg) and 12.5 per cent in the less tight (average blood pressure 154/87 mmHg) control groups (*p* <0.009). This benefit was seen whether the main treatment was with ACE inhibitors or b-blockers.

Secondary prevention

All studies falling into this category have shown a short- to medium-term benefit of all antihypertensive therapies on UAER in the incipient nephropathy range, although, as a general rule, ACE inhibitors seem to be more effective.

In an attempt to explore whether ACE inhibitors are uniquely beneficial, investigators have tried to select normotensive patients and compare active treatment to placebo. In mainly European patients with type 1 diabetes with a mean entry blood pressure of 122/77 mmHg, a combined analysis of one European and one American study (total *n* = 225) showed an adjusted risk reduction of 63 per cent (95 per cent CI, 16–84 per cent; *p* = 0.017) for the development of clinical nephropathy comparing captopril 100 mg/day with placebo. Three smaller studies in normotensive (<140/90 mmHg) type 2 patients have reported a similar reduction in the rate of development of clinical nephropathy. In hypertensive type 2 patients, the angiotensin II receptor blocker irbesartan also reduced the rate of progression from incipient to clinical nephropathy by around two-thirds. The much larger Heart Outcomes Prevention Evaluation (**HOPE**) study demonstrated fewer patients progressing from incipient (albumin:creatinine ratio (ACR) >2 mg/mmol) to clinical nephropathy when treated with 10 mg ramipril. Thus blockade of the renin–angiotensin system by any means appears to confer benefit. Accurate data on GFR are not given in these studies, but in type 1 hypertensive patients, long-term ACE inhibitor therapy appears to stabilize renal function. Interpretation of these studies is difficult: actively treated patients have nearly always had significantly lower blood pressures than the placebo groups, and whilst mathematical corrections for these differences can be applied, the magnitude of the biological consequences of blood pressure reduction cannot be precisely determined.

Tertiary prevention

Studies in the early 1980s established that lowering blood pressure in hypertensive (>160/95 mmHg) type 1 patients with clinical nephropathy resulted in a more than 50 per cent reduction in the UAER and a significant slowing down of the rate of decline of the GFR from 10 to 3 ml/min per year. In those with normal blood pressure, the Collaborative Study Group Trial in type 1 diabetes compared the addition of captopril 100 mg per day to placebo in 409 patients with nephropathy and an entry blood pressure of less than 140/90 mmHg. A significant reduction (35 versus 78 per cent, *p* <0.001) in the numbers of patients doubling their baseline serum creatinine concentration was seen in the captopril-treated patients, although this significance was confined to those with an entry serum creatinine concentration of more than 133 µmol/l (1.5 mg/dl). A similar reduction of 30 versus 70 per cent (*p* = 0.002) in the combined endpoint of death or the need for renal replacement therapy was also seen in the same group.

In patients with type 2 diabetes, the results are less consistent and complicated by the greater frequency of cardiovascular comorbidity. In those studies of more than 2 years' duration, all show sustained reductions in proteinuria but a variable, although usually consistent, slowing of the rate of GFR decline. Two recently reported studies using angiotensin II receptor blocking agents in patients with clinical nephropathy have shown a reduction in the rate of doubling of serum creatinine of between 25 and 33 per cent, less than that seen in type 1 patients but significantly better than that observed in patients randomized to the calcium channel blocker amlodipine. Taken together the studies in type1 and 2 patients support the use of drugs which block the renin–angiotensin system as first-line therapy in both incipient and clinical nephropathy.

Non-renal outcomes

Several large studies of the effect of antihypertensive therapy on cardiovascular mortality and morbidity have been published; many have included sizeable cohorts of

diabetic patients, although rarely specifying their nephropathic status. All have shown that low blood pressure is associated with a reduction in overall mortality and stroke incidence, although the effect on myocardial infarction is inconsistent. Diabetic patients on the whole had greater benefit, with no clear-cut advantage from any specific drug.

Treatment targets

There is uncertainty as to what should be the target blood pressure for diabetic patients, irrespective of their nephropathy status. The recommendation of the British Hypertension Society is 140/85 mmHg, and 130/85 mmHg from the American Diabetes Association. Achieving these targets is difficult, particularly in patients with type 2 disease, and especially for systolic hypertension. In the UKPDS by year 9, 27 per cent of 758 patients in the tight blood pressure control arm were on three or more drugs, their average blood pressure was 144/82 mmHg, and 44 per cent had levels above 150/85. However, as with blood glucose levels, it seems that any reduction confers benefit and the lowest achievable (and tolerated) is probably the best target.

Other treatments

Low-protein diets have been shown by meta-analysis to slow the rate of decline of GFR in diabetic patients. Current dietary recommendations are for an intake of between 0.7 and 0.9 g protein/kg body weight per day.

Aspirin in a dose of 325 mg/day reduced myocardial infarction (relative risk (**RR**) 0.72, 99 per cent CI 0.55–0.95) in 3711 type 1 and 2 patients with retinopathy. Although nephropathy status was not determined in this study, aspirin use is advised for all patients with an increased UAER (unless contraindicated) because of their high risk of cardiovascular disease. Similarly, lipid-lowering therapy should also be considered, but there are no data on the impact of such treatment on the progression of nephropathy.

Experimental therapies include agents that inhibit the formation of advanced glycation endproducts (such as aminoguanidine), and third-generation aldose reductase inhibitors. Antagonists of endothelin and neuroendopeptidases are in advanced phase III studies.

Treatment of endstage renal disease

Diabetic patients do less well on all modalities of renal replacement therapy than their non-diabetic counterparts, with higher cardiovascular mortality. The European survival figures for diabetic patients from 1983 to 1992 are dismal: 23 per cent alive at 5 years, compared to 56 per cent of non-diabetic patients. In the United States, the death rate for never-transplanted, 20- to 44-year-old diabetic patients from 1993–1995 was 160.7 per 1000 patient-years, compared to 83.3 for non-diabetic subjects. Overall survival is best in those with a successful kidney transplant, and recent data from the United States estimates an increased survival of 11 years for diabetic patients receiving an allograft compared to those who remain on dialysis.

Management strategy

Because the outcomes of patients with diabetic nephropathy are so poor, many national guidelines now suggest a multiple risk-factor approach to management. These initiatives have been given impetus by the observation that many patients referred to renal units in Europe have: inadequate blood pressure control; low use of therapies of proven benefit in heart and kidney disease (for example b-blockers, ACE inhibitors, lipid-lowering therapy, low-dose aspirin); and poor assessment of comorbidities such as retinopathy and foot care.

The St Vincent Declaration Taskforce recommends that all patients with nephropathy need to be referred to a nephrologist when their plasma creatinine concentration exceeds 200 µmol/l (2.2 mg/dl). However, before this, many are now proposing multiple cardiovascular risk-factor reduction, aiming for:

- a target blood pressure at least below 140/80 mmHg;
- a target total cholesterol concentration below 5 mmol/l;
- ACE inhibitor use as part of, or in addition to, antihypertensive therapy;
- low-dose aspirin; and
- invasive investigation and correction of coexistent cardio-, cerebro-, and peripheral arterial disease.

Screening for nephropathy

Because of the strong associations between an increased UAER and cardiovascular disease, a case for screening for diabetic nephropathy can be made with some confidence, although the evidence base for beneficial intervention at lower levels of albuminuria is less secure. Current recommendations from national diabetes associations recommends at least annual screening based upon the diagnostic flowchart shown in Fig. 1. Extrapolating the known effects of ACE inhibitors on a reduction of UAER to the prevention of clinical nephropathy and thus endstage renal disease, several authors show a potential cost benefit from the early use of these drugs. However, only long-term prospective studies of primary prevention can conclusively answer this question.

20.10.2 Hypertension and the kidney

Lawrence E. Ramsay

This section describes the effects of hypertension on kidney function; renal and renovascular disease causing hypertension are described in Chapter 15.16.2.2. The impact of accelerated hypertension on renal function, and of hypertension and its treatment on the progression of established renal failure, are reasonably clear. There is debate about whether hypertension causes renal failure in the absence of accelerated phase, renovascular disease, or undetected primary renal disease.

Accelerated hypertension and the kidney

Accelerated (or malignant) hypertension is defined by bilateral fundal haemorrhages and exudates. Papilloedema may be present but is not necessary for the diagnosis. The condition is fully described in Chapter 15.16.3. Pathological changes in the kidney include 'onion skin' intimal proliferation in interlobular arteries with narrowing or loss of the lumen, ischaemic atrophy of nephrons, and fibrinoid necrosis of arterioles. These are caused by disruption of the arteriolar wall by severe or rapidly increasing hypertension, allowing insudation of plasma and fibrin deposition. The clinical correlate is moderate to severe renal impairment in one-third of patients with accelerated hypertension, or (uncommonly) oliguric acute renal failure. When blood pressure is controlled there may be slight deterioration of renal function over 1 to 2 days, but renal function then stabilizes and often recovers slightly. Patients with oliguric acute renal failure caused by accelerated hypertension may have excellent recovery of renal function even after prolonged dialysis. However, those who present with serum creatinine of 300 µmol/l or higher (but not oliguric renal failure) often progress to endstage renal disease despite good control of blood pressure and in the absence of a primary renal or renovascular cause. By contrast, in idiopathic accelerated hypertension with serum creatinine less than 300 µmol/l renal function usually remains stable, and deterioration despite good blood pressure control should raise suspicion of a primary renal or renovascular cause.

The 5-year survival of patients with accelerated hypertension has improved dramatically, from 1 per cent without treatment to 75 per cent with modern treatment, but the prognosis is still impaired, with mortality of 25 per cent over 5 years. Renal impairment is a powerful determinant of prognosis, and prevention by urgent treatment of accelerated hypertension is therefore crucial. Bilateral haemorrhages and exudates, even without papilloedema, constitute a medical emergency requiring immediate admission. An underlying cause for hypertension, commonly renal or renovascular disease, is present in about a quarter of patients with accelerated hypertension (see Chapter 15.16.2.1 and Chapter 15.16.3).

Hypertension and progression of chronic renal failure

Hypertension is the rule in advanced renal failure of any cause, but occurs earlier in glomerular than interstitial renal disease. The mechanism is inability to excrete a sodium load plus inappropriately high peripheral vascular resistance, i.e. an imbalance between volume and vasoconstriction. Uncontrolled hypertension accelerates the progression of renal failure.

Diabetic nephropathy

As discussed in Chapter 20.10.1, antihypertensive treatment retards the progression of diabetic nephropathy from its earliest stages, slowing progression of microalbuminuria to overt proteinuria, and the decline of glomerular filtration rate in established diabetic nephropathy. Treatment with angiotensin converting enzyme inhibitors confers additional protection, but control of blood pressure probably outweighs any specific effect of angiotensin converting enzyme inhibition. The evidence is stronger for type 1 than type 2 diabetes, but all patients with diabetic nephropathy should have antihypertensive treatment that includes an angiotensin converting enzyme inhibitor. The blood pressure target is (in most cases) as low as is achievable, ideally less than 130/80 mmHg, or less than 125/75 mmHg when there is proteinuria greater than 1 g/24 h.

Non-diabetic nephropathy

There is a relation between the level of blood pressure and the rate of decline of the glomerular filtraton rate in patients with renal impairment, suggesting that uncontrolled hypertension accelerates progression. The putative mechanism is impaired autoregulation in damaged kidneys so that systemic hypertension translates to glomerular hypertension, glomerulosclerosis, and progression of renal failure. Control of blood pressure slows progression, and blood pressure of 140/90 mmHg or more should be treated in any patient with renal disease.

Target blood pressure in renal failure

The Modification of Diet in Renal Disease Study, in addition to looking at the effects of diet, compared antihypertensive treatment titrated to targets equivalent to 140/90 mmHg or 125/75 mmHg in patients with various non-diabetic renal diseases and renal impairment. The overall analysis showed no significant relation between target blood pressure and decline of glomerular filtration rate. However, subgroup analysis showed a substantially slower decline in renal function in patients with proteinuria of 3 g/24 h or more, a similar trend with proteinuria of 1.0 to 2.9 g/24 h, but no benefit when proteinuria was less than 1 g/24 h, or in patients with polycystic kidneys (Fig. 1).

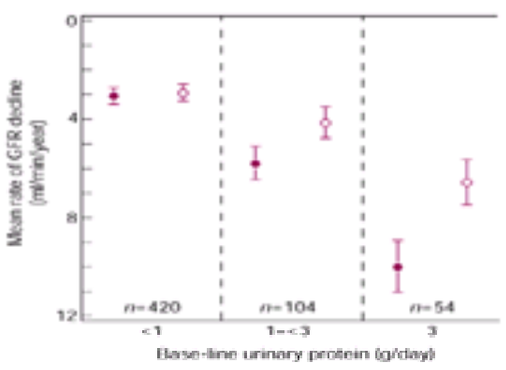

Fig. 1 Decline in glomerular filtration rate related to baseline urinary protein excretion and target blood pressures in patients with non-diabetic chronic renal disease. Solid circles (•) indicate target blood pressure of 140/90 mmHg, open circles () a target blood pressure of 125/75 mmHg. More aggressive blood pressure control

slowed the rate of progression with proteinuria of 3 g/day or more, with similar trends for proteinuria of 1 to 2.9 g/day. There was no apparent effect with proteinuria of less than 1 g/day. (From the Modification of Diet in Renal Disease Study study (Klahr S *et al*. 1994 *New England Journal of Medicine* **330**, 877–84) with permission.)

Angiotensin converting enzyme inhibitors

Treatment that includes an angiotensin converting enzyme inhibitor slows progression of renal failure in selected patients, and the Ramipril Efficacy in Nephropathy (REIN) study suggests specific benefit from angiotensin converting enzyme inhibition over and above reduction of blood pressure. Benefit is large in those with glomerular disease, and small or absent in interstitial disease, polycystic kidneys, or nephrosclerosis. Rapid progression determines the outcome of treatment with angiotensin converting enzyme inhibitors and is predicted by proteinuria and the severity of renal failure. Treatment with angiotensin converting enzyme inhibitors is indicated in any patient with hypertension (³ 140/90 mmHg), renal impairment, and proteinuria of 1 g/24 h or more. Angiotensin converting enzyme inhibitors cause renal failure in critical renovascular disease, and there was concern that patients with renal parenchymal disease could be at similar risk because of 'functional' vascular insufficiency. Trials do not support this concern as withdrawals because of renal failure or hyperkalaemia were no more common with angiotensin converting enzyme inhibitor than with placebo.

Conclusions

Blood pressure of 140/90 mmHg or more should be treated in all patients with renal impairment. When proteinuria exceeds 1 g/24 h the regimen should include an angiotensin converting enzyme inhibitor and the target is less than 125/75 mmHg. Angiotensin converting enzyme inhibitors rarely cause serious adverse effects, but renal function and serum potassium should be monitored.

Idiopathic hypertension and renal failure

Introduction

Renal function is altered in early idiopathic hypertension, with reduced renal blood flow, increased efferent arteriolar tone, but maintained glomerular filtration rate. In experimental animals such changes can cause intraglomerular hypertension, hyperfiltration, and glomerulosclerosis. An unresolved question is whether idiopathic non-accelerated hypertension causes similar renal damage in humans, and, if so, whether antihypertensive treatment prevents this. This question is important. If idiopathic hypertension causes endstage renal disease despite conventional antihypertensive treatment, possible responses are to treat even milder hypertension, to lower blood pressure targets, or to prefer antihypertensive drugs that may be renoprotective. If idiopathic hypertension is an innocent bystander when proteinuria or renal failure develops, the response should be to seek the true cause of the renal abnormality which might be undiagnosed glomerular, interstitial, or vascular renal disease.

Pathology

Nephrosclerosis is characterized by hyaline arteriosclerosis in arterioles and intimal fibroelastic reduplication in interlobular arteries. Some view these these changes as confined to vessels, with no encroachment on lumina, glomerular loss, or other important consequences, and consider them entirely benign and not even specific for hypertension. Others believe that preglomerular arteriosclerosis leads to glomerulosclerosis and loss of renal function through narrowing or occlusion causing ischaemia, or by failure of autoregulation causing intraglomerular hypertension.

Outcome trials

The incidence of endstage renal disease or other renal endpoints has been very low in outcome trials and no effect of treatment on renal function has been observed. These trials have included over 50 000 hypertensives, suggesting that renal failure is at most a rare complication of idiopathic hypertension. However, the trials have been short, averaging 2 to 3 years, and have not studied renal function in detail because of the focus on stroke and coronary complications.

Cohort studies

Uncontrolled studies over 5 to 14 years in treated hypertension have shown renal failure or proteinuria developing in 0 to 18 per cent of patients despite adequate control of blood pressure. These studies were in hospital patients with fairly severe hypertension and had inadequate criteria for excluding intrinsic renal disease causing the hypertension. In the MRFIT study (see below) men with serum creatinine of less than 106 µmol/l and proteinuria of less than 1+ at entry were followed for 16 years. The risk of endstage renal disease almost doubled with increased baseline blood pressure of 15/10 mmHg, but the incidence was still very low in absolute terms. Furthermore, undiagnosed primary renal disease could still have caused the endstage renal disease and explained its relation to blood pressure, even in this cohort, because normal serum creatinine and urine protein do not exclude renal causes for hypertension such as renovascular disease, glomerulonephritis, or renal scarring.

Endstage renal disease

Hypertensive nephrosclerosis is said to account for a quarter of entries to endstage renal disease programmes, but this diagnosis is usually presumptive and may often be incorrect. Presumptive diagnoses will include undiagnosed renovascular disease, undiagnosed parenchymal disease, and undiagnosed or forgotten episodes of accelerated hypertension. In one centre 11 per cent of cases having renal replacement were attributed to hypertension. When examined in detail 45 per cent had documented accelerated phase, 15 per cent had scarring or glomerular disease, 4 per cent renovascular disease, and only 2 per cent had documented hypertensive nephrosclerosis. The remaining 34 per cent of patients had hypertension, endstage kidneys, and no definite diagnosis, but had been labelled as having hypertensive nephrosclerosis.

Epidemiological data

The association of endstage renal disease with seven blood pressure strata in the MRFIT cohort of 332 544 men followed for 16 years is shown in Table 1. There is a clear graded association, but the absolute risk in men with mild to moderate hypertension is very small, for example 1/637 over 10 years with blood pressure of (140 to 159)/(90 to 99) mmHg when compared with blood pressure of less than 120/80 mmHg. As discussed above, this association could be explained by undiagnosed intrinsic renal disease or development of renovascular disease. The significant risk factors for developing endstage renal disease were older age, low income, high cholesterol, smoking, diabetes, and hypertension. Note that these are the major risk factors for atherosclerosis, and development of atherosclerotic renovascular disease could cause endstage renal disease in mild to moderate hypertension.

Conclusions

Renal failure and proteinuria in mild to moderate hypertension usually indicate underlying renal or renovascular disease. When renal damage is present, consider whether the hypertension is, or has been, severe enough to cause accelerated phase. If not, assume that intrinsic renal disease or renovascular disease is present and investigate appropriately. If it has, a presumptive diagnosis of renal damage caused by present or past accelerated hypertension should be confirmed by careful follow-up. Deterioration of renal function despite reasonable blood pressure control should prompt investigation for a cause other than the hypertension.

20.10.3 Vasculitis and the kidney

A. J. Rees

Introduction

This chapter is concerned with a heterogeneous group of disorders commonly referred to as the primary systemic vasculitides. These are defined by the presence of inflammation and necrosis of blood vessels, with the individual clinical syndromes defined by the size and distribution of the vessels involved and whether vasculitis is accompanied by granulomas. The diseases include polyarteritis nodosa, Wegener's granulomatosis, microscopic polyangiitis, and Churg–Strauss syndrome, the renal aspects of which are emphasized in this chapter. The aetiology and pathogenesis of these disorders have not been elucidated, but the strong association between some of them and autoantibodies to neutrophil cytoplasmic antigens (antineutrophil cytoplasmic antibodies: **ANCA**) suggests an autoimmune pathogenesis.

Vasculitis is an important treatable cause of renal failure, most commonly when the glomerular capillaries are involved thus causing focal necrotizing glomerulonephritis. This is common in patients with generalized small vessel vasculitis, such as Wegener's granulomatosis and microscopic polyangiitis, both of which are closely associated with ANCA. Some patients presenting with focal necrotizing glomerulonephritis without evidence of involvement of other organs also have positive assays for ANCA. The appearance on renal biopsy is identical to microscopic polyangiitis, as is the response to treatment. Other organs can be involved later in the course of the disease, and autopsies have demonstrated more widespread disease even at the outset. For these reasons, ANCA-associated focal necrotizing glomerulonephritis in the absence of any evidence of generalized disease is usually considered to be a form of microscopic polyangiitis, and will be discussed as such in this chapter.

Focal necrotizing glomerulonephritis usually presents with rapidly deteriorating renal function (rapidly progressive glomerulonephritis) and is caused most frequently by ANCA-associated vasculitis. However, this is not its only cause: focal necrotizing glomerulonephritis can complicate diseases described in other chapters, including hypersensitivity to drugs, systemic infections such as infective endocarditis, systemic immunological diseases (for example systemic lupus erythematosus, Henoch–Schönlein purpura, and rheumatoid arthritis), and as a paraneoplastic syndrome (Table 1). Whilst there are only subtle differences in the morphological appearances of the different types of focal necrotizing glomerulonephritis, there are marked differences in immunohistology, different types usually being separated on the basis of their pattern of glomerular immunoglobulin deposition (Table 1).

Focal necrotizing glomerulonephritis should be regarded as a medical emergency: because different types respond differently to treatment a precise diagnosis must be made promptly on clinical and serological grounds and confirmed by biopsy.

Historical perspective

Vasculitis was first described in autopsy material in the 1840s by Rokitansky but was not recognized as a specific entity until 20 years later. In 1866, Kussmaul and Maier described the case of a young man who presented with fever and muscle, renal, and gastrointestinal disease and at autopsy had widespread inflammation of medium-sized arteries with aneurysms to which the name periarteritis nodosa was applied. The heterogeneity of the disorder was recognized over the next 100 years and various different clinical syndromes were described. In 1923 Wohlwill distinguished a type of vasculitis that affected arterioles, capillaries, and venules as well as muscular arteries. Davson and his colleagues studied this condition in great detail in the 1940s and called it the microscopic form of polyarteritis (now more accurately called polyangiitis). In the 1930s Klinger, and then Wegener, described patients with microscopic polyarteritis in which many of the arthritic lesions were surrounded by granulomas. Disease in these patients had a predilection for the nose, upper airways, and lungs and constituted a distinct clinical syndrome, now called Wegener's granulomatosis. In 1954 Churg and Strauss described another distinct form of primary vasculitis characterized by granulomatous inflammation of medium-sized vessels associated with eosinophilia and asthma: this disease now bears their names. Despite their obvious differences, it should be remembered that Churg in particular regarded Wegener's granulomatosis, microscopic polyangiitis, and Churg–Strauss syndrome as closely related (with macroscopic polyarteritis regarded as being somewhat separate). The subsequent demonstration that ANCA are commonly present in all three of these conditions (but not in macroscopic polyarteritis) supports this suggestion.

