The most obvious feature which differentiates primary from secondary hypoadrenalism is skin pigmentation (Fig. 17), which is nearly always present in primary adrenal insufficiency (unless of short duration) and absent in secondary. The pigmentation is seen in sun-exposed areas, recent rather than old scars, axillas, nipples, palmar creases, pressure points, and in mucous membranes (buccal, vaginal, vulval, anal). The cause of the pigmentation has long been debated but probably reflects increased melanocyte activity induced by POMC-related peptides including melanocyte stimulating hormone (MSH). In autoimmune Addison's disease there may be associated vitiligo (Fig. 17).

Fig. 17 Pigmentation in a patient with Addison's disease before and after treatment with hydrocortisone and fludrocortisone (by courtesy of Professor C.R.W. Edwards).

Patients with primary adrenal failure usually have both glucocorticoid and mineralocorticoid deficiency. In contrast, those with secondary adrenal insufficiency have an intact renin–angiotensin–aldosterone system. This accounts for differences in salt and water balance in the two groups of patients, which in turn result in different clinical presentations.

Primary adrenal failure may present with hypotension and acute circulatory failure (addisonian crisis). Anorexia may be an early feature, which progresses to nausea, vomiting, diarrhoea, and sometimes, abdominal pain. These crises may be precipitated by intercurrent infection or by stress, such as a surgical operation. Alternatively, the patient may present with vague features of chronic adrenal insufficiency—weakness, tiredness, weight loss, nausea, intermittent vomiting, abdominal pain, diarrhoea or constipation, general malaise, muscle cramps, and symptoms suggestive of postural hypotension. Salt-craving may be a feature and there may be a low-grade fever. The lying blood pressure is usually normal but almost invariably there is a fall in blood pressure on standing.

In secondary adrenal insufficiency due to hypopituitarism, the presentation may relate to deficiency of hormones other than ACTH, notably luteinizing hormone/follicle-stimulating hormone (infertility, oligo-/amenorrhoea, poor libido), thyroid-stimulating hormone (weight gain, cold intolerance), and growth hormone (hypoglycaemia). Patients with isolated ACTH deficiency present with malaise, weight loss, and other features of chronic adrenal insufficiency.

Laboratory investigation of hypoadrenalism

Routine biochemical profile

In established primary adrenal insufficiency, hyonatraemia is present in about 90 per cent of cases and hyperkalaemia in 65 per cent. The blood urea concentration is usually elevated. In secondary adrenal failure there may be a dilutional hyponatraemia with normal or low blood urea because glucocorticoids are required to maintain glomerular filtration rate and excrete a water load. Hypoglycaemia has been found in up to 50 per cent of patients with chronic adrenal insufficiency.

Plasma cortisol/ACTH

Clinical suspicion of the diagnosis should be confirmed with definitive diagnostic tests. Basal plasma cortisol and urinary free cortisol levels are often in the low normal range and cannot be used to exclude the diagnosis. In primary adrenal insufficiency the simultaneous measurement of plasma cortisol and plasma ACTH reveals an ACTH level which is disproportionately elevated in comparison with plasma cortisol (Fig. 18).

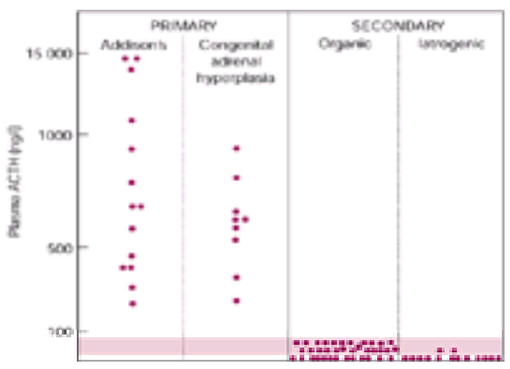

Fig. 18 Morning immunoreactive ACTH values in patients with hypoadrenalism. The reference range is indicated by the horizontal lines (by courtesy of Professor L. H. Rees.)

Mineralocorticoid status

Another difference between primary and secondary hypoadrenalism is in the renin–angiotensin–aldosterone axis. In primary hypoadrenalism there is normally mineralocorticoid deficiency with elevated plasma renin activity and either low or low normal plasma aldosterone. It is remarkable how frequently the investigation of zona glomerulosa activity is ignored in Addison's disease compared with the assessment of zona fasciculata function.

Stimulation tests

In practice all patients suspected of having adrenal insufficiency should have an ACTH stimulation test. This involves the intramuscular or intravenous administration of 250 µg of tetracosactrin (Synacthen ®), comprising the first 24 amino acids of normally secreted 1–39 ACTH. Plasma cortisol levels are measured at 0 and 30 min after ACTH administration and a normal response is defined by a peak plasma cortisol of more than 550 nmol/l. Levels of less than 550 nmol/l in response to Synacthen are found in both primary and secondary adrenal insufficiency, though rarely false-positive results have been reported, particularly in cases of secondary hypoadrenalism. A low-dose ACTH stimulation test giving only 1 µg ACTH has been proposed to screen for adequacy of function of the hypothalamo–pituitary–adrenal axis with the suggestion that it may be more sensitive than the conventional 250 µg test. At present there are insufficient data to support such a concept.

A prolonged ACTH stimulation test, involving the administration of depot tetracosactrin in a dose of 1 mg by intramuscular injection, with measurement of plasma cortisol at 0, 4, and 24 h will differentiate primary from secondary hypoadrenalism. In normal subjects the plasma cortisol at 4 h is more than 1000 nmol/l and the value at 24 h shows little further increase. Patients with secondary hypoadrenalism show a delayed response with usually a much higher value at 24 than at 4 h, but in primary hypo-adrenalism there is no response at either time. However, the test is now rarely required if plasma ACTH has been appropriately measured at baseline.