Classification

The classic accounts of vasculitis established strict clinical and pathological criteria for diagnosis based on clinical histories and autopsies of patients with endstage disease. They defined the different clinical disorders and remain invaluable descriptions of their evolution. However, the diagnostic criteria they introduced are now far too restrictive because nowadays patients usually present at an early stage, with relatively mild or limited disease that can be controlled by present treatments before it has evolved into a 'classical' syndrome. The current emphasis on early diagnosis and treatment demands a more flexible approach. The finding that most patients with active small vessel vasculitis have circulating ANCA has proved to be especially useful, even though the role of ANCA in pathogenesis is uncertain. Differences in ANCA specificity have also tended to reinforce the idea that different vasculitic syndromes are distinct entities. Thus, most patients with active small vessel vasculitis have positive assays for ANCA, whereas patients whose disease in confined to the arteries do not.

The current more pragmatic approach to diagnosis is exemplified by the criteria developed by Lanham for Churg–Strauss syndrome, but generally the move towards more clinically based definitions has been a source of considerable controversy. New terms were introduced to describe 'incomplete variants', the distinction between classic (large vessel) and microscopic forms of polyangiitis became blurred, and different terms were used for the same entities, not only in different parts of the world but—worse still—by physicians practising in different specialties. In 1990, the American College of Rheumatologists attempted to clarify the situation by establishing standard diagnostic criteria for each of the main vasculitic syndromes, analogous to those that had proved highly successful for systemic lupus erythematosus. These criteria were based on clinical and pathological data collected from patients diagnosed as having the various types of systemic vasculitis, the data being used to derive mutually exclusive sets of criteria for diagnosing each condition. Unfortunately, they have not proved to be robust, especially for patients with extensive renal disease: for example, they do not accurately discriminate between patients with small vessel vasculitis and focal necrotizing glomerulonephritis and those with classical polyarteritis nodosa, or between cutaneous leucocytoclastic vasculitis and Henoch–Schönlein purpura. However, the American College of Rheumatologists

project was an important attempt to introduce greater uniformity, although it was flawed because differences in the pattern of disease of patients referred to different physicians was underestimated, and also because the drive for early treatment of patients with vasculitis reversed the injury before patients developed signs that enabled individual conditions to be distinguished from each other with confidence.

In an attempt to overcome these difficulties, the Chapel Hill Consensus Conference in 1994 brought together physicians from all the disciplines to which patients with vasculitis are commonly referred and pathologists with extensive experience of these diseases. The purpose was to establish a classification of vasculitis with a common nomenclature based on set working definitions for the different syndromes. It was recognized that it would not always be possible (or even relevant) to try to distinguish between some of the syndromes before treatment was started, and no attempt was made to establish strict diagnostic criteria although clearly the Chapel Hill classification provided a framework for diagnosis. The definitions of individual clinical syndromes built on previous work that classified vasculitis in terms of the size of vessel involved and the presence or absence of granulomas. Clinical definitions of the different types of vasculitis are shown in Table 2 and illustrated in Fig. 1. The essential feature is that the diagnosis depends on the size of the smallest vessel involved. Thus the term microscopic polyangiitis replaced the term microscopic polyarteritis because capillaries and venules are involved as well as arteries, and the diagnosis depends on their involvement regardless of whether or not small or medium-sized muscular arteries are also affected. By contrast, polyarteritis nodosa was defined as a form of vasculitis in which the vasculitis is confined to muscular arteries and the diagnosis excludes patients with evidence of injury to capillaries or venules. This terminology was justified by differences in the natural history and response to treatment of patients with and without small vessel involvement and is supported by the serological findings. Although not used as a primary diagnostic criterion, ANCA are very frequent in patients with small vessel vasculitis but uncommon in those whose disease is confined to larger vessels.

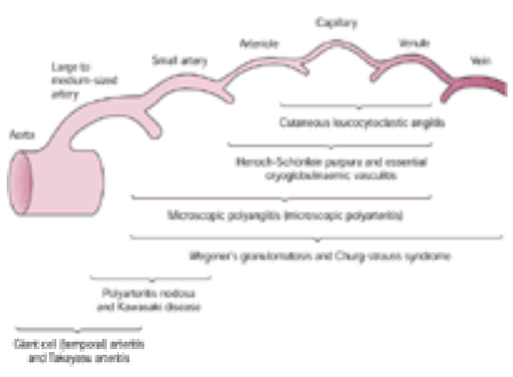

Fig. 1 Summary of the Chapel Hill classification of systemic vasculitis.

The Chapel Hill classification has been increasingly widely used since it was first introduced but should not be regarded as definitive. The very high prevalence of ANCA in patients with small vessel vasculitis has lead to the useful generic term ANCA-associated vasculitis, which includes Wegener's granulomatosis and microscopic polyangiitis as well as patients with isolated focal necrotizing glomerulonephritis without clinical evidence of extrarenal disease.

Antineutrophil cytoplasmic antibodies

ANCA were first identified in patients with small vessel vasculitis thought to be due to Ross River virus and were subsequently reported to be highly specific for Wegener's granulomatosis and microscopic polyangiitis. The antibodies are usually assayed by indirect immunofluorescence using ethanol-fixed normal human neutrophils as the substrate. They are heterogeneous, as reflected in the two distinct patterns of fluorescence that can be seen (Fig. 2 and Plate 1). Some sera display granular staining throughout the cytoplasm (cytoplasmic ANCA or **cANCA**), whereas with others the staining concentrates around the nucleus (perinuclear ANCA or **pANCA**); exceptional patients demonstrate a mixed pattern of staining.

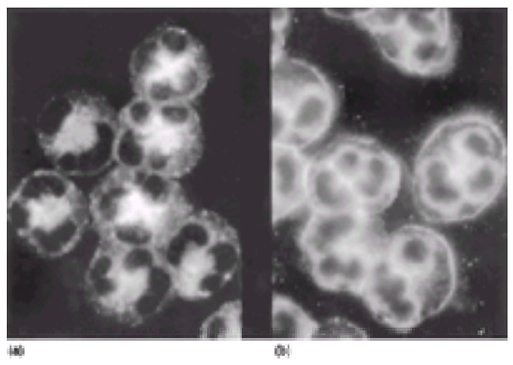

Fig. 2 Indirect immunofluorescence assay for ANCA. (a) Typical staining of cytoplasmic ANCA that is usually due to antibodies to proteinase 3. (b) Typical staining pattern of perinuclear ANCA most often due to antimyeloperoxidase antibodies. (See also Plate 1.)

Most ANCA bind to enzymes found in the neutrophil granules, and the commonest antigens in patients with small vessel vasculitis are proteinase-3, which is the principal target of cANCA, and myeloperoxidase, which is the most common target for pANCA. Antiproteinase-3 antibodies are almost invariably present in untreated patients with active systemic Wegener's granulomatosis, as well as a proportion of those with microscopic angiitis. Antimyeloperoxidase antibodies are usually found in the remaining patients with microscopic polyangiitis and in those with isolated focal necrotizing glomerulonephritis. However, it is important to recognize that ANCA are not unique to small vessel vasculitis and there is a growing list of conditions in which they have also been described, including inflammatory bowel disease, systemic lupus erythematosus, and some chronic infections. In these contexts it is rare for the ANCA detected to be directed against proteinase-3 and uncommon that they recognize myeloperoxidase. ANCA that recognize other antigens are found in a minority of patients with small vessel vasculitis (Table 3), and their targets include elastase, cathepsin G, lactoferrin, bacterial-permeability-increasing peptide, and the lysosomal membrane protein h-lamp-2. This last antigen is interesting in that it is also expressed on glomerular endothelium, and antibodies that recognize glomerular endothelium have previously been described in Wegener's granulomatosis.

A critical issue is whether assays for ANCA are specific and sensitive for small vessel vasculitis. Meta-analyses and large-scale multicentre prospective studies have confirmed the original impression that they are, provided that certain safeguards are met. When used alone, ANCA detected by indirect immununoflurescent assays have a sensitivity of 80 to 85 per cent and a specificity of around 75 per cent compared with disease controls. Specificity improves considerably when indirect immunofluorescence assays are used together with specific enzyme-linked immunoabsorbent assays to exclude patients who have ANCA directed against targets other than proteinase-3 and myeloperoxidase, and those with false positive assays caused by antinuclear antibodies. Combining indirect immunofluorescence with specific immunoassays for antibodies to proteinase-3 and myeloperoxidase increases both the sensitivity and the specificity of the assays for Wegener's granulomatosis and microscopic polyangiitis to over 90 per cent. However, the standard enzyme-linked immunoabsorbent assay for proteinase-3 and myeloperoxidase can occasionally give false negative results when circulating ANCA are bound to their natural inhibitors a $_1$-antitrypsin and caeruloplasmin. There are far fewer data about the use of ANCA for diagnosing Churg–Strauss syndrome: overall about 50 per cent of patients have positive assays for either proteinase-3 or myeloperoxidase, but a sufficiently large cohort of untreated patients has not been studied to establish a true incidence. ANCA are positive in fewer than 10 per cent of patients without evidence of involvement of capillaries or venules.

Incidence and aetiology

Primary systemic vasculitis is relatively uncommon, but the incidence is probably increasing, even allowing for greater awareness and improvements in diagnosis. The overall incidence in southern England is about 20 new patients per million population per year, with a similar incidence reported in Scandinavia. Men are more

commonly affected than women, and the incidence rises progressively with age, amounting to 60 per million per year for those aged 65 to 75. The annual incidence of ANCA-associated crescentic nephritis is 6 to 7 per million **,**accounting for at least 0.5 per cent of patients on dialysis in Europe. However, surveys of the ANCA status of dialysis patients suggest that both figures are underestimates because of underdiagnosis in patients presenting with renal failure and few extrarenal symptoms. The disease appears to be equally common in South Asian caucasoids, but studies from the United States indicate that African Americans are much less susceptible.

Genetic factors

The cause of primary systemic vasculitis is unknown, but heredity undoubtedly influences susceptibility as evidenced by reports of the disease occurring in siblings; however, identical twins discordant for the disease have also been observed. Polymorphisms of the a $_1$-antitrypsin locus influence susceptibility to Wegener's granulomatosis and cANCA positive vasculitis, case control studies showing that the Z allele, which causes relative antitrypsin deficiency, is much more common in patients than in controls. a$_1$-antitrypsin is the natural inhibitor of proteinase-3 (but not of myeloperoxidase) and so loss of this inhibition provides an apparent explanation for the findings, although an unconvincing one given the relatively trivial reduction in a $_1$-antitrypsin activity produced by the Z allele. It should also be noted that nearly 80 per cent of patients have the fully sufficient phenotype. There is a single study describing an association between the complement C3 allele *C3F* and vasculitis, which resulted in a relative risk of 2.6 in heterozygotes and 5.1 in homozygotes. By contrast, studies of the HLA class II complex have produced conflicting results.

Environmental factors

Environmental agents responsible for primary systemic vasculitis have proved even more difficult to identify than genetic factors, but drugs and infections have both been invoked. Hepatitis B carriers have been reported to develop polyarteritis nodosa in some populations (United States and France), but not in others such as the United Kingdom. Infection with parvovirus BIg has also been reported to cause polyateritis nodosa. Hypersensitivity to hydrallazine, rifampicin, and minocycline can cause ANCA-associated vasculitis, and there is convincing evidence that penicillamine causes pANCA-associated crescentic glomerulonephritis with or without pulmonary haemorrhage. Case controlled studies indicate that silica predisposes to ANCA-associated crescentic nephritis and Wegener's granulomatosis. It is difficult to evaluate descriptions of Churg–Strauss syndrome in patients with asthma treated with the leukotriene inhibitor Zafirlukast: asthma could have been the first symptom of the vasculitis, and corticosteroids, which would have been the alternative treatment, would also have been effective treatment for Churg–Strauss.

Pathogenesis

Explanations for the cause of injury in small vessel vasculitis must take account of the close association with ANCA, the extensive infiltration of vessels with neutrophil, endothelial activation, and the near absence of immunoglobulin deposition on immunohistology. Most authorities regard these conditions as autoimmune diseases, but proof is lacking and it is important to remember that 30 years ago they were generally believed to be systemic immune complex diseases.

A direct role for ANCA is suggested by their close association with injury in vasculitis, especially as ANCA titres often, though not invariably, increase before relapses of disease activity. The observation that vasculitis in spontaneous and induced models of autoimmunity in rodents is also associated with ANCA provides further support for the hypothesis. For example, *MRL/lpr* lupus prone mice and Kinjo mice both spontaneously develop vasculitis and focal necrotizing glomerulonephritis in association with ANCA. The real difficulty is to understand how ANCA could cause vasculitis, because neither proteinase-3 nor myeloperoxidase are expressed on endothelium. Three types of explanation have been proposed:

1. They could cause endothelial injury after release from neutrophils and monocytes because they prolong the activity of proteinase-3 and myeloperoxidase by interfering with binding to their natural inhibitors.
2. They activate neutrophils (and possibly endothelium) and so could facilitate endothelial injury.
3. They could bind to endothelium and so facilitate *in situ* immune complex formation between ANCA and their targets.

There has been widespread interest in the effects of ANCA on neutrophil function since the initial reports that they stimulated respiratory burst activity in neutrophils that had been primed with proinflammatory cytokines such as tumour necrosis factor. Proteinase-3 translocates to the plasma membrane when polymorphs are exposed to tumour necrosis factor, and the process is enhanced by the chemokine interleukin 8. *In vivo*, neutrophils from patients with active vasculitis express more proteinase-3 on their surface than neutrophils from controls. Incubation of primed neutrophils with ANCA increases superoxide generation and enzyme release and also interferes with normal control of apoptosis.

Regardless of how ANCA activate neutrophils, there is now a strong body of evidence to show that they facilitate the adherence of neutrophils to endothelium and neutrophil mediated killing of endothelial cells *in vitro*. At one stage it was thought that activated endothelium expressed proteinase-3 but this is now known not to be the case. It seems probable that ANCA aggravate neutrophil-dependent injury once they adhere in the microvasculature.

The question as to whether immune responses to proteinase-3 and myeloperoxidase cause vasculitis and glomerulonephritis directly has also been examined experimentally by infusing neutrophil granule extracts together with hydrogen peroxide (H $_2$O$_2$) into the renal arteries of rats that had previously been immunized with myeloperoxidase. This resulted in the development of severe focal necrotizing glomerulonephritis with very transient deposition of immunoglobulin, hence the injury simulated that seen in ANCA-associated vasculitis. Rats in whom the perfusion with H $_2$O$_2$ was omitted developed less severe injury and more persistent IgG deposits. In most respects this antimyeloperoxidase model is just another example of '*in situ* complex formation nephritis' similar to models used to examine other types of glomerular injury. The main difference is the transience of the IgG deposits, but even this has been recorded previously in models of chronic serum sickness under conditions of marked excess of antigen. These are exactly the conditions that would be expected in inflamed glomeruli in which neutrophils and monocytes continued to release proteinase-3 and myeloperoxidase in the presence of ANCA. Two additional pieces of evidence support the notion that IgG deposition in ANCA-associated crescentic nephritis might be unusually shortlived: first, proteinase-3 degrades IgG including ANCA, even when complexed to it; secondly, it has been known for many years that IgG deposited in vessels in some forms of cutaneous vasculitis rapidly becomes undetectable. Thus it is entirely plausible that IgG is deposited in glomeruli of patients with crescentic nephritis and is then rapidly removed or destroyed.

In summary, there is no decisive proof that autoimmunity to neutrophil antigens cause injury in human vasculitis, but a number of clear statements can be made:

1. Autoantibodies to ANCA are very closely associated with some types of systemic small vessel vasculitis, both clinically and in experimental models.
2. The autoantibodies modify the function of neutrophil enzymes and promote neutrophil mediated endothelial injury *in vitro*.
3. Injection of antimyeloperoxidase antibodies does not in itself cause glomerular injury, except in rats in which myeloperoxidase has been planted in the kidney, when the result is severe glomerulonephritis with very similar morphological and immunohistological characteristics to human ANCA-associated glomerulonephritis.
4. Injection of antirat myeloperoxidase antibodies into rats with nephrotoxic nephritis markedly aggravates injury.

Thus it reasonable to suggest that the cellular or humoral autoimmune response to neutrophil antigens contributes to the pathogenesis of the glomerular injury in vasculitis.

Clinical features of primary vasculitis

Wegener's granulomatosis and microscopic polyangiitis

Wegener's granulomatosis is characterized by a predominantly small vessel vasculitis associated with granulomas and a predilection for involving the upper and lower airways. Microscopic polyangiitis is characterized by a very similar small vessel vasculitis without granuloma formation or a predilection for the upper airways. These two conditions will be considered together because of the many features they share, and because clinically it can be impossible to distinguish between them. Furthermore, the approach to diagnosis and management of both conditions is identical.

Both Wegener's granulomatosis and microscopic polyangiitis present with non-specific symptoms and signs that can be difficult to distinguish from those of viral infection, except that they are more persistent. These consist of flu-like symptoms with muscle pains, night sweats, and weight loss. Many patients also complain of arthralgia, which is symmetrical, relatively mild, and affects the hands and feet; exceptional patients have frank arthritis. These non-specific symptoms either precede

or occur as a background to damage to particular organs, which provides the basis for making a more specific diagnosis.

Features unique to Wegener's granulomatosis

Upper airway involvement

Over 90 per cent of patients with Wegener's granulomatosis have obvious upper airways disease. Nasal discomfort and blockage together with ulceration, crusting, rhinorrhoea, and epistaxis are usually prominent at presentation. Destruction of nasal cartilage with perforation of the nasal septum or the appearance of the characteristic saddle nose deformity rarely occur until much later. Gross destruction of bone is very uncommon and suggests an alternative diagnosis such as malignancy. Disappointingly, nasal biopsies rarely show the characteristic lesions of necrotizing vasculitis with loosely formed granulomas unless special techniques are used to get adequate samples. Nasal disease is frequently accompanied by the involvement of the paranasal sinuses, blockage of the Eustachian tube and otitis media. The larynx is less commonly involved but subglottic stenosis is a characteristic late phenomenon, which may develop insidiously and can be severe.

Pulmonary involvement

Almost all the patients have evidence of granulomatous lung disease at presentation, which is often accompanied by alveolar capillaritis. The bronchi can also be affected and bronchial stenoses occur as late manifestations. Symptoms include cough, dyspnoea, haemoptysis, and chest pain, which can be pleuritic. Signs on chest examination depend on the nature of the pulmonary lesions and include fine crepitations and bronchial breathing or less commonly pleural rubs and signs of pleural effusions. Fixed rhonchi are suggestive of bronchial stenosis and stridor of subglottic stenosis.

Pulmonary granulomas are usually diagnosed from chest radiographs and CT scans. They may appear as single or multiple rounded lesions, which can cavitate (Fig. 3). They are often intermingled with alveolar shadowing to produce composite lesions, which reflect pulmonary capillaritis and haemorrhage as well as granulomas. The radiological findings can be confused with neoplasms, infection, or fluid overload. Results from pulmonary function tests are not specific, but it is important to note that increases in the K_{CO} are a much less sensitive test for pulmonary haemorrhage in vasculitis than in disease mediated by antiglomerular basement membrane antibodies (see Chapter 20.7.9). Bronchoscopy often reveals granulomatous inflammation and the diagnosis can sometimes be made from bronchial biopsies. By contrast, needle biopsies and transbronchial biopsies of pulmonary lesions are rarely adequate and can delay definitive diagnosis by open or video-endoscopic lung biopsy. Histology of lung biopsies reveals pulmonary necrosis, vasculitis affecting alveolar capillaries and bronchial vessels, and loosely formed granulomas together with a mixed inflammatory infiltrate (Fig. 4 and Plate 2).

Fig. 3 Chest radiograph from a patient with Wegener's granulomatosis showing the typical appearance of pulmonary granulomas together with alveolar shadowing caused by capillaritis of lung haemorrhage.

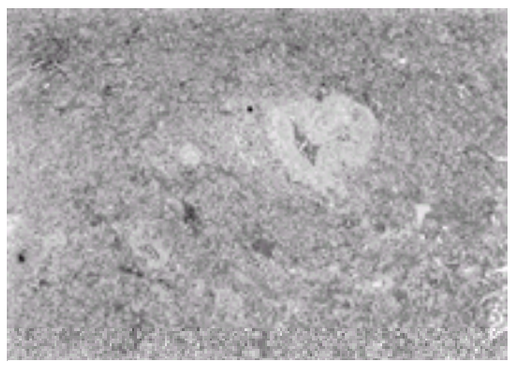

Fig. 4 Morphological appearances of pulmonary granulomas in a specimen obtained by video-endoscopic lung biopsy from a patient with Wegener's granulomatosis. (See also Plate 2.)

Granulomatous inflammation at other sites

Typical Wegener's granulomas have been reported at numerous sites outside the lung, but are much less common in part at least because of the greater difficulty in diagnosing them. Microscopic granulomas are seen in a minority of renal and skin biopsies from patients known to have Wegener's granulomatosis, but macroscopically visible granulomas are rare. However, these have been reported in kidney, simulating carcinoma, in the orbit of the eye, causing exophthalmos, and also in the brain, pituitary, salivary glands, prostate, gingiva, and vertebrae. Masses of inflammatory tissue have also been described in the intestine (simulating Crohn's disease) and breast, as well as in the retroperitoneal space and mediastinum.

Features common to microscopic polyangiitis and Wegener's granulomatosis

Renal disease

Focal necrotizing glomerulonephritis is the characteristic renal lesion of generalized Wegener's granulomatosis and microscopic polyangiitis. Typically it presents with deteriorating renal function that progresses to renal failure within 3 months, i.e. as rapidly progressive glomerulonephritis, although a few patients have more indolent disease. Proteinuria (typically 2 to 3 g/24 h, but occasionally in the nephrotic range) and microscopic haematuria provide clinical evidence of glomerulonephritis, as does urine microscopy that reveals granular and red cell casts. Despite the glomerular inflammation hypertension is uncommon, except in patients with pre-existing hypertension or obvious fluid overload. Renal ultrasound examination and CT scans show normal or enlarged kidneys, isotope renograms reflect the renal function, and renal arteriograms only exceptionally demonstrate aneurysms or other evidence of vascular injury in the renal arteries. The diagnosis is made by renal biopsy, the appearances reflecting the extent of the injury and the speed with which it has developed.

Cutaneous vasculitis

Cutaneous vasculitis occurs with equal frequency in Wegener's granulomatosis and microscopic polyangiitis, being present in about half of patients. Typically there is palpable purpura or splinter haemorrhages. Blistering and urcitarial lesions are less common, as are infarcts. Biopsies reveal leucocytoclastic vasculitis without deposition of immunoglobulins.

Vasculitis of the eye

Involvement of the eye occurs in both diseases but is more common in Wegener's granulomatosis. Orbital granulomas and exophthalmos have already been mentioned as features unique to Wegener's granulomatosis, and other manifestations include episcleritis, uveitis, and retinal vasculitis.