The insulin-induced hypoglycaemia or insulin tolerance test remains one of the most useful in assessing ACTH and growth hormone reserves. It should not be performed in patients with ischaemic heart disease (check ECG before test), epilepsy, or severe hypopituitarism (that is plasma cortisol at 09.00 h less than 180 nmol/l). The test involves the intravenous administration of soluble insulin in a dose of 0.1 to 0.15 U/kg body weight, with measurement of plasma cortisol at 0, 30, 45, 60, 90, and 120 min. Adequate hypoglycaemia (blood glucose less than 2.2 mmol/l with signs of neuroglycopenia—sweating and tachycardia) is essential. In normal subjects the peak plasma cortisol exceeds 500 nmol/l. However, the response to hypoglycaemia can be reliably predicted by the response to acute ACTH stimulation (see above); a safer, cheaper, and quicker test. If the ACTH test is normal, insulin-induced hypoglycaemia testing is not necessary in the vast majority of cases unless there is a need to document endogenous growth hormone reserve in a patient with pituitary disease. An insulin tolerance test is only required if, in a patient with suspected hypopituitarism, there is a subnormal response to ACTH. Some patients have an inadequate response to ACTH but then respond normally to hypoglycaemia. They do not require corticosteroid replacement therapy.

Other tests

Radioimmunoassays to detect autoantibodies such as those against the 21-hydroxylase antigen are now available and should be undertaken in patients with primary adrenal failure. In autoimmune Addison's disease it is also important to look for evidence of other organ-specific autoimmune disease. In long-standing tuberculous adrenal disease there may be adrenal atrophy with calcification on plain radiographs or CT scanning. Early morning urine samples should be cultured for mycobacteria if tuberculosis is suspected.

Treatment of acute adrenal insufficiency

This is an emergency, and treatment should not be delayed while waiting for definitive proof of diagnosis. However, in addition to measurement of plasma electrolytes and blood glucose, appropriate samples for ACTH and cortisol should be taken before giving corticosteroid therapy. If the patient is not critically ill, an acute ACTH stimulation test can be performed. However, if necessary, this can be delayed and carried out with the patient on corticosteroid therapy, provided the drug used does not interfere with the plasma cortisol assay (for example, change from hydrocortisone to dexamethasone).

Intravenous hydrocortisone should be given in a dose of 100 mg every 6 h. If this is not possible, then the intramuscular route should be used. In the shocked patient, 1 litre of normal saline should be given intravenously over the first hour. Because of possible hypoglycaemia, it is normal to give 5 per cent dextrose saline. The subsequent saline and dextrose therapy will depend on biochemical monitoring and the patient's condition. Clinical improvement, especially in the blood pressure, should be seen within 4 to 6 h if the diagnosis is correct. It is important to recognize and treat any associated condition, such as an infection, which may have precipitated the acute adrenal crisis.

After the first 24 h the dose of hydrocortisone can be reduced, usually to 50 mg intramuscularly every 6 h for the second 24 h and then, if the patient can take by mouth, to oral hydrocortisone, 40 mg in the morning and 20 mg at 18.00 h. This can then be rapidly reduced to the normal replacement dose of 20 mg on wakening and 10 mg at 18.00 h. Some patients will require more than 30 mg/day, but increasingly most patients can cope with less than this dose (usually 15 to 25 mg/day in divided doses). In primary adrenal failure, cortisol day curves with simultaneous ACTH measurements may provide some insight into adequacy of replacement therapy, but unfortunately there are no good objective tests in secondary adrenal failure. Nevertheless, crude objectives such as weight, well being, and blood pressure are important in this regard.

In primary adrenal failure, mineralocorticoid replacement is usually also required in the form of fludrocortisone (or 9a-fluorinated hydrocortisone) in a dose of 0.05 to 0.1 mg/day. The mineralocorticoid activity of this is about 125 times that of hydrocortisone. After the acute phase has passed, the adequacy of mineralocorticoid replacement can be assessed by measuring electrolytes, supine and erect blood pressure, and plasma renin activity; too little fludrocortisone may cause postural hypotension with elevated plasma renin activity, whilst too much causes the converse.

Patients receiving glucocorticoid replacement therapy should be advised to double the dose in the event of intercurrent febrile illness, accident, or mental stress such as an important examination. If the patient is vomiting and cannot take by mouth, parenteral hydrocortisone must be given urgently, as indicated above. For minor surgery, 50 to 100 mg of hydrocortisone hemisuccinate is given with the premedication. For major procedures this is then followed by the same regimen as for acute adrenal insufficiency.

Every patient on glucocorticoid therapy should be advised to register for a MedicAlert bracelet or necklace and must carry a 'Steroid card'.

Mineralocorticoid excess

Hypertension affects 10 to 25 per cent of the population. In most cases, no underlying cause for the patient's raised blood pressure is apparent, and they are labelled as having 'essential' hypertension. Mineralocorticoid-based hypertension may account for secondary causes of hypertension, and classically refers to hypertension caused by increased sodium and water retention by the kidney and expansion of the extracellular fluid compartment resulting in suppression of endogenous plasma renin activity. Unlike the majority of cases of secondary aldosteronism which arise either in the setting of reduced oncotic pressure (nephrosis, cirrhosis) or in patients with cardiac failure, oedema is not a feature of primary aldosteronism, probably because of the 'escape' phenomenon. Nevertheless, in the short term, intravascular volume is reset at a higher level and this leads to increased cardiac output and blood pressure. In the chronic state, hypervolaemia cannot be consistently demonstrated and other mechanisms may be equally important in raising blood pressure. Mineralocorticoid receptors have been characterized in the vasculature and heart, and depending upon the activity of local 11b-HSD, either glucocorticoids or mineralocorticoids may increase vascular tone, by potentiating catecholamine and angiotensin II-induced vasoconstriction, or by inhibiting endothelial relaxation. Mineralocorticoids can also modulate blood pressure centrally, independent of changes in renal electrolyte transport or vascular reactivity.

Mineralocorticoid hypertension: differential diagnosis

A comprehensive list of the causes of mineralocorticoid hypertension is given in Table 7.

Primary aldosteronism

First described by Conn in 1955, this is the commonest cause of mineralocorticoid hypertension. Prevalence rates of 0.5 to 2 per cent have been widely reported in the literature in unselected patients with 'essential' hypertension, but many of these studies relied on detecting hypokalaemia and, in the light of recent observations, will have underestimated true prevalence rates. By contrast, studies suggesting much higher prevalence rates of 5 to 12 per cent in hypertensive populations have been conducted in specialist centres and are therefore subject to selection bias.

Symptoms are often absent or non-specific but include tiredness, muscle weakness, thirst, polyuria, and nocturia due to hypokalaemia. Spontaneous hypokalaemia (less than 3.5 mmol/l) is rare in untreated hypertension; when found in a patient on diuretics these should be withdrawn, and potassium stores replenished and remeasured 2 weeks later. Despite this, it is now accepted that up to 40 per cent of patients with surgically confirmed primary aldosteronism will have normal serum potassium concentrations.

In approximately two-thirds of patients, primary aldosteronism is due to a small (0.5 to 2 cm), solitary aldosterone-producing adenoma of the adrenal which is commoner in women than men (male:female ratio 1:3). One-third of cases are caused by bilateral adrenal hyperplasia, and the remaining few (less than 2 per cent) by glucocorticoid-suppressible hyperaldosteronism or adrenal carcinomas. The aetiology of aldosterone-producing adenoma is unknown, although rarely it may have a genetic basis and can occur as a component of multiple endocrine neoplasia type I.

Primary aldosteronism is confirmed by demonstrating subnormal supine and erect plasma renin activity and an elevated plasma aldosterone concentration in a patient with no antihypertensive treatment for at least 3 weeks. However, primary aldosteronism may also occur with suppressed plasma renin activity and normal plasma aldosterone concentration, and some investigators advocate measures of aldosterone secretion over a 24-h period or salt suppression studies to further confirm the diagnosis. If severe hypertension prevents complete cessation of antihypertensive therapy during this diagnostic period, a-blockers such as prazosin or doxazosin interfere least with the renin–angiotensin–aldosterone axis. A single ratio of plasma renin activity/plasma aldosterone concentration may be a sensitive screening test, even in patients still taking antihypertensive medication, but depending upon the assays used and population salt intake, this requires validation in each centre.

The differential diagnosis of aldosterone-producing adenoma, bilateral adrenal hyperplasia, and glucocorticoid-suppressible hyperaldosteronism requires an understanding of the control of aldosterone secretion in each condition. In normal physiology, aldosterone secretion is under the control of angiotensin II through the renin–angiotensin system; ACTH and potassium are less important chronic secretogogues. Aldosterone-producing adenoma represents an autonomous source of aldosterone production which is not regulated by angiotensin II (ACTH assumes more importance in the control of aldosterone secretion in aldosterone-producing adenoma). By contrast, the zona glomerulosa in bilateral adrenal hyperplasia is more sensitive to angiotensin II; for a given angiotensin II infusion there is a much greater aldosterone response than normal. Finally, in glucocorticoid-suppressible hyperaldosteronism, aldosterone secretion and the secretion of intermediary metabolites (18-hydroxy and oxo-metabolites of cortisol and corticosterone) are under the control of ACTH. The optimal method(s) of establishing the differential diagnosis of primary aldosteronism are complicated and still controversial. In our clinical practice this is undertaken as a day case admission as illustrated in Fig. 19, measuring the response of aldosterone to erect posture (high in bilateral adrenal hyperplasia, absent in aldosterone-producing adenoma), to ACTH (absent in bilateral adrenal hyperplasia, increased in aldosterone-producing adenoma, exaggerated in glucocorticoid-suppressible hyperaldosteronism), and 18-hydroxy- or 18-oxo-cortisol/corticosterone in the plasma or urine. This study is only valid if plasma renin activity is seen to rise on adopting the erect posture and cortisol (reflecting underlying ACTH secretion) to fall between 08.00 h and 12.00 h.

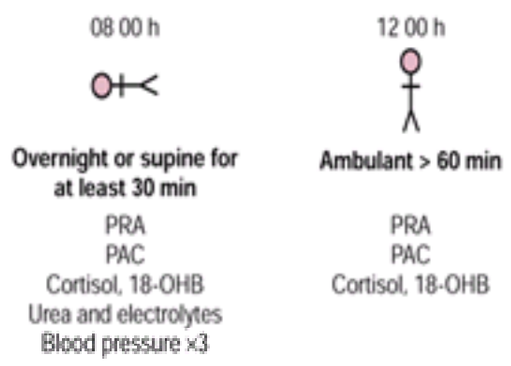

Fig. 19 Day case investigation of a patient suspected of having primary aldosteronism. Supine and erect plasma renin activity (PRA), plasma aldosterone concentration (PAC), cortisol (F), 18-hydroxycorticosterone (18-OHB) (or 18-OHF), electrolytes, and blood pressure are measured as shown. The posture study is only valid if there is a rise in PRA on adopting the erect posture and a fall in F concentrations between 08.00 h and 12.00 h (reflecting a circadian fall in ACTH levels). (Reproduced with permission of the author and *The Lancet.*)

Adrenal MRI/CT scanning should not be performed until a biochemical diagnosis has been made because of the high incidence of non-functioning adrenal incidentalomas. Thereafter, an MRI/CT scan should be the first localization procedure; CT has a better spatial resolution and may be more sensitive in detecting smaller aldosterone-producing adenomas (Fig. 20 and Plate 2). Adrenal scintigraphy studies (iodocholesterol scanning) have been found useful in some centres. Adopting the approach outlined in Fig. 19, few patients need invasive adrenal vein cannulation, although this may be required to make a diagnosis or to assist in the lateralization of a lesion if the posture and/or imaging studies are inconclusive. In particular, angiotensin II-responsive aldosterone-producing adenomas have been reported, and this may explain why the overall accuracy of posture studies in primary aldosteronism is only 70 to 80 per cent. Although technically difficult and not without risk, the demonstration of an aldosterone ratio of greater than 10:1 in one adrenal vein compared with the other remains the most sensitive diagnostic test. Simultaneous cortisol measurements ensure adrenal vein cannulation and, when expressed as an aldosterone/cortisol ratio, improve diagnostic accuracy.