Gastrointestinal vasculitis

Vasculitis of the gut can occur in Wegener's granulomatosis and microscopic polyangiitis. Oral ulceration is relatively common. Intestinal vasculitis usually presents as abdominal pain and bloody diarrhoea. Endoscopy reveals purpuric lesions with or without ulceration, and white cell scans show increased uptake and are a useful way of delineating the extent of disease.

Vasculitis of the nervous system

Small vessel vasculitis can affect both central and peripheral nervous systems. Cranial nerve palsies, mononeuritis multiplex, and symmetrical polyneuropathies are straightforward to diagnose but are relatively uncommon in Wegener's granulomatosis and microscopic polyangiitis. Cerebral vasculitis also occurs: this is difficult to diagnose but can cause strokes and convulsions. Computed tomography and magnetic resonance imaging can demonstrate lesions, but appearances are not specific.

Diagnosis

Diagnosis of Wegener's granulomatosis and microscopic polyangiitis depends on an appropriate clinical history together with clinical evidence of vasculitis or focal necrotizing glomerulonephritis and biopsy evidence that is at least consistent with the diagnosis if not pathognomic of it. A positive assay for ANCA with specificity for proteinase-3 or myeloperoxidase provides strong confirmatory evidence, and negative ANCA assays are grounds for reconsidering the diagnosis. However, it is important to remember that 10 per cent of patients with generalized disease have negative ANCA, as do up to 50 per cent of those with Wegener's granulomatosis apparently confined to the respiratory tract. Early diagnosis of the patients with non-specific 'flu-like' symptoms can be very difficult and the value of urinary dipstick testing to search for asymptomatic proteinuria and haematuria cannot be overestimated.

Haematology and biochemistry

Non-specific haematological abnormalities are the rule. The full blood count shows a normocytic normochromic anaemia and often a neutrophil leucocytosis. Thrombocytosis is almost invariably present (typically in the range of 400 to 800 × 10^{9}/litre) and provides a useful measure of disease activity. Increased values for C-reactive protein and hypoalbuminaemia provide further evidence of the acute phase response. Alkaline phosphatase in often increased, but abnormalities of other liver function tests are much less common. Serum urea and creatinine values reflect the severity of the renal injury.

Serology

The sensitivity and specificity of ANCA for small vessel vasculitis have already been discussed. The results of other serological tests are variable. Up to 50 per cent of patients have detectable antiendothelial cell antibodies, and there is often a polyclonal increase in immunoglobulins. Rheumatoid factors are present in up to a third of patients and positive antinuclear factor without antibodies to double-stranded DNA in at least 10 per cent. Complement concentrations reflect the intensity of the acute phase response and are either normal or increased.

Renal biopsy

Renal biopsies show focal necrotizing glomerulonephritis of varying degrees of severity. Segments of the glomerular tuft are initially infiltrated by leucocytes, individual capillary loops become necrotic, and intravascular contents escape into Bowman's space (Fig. 5(a) and Plate 3(a)). This provokes an intense inflammatory response that is termed extracapillary proliferation, which eventually surrounds the glomerular tuft to form a 'crescent' (Fig. 5(b) and Plate 3(b)). Freshly formed crescents are composed entirely of cells, but gradually these are replaced by fibrosis. Progressively more glomeruli are involved until the disease becomes diffuse, hence it is usual to see crescents in all stages of their evolution, some being entirely cellular whilst others are completely fibrotic. Immunohistology shows that the glomeruli contain scanty deposits of immunoglobulins and complement and for that reason the lesions are often referred to as pauci-immune glomerulonephritis. The glomerular changes are accompanied by interstitial inflammation and progressive tubular atrophy as increasing numbers of nephrons are destroyed. Arteries affected by vasculitis are seen occasionally.

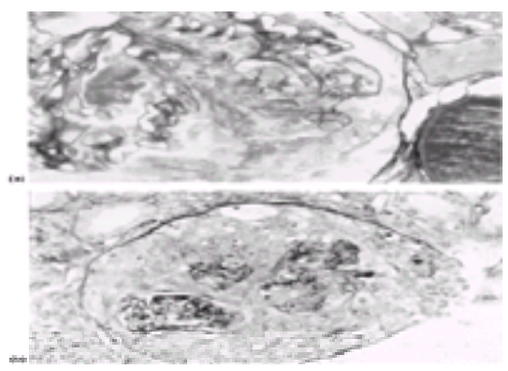

Fig. 5 Morphological appearances on a renal biopsy from a patient with pauci-immune focal necrotizing glomerulonephritis. (a) An early lesion with necrosis of one glomerular segment. (b) A much more florid lesion with the whole glomerular tuft surrounded by a crescent. (See also Plate 3.)

Renal morphology on biopsy is critical for diagnosis but has remarkably little prognostic power. In contrast to the situation with Goodpasture's disease (antiglomerular basement membrane antibody disease), even patients whose biopsies show severe glomerular destruction usually respond to treatment with a marked improvement in renal function. Similarly, patients who appear on biopsy to have indolent disease with marked glomerular scarring and tubular atrophy frequently get worthwhile improvements in function with immunosuppressive therapy. The number of normal glomerular capillary loops provides the best, albeit uncertain, guide to prognosis.

Differential diagnosis

Wegener's granulomatosis and microscopic polyangiitis are distinguished from each other on the basis of evidence for granulomatous inflammation and by whether or not the upper airways are involved. They should also be distinguished from other types of vasculitis. Although they often present with similar symptoms, other types of primary vasculitis are distinguished by clinical (for example asthma and eosinophilia in the case of Churg–Strauss syndrome), serological, radiological, and morphological evidence of the size and distribution of the vessels involved. Recognition of secondary forms of small vessel vasculitis (Table 1) depends on making an alternative diagnosis such as rheumatoid arthritis. In some cases this requires a biopsy: for example in adults Henoch–Schönlein purpura can be difficult to distinguish from microscopic polyangiitis without histological demonstration of prominent granular IgA deposits in glomeruli, or in vessels in vasculitic skin. Mixed essential cryoglobulinaemia, rheumatoid vasculitis, and systemic lupus erythematosus can all be diagnosed on the basis of specific serological tests. Infective endocarditis can cause vasculitis that is sometimes associated with positive ANCA assays (usually with specificity for myeloperoxidase) and should therefore be considered in all patients presenting with a vasculitis.

Other causes of rapidly progressive glomerulonephritis should also be considered in patients with few signs of extrarenal disease. Antiglomerular basement membrane disease and crescentic transformation of other types of chronic glomerulonephritis can be excluded on the basis of serology and renal biopsy. Assays for

antiglomerular basement membrane antibodies are especially important because 10 to 20 per cent of patients with antiglomerular basement membrane disease also have positive ANCA and 1 to 2 per cent of patients with ANCA also have antiglomerular basement membrane antibodies.

Management of small vessel vasculitis

Before any effective treatments were available, Wegener's granulomatosis was a fatal illness with mean survival of less than 6 months. Corticosteroids extended survival, but the benefits were not prolonged and patients still died with progressive disease. The prognosis was transformed in the 1970s by the introduction of regimens that combined cyclophosphamide and steroids. These proved highly effective at suppressing disease activity and are the basis of treatment today. Cyclophosphamide has become the standard immunosuppressive drug, but prolonged treatment imposes considerable morbidity. The goal is to minimize the long-term use of this drug by developing regimens that control disease activity equally well but with less toxicity.

The prognosis of microscopic polyangiitis in the pretreatment era was little better than that of Wegener's granulomatosis, but a greater proportion of patients were treated successfully with corticosteroids alone, with up to 50 per cent survival at 5 years. Again the combined use of steroids and immunosuppressive drugs has improved the prognosis further. This is especially evident in the prognosis for focal necrotizing glomerulonephritis, which previously almost invariably resulted in endstage renal failure, whereas nowadays up to 70 per cent of dialysis-dependent patients with ANCA-associated focal necrotizing glomerulonephritis can be expected to regain independent renal function.

Current approaches to management separate immunosuppressive treatment regimens into induction and maintenance phases (Table 4). Effective regimens have evolved empirically without being assessed by well-designed randomized controlled trials. Formal comparisons are increasingly needed to compare newer and potentially less toxic approaches to treatment with the standard protocols.

Induction treatment

The combination of prednisolone and cyclophosphamide is now established as the standard induction therapy for patients with generalized Wegener's granulomatosis or microscopic polyangiitis. There is consensus on how corticosteroids should be used, but less so for cyclophosphamide. Prednisolone is given in doses of around 1 mg/kg/day initially, after which the dose is reduced rapidly, typically at weekly intervals. Controlled trials show that the addition of pulses of methyl prednisolone is unlikely to confer additional benefit.

Traditionally, patients received daily oral cyclophosphamide (2 mg/kg/day), but latterly intravenous boluses have proved increasingly popular, given in doses of 0.5 to 0.75 g/m^2 body surface area at intervals of 2 weeks (at least for short periods) to 2 months. Pulse therapy has three potential advantages: a lower total dose of cyclophosphamide is used, MESNA (2-mercaptoethane sulfonate sodium) can be given with each dose to minimize bladder toxicity, and compliance is assured. Originally it was believed that pulse therapy might also be more effective, but this has not proved to be the case and indeed the opposite may be true. Results of three randomized prospective controlled trials comparing the two regimens have been reported but are not decisive. They show that both regimens are highly effective for most patients, and that pulse therapy has fewer toxic side-effects, including infections. Importantly, however, they suggest that pulse therapy may be less effective for patients with the most aggressive disease, including those with dialysis-dependent renal failure. Thus the available evidence suggests that the daily oral cyclophosphamide regimen should still be employed for patients with very severe disease. The choice of daily versus pulse therapy is open to personal preference for less severely affected patients.

The duration of induction treatment with cyclophosphamide is also controversial. The approach usually employed in North America and Continental Europe has been to use prolonged courses, albeit with progressively smaller doses. The evident toxicity of this approach has forced a re-evaluation and many now switch to weekly methotrexate after an initial course of cyclophosphamide, but there is a problem in that methotrexate is contraindicated in patients with reduced renal function. Management has been different in the United Kingdom, where it has been routine to use a 3-month induction course of cyclophosphamide and then switch to azathioprine as the immunosuppressive drug. There is now controlled trial evidence that this is as effective as prolonged cyclophosphamide. Thus limiting the induction course of cyclophosphamide to 3 months can be recommended and should be used in all patients with evidence of renal involvement.

Induction treatment for less severely affected patients

Another major issue about induction therapy is whether or not drugs which are less toxic than cyclophosphamide should be used for patients with less severe or more localized disease. In the past, azathioprine was used successfully in this situation, it being clear from uncontrolled studies that it was effective in many patients, but not all, and that its substitution by cyclophosphamide was usually effective in the event of treatment failure. Thus azathioprine did not find a regular place in induction therapy, and weekly pulses of methotrexate at an initial dose of 10 to 15 mg/week, increasing to 20 and then 25 mg/week if necessary, is the current most common alternative to cyclophosphamide. This is an effective treatment but is contraindicated in patients with reduced renal function, which limits its use. Controlled trials are now in progress to compare this approach with standard induction therapy for patients without renal disease. Liver function must be monitored carefully in patients receiving methotrexate because of the risk of hepatotoxicity. Other side-effects of methotrexate include infections and pulmonary fibrosis.

The patient with fulminant disease

The management of patients with fulminant or life-threatening disease presents additional problems. It remains controversial whether they benefit from additional treatment. The two regimens most commonly added in this situation are pulse methylprednisolone (typically 0.5 g/day for three doses) or plasma exchange. A prospective randomized controlled clinical trial of plasma exchange (4 litres daily for 7 to 10 days) demonstrated that this had significant benefit for those already on dialysis, but conferred no benefits over conventional treatment for those with less severe renal disease. A second reported trial showed broadly similar results with no overall benefit but a trend in favour of plasma exchange for those on dialysis. There are no controlled trials of methylprednisolone in dialysis-dependent patients but results of uncontrolled studies of dialysis-dependent patients are similar to those achieved using plasma exchange. A formal controlled comparison of the different regimens is being conducted as part of European Multicentre EUVAS trial group.

Antithymocyte and anti-T-cell antibodies have been used with apparent success in small numbers of patients with severe disease, but this approach should be regarded as experimental and restricted to treatment of patients who have failed to respond to conventional therapy in centres with special experience of these disorders. There is not enough experience of the use of newer immunosuppressive drugs to recommend their use outside the clinical trials.

Maintenance therapy

Systemic vasculitis is a chronic disease and so long-term treatment with steroids and immunosuppressive drugs is required both to maintain remission and to preserve renal function. The key to maintenance therapy is to balance the risks of relapse with those of immunosuppression. For this reason the current approach is to minimize the duration of treatment with cyclophosphamide. The evidence from controlled trials already cited has shown that substituting azathioprine (2 mg/kg) for cyclophosphamide after 3 months is as effective as continuing cyclophosphamide. This is continued for at least a year, together with reducing doses of prednisolone. Thereafter the dose of azathioprine is reduced to 1 mg/kg. An alternative approach is to use weekly pulses of methotrexate (10 to 20 mg/week) instead of azathioprine. Further reductions of treatment can be made during the second year provided that the patient's disease remains in remission, and one can consider stopping treatment altogether in patients who are clinically well provided that their assays for ANCA are negative. Even patients with prolonged clinical remissions are at risk of relapse if immunosuppression is stopped when ANCA are still detectable. There are no data that indicate whether it is best to stop the steroids or cytotoxic drugs first, but there is a strong clinical impression that immunosuppressive drugs are better at maintaining remission than are steroids.

Adjunctive therapy

Intravenous immunoglobulin has been widely used to treat autoimmune disease because of its anti-inflammatory properties and possibly because of its proposed effects on idiotypic networks. It appears to have a modest beneficial effect when used to treat vasculitis, but not sufficient to warrant its regular use. Cotrimoxazole has been widely used as adjunctive therapy both during the induction phase of treatment and to prevent relapses. Evidence from controlled trials demonstrates that it confers significant benefit in reducing the incidence of relapses, especially in those with severe upper airway involvement with Wegener's granulomatosis. It is likely that this effect is mediated through better control of infection. Nasal carriage of *Staphylococcus aureus* is associated with an increased risk of relapse and so long-term use of mupirocin cream may be a useful adjunct in affected patients.

Management of relapses

Relapses are common and occur in between a third and a half of patients with small vessel vasculitis, more frequently in those with Wegener's granulomatosis than with microscopic polyangiitis. They may also be more common in patients with microscopic polyangiitis and antiproteinase-3 antibodies. Relapses can occur at any time, even decades after the initial presentation; they may occur spontaneously or be provoked by a reduction of therapy or by the development of an intercurrent infection. As already stated the risk of relapse is significantly greater in chronic nasal carriers of *S. aureus*.

Most relapses occur in patients who are no longer receiving therapy. Clinical evidence of disease activity is the most important determinant of whether to increase therapy. It is usually unwise to increase therapy in the absence of any clinical signs or symptoms, but it is often wise to do so in patients with minimal non-specific symptoms in whom a change in ANCA assays from negative to positive or an increase in titre provide additional evidence of grumbling activity. Minor relapses can usually be managed by minor adjustments to the maintenance dose of steroids, whereas severe ones require more drastic measures. High-dose corticosteroids may need to be introduced, and depending on baseline therapy the dose of azathioprine may need to be increased or cyclophosphamide reintroduced.

Whenever possible overt relapses should be anticipated by prolonged follow-up of patients. This requires careful monitoring, both of clinical symptoms and signs, and also of investigations including full blood count, biochemical profile, urinary protein and sediment, C-reactive protein, and ANCA. Clinical relapses often affect different organs from those of the presenting illness, and the nature of the inflammation can be different, for example granulomas can develop in patients previously thought to have microscopic polyangiitis. The Birmingham vasculitis activity score has been developed to provide an objective assessment of disease activity. Use of such tools is essential for clinical trials and can also be useful in routine practice for monitoring the activity of patients with difficult disease.

Prognosis

Conventional treatments are very effective at suppressing disease activity, with numerous reports in recent literature indicating that more than 90 per cent of patients achieve remission. Resolution of inflammation often leaves patients with long-standing damage to particular organs, including the kidney. None the less, up to 70 per cent of patients with focal necrotizing glomerulonephritis severe enough to require dialysis at presentation regain independent renal function, which is sustained for many years.

One-year survival is around 80 per cent, with 5-year survival in the region of 55 to 75 per cent. About 10 per cent of patients with small vessel vasculitis die early, usually with uncontrolled disease. Opportunist infections contribute to deaths later in the first year, but have become uncommon with increased experience in the use of immunosuppressive drugs in this group of patients. Some units use cotrimoxazole as prophylaxis against *Pneumocystis carinii*. Some late deaths are due to unrelated causes in this elderly population, while others can be attributed to complications of therapy including haematological malignancies and other tumours. Patients with severe renal disease have a worse mortality, as inevitably do the elderly.

Dialysis and transplantation

Patients who develop endstage renal failure due to vasculitis appear to do no worse than other groups when treated by dialysis. Similarly, successful transplantation has been repeatedly reported and recurrence of small vessel vasculitis in renal transplants is exceptional.

Special problems in pregnancy

Vasculitis is uncommon in women of child-bearing age and so pregnancy is rare in these conditions. However, Wegener's granulomatosis has occasionally been reported to present in pregnancy and the puerperium, and there are also reports of a relapse of disease activity in the third trimester. Women of child-bearing age should be warned of the potential teratogenic effects of drugs that they may be taking to control vasculitis, for example cyclophosphamide and cotrimoxazole. Azathioprine does not pose a threat to the fetus but is a contraindication to breast feeding.

Renal involvement in other vasculitic disorders

Churg–Strauss syndrome

Churg–Strauss syndrome (see Chapter 17.11.5) is a small to medium-sized vasculitis frequently associated with ANCA and sometimes with focal necrotizing glomerulonephritis. Characteristic clinical features are those of asthma and transient pulmonary infiltrates, eosinophilia, and a necrotizing vasculitis affecting particularly the peripheral nervous system (mononeuritis multiplex), the bowel, and sometimes the heart and the skin. The full blood count shows normochromic normocytic anaemia and eosinophilia, which may exceed 1.5×10^9/litre, and a raised platelet count. The chest radiograph reveals pulmonary infiltrates and, as with other forms of vasculitis, severe pulmonary haemorrhage can occur. Renal disease is much less common in Churg–Strauss syndrome than in Wegener's granulomatosis or microscopic polyangiitis. When present, it consists of a focal necrotizing glomerulonephritis or, less commonly, a severe interstitial nephritis with large numbers of eosinophils.

Steroids have been the main treatment for many years, but many would advocate the concurrent use of other immunosuppressive drugs in those with severe disease. This should include those with life-threatening pulmonary haemorrhage, apidly developing mononeuritis multiplex, or focal necrotizing glomerulonephritis. Overall the prognosis of Churg–Strauss syndrome is good with initial clinical remission being achieved in over 90 per cent of patients and a 5-year survival of in excess of 75 per cent. However, it should be emphasized that patients with mononeuritis may be left with considerable disability.

Polyarteritis nodosa

Polyarteritis nodosa is an uncommon condition characterized by necrotizing vasculitis affecting small and medium-sized muscular arteries. Affected arteries often develop aneurysmal swellings (Fig. 6 and Plate 4), which can be palpable as nodules when they occur in subcutaneous tissue. By definition the diagnosis excludes patients who also have involvement of capillaries, arterioles, and venules. Typically it is a disease of the middle aged, with males being affected twice as commonly as females. Patients usually present with fever, weight loss, and night sweats. Other symptoms depend on which vessels are involved. Abdominal pain is common and is due to intestinal ischaemia or pressure from aneurysms; some patients present with symptoms of hypertension caused by renal ischaemia.

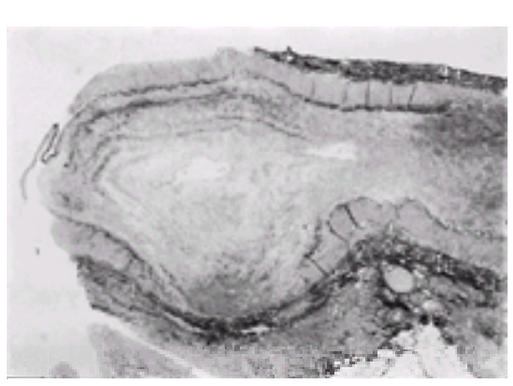

Fig. 6 Morphological appearances of a renal artery from a patient with polyarteritis nodosa. The elastic lamina has been destroyed and the artery has become aneurysmal. (See also Plate 4.)

The aetiology is unknown in most patients, but polyarteritis nodosa has been reported in carriers of hepatitis B virus and also after infection with parvovirus. Further

evidence of infective aetiology comes from reports of polyarteritis nodosa in intravenous drug users.

Diagnosis

Polyarteritis nodosa is associated with the usual non-specific signs of inflammation, but in marked contrast to small vessel vasculitis, ANCA are usually negative. The diagnosis depends on the angiographic demonstration of vasculitis in muscular arteries. All patients should be tested to determine whether they are carriers of hepatitis B or infected with hepatitis C.

Treatment

Polyarteritis nodosa is treated with corticosteroids and cytotoxic drugs using the regimen described for small vessel vasculitis (Table 4). This regimen is effective in the short term in those with hepatitis B, but may be deleterious in the longer term, and success has been reported when these patients are treated with antiviral therapy alone, for example interferon-a or lamivudine.

Conclusion

There has been enormous progress in the management of patients with systemic vasculitis over the past decade, in particular for those with severe renal involvement. Common approaches to classification, diagnosis, and treatment have been developed that for the first time provide a basis for prospective randomized controlled trails of treatment methods. There is no doubt that current treatment regimens are highly effective in the short and medium term, but minimizing long-term toxicity of treatment remains a major issue.

The identification of ANCA in patients with vasculitis has been extremely valuable, both for purely practical reasons as an aid to diagnosis, and more generally as a focus for investigation of these disorders. Nevertheless, it is disappointing that despite nearly two decades of research no clear conclusions can be drawn about why ANCA are so closely associated with systemic vasculitis, or about their roll in pathogenesis.

There is an urgent need for better understanding of pathogenesis to rationalize therapy. Controlled clinical trials designed to optimize the use of currently available drugs are certainly needed, but assessing the potential of the large numbers of new immunosuppressive drugs and recombinant molecules presents impossible difficulties. A better understanding of pathogenesis would help in choosing which other new approaches are most likely to be valuable.

20.10.4 The kidney in rheumatological disorders

D. Adu

Lupus nephritis

Systemic lupus erythematosus is a multisystem autoimmune disease that is characterized by the presence of antinuclear antibodies (see Chapter 18.10.2). The overall survival of patients with systemic lupus erythematosus and a nephritis has improved considerably over the last few decades; from less than 50 per cent survival at 5 years in the 1960s to over 80 per cent survival at 10 years in the 1990s. This is due the wider use of corticosteroids and immunosuppressants and the availability of more effective antihypertensive drugs, antibiotics, renal dialysis, and transplantation.

Pathogenesis

The pathogenesis of systemic lupus erythematosus in general, and lupus nephritis in particular, is complex and multifactorial. Immunological dysregulation leads to the production of autoantibodies to nuclear (in particular double-stranded DNA) and other cellular antigens. The renal lesions of lupus nephritis show glomerular and (less often) tubular deposits of immunoglobulins and complement in a granular pattern indicating immune aggregation. It now seems likely that this is due to *in situ* assembly of antigen–antibody complexes rather than the deposition of immune complexes from the circulation.

Clinical presentation

Renal disease may rarely be the presenting feature of systemic lupus erythematosus, although at presentation 10 to 20 per cent of patients with the condition have evidence of renal involvement, and this develops in about 40 to 50 per cent of patients, typically during the first 5 years after diagnosis. Whilst renal disease is a major complication of systemic lupus erythematosus it is always important to recognize that lupus is a systemic disease and that nephritis typically occurs in patients with extrarenal symptoms such as a rash, arthralgia, Raynaud's phenomenon, and pleuropericarditis. Other major organ systems may be involved including the central nervous system, heart, and lungs.

Proteinuria is found in all patients with lupus nephritis and in 50 to 60 per cent of cases is heavy enough to lead to a nephrotic syndrome. Microscopic haematuria accompanies the proteinuria in about 80 per cent of patients; hypertension is found at presentation in 20 to 50 per cent; and some 20 to 30 per cent present with rapidly deteriorating renal function that may occasionally be severe enough to lead to acute renal failure.

Diagnosis

Immunology

A fluorescent antinuclear test is positive in more than 95 per cent of patients with systemic lupus erythematosus although it lacks specificity as it is also found in other connective tissue diseases. More specific, but less sensitive, tests include antidouble-stranded DNA and anti-Sm (Smith) autoantibodies. (For discussion of immunological tests for systemic lupus erythematosus see Chapter 18.10.1 and Chapter 18.10.2.) In general antidouble-stranded DNA antibody levels reflect disease activity, particularly if accompanied by falling complement levels, but as regards the kidney they are less consistently related to features of active glomerulonephritis. Reduced serum concentrations of the complement proteins C1q and C4 as well as C3 indicate activation of the classical pathway of complement. These are useful in the diagnosis of systemic lupus erythematosus, but although more commonly found in lupus nephritis they are not useful in predicting its onset. Patients with lupus nephritis have antibodies to phospholipids in 30 to 50 per cent of cases, resulting in prolongation of the partial thromboplastin time and leading to the term lupus anticoagulant.

Pathology

A renal biopsy is justified when there is evidence of glomerular disease in the form of proteinuria (more than 200 mg/24 h), microscopic haematuria, a urinary sediment indicative of active nephritis (more than 10 dysmorphic red blood cells per high-power field and/or casts of red and white blood cells), or renal insufficiency. Histology allows an assessment of disease activity and provides a basis for therapy and prognosis.

A distinctive feature of lupus nephritis on light microscopy is the variability of the glomerular changes seen in a single biopsy, and sometimes within the same glomerulus. This makes classification of renal histology difficult, but that most widely used is the modified World Health Organization (**WHO**) classification shown in Table 1. Segmental glomerular thrombosis, necrosis, and extracapillary proliferation (crescents) are frequently found in association with the proliferative type lesions (WHO class III and IV). On immunofluorescent microscopy there is often florid deposition of immunoglobulins IgG, IgA, and IgM as well as complement proteins C3, C4, and C1q.

Patients with minimal changes or mesangial glomerulonephritis (WHO class I and II lesions) (Fig. 1 and Plate 1) usually have an inherently low rate of progressive renal failure. Patients with membranous nephropathy (WHO class V) have an intermediate prognosis for renal function. By contrast, patients with focal or diffuse proliferative glomerulonephritis (WHO class III and IV) (Fig. 2 and Plate 2) have a high risk of progressive renal failure.

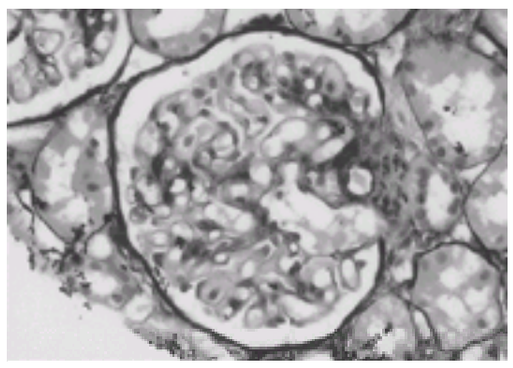

Fig. 1 Lupus nephritis. The glomerulus has mild mesangial increase (WHO class II). Periodic acid-methenamine silver staining (×50). (By courtesy of Dr A. J. Howie.) (See also Plate 1.)

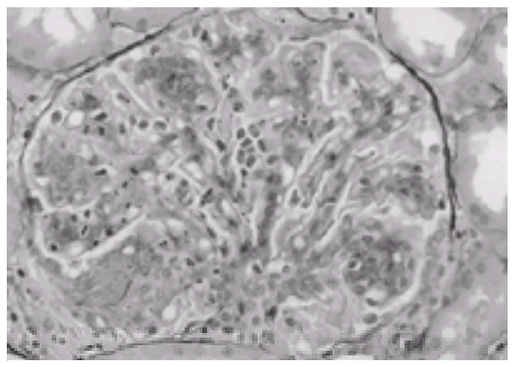

Fig. 2 Lupus nephritis. The glomerulus has marked mesangial increase with wire loops, a few doubled basement membranes and segmental lesions (WHO class IV). Periodic acid-methenamine silver staining (×40). (By courtesy of Dr A. J. Howie. (See also Plate 2.)

Treatment

There are several considerations in the approach to the treatment of patients with lupus nephritis. The first is based on the histological severity of the renal lesion. The second is based on the severity of the clinical presentation. The third consideration is the choice of therapy for inducing remission of acute disease and for maintaining remission and treating relapses. The heterogeneity of the clinical course of lupus nephritis and the relatively few randomized controlled trials means that decision making is difficult and there are still substantial disagreements on the optimum treatment. Steroids and/or immunosuppressants are used—drugs with major toxicities that need to be offset against any benefit.

Treatments for particular classes of lupus nephritis

Mesangial proliferative glomerulonephritis (WHO class II)

Most such patients present with proteinuria and microscopic haematuria, often with little in the way of renal impairment. There are no controlled trials to guide treatment. We treat such patients with corticosteroids in the hope that this will prevent progression to a more severe glomerulonephritis, but this is not certain.

Membranous nephropathy (WHO class V)

In patients with lupus nephritis the frequency of membranous nephropathy is approximately 12 per cent when the definition of the renal histology is confined to pure membranous nephropathy with or without mild mesangial hypercellularity, expansion, and scattered deposits (WHO classes Va and Vb). With the revision of the WHO criteria in 1995, biopsies with focal segmental proliferative or diffuse proliferative glomerulonephritis in addition to membranous changes are now classified as WHO classes III and IV because they behave similarly: this causes some difficulties in interpreting earlier studies where these appearances were classified as Vc and Vd.

The clinical presentation of lupus membranous nephropathy is with proteinuria and in about 50 per cent of cases a nephrotic syndrome. Patients with WHO class Va and Vb lesions have a low rate of progressive renal failure. There are no controlled trials of treatment and thus there is no consensus on treatment. In some studies patients with WHO class Va and Vb disease have been treated with prednisolone, with a smaller proportion also receiving pulses of methylprednisolone or oral cyclophosphamide and azathioprine. By contrast, most patients previously classified as WHO class Vc and Vd have been treated with cyclophosphamide or azathioprine in addition to prednisolone. With these approaches to treatment the 10-year survival free of death and renal failure in WHO class Va and Vb was 72 to 92 per cent and in WHO class Vc and Vd was 35 to 81 per cent.

Most nephrologists treat patients with pure lupus membranous nephropathy with or without minor mesangial proliferation with prednisolone and consider adding in azathioprine as a corticosteroid sparing agent.

Focal and diffuse lupus proliferative glomerulonephritis (WHO class III and IV)

It has been argued that the addition of immunosuppressive drugs to corticosteroids does not improve the prognosis of lupus. Others have concluded that patients treated with prednisolone plus cyclophosphamide or azathioprine have fewer unfavourable outcomes than patients treated with prednisolone alone. Formal meta-analysis has shown that treatment with cyclophosphamide or azathioprine combined with prednisolone reduced the risk of developing endstage renal disease and possibly mortality when compared with prednisolone alone.

A series of clinical trials from the National Institutes of Health provided evidence of the effectiveness of intermittent intravenous cyclophosphamide together with oral prednisolone in preserving renal function in patients with severe lupus nephritis. This regimen is preferable to continuous oral cyclophosphamide as it leads to less bladder toxicity, although the frequency of gonadal toxicity is unaffected and it is not yet known whether pulse cyclophosphamide is less carcinogenic than continuous oral therapy, although this is unlikely. From the National Institutes of Health data, monthly pulse cyclophosphamide (0.5 to 0.75 g/m ^{2}) adjusted for the glomerular filtration rate and leucocyte count at 10 to 14 days is given monthly for the first 6 months, then quarterly for 18 to 24 months, the longer course of cyclophosphamide being associated with fewer relapses than a shorter 6-month course, but at the expense of greater gonadal toxicity. Preliminary data with pulse oral cyclophosphamide have shown encouraging results and, if validated, will minimize the inconvenience associated with intravenous therapy. To reduce the bladder toxicity of intravenous cyclophosphamide patients should be hydrated either with oral or intravenous fluid and mesna given concomitantly. Prednisolone is given in conjunction with the cyclophosphamide at an initial dose of 0.5 to 1 mg/kg/day for 6 to 8 weeks with gradual tapering, preferably to an alternate day regimen to minimize toxicity.

In other uncontrolled but extensive observations, treatment with intravenous methylprednisolone followed by combined prednisolone and azathioprine or oral cyclophosphamide gave long-term results comparable with those of the National Institutes of Health data. It has also been reported that azathioprine may prevent relapse. However, on the basis of the randomized controlled data, we feel that the National Institutes of Health regimen is a reasonable initial treatment for severe lupus nephritis. Much of the toxicity is due to the prolonged maintenance course of pulse cyclophosphamide: whether conversion after 6 months to azathioprine is as effective in maintaining remission as continued pulse cyclophosphamide remains to be established.

A key feature of the care of patients with lupus nephritis is close monitoring of the white cell count and renal function and detailed surveillance and management of

infection, extrarenal lupus, and hypertension. A summary of the treatment strategies for lupus nephritis is shown in Table 2.

Notes on particular treatments for lupus nephritis

Toxicity of cyclophosphamide

Intravenous cyclophosphamide often leads to nausea and vomiting: giving serotonin antagonists such as ondansetron together with dexamethasone can control this. The most common toxic effect is depression of normal haematopoiesis, which is dose dependent and reversible on discontinuing therapy. A further major side-effect is an increased risk of infections, worsened by the concomitant use of corticosteroids. In particular, an increased incidence of herpes zoster is seen with cyclophosphamide.

Cyclophosphamide is metabolized to phosphoramide mustard and acrolein that are excreted by the kidneys. Acrolein can lead to a haemorrhagic cystitis, which is particularly common with oral cyclophosphamide. The use of intravenous cyclophosphamide with vigorous hydration and concomitant administration of 2-mercaptoethane sulfonate sodium has essentially eliminated bladder complications. Prolonged oral cyclophosphamide is associated with an increased risk of malignancy and it is likely that intravenous cyclophosphamide also carries this risk.

Cyclophosphamide causes dose- and age-related gonadal toxicity with oligospermia in men and premature ovarian failure in women. Few data on gonadal toxicity in men with lupus are available. In one study of six men treated with oral cyclophosphamide at a daily dose of 50 to 100 mg, germinal aplasia occurred after a cumulative dose of 9 to 18 g. All studies show that the risk of ovarian toxicity rises substantially with age and is correlated with the duration of treatment and the cumulative dose of cyclophosphamide. In patients aged less than 25 the risk of ovarian failure after 6 months of monthly intravenous cyclophosphamide was nil, whilst a further 24 months of quarterly cyclophosphamide increased this risk to 17 per cent. Comparable figures for women aged over 31 years were 25 per cent and 100 per cent respectively. By contrast, one out of 20 patients (5 per cent) treated with azathioprine developed ovarian failure. Since lupus nephritis chiefly afflicts women of reproductive age, one must balance this risk of premature ovarian failure, which may be permanent, with the benefits of treatment. Cyclophosphamide, unlike azathioprine, is a potent teratogen and must not be used in pregnancy.

Toxicity of azathioprine

Some patients are intolerant of azathioprine and develop nausea, vomiting, and diarrhoea. It also causes marrow suppression, which can be severe in individuals who have a deficiency of thiopurine methyltransferase. Other toxicities include an increased risk of infection and the development of malignancies with prolonged usage.

Pulse methylprednisolone

Pulse methylprednisolone has been used in at least two different ways. In the first, pulse methylprednisolone has been used in three consecutive daily doses of 0.5 to 1 g at the initiation of treatment of severe proliferative lupus nephritis or for the treatment of renal flares. This has been used together with cyclophosphamide or azathioprine and in conjunction with oral prednisolone. The long-term results of this approach are good, although this approach has not been examined in a randomized controlled study. The second way that methylprednisolone has been used is as monthly pulses together with continuous low-dose prednisolone. However, this is less effective in inducing remission and preventing endstage renal failure than treatments that include cyclophosphamide and it cannot be recommended.

Plasma exchange

Several studies have examined the role of plasmapheresis in the treatment of patients with lupus nephritis: although it was well tolerated with few adverse effects the impact on renal function was disappointing. Controlled trials of plasmapheresis in patients with all types of proliferative or membranous glomerulonephritis showed no benefit over treatment with prednisolone and immunosuppressants alone. We currently use plasma-pheresis only in patients with a severe diffuse proliferative glomerulonephritis and pulmonary haemorrhage whose disease does not respond to prednisolone and cyclophosphamide.

Intravenous immunoglobulins

Uncontrolled studies have shown a temporary benefit in patients with systemic lupus erythematosus from the infusion of high doses of intravenous immunoglobulin. Prospective controlled studies are needed to evaluate critically the efficacy of this therapy.

Cyclosporin A

Several studies have examined the effectiveness of cyclosporin A in the treatment of lupus nephritis: none of these were controlled and it is difficult to discern whether cyclosporin was of any benefit. The nephrotoxicity of cyclosporin is a major problem, and pending randomized controlled studies comparing this drug with other immunosuppressive agents we cannot recommend its use in lupus nephritis.

Methotrexate

Methotrexate may be useful as a steroid-sparing agent in lupus with arthritis and serositis, and may have potential benefits in mild nephritis. However, methotrexate is excreted by the kidneys and cannot be used safely in patients with renal impairment.

Mycophenylate mofetil

The active metabolite of mycophenylate mofetil inhibits inosine monophosphate dehydrogenase and thereby the *de novo* pathway of guanosine nucleotide synthesis. Preliminary experimental and clinical studies have indicated a potential role in systemic lupus erythematosus, but this awaits confirmation in controlled trials.

Prognostic factors in lupus nephritis

Patients with proliferative glomerulonephritis (WHO classes III and IV) tend to have a worse outcome for renal function than those with milder lesions, although with treatment this difference is now small. The combination of severe active and chronic histological changes on a renal biopsy adversely affects outcome. Even in the face of active lupus nephritis, patients without chronic histological changes have a lower risk of developing renal failure, 90 per cent or more remaining free of renal failure after 10 years. A number of clinical variables are associated with a greater probability of renal progression in lupus nephritis, including low haematocrit, raised serum creatinine level at diagnosis, 'nephritic flares', hypertension, heavy proteinuria, and poor socio-economic status.

Long-term outcome

Studies reported in the 1990s show a 10-year patient survival in lupus nephritis that ranges from 70 to 90 per cent. Renal failure can now be treated by dialysis and transplantation, the major causes of death now being treatment-related sepsis, which occurs early, and myocardial ischaemia, which occurs late. The other major cause of death is extrarenal lupus.

Between 17 and 30 per cent of patients with lupus nephritis develop endstage renal failure by 10 years. Both haemodialysis and continuous ambulatory peritoneal dialysis are well tolerated and there is a tendency for the activity of lupus disease to diminish after the start of dialysis. We discontinue immunosuppressants in patients on dialysis if there is no overt disease activity, only persisting with a small dose of prednisolone. Overall survival on dialysis is good, being 75 per cent at 10 years. After transplantation, graft survival and function in patients with lupus are comparable to those obtained in patients with other diseases, and recurrence of lupus nephritis is uncommon.

Renal disease in systemic sclerosis

Systemic sclerosis is a systemic disorder characterized by skin thickening due to the deposition of collagen in the dermis (see Chapter 18.10.3). Adverse prognostic features are renal, cardiac, and pulmonary involvement. A major complication is the development of scleroderma renal crisis, which is characterized by the abrupt

onset of severe hypertension, usually with retinopathy, together with the rapid deterioration of renal function and heart failure. Scleroderma renal crisis develops in approximately 8 to 15 per cent of patients with diffuse systemic sclerosis, the most important risk factor being the rapid progression of diffuse skin disease. It usually occurs early, within 3 years of the onset of illness, and develops more commonly in the autumn and winter.

Pathogenesis

The pathogenetic mechanisms leading to renal damage in systemic sclerosis are not known. Whilst plasma renin activity is almost always raised in scleroderma renal crisis, there is no evidence that this occurs before the development of this complication and plasma renin activity does not predict the problem. Patients with systemic sclerosis may show cold-induced reduction in renal perfusion and increased plasma renin activity, but this does not correlate with the presence of renal histological vascular abnormalities. There is evidence of endothelial activation in patients who develop renal damage with raised serum levels of circulating endothelial derived adhesion molecules including s-ELAM, s-VCAM, and s-ICAM, but these are likely to reflect the presence of endothelial injury rather than being of pathophysiological significance.

Antecedent hypertension does not increase the risk of development of scleroderma renal crisis, which is as common in men as in women, although systemic sclerosis is more common in the latter, with a female to male ratio between 3:1 and 4:1. In one retrospective case-controlled study the risk of scleroderma renal crisis was increased by prior treatment with steroids (more than 15 mg prednisolone/day) with an odds ratio of 4.37 (95 per cent confidence interval 2.03–9.42) and reduced by treatment with penicillamine (odds ratio 0.41, 95 per cent confidence interval 0.24–0.69). One report suggests that cyclosporin A may predispose to the development of scleroderma renal crisis.

Pathology

The smaller arcuate and interlobular arteries are predominantly involved in scleroderma renal crisis, showing intimal hyperplasia with concentric mucoid intimal degeneration, but the internal and external elastic laminae remain intact. In addition the adventitia of interlobular arteries show an abnormal degree of fibrosis. There is fibrinoid necrosis of afferent arterioles and glomeruli and also glomerular thrombosis. Ischaemia of the glomerular tuft leads to wrinkling and thickening of the glomerular basement membrane and glomerular sclerosis (Fig. 3 and Plate 3). These lesions resemble those seen in accelerated hypertension or the haemolytic uraemic syndrome, although the vessels involved tend to be larger and adventitial fibrosis is not seen in accelerated hypertension.

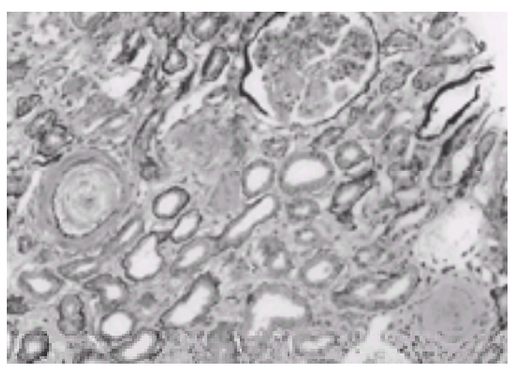

Fig. 3 Scleroderma kidney. A small artery has concentric mucoid intimal thickening, an arteriole has thrombosis and fibrinoid necrosis, and tubules and a glomerulus have ischaemic damage. Periodic acid-methenamine silver staining (×25). (By courtesy of Dr A. J. Howie.) (See also Plate 3.)

Clinical presentation

Hypertensive scleroderma renal crisis

The clinical presentation is typically with the symptoms of malignant hypertension with headaches, blurred vision, fits, and heart failure. Renal function is impaired and deteriorates rapidly. The hypertension is almost always severe with a diastolic blood pressure in excess of 100 mmHg in 90 per cent of patients. There is hypertensive retinopathy in about 85 per cent of cases with exudates and haemorrhages and at times papilloedema.

Normotensive scleroderma renal crisis

Scleroderma renal crisis can also develop in individuals with a normal blood pressure. They are more likely to have a microangiopathic haemolytic anaemia (90 per cent versus 38 per cent), thrombocytopenia (83 per cent versus 21 per cent), and pulmonary haemorrhage than patients with hypertensive scleroderma renal crisis.

Diagnosis

The clinical presentation described above in a patient with the typical diffuse skin thickening of systemic sclerosis is diagnostic. Typically the renal impairment is accompanied by a microangiopathic haemolytic anaemia with thrombocytopenia and fragmented red blood cells (schistocytes or burr cells). Once the blood pressure has been well controlled for at least 7 days then, if there is doubt, the diagnosis can be established by renal histology.

Treatment

Scleroderma renal crisis is a medical emergency. The hypertension should be treated with an angiotensin converting enzyme inhibitor, which can also help with the treatment of the heart failure. The aim should be for a slow and gradual reduction in blood pressure as an abrupt fall can lead to cerebral ischaemia or infarction, as it can in accelerated phase hypertension. Calcium channel blockers may be required in addition to the angiotensin converting enzyme inhibitors. Deterioration of renal function in these patients is often rapid and they can precipitately develop pulmonary oedema, hence they should be treated in a hospital with facilities for dialysis.

Prognosis

Prior to the early 1970s scleroderma renal crisis was almost always a fatal illness with most patients dying within a year. The survival improved slightly with the use of dialysis and better hypotensive agents, but it is only since the introduction of angiotensin converting enzyme inhibitors that prognosis has improved. In one study of 23 patients treated with captopril, 20 responded favourably and in 14 the serum creatinine fell. After a median follow-up of 29 months, six patients had died and four remained dependent on dialysis. Prior to treatment with angiotensin converting enzyme inhibitors, patients with normotensive scleroderma renal crisis had a worse prognosis, with a 1-year survival of 13 per cent as compared with 35 per cent in those who were hypertensive.

Although the renal vascular lesions are acute, recovery of function is unusual once renal failure has developed and most patients require long-term dialysis. However, some patients may recover renal function after a period of dialysis, and there is a tendency for the skin lesions of scleroderma to improve on this treatment.

Renal disease in rheumatoid arthritis

Death certificate and autopsy studies in rheumatoid arthritis show that there is an excess mortality from renal failure, which accounts for between 3 and 20 per cent of deaths. About a half of these are due to amyloid, the remainder being due to nephritis and renal infections. There are no good figures on the prevalence of renal disease during life in rheumatoid arthritis, although this does seem to be lower.