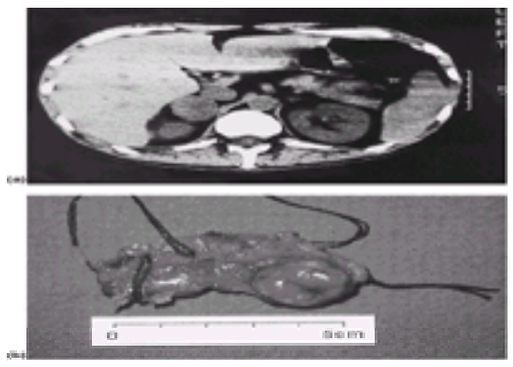

Fig. 20 (a) Adrenal CT scan demonstrating a solitary adrenal adenoma in a patients with Conn's syndrome. (b) The characteristic yellow appearance of the cut surface of the excised tumour reflects the high cholesterol content of these tumours. (See also Plate 2.)

One reason for establishing a definitive diagnosis is that treatment is surgical excision in the case of aldosterone-producing adenoma, but strictly medical for bilateral adrenal hyperplasia and glucocorticoid-suppressible hyperaldosteronism. The last responds well to dexamethasone at 0.25 to 0.5 mg/day. Patients with aldosterone-producing adenoma who are not suitable for surgery or decline operation and patients with bilateral adrenal hyperplasia should be treated with amiloride (starting dose 5 to 10 mg/day increasing to 30 mg/day depending upon blood pressure, urea, and electrolyte response). Spironolactone is as effective but in high doses frequently causes painful gynaecomastia and menstrual irregularity. In aldosterone-producing adenoma, normokalaemia is restored in 100 per cent of patients postoperatively and blood pressure falls to normal values in 70 per cent. With the ever increasing experience of laparascopic adrenalectomy, surgical morbidity can be kept to a minimum. Pre- and perioperative treatment should involve the co-ordinated management of surgeon and endocrinologist. Aldosterone secretion from the contralateral normal adrenal gland may be suppressed and hypoaldosteronism postoperatively should be anticipated and treated appropriately by increasing sodium intake and/or transient fludrocortisone therapy.

Monogenic hypertension

Hypertension is known to be a phenotype of some well-documented gene mutations; 17a-hydroxylase deficiency and 11b-hydroxylase deficiency are forms of congenital adrenal hyperplasia in which mineralocorticoid excess occurs because of ACTH-driven deoxycorticosterone excess. A similar process is thought to explain the hypertension seen in patients with glucocorticoid resistance due to mutations in the glucocorticoid receptor (GR) gene (Table 1). More recently, a significant advance in our understanding of the molecular basis of cardiovascular disease has been the elucidation of other single gene defects causing mineralocorticoid hypertension (Fig. 21).

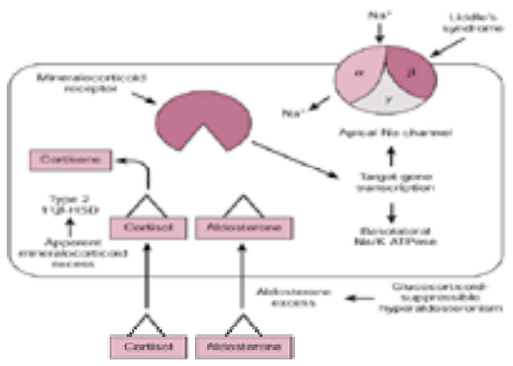

Fig. 21 Three causes of monogenic mineralocorticoid hypertension are detailed. A schematic diagram representing an epithelial cell in the distal colon or distal nephron is shown. In normal physiology, aldosterone interacts with the mineralocorticoid receptor (MR) to stimulate sodium reabsorption via induction of the apical sodium channel and serosal Na^+/K^+-ATPase pump. GSH (glucocorticoid-suppressible hyperaldosteronism) is a cause of aldosterone excess due to the production of a chimeric gene, 11b-hydroxylase/aldosterone synthase, within the adrenal cortex. Apparent mineralocorticoid excess results because cortisol cannot be inactivated to cortisone by the type 2 isoform of 11b-hydroxysteroid dehydrogenase (11b-HSD2); cortisol can then act as a potent mineralocorticoid. Liddle's syndrome occurs because of constitutively active mutations in the b- or g-subunits of the apical sodium channel.

Glucocorticoid-suppressible hyperaldosteronism

Glucocorticoid-suppressible hyperaldosteronism was first reported in 1966 and is an autosomal dominant form of low-renin hypertension characterized by aldosterone excess under the control of ACTH rather than the normal principal secretogogue, angiotensin II. There are two important consequences of this; first, there is dysregulation of aldosterone secretion because of loss of the negative feedback loop (aldosterone does not suppress ACTH secretion), and second, the exogenous administration of a glucocorticoid such as dexamethasone, by decreasing ACTH secretion, results in suppression of aldosterone secretion and can be used therapeutically. Long-term glucocorticoid therapy leads to reactivation and normal regulation of the renin–angiotensin–aldosterone axis. A further characteristic of glucocorticoid-suppressible hyperaldosteronism is the secretion of large quantities of 18-hydroxy- and 18-oxo-corticosterone/cortisol metabolites, again under the control of ACTH, and while there is some overlap with levels seen in aldosterone-producing adenoma, these provide a diagnostic marker for the condition.