There are three broad categories of renal disease in rheumatoid arthritis (Table 3). The first and the most common is nephrotoxicity from the drugs used in the treatment (see Chapter 18.5). Gold and penicillamine lead to proteinuria and glomerulonephritis in between 10 and 30 per cent of patients, often severe enough to

cause a nephrotic syndrome. Non-steroidal anti-inflammatory drugs are widely used for pain relief and are associated with the development of a variety of renal syndromes ranging from a reversible reduction in glomerular filtration rate to acute renal failure, either due to an acute tubular necrosis or an acute interstitial nephritis. The latter may be complicated by nephrotic range proteinuria. The second major but diminishing cause of renal disease in rheumatoid arthritis is amyloidosis. Thirdly, patients with rheumatoid arthritis may develop a renal vasculitis and also a glomerulonephritis.

Secondary amyloidosis in rheumatoid arthritis

Secondary amyloidosis results from deposition of fibrils containing amyloid A protein that is antigenically related to the acute phase reactant serum amyloid A (see Chapter 11.12.1 and Chapter 11.12.4 for further discussion). Rheumatoid arthritis is the commonest disease producing secondary amyloidosis in developed countries. At autopsy, prevalence rates of 8 to 17 per cent are found, whilst data from biopsy series show a lower prevalence of around 5 to 10 per cent. There is some evidence for a decline in prevalence of amyloid over the last 20 years, and in the last 5 years the incidence appears to have dropped dramatically (unpublished evidence). The reason for this is likely to be much more aggressive therapy, with fewer patients being left with a persistently elevated acute phase response.

Clinical presentation and diagnosis

The presentation of renal amyloid is with proteinuria that is often severe enough to cause a nephrotic syndrome. Renal vein thrombosis is particularly common. Diagnosis is established by renal biopsy (Fig. 4 and Plate 4), where histological Congo red staining, which is birefringent in polarized light, is characteristic of amyloid. This staining is abolished by potassium permanganate in reactive amyloidosis but not in primary amyloidosis. Monoclonal and polyclonal antibodies that specifically bind amyloid A are now available and are of use for histological diagnosis. The diagnosis of amyloid has also been aided by the availability of scans using radiolabelled serum amyloid P (SAP) protein, utilizing the strong calcium dependent affinity of SAP for amyloid fibrils of any protein type.

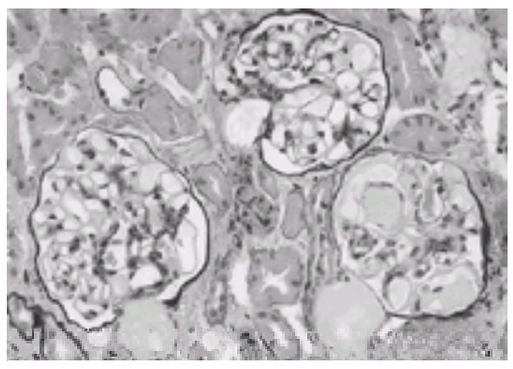

Fig. 4 Amyloidosis in rheumatoid arthritis. Arterioles and glomeruli contain acellular masses of amyloid. Periodic acid-methenamine silver staining (×40). (By courtesy of Dr A. J. Howie.) (See also Plate 4.)

Treatment and prognosis

There is no specific therapy for amyloid A amyloidosis, the general principle being suppression of the underlying chronic inflammation. Uncontrolled evidence suggests that aggressive treatment of rheumatoid arthritis may be effective in delaying the deterioration of renal function in patients with renal amyloid. There are some reports that treatment with prednisolone and cyclophosphamide or methotrexate can induce remission of the nephrotic syndrome due to amyloid in patients with rheumatoid arthritis, but in other studies no benefit was seen. Randomized controlled studies are needed to establish the role of aggressive treatment of renal amyloid in this condition.

Renal amyloid leads to progressive renal failure. After 5 years 50 per cent of patients develop endstage renal failure and this rises to 90 per cent at 10 years. Treatment of endstage renal failure from amyloid is by dialysis and renal transplantation.

Gold and penicillamine nephropathy

Clinical features

The most frequent presenting feature is proteinuria, which occurs in approximately 10 per cent of patients receiving gold and up to 30 per cent of those taking penicillamine. This progresses to the nephrotic syndrome in 30 and 16 per cent respectively. Haematuria is uncommon, although it is seen more frequently with penicillamine, and still requires the exclusion of other causes when occurring in the context of therapy with these drugs. Renal function is usually normal.

Pathology

About 80 per cent of patients who present with D-penicillamine or gold-induced proteinuria will have a membranous glomerulonephritis. Subepithelial spikes and a mild increase in mesangial cells are usually seen, and the diagnosis can be confirmed with immunofluorescence/immunoperoxidase microscopy that shows granular subepithelial deposits of predominantly IgG. On electron microscopy electron-dense subepithelial deposits are seen.

Other renal lesions are less common and include a mesangial glomerulonephritis, minimal change nephropathy, and tubulointerstitial inflammation. Penicillamine may lead to the development of a rapidly progressive glomerulonephritis with crescents and the clinical picture of Goodpasture's syndrome, also to a renal vasculitis.

Treatment and prognosis

In general gold and penicillamine should be discontinued when significant proteinuria develops (more than 0.5 g/24 h). Renal biopsy should be confined to those patients who have deteriorating renal function, or who fail to improve after withdrawal of the drug. Regular monitoring of proteinuria and the glomerular filtration rate are mandatory. No specific immunosuppression is required although supportive measures for the nephrotic syndrome are given as indicated (see Section 20.3).

After cessation of the drug, proteinuria peaks at around a month then gradually disappears; the majority of patients will have clear urine by 1 year and almost all will achieve this by 2 years. Renal function does not deteriorate in uncomplicated cases.

The susceptibility to gold- or penicillamine-induced nephrotoxicity is linked to the major histocompatibility genes: HLA DR3 confers a relative risk of 14.0 to 32.0 for gold-induced nephropathy and 3.2 to 10.0 for D-penicillamine-induced nephropathy. There also appear to be metabolic factors that determine the toxicity of these drugs: individuals with poor sulphoxidation appear to be at increase risk. Given this basis it is not surprising that rechallenge with the same drug at the same dose usually leads to a recurrence of the renal problem, although a lower dose may be tolerated. The dilemma of whether to restart treatment is now less of a problem because of the increasing number of alternative therapies.

Cyclosporin A nephrotoxicity

The renal toxicity of cyclosporin in rheumatoid arthritis is well documented, hence in these patients cyclosporin should be started at a dose of 2.5 mg/kg/day and not exceeding 5 mg/kg/day, with a reduction of cyclosporin if creatinine rises to 130 per cent of baseline. Indeed, so sensitive is the rise in creatinine in patients with rheumatoid arthritis that other measures of renal function are used only to confirm changes.

Non-steroidal anti-inflammatory drugs increase the nephrotoxicity of cyclosporin A, which can lead to chronic irreversible renal failure: this is more common with doses in excess of 5 mg/kg, in patients with pre-existing renal impairment, in elderly patients, and in those treated for more than 6 months. Renal function should be carefully

monitored in patients on cyclosporin therapy.

Non-steroidal anti-inflammatory drugs

Non-steroidal anti-inflammatory drugs are potentially nephrotoxic and in patients with rheumatoid arthritis may lead to a reversible reduction in glomerular filtration rate, acute tubular necrosis, an acute interstitial nephritis often with heavy proteinuria, renal papillary necrosis, and chronic tubulointerstitial nephritis.

Glomerulonephritis

The most commonly described glomerulonephritis in rheumatoid arthritis that is not related to drug use is a mesangial proliferative glomerulonephritis, which in many cases is accompanied by IgA deposits (IgA nephropathy). The other major type of glomerulonephritis reported in rheumatoid arthritis is membranous nephropathy.

Renal vasculitis

The clinical spectrum of rheumatoid arthritis includes a systemic necrotizing vasculitis with involvement of blood vessels ranging in size from capillaries to small and medium-sized arteries. The clinical presentation includes nailfold infarcts, a leucocytoclastic vasculitis, a peripheral neuropathy, pericarditis, gastrointestinal infarcts, and renal vasculitis. Renal abnormalities are found in about 25 per cent of patients with rheumatoid vasculitis, usually microscopic haematuria, proteinuria, and renal impairment. Renal histology shows a large vessel renal arteritis and a segmental necrotizing glomerulonephritis with crescent formation (vasculitic glomerulonephritis) (Fig. 5 and Plate 5). Treatment is with prednisolone and cyclophosphamide, usually leading to improvement of renal function.

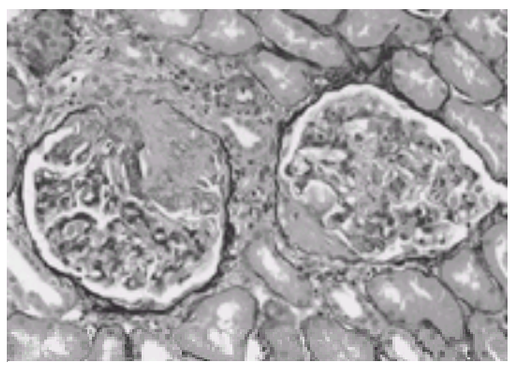

Fig. 5 Vasculitic glomerulonephritis in rheumatoid arthritis. Two glomeruli have sharply defined segmental lesions where there has been disruption of the tuft and partial obliteration of Bowman's space. Periodic acid-methenamine silver staining (×32). (By courtesy of Dr A. J. Howie.) (See also Plate 5.)

Renal disease in juvenile chronic arthritis

Renal failure accounts for 38 per cent of deaths in patients with juvenile chronic arthritis. Proteinuria is found in between 3 and 12 per cent and microscopic haematuria in between 3 and 8 per cent of these patients. Nephrotic range proteinuria is commonly due to renal amyloid, found in between 1.2 and 6.7 per cent of patients with juvenile chronic arthritis, whilst haematuria and proteinuria may be due to amyloid or to gold treatment. Interstitial nephritis is also common and may be due to drug treatment. Amyloid is a major problem, accounting for more than 40 per cent of deaths, the majority due to renal failure.

Renal disease in primary Sjögren's syndrome

Sjögren's syndrome is characterized by a lymphocytic infiltration of exocrine glands leading to a dry mouth (xerostomia) and dry eyes (keratoconjunctivitis sicca) (see Chapter 18.10.4). It may be primary or secondary to a variety of autoimmune disorders including rheumatoid arthritis, systemic lupus erythematosus, systemic sclerosis, and mixed connective tissue disorder.

Clinically significant renal disease has been reported in about 10 to 25 per cent of patients with Sjögren's syndrome. The most common renal disorder is mild and often subclinical distal renal tubular acidosis, impairment of urinary concentration, and rarely hypokalaemia. Clinical manifestations of these renal tubular disorders include the development of renal calculi, polyuria, and rarely hypokalaemic periodic paralysis. Renal biopsy in these patients shows a tubulointerstitial nephritis with interstitial lymphocytic infiltrates. Glomerulonephritis is rare in primary Sjögren's syndrome, and is most commonly membranoproliferative glomerulonephritis or membranous nephropathy.

Renal disease in mixed connective tissue disease

Some patients with a connective tissue disorder do not fit easily into the accepted definitions of a single disease. In patients with mixed connective tissue disease there is the sequential or concurrent development of the clinical features of systemic lupus erythematosus, systemic sclerosis, polymyositis, and less commonly of rheumatoid arthritis (see Chapter 18.10.2). Renal involvement is found in 10 to 47 per cent of patients with mixed connective tissue disease, the clinical presentation being with asymptomatic proteinuria or haematuria and less commonly with a nephrotic syndrome.

Membranous nephropathy and a mesangial proliferative glomerulonephritis are the most common histological changes, found in 34 and 30 per cent of cases respectively. A focal or diffuse proliferative glomerulonephritis is found in 17 per cent, a mixed lesion with membranous nephropathy in 5 per cent, and in 7 per cent renal histology is normal. Immunofluorescent microscopy of glomeruli in patients with mixed connective tissue disease has shown immunoglobulin and complement deposits; dense deposits are found on electron microscopy.

Treatment of renal disease in mixed connective tissue disease is with steroids, initially in high doses, subsequently tapering to a low maintenance dose over weeks. Treatment of patients with a nephrotic syndrome with high-dose steroids leads to a significant reduction of proteinuria in 62 per cent of cases. Whether those with renal disease resistant to steroids would benefit from the addition of immunosuppressant drugs is not known. Some 14 per cent of patients with mixed connective tissue disease and renal disease develop chronic renal failure.

20.10.5 Renal involvement in plasma cell dyscrasias, immunoglobulin-based amyloidoses, and fibrillary glomerulopathies, lymphomas, and leukaemias

P. Ronco

Introduction

Plasma cell dyscrasias are characterized by uncontrolled proliferation of a single clone of B cells, usually with plasma cell differentiation, that is responsible for the secretion in blood of a monoclonal immunoglobulin (**Ig**) or Ig subunit. This monoclonal component can become deposited in tissues, and the recognized spectrum of renal diseases in which there is deposition or precipitation of Ig-related material has expanded dramatically in recent years.

These conditions can be classified into two categories on the basis of their ultrastructural appearances (Table 1). Those with organized deposits include diseases with crystal formation, mainly myeloma cast nephropathy; diseases with fibril formation, mainly light-chain amyloidosis; and diseases with microtubule formation, including cryoglobulinaemia kidney and immunotactoid glomerulonephritis. A second category of diseases is characterized by the presence of non-organized granular electron-dense deposits made of light and/or heavy chains along the basement membranes of many tissues, most importantly the kidney. First described by Randall and associates, they are named monoclonal immunoglobulin deposition diseases. It is now well established that the spectrum of plasma cell dyscrasia-related renal complications is due to intrinsic properties of the monoclonal component.

Except for myeloma cast nephropathy, diagnosis often relies on careful analysis of a biopsy specimen taken from the kidney, which should systematically include immunohistochemical studies with specific antibodies and also electron microscopy in all ambiguous cases. Since most of these patients will develop renal failure, it is essential to identify the underlying plasma cell dyscrasia because appropriate treatments may halt the extension of visceral deposits, and even induce their regression. Except in patients with myeloma cast nephropathy, who usually present with a high-mass myeloma, 'malignancy' more often results from life-threatening visceral deposits than from the Ig-secreting clone itself.

Renal involvement in Ig light-chain amyloidosis

Definition and epidemiology

Amyloidosis is a general term for a family of diseases defined by morphological criteria and characterized by deposition in extracellular spaces of a proteinaceous material that stains with Congo red and is metachromatic. Amyloid deposits are composed of a felt-like array of 10-nm wide rigid, linear, aggregated fibrils of indefinite length with a b-pleated sheet configuration. They occur in a variety of conditions including Alzheimer's disease and other neurodegenerative disorders, tumoural and inflammatory diseases, and plasma cell dyscrasias. The various types of amyloidosis differ essentially by the nature of the precursor protein that yields the main component of fibrils, and are classified accordingly. (See Chapter 11.12.4 for further discussion.)

Light-chain amyloidosis has become the most frequent form of amyloidosis with renal involvement. Amyloid deposits are found in approximately 10 per cent of myeloma patients, their prevalence reaching 20 per cent in those with pure light-chain myeloma. (Fig. 1 and Plate 1)

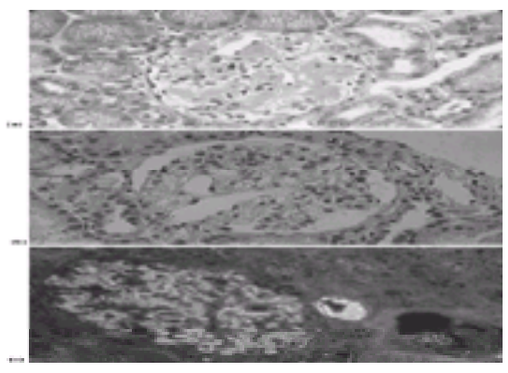

Fig. 1 Light-chain amyloidosis. (a) Amyloid deposits in a renal glomerulus (Masson's trichrome stain, ×312). (b) Congo red stain. Apple-green/yellow dichroism under polarized light (×312). (c) Immunofluorescence with anti-l antibody. Note glomerular and arteriolar deposits (×312). (From Béatrice Mougenot's personal collection.) (See also Plate 1.)

Clinical presentation

The main clinical features of light-chain amyloidosis at presentation are fatigue (62 per cent) and weight loss (52 per cent), followed by purpura (15 per cent), pain (5 per cent), and gross bleeding (3 per cent). Hepatomegaly is found in 24 per cent of patients, and macroglossia in 9 per cent. A palpable spleen and lymphadenopathy can also be found.

Proteinuria is the usual symptom of renal amyloidosis, detected in 55 per cent of patients at presentation and often progressing to a severe nephrotic syndrome, which can be complicated by renal vein thrombosis. Haematuria is uncommon, and when present should prompt examination for a bleeding lesion of the urinary tract. Progressive decline in renal function usually occurs, leading finally to endstage renal failure. In those rare patients in whom renal tubulointerstitial deposits predominate, renal failure may progress without a nephrotic stage, and in some of these cases renal tubular dysfunction may be the presenting problem, including Fanconi syndrome, renal tubular acidosis, or even nephrogenic diabetes insipidus. Hypertension is uncommon but may develop concomitantly with renal failure. The kidneys are generally of normal size or large, even when renal function is impaired.

Light-chain amyloidosis can infiltrate almost any organ and thus be responsible for a wide variety of clinical manifestations. It frequently involves the tongue, gastrointestinal tract, peripheral neural system, carpal tunnel, heart, and skin. Purpuric macules of the superior eyebrow are very typical of light-chain amyloidosis.

Diagnosis

Light-chain amyloidosis should be suspected when the clinical manifestations described above are associated with a monoclonal component. Monoclonal light chains can be detected by immunoelectrophoresis of urine in around 73 per cent of cases, with the l isotype being twice as frequent as the _. With the use of more sensitive techniques (immunofixation), a monoclonal Ig is found in the serum and/or the urine in nearly 90 per cent of patients, but still not in all of them. Light-chain amyloidosis is, however, always the result of the proliferation of a plasma cell clone. Fifty six per cent of patients with light-chain amyloidosis have an increased number of plasma cells in the bone marrow, and 15 per cent of them have a true myeloma.

In all cases, diagnosis of light-chain amyloidosis should be established by taking a biopsy specimen from a superficial organ including skin, salivary glands, gum, or by aspiration biopsy of abdominal fat. These biopsies should be performed before biopsies of rectal mucosa (which should include vessels of the submucosa where amyloid deposits usually start) and/or of kidney because of the risk of bleeding complications due to factor X deficiency or amyloid infiltration of vascular walls. After Congo red staining, amyloid deposits appear faintly red and show the characteristic apple-green birefringence under polarized light. Metachromasia is also observed with crystal violet, which stains the deposits in red. In the kidney, the earliest lesions are located in the mesangium, along the glomerular basement membrane, and in the blood vessels. Because there are specific diagnostic and therapeutic strategies depending on the type of protein deposited within tissues, immunofluorescence with specific antisera including anti-_ and anti-l light chains should be performed routinely.

Treatment

Light-chain amyloidosis is a wasting disease with a poor outcome irrespective of the underlying haematological abnormality. Median survival is 18 months in patients treated with chemotherapy (melphalan and prednisolone) and less than 9 months in those given colchicine only. Among patients with the nephrotic syndrome, a normal serum creatinine and no echocardiographic evidence of heart amyloidosis are associated with a higher response rate (39 per cent) to chemotherapy, as defined by a 50 per cent reduction in proteinuria without an increase in serum creatinine.

The results of chemotherapy in amyloidosis are difficult to document because there is no easy way to measure the amount of amyloid present. Resolution of the nephrotic syndrome does not necessarily reflect the disappearance of amyloid deposits, and the progressive deposition of amyloid can occur in the presence of improved clinical and laboratory findings. Scintigraphy after the injection of ^{123}I-labelled SAP may be helpful for monitoring the extent of systemic amyloidosis, but it is available in a rather limited number of centers (see Chapter 11.12.4). The effects of chemotherapy are better evaluated by the level of circulating monoclonal immunoglobulin and by the daily urinary excretion of Ig light chain.

Amyloid nephropathy requires symptomic management of the nephrotic syndrome and of renal failure. Patients in endstage renal disease are candidates for regular dialysis and/or kidney transplantation. Their prognosis is compromised by the risks of extension of extrarenal deposition, especially to the heart, and by recurrence of amyloidosis in the graft, although the latter is uncommon.

Based on promising results in myeloma patients, high-dose melphalan treatment with autologous bone marrow or blood stem cell transplantation is being attempted in light-chain amyloidosis with interesting results. It should be applied in appropriately designed trials in centres with special expertise.

Renal involvement in myeloma

Definition and epidemiology

Renal failure is one of the major complications of myeloma, found at presentation in 20 per cent of patients and occurring in 50 per cent of patients during the course of the disease. It is mostly due to cast nephropathy, although other forms of renal disease can occur as well, including light-chain amyloidosis (10 per cent of myeloma patients), light-chain deposition disease (5 per cent), fanconi syndrome, infiltration of renal interstitium by plasma cells, calcium precipitation, and renal infection. Myeloma cast nephropathy is due both to alterations in tubule cells induced by massive reabsorption of light chains in proximal tubule cells and to cast formation involving light chains and Tamm–Horsfall protein in the distal tubule. The risk of developing renal failure is twice as high in patients with pure light-chain myeloma, and five to six times greater in patients with light-chain proteinuria of more than 2.0 g/day compared with those with proteinuria of less than 0.05 g/day.

Clinical presentation

Myeloma cast nephropathy usually presents as acute or subacute renal failure, often revealing myeloma with a high tumour burden (found in 70 to 80 per cent of myeloma patients with renal failure). Common triggering factors include hypercalcaemia, dehydration, infection, use of toxic compounds including radiocontrast media, non-steroidal anti-inflammatory drugs, and angiotensin converting enzyme inhibitors, all of which reduce renal perfusion, especially in those who are dehydrated.

Renal failure induced by cast nephropathy is remarkably silent. The clinical and urinary syndrome is characterized by non-specific signs including weakness, weight loss, bone pain, and signs of infection, all due to myeloma, and by urinary excretion of a monoclonal light chain. It must be emphasized that urinary dipsticks do not detect the light chain, which is measured by quantitative tests of proteinuria. Light chain accounts for more than 70 per cent of total proteinuria by urine electrophoresis.

Tubular dysfunction is rarely a presenting symptom. fanconi syndrome due to proximal tubule impairment may result from intratubular crystalline inclusions of _ light chains. This can lead to osteomalacia and may precede the diagnosis of myeloma by several years.

Diagnosis

Diagnosis of myeloma cast nephropathy relies on the detection of a urinary monoclonal light chain in patients with subacute or acute renal failure of apparently unknown origin. In those patients with pure light-chain myeloma, diagnosis can be suspected before urinalysis on the basis of dramatic hypogammaglobulinaemia detected by serum electrophoresis.

A renal biopsy should not be performed routinely in patients with a presumed diagnosis of myeloma cast nephropathy. It can, however, be useful for a number of reasons: firstly, to analyse tubulointerstitial lesions and allow diagnosis and treatment of other potential causes of renal impairment in those with multiple possible precipitating factors (infection, drugs, etc.). Secondly, to establish the diagnosis of Fanconi syndrome. Thirdly, to identify glomerular lesions in patients with albuminuria over 1 g/day and no evidence of amyloid deposits in 'peripheral' biopsies. Myeloma casts have unique characteristics, including a 'fractured' appearance due to crystal formation, polychromatism upon staining with Masson's trichrome, and the presence of multinucleated giant cells. They are consistantly associated with

dramatic epithelial tubular lesions.

Treatment

The first aim of treatment is to prevent or retard renal impairment in all patients with myeloma, most particularly those with light-chain myeloma, by prevention of dehydration, maintenance of a high urinary output and urine alkalinization, avoidance of nephrotoxic drugs, and control of hypercalcaemia (if present). hypercalcaemia requires correction of salt and water deficit, steroids, and/or bisphosphonates, which are potent inhibitors of osteoclast activity. Renal failure of recent onset should be promptly and vigorously managed. Adequate administration of salt and water and forced alkaline diuresis (which may help to prevent intratubular light-chain precipitation) are required when urine output persists. Plasma exchange has been advocated to remove light chains more rapidly, but its value is unproven. In patients with oliguria, dialysis should be provided early.

Most patients with overt myeloma cast nephropathy should be given chemotherapy to reduce the production of monoclonal light chains, which is justified because partial or complete recovery of renal failure occurs in about half of patients. Only patients with refractory haematological disease should be given purely symptomatic treatment. However, median survival in those with progressive renal failure (about 2 years) remains shorter than that of patients without renal failure (3 to 4 years). Two main options should be discussed. Firstly, conventional chemotherapy regimens can induce remissions, but they have not markedly lengthened median survival. The melphalan–prednisone regimen remains the first choice for chemotherapy, but its drawbacks are slow antitumour action and the necessity of reducing melphalan doses because the drug is renally eliminated. Regimens including vincristine and doxorubicin induce earlier remission and are safer in those with renal failure since the drugs are metabolized in the liver. Secondly, in younger patients (those aged less than 65), high-dose chemotherapy with the support of autologous bone marrow or blood stem cell transplantation should systematically be considered because substantially longer survival can be achieved.

In patients with irreversible renal failure and in those whose renal function deteriorates later, regular dialysis may be indicated if the clinical condition and bone lesions allow it. Recombinant human erythropoietin may be helpful to correct anaemia, although very high doses (and therefore great expense) are likely to be needed.

Light-chain and heavy-chain deposition disease

Definition and epidemiology

It has been known since the late 1950s that non-amyloidotic forms of glomerular disease resembling the lesion of diabetic glomerulosclerosis could occur in multiple myeloma. Randall and associates recognized the presence of monoclonal light chains in these lesions in 1976, defining light-chain deposition disease. Monoclonal heavy chains can also be found in association with light chains (defining light- and heavy-chain deposition disease) or occasionally in the absence of light chains (heavy-chain deposition disease). In clinical and pathological terms light-chain deposition disease, light- and heavy-chain deposition disease, and heavy-chain deposition disease are similar and hence are also collectively referred to as monoclonal immunoglobulin deposition disease. They differ from amyloidosis by the lack of affinity for Congo red and fibrillar organization. Monoclonal immunoglobulin deposition disease occurs in a wide range of ages (31 to 79 years) with a slight male preponderance. Myeloma accounts for only 45 per cent of cases, but as in amyloidosis a monoclonal plasma cell proliferation can be found in virtually all patients by immunofluorescence examination of the bone marrow with specific antiheavy- and antilight-chain antisera.

Clinical presentation

Light-chain deposition disease is a systemic disease with deposition of Ig light chains along basement membranes in most tissues. However, deposition in tissues other than the kidney is often (but not always) totally asymptomatic and renal involvement dominates clinical presentation, mainly in the form of proteinuria and renal failure. In 23 to 67 per cent of patients with light-chain deposition disease, albuminuria is associated with the nephrotic syndrome. In 25 per cent, the urinary albumin output is less than 1 g/day, and these patients mainly exhibit a tubulointerstitial syndrome. Haematuria is more frequent (44 per cent) than one would expect for a nephropathy in which cell proliferation is usually modest. Renal failure is remarkable for its high prevalence (89 per cent), early appearance, and severity, irrespective of urinary albumin output. Hypertension occurs in about half of the patients.

Diagnosis

Diagnosis of monoclonal immunoglobulin deposition disease relies on the association of the clinical features described above with the finding of a monoclonal Ig component in the serum and/or the urine. Since this component cannot be detected even by immunofixation in 15 to 30 per cent of patients, the diagnosis of monoclonal immunoglobulin deposition disease is often made by renal biopsy. In virtually all patients with this condition tubular lesions are characterized by the deposition of a periodic acid-schiff positive ribbon-like material along the basement membrane. This is usually associated with a marked interstitial fibrosis and nodular glomerulosclerosis (found in two-thirds of patients with light-chain deposition disease and in all patients with heavy-chain deposition disease reported so far). Nodules are composed of membrane-like material with nuclei at the periphery (Fig. 2 and Plate 2). A key step in the diagnosis of the various forms of monoclonal immunoglobulin deposition disease is immunofluorescence examination of the biopsy specimen, revealing evidence of monotypic light- and/or heavy-chain deposits along glomerular and tubular basement membranes in all cases. By contrast with light-chain amyloidosis, the _ isotype is two to three times more frequent than the l one. In those patients with heavy-chain deposition disease, a deletion of the first constant domain of the heavy chain can invariably be demonstrated by immunofluorescence analysis of the kidney specimen with specific antisera. Finally, non-fibrillar granular electron-dense deposits are visible by electron microscopy along tubular basement membranes and in glomerular lesions.

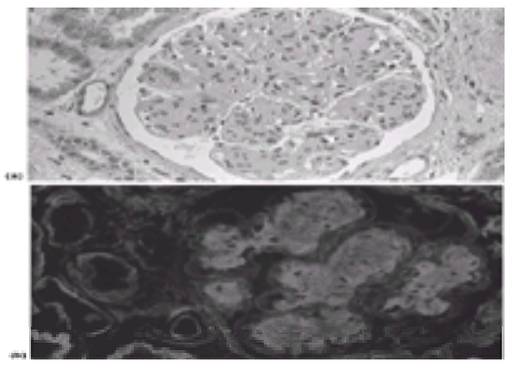

Fig. 2 Monoclonal immunoglobulin deposition disease. (a) Typical nodular glomerulosclerosis. Note the membrane-like material in the centre of the nodules and nuclei at the periphery. Some glomerular capillaries show double contours. Note also thickening of the basement membrane of atrophic tubules (Masson's trichrome stain, ×312). (b) Bright staining of tubular basement membranes and mesangial nodules and, to a lesser extent, of glomerular basement membrane with anti-_ antibody in a case of _ light-chain deposition disease (immunofluorescence, ×312). (See also Plate 2.)

Treatment

The natural history of monoclonal immunoglobulin deposition disease is more uncertain than that of light-chain amyloidosis because extrarenal deposits can be totally asymptomatic or cause severe organ damage, including severe heart failure and occasionally hepatic insufficiency and portal hypertension. The 5-year actuarial rates for patient survival and survival free of endstage renal failure (with chemotherapy) are 70 and 39 per cent respectively.

Patients with monoclonal immunoglobulin deposition disease and myeloma should be treated with conventional chemotherapy if they are over 60 years of age, but intensive therapy with blood stem cell autografting should be discussed in younger patients (see above). As in light-chain amyloidosis, deposited light chains have disappeared in isolated instances after intensive therapy. The correct treatment for those without myeloma is uncertain, the rarity of the disease meaning that there are no controlled trials. A pragmatic approach is to use alkylating agents plus prednisolone in those with moderate but rapidly progressive renal insufficiency in an endeavour to prevent progression to endstage renal failure, but not to treat those with severe renal failure unless there are significant extrarenal complications.

Recurrence of the disease has usually been observed in the few patients who have received renal transplants.

Non-amyloid fibrillary and immunotactoid glomerulopathies

Definition and epidemiology

Fibrillary glomerulonephritis and immunotactoid glomerulopathy are recently described entities characterized, respectively, by fibrillar and microtubular deposits in the mesangium and the glomerular capillary loops. These deposits do not have a b-pleated sheet organization and are readily distinguishable from amyloid by the larger thickness of fibrils and the lack of Congo red staining. Whether they are totally distinct entities remains the subject of considerable debate. However, the distinction between the two diseases may be of great clinical and pathophysiological interest in the context of plasma cell dyscrasias because monotypic deposits are detected in 50 to 80 per cent of immunotactoid glomerulopathies, whilst they are found in fewer than 20 per cent of fibrillary glomerulopathies.

The prevalence of glomerulopathy with non-amyloid deposition of fibrillary or tubular material in a non-transplant adult biopsy population is around 1 per cent, but this is almost certainly an underestimate because insufficient attention is given to atypical reactions with histochemical stains for amyloid and the fact that most specimens are not examined by electron microscopy. The age range extends from 10 to 80 years with a peak incidence between 40 and 60 years.

Clinical presentation

The usual presentation is with the nephrotic syndrome and microscopic haematuria, often in the setting of chronic lymphocytic leukaemia or lymphoma.

Diagnosis

Diagnosis relies entirely on analysis of the renal biopsy specimen by immunofluorescence microscopy with antilight-chain antibodies and by electron microscopy. In immunotactoid glomerulopathy this reveals either membranous glomerulonephritis (often associated with segmental mesangial proliferation) or lobular membranoproliferative glomerulonephritis. Immunofluorescence shows coarse granular deposits of IgG and IgC3 along capillary basement membranes and in mesangial areas. Although monotypic deposits are common, a circulating monoclonal Ig is detected in only a minority of patients. Electron microscopy shows immunotactoid glomerulopathy to be remarkable for the presence of organized deposits of large, thick-walled microtubules, usually greater than 30 nm in diameter, at times arranged in parallel arrays. When immunotactoid glomerulopathy occurs in the setting of chronic lymphocytic leukaemia or related B-cell lymphoma, inclusions showing the same microtubular organization and containing the same IgG subclass and light-chain type as the renal deposits are then often detected in the cytoplasm of leukaemic lymphocytes in the blood (Fig. 4).

Mesangial proliferation and membranoproliferative glomerulonephritis are the commonest lesions observed in fibrillary glomerulonephritis. Immunofluorescence studies mainly show polyclonal IgG deposits (of the g4 isotype in one series). Electron microscopy shows the fibrils to be randomly arranged with a diameter varying between 12 and 22 nm.

Infection wuth hepatitis c virus has recently been reported in patients with non-amyloid fibrillary glomerulonephritis and immunotactoid glomerulopathy.

Treatment

In patients with immunotactoid glomerulopathy and monotypic immunoglobulin deposits, especially in those with chronic lymphocytic leukaemia, corticosteroids and/or chemotherapy are associated with partial or complete remission of the nephrotic syndrome, parallel with improvement of the haemopathy. More variable results are obtained with these treatments in patients with crescentic fibrillary glomerulonephritis. Recurrence of these diseases has been reported in patients receiving a renal allograft.

Renal involvement in cryoglobulinaemia

Definition and epidemiology

Cryoglobulinaemia is a pathological condition in which the blood contains immunoglobulins that precipitate on cooling (4 °C) and resolubilize on warming (37 °C). according to Brouet's classification, there are three types of cryoglobulinaemia defined by their composition. Renal involvement is observed mainly in patients with mixed type II cryoglobulinaemia involving a monoclonal IgM (most often including a _ light chain) with rheumatoid factor activity and a polyclonal IgG. Type II cryoglobulinaemia can be associated with overt lymphoproliferative disorders of the B-cell lineage, although in many cases no underlying haemopathy is found. Therefore, this type of cryoglobulinaemia has long been referred to as essential mixed cryoglobulinaemia (Fig. 3 and Plate 3).

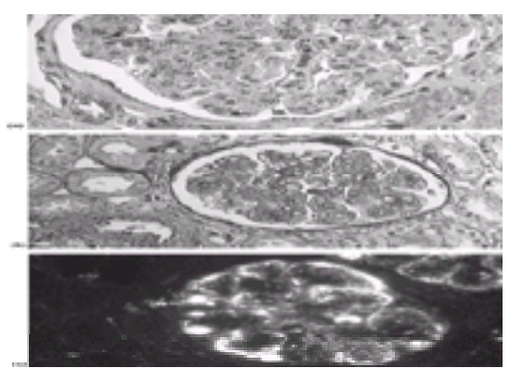

Fig. 3 Cryoglobulinaemic glomerulonephritis. (a) The glomerulus shows a marked endocapillary hypercellularity with massive infiltration of mononuclear leucocytes (Masson's trichrome stain, ×500). (b) Frequent double-contour aspect, and intraluminal thrombi (periodic acid-Schiff stain, ×312). (c) thrombi and segments of glomerular basement membrane are brightly stained with anti-IgM antibody (immunofluorescence, ×312). (From Béatrice Mougenot's personal collection.) (See also Plate 3.)

Viral infections may trigger the formation of cryoglobulin. Whereas hepatitis B and Epstein–Barr virus infections have been implicated in the past, the role of hepatitis C virus infection is now recognized to be an important factor in the pathogenesis of type II cryoglobulinaemia. Antibodies to hepatitis C virus and hepatitis C virus RNA are frequently found in the sera of patients with type II cryoglobulinaemia, probably explaining the uneven geographical distribution of mixed cryoglobulinaemias, which predominate in southern Europe where hepatitis C infection is more prevalent.

The condition is commonest in adults in the fifth and the sixth decades of life, with a slight female predominance.

Clinical presentation

Renal disease most often occurs in patients with a long history of cryoglobulinaemia-related vasculitis symptoms including palpable purpura (70 per cent), arthralgias (50 per cent), fatigue, Raynaud's phenomenon, peripheral neuropathy (22 per cent), and hepatic involvement.

The renal disease may present as an acute nephritic syndrome (in 20 to 30 per cent of cases) with gross haematuria, heavy proteinuria, hypertension, and renal failure of sudden onset, sometimes with oliguria (5 per cent of cases). The pathological finding in these patients is membranoproliferative glomerulonephritis with the presence of numerous intraluminal thrombi and/or necrotic vasculitic lesions. Remission may occur spontaneously or during therapy, with relapses following in up to

20 per cent of cases.

Most patients with mixed cryoglobulinaemia (55 per cent) have an indolent and protracted renal course, presenting with proteinuria, haematuria, and hypertension. The usual renal lesion in this context is membranoproliferative glomerulonephritis, with some of the peculiarities described above.

Nephrotic syndrome affects another 20 per cent of patients. Arterial hypertension is observed in more than 80 per cent of patients at the time of onset of renal disease. Endstage uraemia develops in fewer than 10 per cent of patients.

Diagnosis

Mixed type II cryoglobulinaemia should be suspected in patients with the clinical picture described above, an IgM rheumatoid factor, and a very low serum C4 fraction and total haemolytic activity of complement. In this context a careful search for the presence of cryoglobulin must be made, requiring that a blood sample from a fasting patient should be placed in warm water and taken promptly to the laboratory, which needs to be forewarned that such a sample will arrive.

Cryoglobulinaemia-related membranoproliferative glomerulonephritis usually shows several distinctive histological features, including massive subendothelial deposits filling the capillary lumen and forming so-called thrombi, and dramatic infiltration by leucocytes, mainly monocytes. The thrombi are brightly stained with anti-µ and anti-_ antibodies and present a microtubular crystalline structure similar to that of the cryoprecipitate. These glomerular changes may be associated with acute vasculitis of the small and medium-sized arteries (33 per cent) and lymphocytic infiltrates in interstitium. Crescentic extracapillary proliferation is rare and always limited.

Treatment

The best treatment is not firmly established because the course of the disease is unpredictable and acute exacerbations may remit spontaneously. High-dose steroids, cyclophosphamide, and plasma exchanges are used in the more severe cases, particularly those with signs of systemic vasculitis. The place of antihepatitis C virus therapy including interferon-a and vidarabine has still to be evaluated. These antiviral drugs may be useful for controlling virus replication enhanced by steroids and/or immunosuppressive agents. Hypertension needs to be carefully controlled because cardiovascular complications are the major causes of death.

Renal involvement in Waldenström's macroglobulinaemia

A glomerulonephritis with intracapillary thrombi of IgM is rare, but is almost specific for Waldenström's macroglobulinaemia. It is characterized by periodic acid-Schiff positive, non-congophilic endomembranous deposits in a variable number of capillary loops, which are sometimes so large as to occlude the capillary lumen either partially or completely, thus forming thrombi. There may also be a B-cell interstitial infiltrate. Renal presentation is with proteinuria or renal impairment. Some patients have a cryoglobulin, in others the amount of circulating IgM seems to be higher than that in patients with Waldenström's without obvious renal involvement, or with amyloidosis, leading to the suggestion that hyperviscosity is important in pathogenesis of the renal lesion. The haemopathy is treated on its own merits (see Section 22). In those with acute renal failure there is anecdotal experience that plasma exchange can be effective in restoring renal function at least temporarily, allowing time for other treatments to be applied.

Renal involvement in lymphomas and leukaemias

Renal complications of lymphomas and leukaemias are summarized in Table 2. Patients with unexplained renal failure should undergo ultrasound examination of the kidney, which should be arranged as a matter of urgency, to identify either enlarged kidneys due to tumour infiltration or hydronephrosis. The presence of heavy albuminuria in this setting is suggestive of paraneoplastic glomerulopathy.

Hodgkin's disease and non-Hodgkin's lymphoma

Glomerulonephritis is a rare complication of lymphoma, most often described in patients with Hodgkin's disease, of whom 0.4 per cent have minimal change disease and 0.1 per cent have AA amyloidosis. This low incidence of amyloidosis in patients with Hodgkin's disease is most likely attributable to modern treatment protocols that induce a rapid remission of the haemopathy. Hodgkin's lymphoma-related minimal change disease shows features of a paraneoplastic glomerulopathy: the nephrotic syndrome usually appears early, revealing the haemopathy in about one-half of the cases; it rapidly disappears after effective treatment of Hodgkin's disease and it usually relapses simultaneously with the haemopathy. Cases of crescentic glomerulonephritis with rapidly progressive renal failure due to antiglomerular basement antibodies have also been reported.

There are about 50 reports of glomerulonephritis in patients with non-Hodgkin's lymphoma, including both T- and B-cell proliferations. In these conditions, unlike in Hodgkin's lymphoma, minimal change disease is uncommon, and membranoproliferative glomerulonephritis and necrotizing crescentic glomerulonephritis with or without vasculitis are the most frequent lesions. Some cases are associated with type II cryoglobulinaemia or immunotactoid glomerulopathies with monotypic immune deposits. In other cases the association between non-Hodgkin's lymphoma and renal involvement may be coincidental. Presenting renal symptoms are nephrotic syndrome and/or renal impairment. Full remission of these symptoms can be achieved in some patients by aggressive therapy of the lymphoma.

Chronic lymphocytic leukaemia and low-grade B-cell lymphoma

These haemopathies, particularly chronic lymphocytic leukaemia, have been reported in association with glomerular disease in about 50 cases. Most commonly the nephropathy, usually manifesting as nephrotic syndrome with impaired renal function, and the leukaemia are detected simultaneously. The most frequent glomerular disease is membranoproliferative glomerulonephritis with or without cryoglobulinaemia. In the absence of cryoglobulinaemia, a molecular link can be established between the haemopathy and the glomerulopathy when monotypic Ig deposits are found in the glomerulus, which can occur even in the absence of detectable circulating M component. Some of these patients present with typical immunotactoid glomerulopathy or monoclonal immunoglobulin deposition disease (Fig. 4 and Plate 4). Improvement of the nephropathy after treatment for the leukaemia is well described.

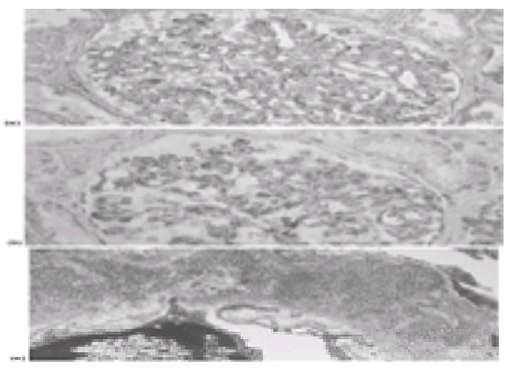

Fig. 4 Immunotactoid glomerulopathy in a patient with chronic lymphocytic leukaemia. Atypical membranous glomerulonephritis showing exclusive staining of the deposits with anti-g (a) and anti-_ (b) antibodies (immunohistochemistry, alkaline phosphatase, ×312). (c) Electron micrograph of glomerular basement membrane, showing the microtubular structure of the subepithelial deposits (uranyl acetate and lead citrate, ×12 000). (From Béatrice Mougenot's personal collection.) (See also Plate 4.)

Acute leukaemias

Disseminated intravascular coagulation has been associated with acute progranulocytic leukaemia. Other renal complications are commonly due to treatment, most

particularly the tumour lysis syndrome (see below).

Tumour lysis syndrome

Tumour lysis syndrome is a life-threatening metabolic emergency. It occurs in patients with haemopathies involving a high cell turnover, mostly at the onset of chemotherapy and/or upon radiation therapy. The ensuing massive cytolysis generates high levels of uric acid, phosphate, potassium, and xanthine (especially in patients treated with allopurinol), with a concomitant decrease in serum calcium concentration. Oliguric or anuric acute renal failure may occur, especially in those who are dehydrated or have pre-existing impairment of kidney function. This acute renal failure is mostly the consequence of acute precipitation of urate crystals in the tubular lumen, but in those with a moderate increase in uric acid concentration, the role of severe hyperphosphataemia causing precipitation of calcium/phosphate complexes in renal interstitium and the tubular system has been assumed.

Prevention is better than cure and intensive monitoring is mandatory to prevent the development and the consequences of this syndrome. Patients at risk of the tumour lysis syndrome should be vigorously hydrated with 0.9 per cent saline (assuming normal or near normal baseline renal function, and with care taken to avoid inducing pulmonary oedema) before receiving chemotherapy or radiotherapy. Some physicians would also pretreat with allopurinol, but this does carry the risk of formation of xanthine nephropathy/stones due to accumulation of xanthine and cannot be generally recommended. Urine alkalinization should be avoided because it increases the risk of phosphate precipitation. In those who develop tumour lysis syndrome but are passing urine, vigorous hydration with 0.9 per cent saline to encourage urine output is required, with close clinical monitoring to prevent iatrogenic fluid overload should the urine output drop. Administration of urate oxidase has been advocated as a treatment for acute hyperuricaemia, but experience is very limited and there is no therapeutic formulation that is widely available. Patients with severe acute renal failure should be treated with haemodialysis, which allows recovery of renal function following the reduction of serum phosphate and serum uric acid concentrations.

20.10.6 Haemolytic uraemic syndrome

Paul Warwicker and Timothy H. J. Goodship

Introduction

The haemolytic uraemic syndrome (**HUS**) is characterized by the triad of microangiopathic haemolytic anaemia (Coombs' test negative), thrombocytopenia, and acute renal failure. In thrombotic thrombocytopenic purpura (**TTP**) neurological manifestations and fever occur in addition.