The molecular basis for glucocorticoid-suppressible hyperaldosteronism was described by Lifton and colleagues following the cloning and characterization of the two final enzymes in cortisol and aldosterone synthesis, 11b-hydroxylase and aldosterone synthase, respectively. 11b-Hydroxylase converts 11-deoxycortisol to cortisol in the zona fasciculata, and aldosterone synthase converts corticosterone to aldosterone through an enzymatic step involving 11b-hydroxylation and 18-hydroxylation and oxidation. These enzymes are encoded by two genes, *CYP11B1* and *CYP11B2*, lying in tandem on chromosome 8. Despite the similarity in the coding sequences of 11b-hydroxylase and aldosterone synthase (more than 95 per cent), their 5' sequences differ, permitting regulation of 11b-hydroxylase by ACTH through cAMP and aldosterone synthase by angiotensin II through intracellular calcium ions, thereby establishing functional zonation of the adrenal cortex. In glucocorticoid-suppressible hyperaldosteronism a hybrid gene is formed at meiosis from unequal cross-over of the *CYP11B1* and *CYP11B2* genes and this contains proximal components of *CYP11B1* and distal components of *CYP11B2*. As long as the breakpoint of the hybrid gene is in or 5' to exon IV of the *CYP11B1* gene, the product of this gene can synthesize aldosterone, but is now under the control of ACTH (Fig. 22). The chimeric gene can be detected by Southern blotting or by long polymerase chain reaction, providing a screening test for glucocorticoid-suppressible hyperaldosteronism and the facility for prenatal diagnosis.

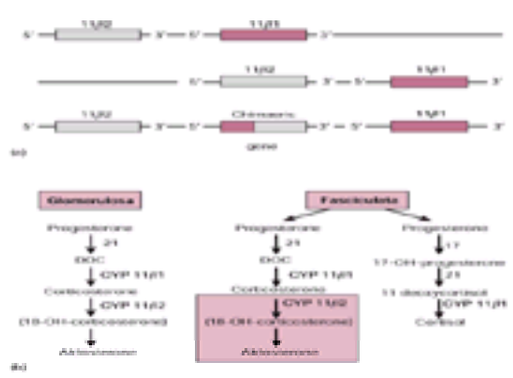

Fig. 22 (a) Chimeric gene responsible for glucocorticoid-remediable hyperaldosteronism and its impact upon adrenal steroid secretion. (b) The chimeric gene is

expressed in the zona fasiculata (boxed area) and can synthesize aldosterone but is under the regulatory control of ACTH.

In the wake of such advances, numerous kindreds have been reported with glucocorticoid-suppressible hyperaldosteronism and an international register for such cases has been established, which to date comprises 167 cases from 27 genetically proven pedigrees. Interesting observations to come from these larger cohorts are that potassium may be normal in up to 50 per cent of cases and there is poor correlation between genotype and phenotype (potassium, blood pressure) both between and within families. Severe mineralocorticoid excess has been reported in some individuals with this gene defect, but in other members of the same family, the gene defect has caused no abnormal phenotype. Patients with glucocorticoid-suppressible hyperaldosteronism are more susceptible to cerebrovascular haemorrhage.

Liddle's syndrome

In 1963, Grant Liddle described a family with several siblings affected by early-onset hypertension and hypokalaemia associated with low renin and low aldosterone levels. The condition responded well to inhibitors of epithelial sodium transport such as triamterene, but not to mineralocorticoid receptor antagonists such as spironolactone, and studies on erythrocytes suggested a generalized defect in sodium transport. Furthermore, in the proband of one of Liddle's original patients, renal transplantation resulted in blood pressure and potassium returning to normal levels, arguing against a circulating mineralocorticoid.

Mineralocorticoid-dependent epithelial sodium transport requires the activation of the apical sodium channel. Three subunits of this channel, a, b, and g, have been cloned and characterized. Full sodium conductance requires the concerted action of a/b or a/g subunits and cannot be sustained by any subunit in isolation. The b and g subunits lie in close proximity on chromosome 16 and mutations in these subunits have been described in kindreds affected with Liddle's syndrome. In each case these cause deletions of the C-terminus part of the protein (45 to 75 amino acids) producing a sodium channel which is constitutively active. Liddle's syndrome is inherited as an autosomal dominant trait and several other kindreds have been reported following the description of the genetic basis for the condition. As is the case with glucocorticoid-suppressible hyperaldosteronism, potassium has been reported to be normal in several patients.

Apparent mineralocorticoid excess and abnormalities of 11b-hydroxysteroid dehydrogenase type 2

Apparent mineralocorticoid excess was first described in detail by Ulick and New in the late 1970s. This is an autosomal recessive form of low renin, low aldosterone hypertension in which cortisol, conventionally regarded as a glucocorticoid, is able to act as a potent mineralocorticoid. The condition can be diagnosed from a 24-h urine collection analysed for cortisol metabolites using gas chromatography. Affected individuals have a characteristic increase in urinary cortisol compared with cortisone metabolites (tetrahydrocortisols/tetrahydrocortisone ratio or urinary free cortisol/urinary free cortisone ratio). Serum cortisol levels are unhelpful because although patients with apparent mineralocorticoid excess have a prolonged plasma cortisol half-life, a reduction in cortisol secretion rate mediated by the negative feedback mechanism ensures normal circulating concentrations. This defect in cortisol metabolism occurs because of loss of 11b-hydroxy-steroid dehydrogenase (11b-HSD) activity.

Two isozymes of 11b-HSD catalyse the interconversion of hormonally active cortisol (**F**) to inactive cortisone (**E**). 11b-HSD1 is predominantly found in the liver, adipose tissue, and gonad and acts principally as an oxo-reductase generating F from E, but it is the 11b-HSD2 isoform, acting as an efficient dehydrogenase inactivating F to E which is expressed in the mineralocorticoid target tissues, kidney, colon, and salivary gland, that is more important in modulating corticosteroid control of blood pressure. Aldosterone gains access to the mineralocorticoid receptor *in vivo* only when 11b-HSD2 activity is intact and F can be inactivated to E at a prere-ceptor level (Fig. 23). Homozygous inactivating mutations in the human 11b-HSD2 gene have been identified in over 20 patients with apparent mineralocorticoid excess and result in cortisol-mediated, mineralocorticoid hypertension. The condition is inherited as an autosomal recessive trait and the majority of heterozygotes, with a few notable exceptions, have a normal phenotype. Milder forms of apparent mineralocorticoid excess have been described and there appears to be a close correlation between genotype and phenotype. Spironolactone or amiloride (often in higher doses than those used to treat primary aldosteronism) can be used therapeutically, as can dexamethasone, which suppresses endogenous cortisol secretion, but itself is not a good substrate for 11b-HSD2.

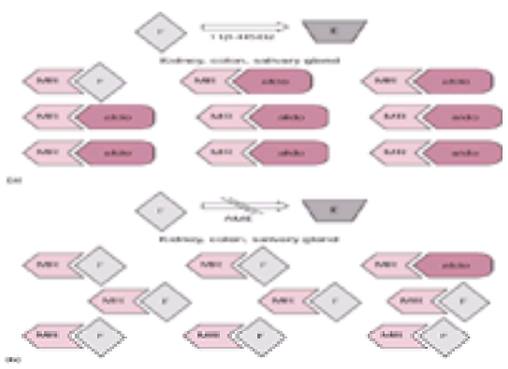

Fig. 23 (a) The role of 11b-hydroxysteroid dehydrogenase (11b-HSD2) in protecting the non-specific mineralocorticoid receptor from cortisol. (b) With congenital or acquired deficiency of the enzyme, F (cortisol) cannot be inactivated to E (cortisone) and acts as a potent mineralocorticoid.

Liquorice has been associated with a mineralocorticoid excess state since the late 1940s when Reevers, a Dutch Physician, used a liquorice preparation, 'succus liquoritiae', to treat patients with dyspepsia. This was the origin of the antiulcer drug, carbenoxolone, which also resulted in mineralocorticoid side-effects in up to 50 per cent of patients. The active 'mineralocorticoids' in both cases are glycyrrhizic acid and its hydrolytic product, glycyrrhetinic acid, which themselves have little inherent mineralocorticoid activity, but cause hypertension and hypokalaemia by inhibiting 11b-HSD2. Such patients will also have an increase in the urinary ratio of cortisol to cortisone metabolites (THF+allo-THF/THE), although not to the same degree as patients with apparent mineralocorticoid excess.

Cortisol is also the offending mineralocorticoid in patients with some forms of Cushing's syndrome. In ectopic ACTH syndrome, for example, the high cortisol secretion rate overwhelms renal 11b-HSD2, resulting in spill over on to the mineralocorticoid receptor. A high THF+allo-THF/THE ratio is also observed in some patients with pituitary-dependent Cushing's syndrome and this may explain the hypertension in these cases.

These unusual causes of mineralocorticoid hypertension have significantly enhanced our understanding of corticosteroid biosynthesis and hormone action. In addition they raise new questions as to the role of adrenal steroids in wider populations of patients with hypertension. Defects in the activity of 11b-HSD have been reported in patients with 'essential hypertension', but have not consistently been associated with mineralocorticoid excess. Endogenous circulating inhibitors of 11b-HSD2 have also been described, so-called 'glycyrrhetinic acid-like factors' or GALFs. Levels are higher in pregnancy, and some studies, but not others, report increased levels in patients with hypertension. At present, however, the identity of such GALFs is unknown.

Who should we suspect as having mineralocorticoid-based hypertension?

All patients with hypertension should have serum electrolytes measured and those with hypokalaemia must be investigated (Fig. 24). Because hypokalaemia may be absent in many cases of proven mineralocorticoid hypertension, patients with severe hypertension (for example those on triple antihypertensive therapy) and those with a family history of hypertension or cerebrovascular disease should also be screened. At present the incidence of primary aldosteronism, glucocorticoid-suppressible hyperaldosteronism, Liddle's syndrome, and apparent mineralocorticoid excess in unselected (that is, community rather than hospital-based) populations with 'essential' hypertension is unknown. Until this is defined, one cannot be more dogmatic in deciding who should and should not be screened for mineralocorticoid-based hypertension. In the interim these diagnoses will not be made unless they are considered. Wherever possible the elucidation of the underlying basis of a patient's hypertension should be sought so that appropriate therapy can be targeted to the patient.

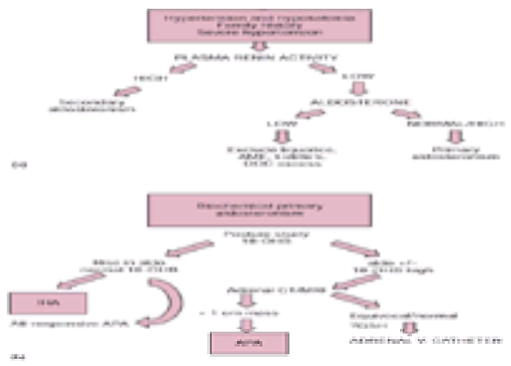

Fig. 24 Proposed algorithm for investigating mineralocorticoid-based hypertension. In practice the posture study (Fig. 19) can be included when the initial biochemical confirmation studies are performed.

Glucocorticoid resistance

A small number of patients have been described who have increased cortisol secretion but with none of the stigmas of Cushing's syndrome. These patients are resistant to suppression of cortisol with low-dose dexamethasone but respond to high doses. ACTH levels are elevated and lead to increased adrenal production of androgens and deoxycorticosterone. Thus the patients may present with the features of androgen and/or mineralocorticoid excess. Treatment with a dose of dexamethasone adequate to suppress ACTH (usually 3 mg/day) results in a fall in adrenal androgens and often return of plasma potassium and blood pressure to normal levels. Many of these patients have been found to have point mutations in the steroid-binding domain of the glucocorticoid receptor, with consequent reduction of glucocorticoid-binding affinity.

Mineralocorticoid deficiency

These syndromes are listed in Table 8. They can be divided into those that are congenital and others that are acquired.

Adrenal insufficiency

Mineralocorticoid deficiency may occur in some forms of congenital adrenal hyperplasia and these are discussed elsewhere (see Chapter 12.7.2). Similarly, other causes of adrenal insufficiency (for example Addison's disease and congenital adrenal hypoplasia) are discussed above.