Classification (Table 1)

HUS can be divided into diarrhoeal (D+)- and non-diarrhoeal-associated (D–) disease. Historically, some disorders that present with the characteristic triad of features have been considered separately from HUS. This is illogical, and they too are listed as forms of D– HUS. Because the clinical presentation, prognosis, and treatment differ for each form of HUS they are described separately in this chapter.

Pathogenesis of HUS

The anticoagulant state of normal endothelium is maintained by: (1) a lack of the constitutive expression of tissue factor; (2) the endothelial expression of heparin, tissue-plasminogen activator, and thrombomodulin; and (3) the local secretion of vasoactive substances preventing platelet aggregation, including nitric oxide, prostacyclin, and adenosine.

In HUS, several factors can result in endothelial cell activation, these include: antiendothelial antibodies, immune complexes, lipopolysaccharides, toxins, complement, and drugs. Tissue factor and tissue-plasminogen activator inhibitor are expressed. In addition, von Willebrand factor (**vWF**) is synthesized and secreted in increased amounts, promoting platelet aggregation by binding to the $a_{iiib}b_3$ integrins on the platelet surface and to the endothelial matrix. Downregulation of this process is usually achieved by endothelial secretion of a metalloproteinase that cleaves vWF, rendering it inactive.

The effect of endothelial activation, a crucial feature of all the conditions listed in Table 1 as causing HUS, is that five core changes occur: loss of vascular integrity, expression of leucocyte-adhesion molecules, cytokine production, upregulation of HLA molecules, and the change in phenotype from an anticoagulant to a procoagulant state. It is the latter that predisposes to the development of a thrombotic microangiopathy.

There have been many descriptions of phenomena associated with HUS, such as complement activation and the secretion of ultra-large vWF, selectins, and tissue plasminogen activator-I. Causal relationships have been proposed. In retrospect many of these observations merely reflect a state of endothelial activation. However, if the mechanisms responsible for downregulating the sequelae of endothelial activation are impaired then it is possible that a procoagulant state will be maintained. This has recently been shown for both HUS (overactivity of the alternative complement pathway) and TTP (abnormalities of the metalloproteinase that cleaves vWF).

Histopathology (Fig. 1 and Plate 1)

In D+ HUS it is predominantly the glomerular endothelium that is affected (hence termed 'thrombotic glomerulopathy'), whilst in D– HUS it is the endothelium of the preglomerular vessels (hence termed 'arterial thrombotic microangiopathy'). Severe intimal proliferation and luminal stenosis also affects arterioles and interlobular arteries in some forms of D– HUS. The subendothelial spaces are widened and these may contain fibrin deposits.

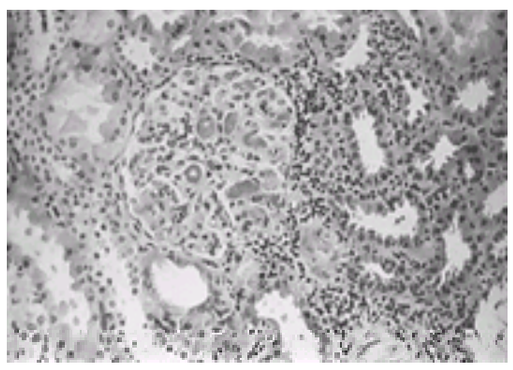

Fig. 1 Typical changes of glomerular thrombotic microangiopathy in a patient with HUS (figure kindly provided by Dr Marie O'Donnell). (See also Plate 1.)

Diagnosis and laboratory features

The diagnosis of HUS is based on demonstrating the aforementioned triad of microangiopathic haemolytic anaemia, thrombocytopenia, and acute renal failure. It should be considered and excluded in all cases of acute renal failure, especially those associated with diarrhoea and/or severe hypertension. Urine output may be reduced, although non-oliguric renal failure is also seen. Urinalysis usually shows microscopic haematuria and proteinuria.

The anaemia of HUS may be severe, with features of haemolysis, including reticulocytosis and increased unconjugated bilirubin, decreased haptoglobin, and raised lactate dehydrogenase (**LDH**) levels, which can be used as a marker of disease. The Coombs' test is negative, and careful examination of the blood film may reveal fragmented and deformed red cells. Thrombocytopenia ranges from severe to mild: 50 per cent of patients will have platelet counts in excess of 100×10^9/l. There may be an associated leucocytosis, the extent of which is correlated with disease severity in D+ HUS. Fibrinogen degradation products may be increased, but clotting tests are characteristically normal. If they are deranged, then septicaemia and disseminated intravascular coagulation should be considered.

Hyponatraemia may complicate D+ HUS, which can then be associated with seizures. Hyperkalaemia is occasionally severe. Complement levels should be measured: C3 is often low in both D+ HUS, where it is associated with a poor prognosis, and D– HUS, where it is associated with recurring or familial types of disease. Human immunodeficiency virus (**HIV**) infection should also be considered in appropriate risk groups.

Diarrhoeal (D+) HUS

Incidence

This is the commonest form of HUS, accounting for over 90 per cent of cases in industrialized countries. It is the commonest cause of renal failure in children and is associated with a diarrhoeal prodrome, hence D+ HUS. The bloody diarrhoea is caused by bacterial infection, predominantly with strains of enterohaemorrhagic *Escherichia coli*, notably *E. coli* O157:H7. This strain has only recently become a significant health hazard—the first descriptions of haemorrhagic colitis and HUS associated with it appeared in 1983. Since then there has been a rapid increase in the number of cases reported. One of the largest and most serious outbreaks was the Central Scotland outbreak of 1996 where 496 individuals were infected, 27 developed HUS, and 18 died. Other diarrhoeal pathogens, particularly *Shigella dysenteriae*-type 1, can also cause D+ HUS.

Clinical features

E. coli is very virulent with as few as 50 organisms causing disease. The bacteria adhere to the large bowel and release a toxin, known as verocytotoxin or Shiga toxin, into the bloodstream. This toxin belongs to the **RIP** (ribosomal inhibitory protein) group of proteins which are amongst the most potent toxins known to man. They include ricin, which gained notoriety in 1978 when an iridium pellet containing trace amounts of the toxin was injected with the aid of an umbrella into the calf of the dissident Bulgarian journalist, Georgi Markov, on Waterloo bridge in London. He subsequently died from multiorgan failure. These toxins consist of five b-subunits and a single a-subunit. The b-subunit binds to Gb3 (a glycolipid found in the membranes of eukaryotic cells), following which the toxin enters the cell by endocytosis and the a-subunit blocks protein synthesis at the ribosome.

The delay between exposure and illness is on average 3 days, typically starting with abdominal cramps and diarrhoea, which becomes bloody over the following 2 days. The majority of patients then recover, although late sequelae such as colonic strictures and chronic pancreatitis are occasionally seen. Between 3 and 20 per cent go on to develop HUS of varying severity. Approximately 50 per cent of patients with D+ HUS require renal replacement therapy, 5 per cent are left with chronic renal failure, and 3 to 5 per cent die of the acute illness. In those who do recover, between 15 and 40 per cent show evidence of persistent renal damage with proteinuria and/or hypertension. Acute neurological complications such as cerebrovascular accident, seizures, and coma develop in approximately 25 per cent of patients with D+ HUS.

Diagnosis

E. coli O157:H7 infection is diagnosed by stool culture and subsequent detection of the O157:H7 antigen. It is also possible to detect antibodies to the O157 lipopolysaccharide in sera from convalescent patients, although this is of limited use in acute illness and is not widely available.

Treatment

Identification of infection and early diagnosis of HUS are important. However, it is unclear whether antibiotics in the early stages of the disease are of benefit, and it is possible that they may increase the risk of developing HUS. Antimotility agents are contraindicated in the early stages as they too may increase the risk of HUS. Treatment of D+ HUS is predominantly supportive, including careful fluid and electrolyte balance, control of hypertension, nutritional support, and renal replacement therapy if necessary. Vigilance should be maintained for complications such as ischaemic colitis, myocardial dysfunction, and pancreatitis. There is limited evidence for a benefit of either plasma exchange or plasma infusion, but plasma exchange continues to be used, particularly in complicated and prolonged cases. Specific treatments such as toxin-binding resins and toxoid vaccines are currently being investigated. Prevention and good public health policy is likely to be of the utmost importance in the future. The recent outbreak in Scotland led to the commissioning of the *Pennington report*, which produced recommendations for disease prevention ranging from the 'farm to the table'.

Non-diarrhoeal (D–) HUS

Different forms of D– HUS

Idiopathic

Idiopathic, also known as sporadic or atypical, HUS accounts for approximately 5 to 10 per cent of cases. It is typically insidious, although it may present following an upper respiratory tract infection. People of all ages can be affected, and there is no seasonal incidence. Severe hypertension is frequent and mortality is higher than with D+ HUS. Renal involvement is usually pronounced with significant proteinuria and uraemia. The disease may recur in both native kidneys and allografts.

As the name suggests, the cause of idiopathic HUS is unknown. Recent research has focused on a dysfunction of complement-pathway modulators; case reports often reveal low levels of C3, indicating overactivity of the alternative complement pathway (see familial HUS below). Other possible aetiological factors implicated include dysfunction of prostacyclin metabolism, abnormalities of von Willebrand factor multimers (see the section on TTP), abnormalities of platelet-activating factor, and tissue plasminogen activator inhibitor-type 1.

Familial HUS

HUS may be inherited as both autosomal recessive and autosomal dominant forms. In autosomal recessive disease the onset is early, with a peak incidence in infancy. Affected children may suffer recurrent episodes. Autosomal dominant disease can affect all ages, and may be precipitated by pregnancy. Phenotypically, familial HUS most closely resembles idiopathic HUS. Severe hypertension is a prominent feature, being found in approximately 80 per cent of autosomal dominant and 40 per cent of autosomal recessive cases. There is usually no diarrhoeal prodrome, prognosis is poor, mortality is high (often over 50 per cent), and recurrence is common. Management includes aggressive control of blood pressure, particularly with angiotensin-converting enzyme (**ACE**) inhibitors, careful fluid balance, and plasma exchange (although it is often unsuccessful in reversing the disease).

Although familial HUS is rare, it affords an opportunity to elucidate underlying mechanisms relevant to the acquired form of D– HUS. Genetic linkage of the familial form of the disease has been established to an area of chromosome 1q32 containing the gene for complement factor H. This is a soluble serum protein that downregulates the spontaneous activity of the alternative complement pathway. Factor H deficiency has now been described in several families with HUS. Mutations in the factor H gene have been identified in both familial and sporadic HUS.

Transplantation

Both *de novo* and recurrent HUS are seen following renal transplantation. HUS is a well-established side-effect of both ciclosporin and tacrolimus (FK506). Other risk factors include acute rejection, cytomegalovirus (**CMV**) infection, and simultaneous pancreas transplantation. Treatment includes discontinuation of the drug, the use of intravenous corticosteroids, and the substitution of other immunosuppressive agents.

HUS is also seen with other forms of transplantation, particularly that of bone marrow, where between 6 and 26 per cent of patients show evidence of a microangiopathy. The aetiology is unclear, but may be related to endothelial damage secondary to total body irradiation, intensive conditioning chemotherapy, ciclosporin treatment, CMV infection, or graft-versus-host disease. Management is supportive, including renal replacement therapy, the aggressive treatment of hypertension with ACE inhibitors, and the withdrawal of ciclosporin. Fresh-frozen plasma replacement may be of benefit, but treatment is usually unsuccessful in the more fulminant forms of the disease and prognosis is poor.

Drug-related

Other drugs besides ciclosporin and tacrolimus are associated with HUS. In particular, several cytotoxic drugs used in chemotherapy are complicated by the syndrome (so-called **C-HUS** or cancer-chemotherapy HUS). They include mitomycin C, 5-fluorouracil, and cisplatin either alone or in combination with daunorubicin, vinblastine, and bleomycin. The disease may be associated with severe hypertension, pulmonary oedema (often after transfusion of blood products), neurological features, and a high mortality (60 to 75 per cent in some series). With mitomycin C the disease is dose-related: it is rarely seen in patients receiving less than 30 mg/m^2, but more frequently at doses above 60 mg/m^2. The incidence is between 2 and 15 per cent, and usually presents weeks or months after the last treatment with mitomycin, often when the patient is in clinical remission. Few treatments have proven effective, although staphylococcal protein-A column perfusion to remove

circulating immune complexes seems to be more effective than plasma exchange and may be of benefit in less severe forms of the disease.

Other drugs implicated in HUS include crack cocaine, ticlopidine, and quinine. Use of the oral contraceptive has also been said to be associated with HUS, although with such a commonly prescribed medication it is difficult to be certain whether the association is coincidental. However, it is wise to advise against its use in survivors of D– HUS and in families with the inherited form of HUS.

Pregnancy-related

The incidence of HUS in pregnancy is approximately 1 in 25 000. Presentation is usually peripartum or within a few weeks after delivery, when it is also known as postpartum renal failure. In women presenting in the third trimester, it may be difficult to differentiate HUS from severe forms of pre-eclampsia, such as the **HELLP** syndrome (haemolysis, elevated liver enzymes, and low platelets). Pre-eclamptic syndromes tend to be associated with less severe haemolytic anaemia, the presence of hepatocellular necrosis, and a rapid improvement postdelivery. Features of pregnancy-related HUS include severe hypertension, neurological symptoms, fever, and renal failure requiring renal replacement therapy. Although plasma exchange increases survival rates, maternal mortality remains between 5 and 20 per cent, and preterm delivery and intrauterine fetal death (approximately 30 per cent) are frequent complications. Long-term follow-up is important because of the later development of renal failure and hypertension. HUS will reoccur in approximately 50 per cent of patients, not only during a further pregnancy but also at other times.

Malignancy-related

HUS is associated with malignancy, particularly adenocarcinoma. Patients with a gastric primary and metastatic disease are at increased risk.

HIV-related

There are several forms of nephropathy associated with HIV infection, and a thrombotic microangiopathy with features resembling both idiopathic HUS and TTP is being increasingly recognized. The incidence of HUS in patients infected with HIV is estimated at approximately 1 per cent; although it usually presents in the later stages of the disease, occasionally it can be the first presentation. HIV infection should be considered in the differential diagnosis of HUS and TTP in high-risk groups and in patients originating from a high-prevalence area. The p24 antigen in endothelial cells may reflect either a direct cytopathic effect of the virus or functional impairment of the endothelium. Concurrent CMV infection has also been associated with HUS. Neurological involvement is common and severe hypertension is a prominent feature. Plasma exchange can lead to renal recovery, but overall the prognosis is poor and few patients survive 1 year from diagnosis. Since ACE inhibitors are used in the therapy of other forms of HIV-associated nephropathy, they would seem a logical choice in the treatment of hypertension.

Other infective causes

Non-diarrhoeal bacterial infections are occasionally associated with HUS. *Pneumococcus* and some *Clostridia* species can produce neuraminidase which strips sialic acid from cell membranes, thereby exposing the cryptic Thomsen–Friedenreich antigen on erythrocytes, platelets, and glomerular cells. An IgM antibody, present in most plasma, causes agglutination, endothelial injury, and HUS. Plasma exchange is therefore contraindicated and treatment consists of washed red cells and antibiotics. Difficulty in red cell typing and a blood film demonstrating both agglutination and red cell fragments may give a clue to diagnosis. Capnocytophagia sepsis from dog bites has recently been associated with cases of HUS.

Immunological disorders

HUS has been reported in association with systemic lupus erythematosus, primary antiphospholipid syndrome, and a variety of glomerulonephritides.

'HUS-like' syndromes

As the renal crisis of systemic sclerosis can be clinically and histologically indistinguishable from idiopathic D– HUS, a diagnosis of systemic sclerosis is often made retrospectively from serological markers or with the development of other features of the disease. Likewise, the thrombotic microangiopathy of accelerated hypertension may be difficult to distinguish from HUS. The most important aspect of treatment in these syndromes is good blood pressure control; ACE inhibitors should be prescribed early, balanced with the requirement to reduce blood pressure gradually. In the renal crisis of systemic sclerosis there may be late recovery of renal function, even when the patient has been established on dialysis for some weeks or months.

Treatment of D– HUS

Few randomized controlled trials have been conducted into the treatment of D– HUS.

Supportive

This consists of careful fluid balance, blood transfusion, and renal replacement therapy. In oliguric patients care should be taken to prevent fluid overload, and central venous monitoring may be required. Platelet transfusions should be avoided, unless there is evidence of bleeding. Patients with deteriorating renal function should always be referred to a renal unit.

Plasma treatment

Previous studies of the efficacy of plasma treatment in HUS are difficult to interpret because of the inclusion of patients with TTP who respond well to plasma exchange. Nevertheless plasma exchange is recommended for most forms of D– HUS.

Corticosteroids

The use of corticosteroids is controversial. Although there is evidence of their efficacy in the treatment of TTP, in small retrospective studies of D– HUS they appear to have no significant effect on survival or the need for renal replacement therapy.

Hypertension

Because of the histological changes in HUS, it is not surprising that hypertension, presumably renin driven, is common. ACE inhibitors are the treatment of choice, with clear parallels existing with their use in the renal crisis of systemic sclerosis. Bilateral nephrectomy has been advocated for severe D– HUS with widespread manifestations unresponsive to plasma exchange. In a series of four patients (three of whom suffered ACE inhibitor-resistant hypertension), bilateral nephrectomy led to complete haematological and clinical remission within 2 weeks.

Renal transplantation

Renal transplantation in patients with renal failure secondary to D+ HUS is safe, with little risk of disease recurrence. In contrast, patients with D– HUS have a 30 to 50 per cent chance of recurrence, usually within the first 2 months, and often within the first 2 weeks. Once recurrent HUS is established, most grafts are lost despite treatment with plasma exchange. This is reflected in the poor 2-year overall graft survival rate of 35 per cent. Graft nephrectomy should not be delayed in this situation. Acute vascular rejection may be difficult to differentiate from recurrent HUS, both clinically and histologically.

20.10.7 Sickle-cell disease and the kidney

G. R. Serjeant

Homozygous sickle-cell (**SS**) disease results in anaemia, a hyperdynamic circulation, less deformable red blood cells, and probably widespread endothelial damage and dysfunction. These processes affect structure and function in the kidney: medullary and glomerular involvement occurs at different ages and with different implications for outcome. Other genotypes of sickle-cell disease such as sickle-cell haemoglobin C (SC) disease, sickle-cell b°-thalassaemia, and sickle-cell b^+-thalassaemia manifest similar but less frequent and less severe changes. Even the sickle-cell trait is associated with some abnormalities of renal function.

Medullary involvement

Vascular damage

The vasa rectae system of the renal medulla with its low oxygen tension, high pH, and hypertonicity is uniquely conducive to sickling, causing disruption of the blood vessels and secondary damage to the renal tubules. Microradioangiographic studies have shown almost complete obliteration of the fine-vessel system of the vasa rectae, the remaining vessels being distorted into spirals, dilatations, and appearing to end blindly. These changes have been observed in SS disease in childhood and occur to a lesser extent in the sickle-cell trait in which haemoglobin S levels are only 20 to 45 per cent of total haemoglobin.

Tubular dysfunction

The functional effect of these vascular changes is an inability to concentrate the urine normally, which becomes worse with age but can be improved by transfusion in children under 2 years. Proximal tubular functional abnormalities include an increased secretion of urate and an increased reabsorption of phosphate and of b_2-microglobulin. Distal tubular functional abnormalities include an inability to excrete an acid load, defective maximal potassium excretion, and occasionally evidence of hyporeninaemic hypoaldosteronism.

Clinically, these changes are reflected in hyposthenuria with larger urinary volumes contributing to nocturia, enuresis, and possibly a tendency to dehydration.

Glomerular involvement

Large hypercellular glomeruli are characteristic of SS disease from the age of 2 years, the size continuing to increase with age even over the age of 40 years. The large glomeruli in childhood are associated with supranormal glomerular filtration rates, effective renal blood flows, and effective renal plasma flows. All these indices fall with age and in many patients aged 30 to 40 years are below normal, with particularly rapid decline occurring in some patients who proceed to chronic renal failure. This functional deterioration is assumed to reflect progressive glomerular loss, the mechanism of which is unclear, but there may be contributions from immune complexes derived from renal tubular epithelial antigen and mechanical damage to the nephron from hyperfiltration. The notion that glomerular capillary hypertension might be involved gained support from the observation that angiotensin-converting enzyme inhibitors significantly reduce proteinuria in some proteinuric patients with SS disease.

Clinical syndromes

Nocturnal enuresis

Enuresis is common in SS disease, and in the Jamaican Sickle Cell Cohort study occurred at least 2 nights weekly in 52 per cent of SS males and 38 per cent of SS females aged 8 years compared with values of 22 and 17 per cent in normal control children. Enuretic children with SS disease have slightly higher urine volumes and lower mean maximal functional bladder capacities than those without enuresis, and the ratio of overnight urine volume to bladder capacity was significantly greater in enuretic subjects. Enuresis alarms may therefore be the most appropriate therapy but require testing in controlled studies.

Haematuria

Haematuria occurs in both sickle-cell disease and sickle-cell trait and is believed to result from ischaemic lesions of the renal papilla, varying from minute ulcerations to renal papillary necrosis. Treatment is conservative, although prolonged haematuria may require blood transfusion or rarely limited surgery. Epsilon aminocaproic acid, which inhibits urokinase, has been effective in some cases, but promotes clots that may obstruct the ureters and its use requires assessment in controlled trials.

Urinary tract infections

The frequency of urinary tract infections is increased in subjects with the sickle-cell trait during pregnancy, and may be increased in SS disease, although no reliable data are available. *Escherichia coli*, *Klebsiella*, and *Enterobacter* spp. are most commonly responsible.

Acute glomerular disease

Poststreptococcal glomerulonephritis occurs in SS disease and may affect patients at a later age than the normal population. An association of proteinuria with leg ulceration raised the possibility that leg ulcers acted as a portal of entry for b-haemolytic streptococci, but further analysis did not support this hypothesis.

Nephrotic syndrome

It is unclear whether patients with SS disease are more prone to nephrotic syndrome, but the histological picture of membranoproliferative glomerulonephritis accounts for over half of adult cases. Nephrotic syndrome has been reported following parvovirus B19 infection, and B19-specific DNA demonstrated within renal biopsy tissue 1 year after the onset of nephrotic syndrome. If nephrotic syndrome is due to acute glomerulonephritis, the prognosis is good, but it is not if the cause is otherwise, with a 50 per cent mortality occurring within 16 months in one study.

Chronic renal failure

This is an important contributor to illness and death among adults with SS disease, especially those over 40 years of age. It is usually insidious in onset, manifested initially by a falling haemoglobin level attributable to lowered erythropoietin levels. The renal function of older patients should therefore be monitored regularly. Serum

creatinine levels tend to be lower than normal in steady-state SS disease and creatinine levels within the accepted normal range should not be interpreted as indicating normal renal function, indeed in SS disease it is likely that levels of 60 to 70 µmol/l reflect significant renal damage.