Primary defects in aldosterone biosynthesis

Failure of conversion of corticosterone to 18-hydroxycorticosterone or of 18-hydroxycorticosterone to aldosterone usually presents as a salt-wasting crisis in neonatal life (Fig. 1). Hyperkalaemia, metabolic acidosis, dehydration, and hyponatraemia are found. The condition has been called corticosterone methyl oxidase (**CMO**) deficiency, but this was before the final enzyme(s) involved in the conversion of deoxycorticosterone to aldosterone were characterized and cloned. In fact a single enzyme, aldosterone synthase carries a multistep reaction involving 11-hydroxylation of deoxycorticosterone to corticosterone, 18-hydroxylation of corticosterone to 18-hydroxycorticosterone, followed by 18-dehydrogenation to aldosterone. Two variants of CMO deficiency are described; CMO I is characterized by low 18-hydroxycorticosterone and aldosterone levels, whereas patients with CMO II deficiency have hypoaldosteronism but high 18-hydroxy-corticosterone concentrations. In both cases, mutations in the gene encoding aldosterone synthase have been described and the discrepant 18-hydroxycorticosterone levels seem likely to be explained on the basis of variable 18-hydroxylase activity of the related CYP45011b-hydroxylase 1 enzyme. CMO II is much more common in Iranian Jews than in the Caucasian population.

Defects in aldosterone action: pseudohypoaldosteronism

Pseudohypoaldosteronism type I presents in infancy with severe salt-wasting and failure to thrive but with very high plasma aldosterone, and plasma renin activity levels with inappropriate urinary sodium loss. The mineralocorticoid receptor appears to be defective, as judged by studies looking at the binding of aldosterone to monocytes, but molecular studies have failed to show any abnormality in the mineralocorticoid receptor itself. Recently, inactivating mutations in the a, b, and g subunits of the epithelial sodium channel have been shown to explain the condition, that is, exactly the opposite phenotype of Liddle's syndrome. Acquired forms of pseudohypoaldosteronism can occur in patients after renal transplantation, following obstructive uropathy, and in premature infants.

Pseudohypoaldosteronism type II or Gordon's syndrome is an autosomal dominant disorder characterized by hyperkalaemia but not salt-wasting in contrast to the type I condition. Patients have resistance to the mineralocorticoid effects of aldosterone on tubular potassium transport, but not to those of sodium and chloride transport. As a result, affected individuals have hyperchloraemia, hypertension, and suppression of plasma renin activity. Recent intronic deletions in the gene encoding a serine-threonine kinase, WNK, have been described in affected cases.

Hyporeninaemic hypoaldosteronism

Angiotensin II is a key stimulus to aldosterone secretion, and thus damage or blockade of the renin–angiotensin system may result in mineralocorticoid deficiency. Various renal diseases have been associated with damage to the juxtaglomerular apparatus and hence renin deficiency. Of these the most common (more than 75 per cent of cases) is diabetic nephropathy.

The usual picture is of an elderly patient with hyperkalaemia, acidosis, and mild to moderate impairment of renal function. Plasma renin activity and aldosterone are low and fail to respond to sodium depletion, the erect posture, or frusemide administration. Unlike those with adrenal insufficiency, patients with hyporeninaemic hypoaldosteronism have normal or elevated blood pressure but no postural hypotension. Muscle weakness and cardiac arrythmias may also occur. Other factors may also contribute to the hyperkalaemia, including the use of potassium-sparing diuretics, potassium supplementation, insulin deficiency, and b-adrenoceptor blocking drugs, and prostaglandin synthetase inhibitors which inhibit renin release.

Treatment of primary renin deficiency is with fludrocortisone in the first instance together with dietary potassium restriction. However, these patients are not salt depleted and may become hypertensive with fludrocortisone. In such a setting, the addition of a loop-acting diuretic such as frusemide is appropriate. This will also increase the excretion of acid and thus improves the metabolic acidosis.

Adrenal 'incidentalomas'

With the more widespread use of high-resolution imaging procedures (CT, MRI), incidentally discovered adrenal masses have become a common problem. An adrenal mass will be uncovered in up to 4 per cent of patients imaged for non-adrenal pathology. Over 80 per cent of cases are non-functioning with phaeochromocytomas and cortisol- or aldosterone-secreting adenomas comprising the remainder. As a result, all patients with incidentally discovered adrenal masses should undergo appropriate endocrine screening tests (24-hour urinary catecholamines, urinary free cortisol and overnight dexamethasone suppression tests, plasma renin activity/aldosterone, adrenal androgens) to exclude a functional lesion. The possibility of malignancy should be considered in each case. In patients with a known extra-adrenal primary, the incidence of malignancy is obviously much higher (up to 20 per cent of patients with lung cancer, for example, have adrenal metastases on CT scanning). Primary adrenal carcinoma is rare—in one study only 26 of 630 incidentalomas were found to be adrenal carcinomas. In true incidentalomas, size appears to be predictive of malignancy—a lesion of less than 5 cm in diameter is most unlikely to be malignant. Non-functioning lesions of less than 5 cm can therefore be treated conservatively and patients followed with annual imaging. Functional lesions, or tumours larger than 5 cm in diameter should be removed by laparascopic adrenalectomy.

12.7.2 Congenital adrenal hyperplasia

I. A. Hughes

Congenital adrenal hyperplasia comprises a family of inherited disorders of adrenal steroidogenesis, characterized by deficiency of cortisol and an accumulation of substrate precursors. A pathophysiological consequence of inadequate cortisol and aldosterone production is ACTH hypersecretion and hyperplastic adrenals. Genital abnormalities are not a universal feature of all forms of congenital adrenal hyperplasia and the original adrenogenital syndrome nomenclature is now seldom used. Figure 1 shows the pathways of adrenal steroidogenesis. The rate-limiting step is the delivery of cholesterol from the outer to the inner mitochondrial membrane to act as substrate for the action of P450scc, a mixed-function oxidase side-chain cleavage enzyme. The intracellular transport of cholesterol is controlled by a number of proteins, including steroid acute regulatory (StAR) protein. The synthesis of cortisol is predominantly controlled by ACTH acting via a G protein-coupled receptor activation of cyclic AMP. Table 1 is a summary of the types of enzymes involved in adrenal steroidogenesis and the known localization of the genes that encode each enzyme. Deficiency of 21-hydroxylase activity is the cause for congenital adrenal hyperplasia in more than 90 per cent of cases.