Since the early symptoms of chronic renal failure in those with SS disease are principally due to a low haemoglobin level, patients may be maintained in tolerable health for years by regular transfusion. The response to subcutaneous erythropoietin is unpredictable, large doses of erythropoietin being required to induce a response, but some patients showing dramatic increases in haemoglobin that may precipitate painful crises. Endstage renal failure may require long-term renal replacement therapy or renal transplantation, but there are conflicting data on outcome. Successful transplantation can be followed by striking increases in haemoglobin levels sufficient to precipitate painful crises, and recurrent sickle nephropathy may affect the transplanted kidney.

20.11 Renal involvement in genetic disease

J. P. Grünfeld

The spectrum of inherited renal disorders (and of inherited diseases with kidney involvement) is summarized in Table 1. Attention will be focused in this section on the commonest inherited kidney diseases leading to renal failure.

Cystic kidney diseases

Autosomal dominant polycystic kidney disease

Autosomal dominant polycystic kidney disease is by far the most frequent inherited kidney disorder, accounting for approximately 7 per cent of cases of endstage renal failure in Western countries. It is one of the most frequent human inherited monogenic diseases (approximately 1 in 1000 individuals). The spectrum of genetic cystic kidney diseases is summarized in Table 2.

Definition

The disease is characterized by the presence of multiple cysts, arising from various segments of the nephrons and involving both kidneys. The mechanisms underlying cyst formation and progression are poorly understood: cysts develop only in a small percentage of nephrons and only focally, whereas all nephron cells carry the mutated gene. This has been explained by a two-hit phenomenon which postulates that renal tubular (or liver biliary) cells which are at the origin of cysts bear first the germinal *PKD* gene mutation, and then acquire a somatic *PKD* gene mutation involving the other allele, this event occurring at random in a limited number of cells. This explanation does not exclude other mechanisms. The link between the genetic event(s) and cystic fluid accumulation is not known.

The disease is also characterized by its autosomal dominant mode of inheritance, so that the risk of any child of either parent carrying the abnormal gene is one in two. New mutations are very rare. The mutant gene responsible for 85 per cent of cases of autosomal dominant polycystic kidney disease has been located to the short arm of chromosome 16 (*PKD1* gene) by linkage analysis, and then identified. A second gene (*PKD2*) has been located to the long arm of chromosome 4 and cloned. The corresponding gene products have been named polycystin 1 and 2. Their normal function is unknown, but the two proteins interact. There is possibly a third locus, so far unidentified.

The diagnosis of autosomal dominant polycystic kidney disease is therefore based on the two following features:

1. evidence for autosomal dominant inheritance;
2. demonstration of multiple renal cysts in both kidneys, which are often enlarged, by ultrasonography (Fig. 1).

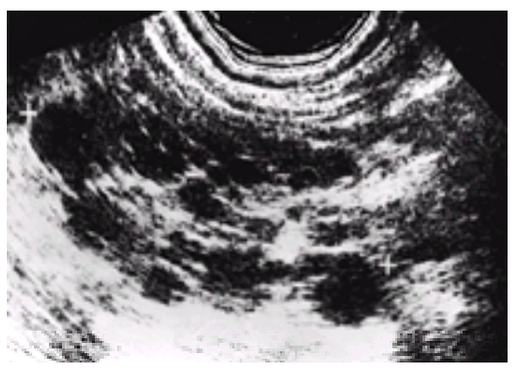

Fig. 1 Typical ultrasonographic findings in a patient with autosomal dominant polycystic kidney disease. The kidney is enlarged and contains multiple cysts of different sizes; the contralateral kidney had similar changes. The concentration of serum creatinine was 120 µmol/l at the time of ultrasonography. (By courtesy of Dr O. Helenon.)

The latter criterion deserves further comment. Renal cysts are initiated in the fetal kidney and develop progressively in life over the course of years. They may be too small to be detected by ultrasound in childhood, and kidney enlargement also progresses with age. Thus the sensitivity of ultrasonography for detecting autosomal dominant polycystic kidney disease is poor before 20 years of age (but the specificity is high since solitary renal cysts, *a fortiori* bilateral, are very rare at this age). In families with the *PKD1* gene mutation, false-negative ultrasonographic diagnosis is very unlikely at ages above 30 years, and rare at ages 20 to 29 years. Routine screening in asymptomatic members of affected families should not be performed before 20 years of age. By contrast, renal cysts, even bilateral, are relatively common in patients aged 50 years or more, hence strict criteria (multiple cysts in both enlarged kidneys and clear-cut inheritance) are required for diagnosing autosomal dominant polycystic kidney disease in older patients.

Symptoms

Renal manifestations

In some patients, autosomal dominant polycystic kidney disease is asymptomatic and discovered during family investigation or by chance on abdominal ultrasonography. In most cases, however, there are symptoms and patients complain of one or more of the following at some time during their life: renal pain due to cyst development, or stone or blood clot migration; bleeding within a cyst, leading to flank pain, the hyperdense cyst fluid then being visualized by computed

tomography; bleeding into the urinary tract, with gross haematuria occurring in approximately 30 per cent of cases; fever due to upper urinary tract infection, which is more frequent in women, or to cyst fluid infection. Renal stones, predominantly uric acid (for unknown reasons), develop in about 20 per cent of the patients.

Hypertension is a common and early finding in autosomal dominant polycystic kidney disease, occurring in about 30 to 50 per cent of patients at a stage when renal function is normal. Subsequently, with the development of renal failure, up to 80 per cent of patients become hypertensive. Why hypertension develops is not known: it has been ascribed to compression and ischaemia of the normal renal parenchyma by cysts.

Renal failure is also a common finding in autosomal dominant polycystic kidney disease. When it occurs, it usually progresses to endstage at between 40 and 60 years of age. However, in 30 per cent of cases it reaches endstage later, and in 5 per cent earlier, including very rare instances when it develops in the first years of life. Recent epidemiological studies have indicated that autosomal dominant polycystic kidney disease may have a much more indolent course in a substantial number of cases: 25 to 50 per cent of affected subjects are not in endstage renal failure by 70 years of age, and some patients may reach 80 or 90 years without the need for renal replacement therapy. This information is crucial for genetic counselling.

Genetic and non-genetic factors determine renal prognosis: the renal disease may progress more slowly in families with *PKD2* disease (mean age at endstage renal disease 55 years in *PKD1* disease compared with 70 years in *PKD2* disease), it progresses more slowly in women than in men, and control of hypertension may reduce the rate of progression.

Extrarenal manifestations

Liver cysts

These develop in 70 per cent of patients, usually later in life than renal cysts. Liver cysts are more frequent and more diffuse in women than in men. They are usually asymptomatic, detected by ultrasonography, but may be clinically palpable. Liver function tests are usually normal. Liver cyst infection may occur, particularly in patients on dialysis or transplant recipients. Massive liver involvement can cause severe discomfort in some cases, mostly in women.

Cardiovascular abnormalities

These include intracranial aneurysms and mitral valve prolapse. Subarachnoid haemorrhage or intracerebral bleeding due to rupture of intracranial aneurysm are among the most severe complications of autosomal dominant polycystic kidney disease and occur in approximately 1 to 2 per cent of patients. Rapid diagnosis and urgent neurosurgical opinion are required. Diagnosis should be suspected early, before complete rupture, in patients with autosomal dominant polycystic kidney disease with recent and severe headache or with any transient focal neurological deficit.

In cross-sectional studies performed using non-invasive screening methods such as high-resolution computed tomography or magnetic resonance angiography, intracranial aneurysms have been found in 7 to 8 per cent of asymptomatic middle-aged patients with autosomal dominant polycystic kidney disease. The prevalence is higher in those with a family history of intracranial aneurysm. The risk of rupture is largely dependent on aneurysm size. Routine screening by non-invasive methods is not indicated for all asymptomatic patients with autosomal dominant polycystic kidney disease, but it seems reasonable in certain subgroups, in particular those with a family history of intracranial aneurysm or subarachnoid haemorrhage, those who have already bled from an aneurysm (since recurrent aneurysm is possible), and possibly those who are to undergo major elective surgery. In high-risk groups, screening should be repeated every 5 to 10 years since the cerebral vascular disease is progressive.

Mitral valve prolapse is discovered in 20 per cent of patients with autosomal dominant polycystic kidney disease by echocardiography, whereas it is found in only 2 to 3 per cent of the general population. Other cardiac valve abnormalities and occasionally artery dissection or aneurysm may also be detected.

Other extrarenal defects are observed in autosomal dominant polycystic kidney disease: pes excavatum, colonic diverticulas, and abdominal hernias are more prevalent than in the general population.

Treatment

High fluid intake and regular follow-up of blood pressure and renal function are indicated in all patients with autosomal dominant polycystic kidney disease. The control of hypertension is an essential part of management, achieved with standard antihypertensive agents. Haematuria requires conservative management, although bleeding may sometimes be prolonged over several days and even weeks.

The relief of pain or abdominal discomfort can be difficult. In addition to symptomatic treatment, surgical renal cyst decompression should be restricted to very selected cases. Surgery is rarely needed in the management of renal stones. Liver cyst aspirations by needle under CT guidance, fenestration, or resection may be needed when massive involvement gives rise to pain; and in very rare cases such patients have come to liver transplantation.

Kidney infection requires administration of antimicrobials currently used in upper urinary tract infection. In some cases control of infection is not obtained, most probably because agents penetrate some infected cyst fluids poorly and do not achieve adequate concentration. Lipophilic drugs such as trimethoprim–sulphamethoxazole and ciprofloxacin have the best penetration into cyst fluid. Liver cyst infection also requires antimicrobials and drainage if infection is not controlled. Ciprofloxacin penetrates well into liver cyst fluid.

Standard medical management of chronic renal failure is indicated, as are renal replacement therapy and kidney transplantation when the patient reaches endstage, the results being similar to those obtained in other renal diseases.

Genetic counselling

The pattern of inheritance of autosomal dominant polycystic kidney disease means that the offspring of an affected subject have a 50 per cent risk of having the disease. The disease has a highly variable clinical course, even within a given family. Prenatal diagnosis by gene linkage studies using material derived from chorionic villous sampling has been performed and can be considered if required and if adequate family information is available. The demand for such prenatal diagnosis has, however, been very low in Western countries. This is explained by the late onset and the variable clinical course of the disease, often relatively benign, which cannot yet be predicted by DNA analysis.

Ultrasonography may occasionally show renal cysts in the fetus, but late in pregnancy. Obviously, due to the slow and late development of macrocysts, negative ultrasonography in the fetus (as well as in a child) does not rule out the disease.

Autosomal recessive polycystic kidney disease

Autosomal recessive polycystic kidney disease is a rare inherited disease (approximately 1 in 40 000 individuals), the first manifestations of which appear early in childhood.

Three features characterize this disease:

1. its recessive nature: both heterozygous parents are unaffected, with normal renal ultrasonography; parental consanguinity is found in some families; the mutant gene has been located on chromosome 6;
2. renal cysts derive from the collecting ducts, accounting for the striations in the dilated collecting system seen on intravenous pyelography; and
3. the renal disease is invariably associated with congenital hepatic fibrosis: this may be responsible for portal hypertension due to presinusoidal block, or for bacterial angiocholitis due to intrahepatic bile duct dilatation.

In children, autosomal recessive polycystic kidney disease should be differentiated from autosomal dominant polycystic kidney disease, which can be detected in childhood, even in neonates. Family history and renal ultrasonography in parents are decisive for correct diagnosis. In very rare families with *PKD1* disease, renal

involvement may be revealed in neonates and may progress to endstage within the first year of life.

The diagnosis of autosomal recessive polycystic kidney disease may be made before birth by antenatal ultrasonography, showing renal enlargement and increased echogenicity (as well as oligohydramnios). However, prenatal diagnosis may be uncertain and, since cystic changes occur in well-developed collecting ducts, these are detected only in the second half of pregnancy. When there is huge renal enlargement, pulmonary hypoplasia and respiratory distress may lead to death within hours after birth. With prolonged survival, liver and renal involvement becomes prominent. Gastrointestinal bleeding due to portal hypertension may be life-threatening and necessitate surgical portocaval shunt. Systemic hypertension is a frequent finding in the first year of life but, surprisingly, it may regress in subsequent years. Urinary tract infection is common. The rate of progression of renal failure is variable. Among patients who survive the neonatal period, approximately 50 per cent reach endstage in childhood, whilst this occurs in adulthood in the remainder.

Other cystic kidney diseases

Renal cysts may be found in von Hippel–Lindau's disease and in tuberous sclerosis (see below). Renal medullary cysts are also found in juvenile nephronophthisis, but not early in the course (see below). By contrast, such cysts—well localized in adults by ultasonography or CT scan—are seen early in autosomal dominant renal medullary cystic disease. This very rare condition progresses to endstage renal failure. Three different genetic loci have so far been localized.

Inherited diseases with glomerular involvement

Alport's syndrome

First described in 1927 by Dr Arthur Cecil Alport, this syndrome is characterized by the association of progressive haematuric hereditary nephritis and bilateral sensorineural hearing loss. Its prevalence is approximately 1 in 5000 individuals. In 85 per cent of kindreds the mode of transmission is compatible with X-linked dominant inheritance. In the remaining families, autosomal dominant or recessive inheritance should be considered.

Symptoms

Renal manifestations

The first clinical manifestation is typically gross haematuria, occurring sometimes in the first year of life, recurring during childhood, and followed by permanent microscopic haematuria. Proteinuria appears later. A nephrotic syndrome, usually moderate, develops in 30 to 40 per cent of patients. In other cases, moderate proteinuria and microscopic haematuria are the presenting symptoms in adulthood. The disease is progressive, leading to renal failure in all affected males, but the rate of progression is heterogeneous from one family to another, although usually homogeneous within a given family. In some endstage is reached at or before 30 years of age, sometimes in childhood; in others renal failure progresses to endstage between the ages of 30 to 60 years.

Carrier females of X-linked Alport's syndrome often have slight or intermittent urinary abnormalities. They may develop mild impairment of renal function late in life but do not usually have progressive renal disease as occurs in males, although this does happen in a few cases. In the autosomal recessive form of Alport's syndrome, renal disease progresses to endstage before 20 to 30 years of age at a similar rate in both affected men and women.

Extrarenal manifestations

The hearing defect may lead to severe perceptive deafness, but it is often moderate or slight, only detected at audiometric testing. The hearing loss labels a given family but is not found in all patients with renal disease. In some kindreds, familial haematuric progressive nephritis without hearing defect is documented: this form belongs to the spectrum of Alport's syndrome.

Other extrarenal manifestations may be found. Eye abnormalities are detected in 30 to 40 per cent of cases. These include bilateral anterior lenticonus detected by slit-lamp examination—a pathognomonic abnormality—and perimacular or macular retinal flecks that are seen by fundoscopic examination and do not alter visual acuity. Recurrent corneal erosions occur in some patients. In some families, macrothrombocytopenia is associated with nephritis and hearing defect. In other rare kindreds the latter features are found in association with diffuse leiomyomatosis, mainly oesophageal, and congenital cataracts.

Pathogenesis

The primary defect in Alport's syndrome involves the glomerular basement membrane. By electron microscopy, this membrane can be abnormally thickened with splitting of the lamina densa, thinned with focal thickening, or diffusely thin in younger children. In some patients, antigenicity of the glomerular basement membrane is abnormal: antiglomerular basement membrane antibodies do not bind linearly along the Alport glomerular basement membrane, whereas they show linear fixation along the glomerular basement membranes of normal and diseased kidneys which contain the corresponding Goodpasture antigen (the Goodpasture syndrome, an autoimmune disorder characterized by the development of antiglomerular basement membrane antibodies directed against this antigen (see Chapter 20.7.7).

In X-linked Alport's syndrome, the molecular defect involves the gene encoding for the a5 chain of the type IV collagen molecule. Type IV collagen is a major component of basement membranes. Six a chains of type IV collagen have been identified so far, with each molecule of type IV collagen being made up of three of these chains, differently associated in various basement membranes. In Alport's syndrome, mutations have been identified in the gene encoding for the a5 chain that maps to the long arm of the X chromosome. The Goodpasture antigen is located in the a3 chain, the gene of which has been mapped on chromosome 2. Absence or severe alteration of the a5 chain possibly prevents normal integration of the a3 chain into the glomerular basement membrane, leading to the defect in antigenicity.

In the autosomal recessive form of Alport's syndrome, the genes encoding for a3 or a4 chains are mutated. Affected subjects are homozygotes in consanguineous families, or compound heterozygotes in other cases. In families with leiomyomatosis, a5 and a6 genes, located contiguously on the X chromosome, are both involved in a large deletion.

Skin biopsy has become valuable for diagnosis of Alport's syndrome. Epidermal basement membrane normally contains a5 but not a3/a4 chains. Thus negative a5 staining by immunofluoresence is highly specific for X-linked Alport's syndrome, but is found in only 75 per cent of cases because a5 chains that are only slightly mutated can be detected. a5 Staining is normal in the autosomal recessive forms of Alport's syndrome.

In the disease with macrothrombocytopenia, mutations involve the *MYH9* gene, encoding the non-muscle myosin heavy chain IIA.

Genetic counselling and treatment

Genetic counselling first requires the correct identification of the mode of inheritance. If X-linked dominant inheritance is documented, affected men will not transmit the disease to their sons, whereas all their daughters will carry the mutant gene; affected women will transmit the mutant gene to 50 per cent of either sons or daughters. DNA analysis may be helpful for genetic counselling in these families.

Treatment of hypertension and supportive management of renal failure are indicated in patients with progressive disease. The results of kidney transplantation are similar to those obtained in other renal diseases. In rare cases, however, antiglomerular basement membrane crescentic glomerulonephritis develops in the graft. It is assumed that this complication is related to alloimmunization to the 'missing antigen' introduced by the transplant.

Benign familial haematuria

This disease is characterized by isolated microhaematuria, without proteinuria and progression to renal failure, in both men and women. Renal biopsy usually shows a thin glomerular basement membrane and immunofluorescence studies are negative. The mode of transmission is compatible with autosomal dominant inheritance. In some families, subjects with microhaematuria are heterozygotes carrying mutations involving the a3 or a4 chain gene.

Congenital nephrotic syndrome of the Finnish type

This disease specifically affects the kidney and is characterized by massive proteinuria, which occurs already *in utero* and then persists in infancy. Intense therapy is needed to afford the children a chance of survival: nutritional support to compensate for protein loss, prevention of infection and thrombosis, bilateral nephrectomy, continuous peritoneal dialysis, and finally kidney transplantation.

It is an autosomal recessive disease. The gene has been located on chromosome 19q and cloned. It encodes for a protein named nephrin, localized at the slit diaphragm between podocyte foot processes, which are both absent in affected subjects. Nephrin probably has a zipper-like structure and plays a key role in the normal glomerular filtration barrier.

Nail–patella syndrome

This syndrome, also known as hereditary osteo-oncho dysplasia, is a rare autosomal dominant disorder, defined by the association of nail hypoplasia or dysplasia, bone abnormalities (including iliac horns), and renal disease. The latter is found in 50 to 60 per cent of cases, progressing to endstage in approximately 15 per cent. The hallmark of renal involvement is the detection by electron microscopy of fibrillar collagen bundles within the glomerular basement membrane. Open angle glaucoma is a feature in rare families.

The mutated gene, *LMX1B* (located on 9q), belongs to a family of transcription factors that are involved in pattern formation during development. *LMX1B* is more specifically involved in the dorsoventral patterning of the limbs, and mice with a deletion in their *lmx1*-homologue exhibit skeletal defects similar to those observed in nail–patella syndrome and abnormal dorsoventral patterning of the extremities of the limbs.

Metabolic diseases with glomerular involvement

Anderson–Fabry disease

This disease is X-linked recessive (prevalence approximately 1 in 40 000 individuals) and due to a-galactosidase A deficiency resulting in glycosphingolipid deposition, mainly in the cardiovascular and renal system. The first manifestations in hemizygotes are painful acroparaesthesias, appearing in childhood, often prevented by continuous administration of carbamazepine or diphenylhydantin. Subsequently, angiokeratomas, anhydrosis, and corneal deposits develop. Ischaemic cerebrovascular complications, cardiac valve abnormalities, myocardial deposition of glycolipids, and coronary accidents are the most severe manifestations, along with renal involvement.

In the kidney, glycolipid deposition involves glomerular epithelial cells, tubular cells, and endothelial and smooth muscle cells of intrarenal arteries. The latter changes are responsible for progressive renal ischaemia. Renal disease is revealed by proteinuria at around 20 years, and then progresses to endstage between 40 and 60 years of age, necessitating regular dialysis and/or kidney transplantation. Glycolipid deposition does not recur in the renal graft that contains normal a-galactosidase activity. Enzyme replacement therapy is available.

Heterozygote female carriers usually have few symptoms. Corneal deposits are found in 70 per cent of them. They can develop cardiac changes and, very rarely, symptomatic renal disease.

Lecithin-cholesterol acyl-transferase (LCAT) deficiency

This is a very rare autosomal recessive disorder. LCAT is a key enzyme in the metabolism of cholesterol, responsible for its esterification. In affected subjects the proportion of cholesteryl ester to total cholesterol is very low. Lipid accumulation occurs in the eyes (causing corneal deposits), erythrocyte membranes (leading to low-grade haemolytic anaemia), arterial walls (contributing to premature atherosclerosis), and kidneys, predominating in glomerular mesangial cells and progressing to endstage renal disease. LCAT is expressed primarily in the liver, hence liver transplantation would theoretically be the treatment of choice, but it has not so far been performed in this disease. Patients have received kidney transplants: lipid deposition recurs slowly in the graft.

Type I glycogen storage disease

Also named von Gierke's disease (see Chapter 11.2), this disease is due to glucose-6-phosphatase deficiency. Affected infants develop hypoglycaemia, growth retardation, and hepatomegaly. Fanconi syndrome may occur as a consequence of glycogen deposition in the proximal tubule. Progressive renal involvement is not due predominantly to glycogen accumulation. It is rather related to the development of focal segmental glomerulosclerosis, the mechanism of which is unclear, usually after 20 years of age. This complication has only been recognized recently since children with severe hypoglycaemia have now survived to adulthood thanks to the progress achieved by paediatricians, dieticians, and families in providing adequate feeding and nutrition.

Familial primary glomerulonephritis

In most types of primary glomerulonephritis, familial cases have been anecdotally reported. The most frequent form, albeit rare, is probably familial IgA nephropathy, either primary (Berger's disease) or associated with Henoch–Schönlein purpura. Familial focal segmental glomerulosclerosis with either autosomal dominant or autosomal recessive inheritance has also been well characterized and several genetic loci have been identified.

Inherited tubulointerstitial disorders

Juvenile nephronophthisis

This complex represents an inherited form of chronic tubulointerstitial disease. Cysts located at the corticomedullary junction or in the medullary region appear late in the course of the disease. Renal pathological examination reveals tubular atrophy and interstitial fibrosis (which are non-specific lesions), and extreme thickening and multilamellation of the tubular basement membrane.

Juvenile nephronophthisis is a major cause of endstage renal disease in children, accounting for 10 to 20 per cent of cases. It is transmitted as an autosomal recessive trait. The gene involved, *NPH1*, has been mapped to the short arm of chromosome 2 and its product has been named nephrocystin. In 80 per cent of cases a homozygous deletion is found. Heterozygotes are asymptomatic.