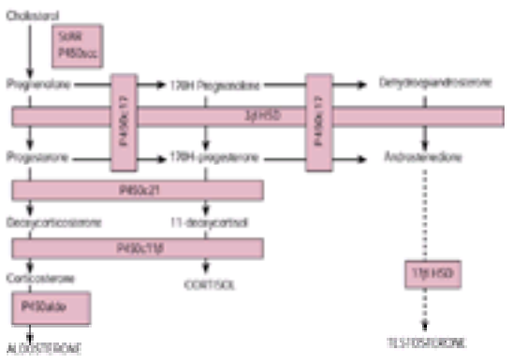

Fig. 1 Pathways of adrenal steroidogenesis. Enzymes involved as defined in the text are represented within the boxes. The dashed line denotes extra-adrenal synthesis of testosterone, catalysed by 17b-hydroxysteroid dehydrogenase. StAR, steroid acute regulatory protein.

21-Hydroxylase deficiency

Clinical presentation

Congenital adrenal hyperlasia due to 21-hydroxylase deficiency is a continuum of disorders which can manifest from birth to adult life (Table 2). The classical form of this enzyme deficiency presents in infancy in one of two forms. The most dramatic is with ambiguous genitalia of the newborn, whereby a female fetus becomes virilized *in utero* due to the effect of excess adrenal androgen converted peripherally to testosterone and masculinizing the external genital anlagen. Milder forms of virilization manifest either as isolated clitoromegaly or as isolated labial fusion. There is evidence that aldosterone biosynthesis is deficient in up to 75 per cent of cases; in affected males, salt loss is initially the sole manifestation as the onset of virilization in males is delayed beyond infancy.

Late-onset or non-classical forms of congenital adrenal hyperplasia are also recognized. There may be delay in the onset of virilization in the non-salt-losing male. The signs of precocious sexual development are also accompanied by tall stature, due to the growth-promoting effect of androgens. The testes remain prepubertal in size (less than 4 ml in volume), which is a useful distinguishing feature from other causes of precocious puberty associated with increased gonadotrophin secretion. The non-classical form of congenital adrenal hyperplasia in females may present with early onset of pubic hair growth or later after puberty with signs of hirsutism and symptoms of menstrual dysfunction. It is important to exclude an adrenal tumour as the cause of late-onset signs of virilization. In adult females, the symptoms and signs are similar to those associated with polycystic ovarian syndrome. Male infertility has also been ascribed to 21-hydroxylase deficiency. Tumours arising from testicular adrenal rests are a complication generally, but not exclusively, in inadequately treated males.

Tests to establish a diagnosis

The characteristic biochemical hallmark is an elevated plasma concentration of 17OH-progesterone, generally greater than 300 nmol/l (normal less than 10 nmol/l). Newborn screening for congenital adrenal hyperplasia is established in several countries in an effort to identify affected males before the onset of life-threatening salt loss. The world-wide incidence of 21-hydroxylase deficiency is approximately 1 in 14 000 births.

The diagnosis of late-onset 21-hydroxylase deficiency requires an ACTH stimulation test. Studies of women with signs of hyperandrogenism show only about 5 per cent of hormone profiles consistent with late-onset congenital adrenal hyperlasia. Polycystic ovarian syndrome is a well recognized and more frequent cause of hirsutism and infertility, although ultrasonographic evidence of polycystic ovaries is common in congenital adrenal hyperplasia. The disease frequency for the late-onset form is estimated as 0.1 per cent of the general population, but as high as 3 to 4 per cent of Ashkenazi Jews.

Treatment in early infancy, childhood, and adolescence

Glucocorticoid replacement in the form of hydrocortisone should be started; if the infant is in salt-losing crisis, parenteral hydrocortisone with intravenous saline and dextrose is needed. Hypoglycaemia may be a problem. The cortisol secretion rate is about 6 to 8 mg/m^2 per day so that an oral hydrocortisone dose no more than 15 to 20 mg/m^2 per day should be used initially. For salt-losers, aldosterone replacement is given in the form of 9a-fludrocortisone (florinef), 100 to 150 µg daily. Salt added to the feeds is sometimes needed during the first few months of life.

Surgical reconstruction of the external genitalia is required for the virilized female infant at 6 to 12 months of age. The procedure involves reducing the size of the clitoris and exposing the opening of the vagina on to the perineum. Further assessment of the vaginal opening is undertaken around puberty to determine whether treatment with dilators is required. Ongoing medical treatment is adjusted according to body surface area. The hydrocortisone dose should be trebled in times of stress, and parenteral steroids given to cover surgical procedures. Other glucocorticoid preparations used include cortisone acetate, prednisolone, and dexamethasone. Prednisolone and dexamethasone are both longer-acting glucocorticoids which appear to be useful for treatment in the postpubertal age group. Dexamethasone can be used as a single daily dose and appears to regulate menses more efficiently in the young adult female patient. Some girls, however, develop

side-effects, such as excessive weight gain and striae formation on quite small doses of dexamethasone. Dexamethasone is 80 to 100 times more potent than hydrocortisone in suppressing 170H-progesterone levels.

Monitoring treatment

The rate of linear growth is the main clinical yardstick of control before puberty (Table 3). Growth is normally rapid during infancy; over-treatment during this period may be a factor leading to reduced final height and to obesity in childhood. Growth monitoring is supplemented by bone age measurements. Androgens stimulate epiphyseal maturation through local conversion to oestrogens so that advanced skeletal maturation inevitably reduces the length of growing time and leads to short adult stature. The onset of the pubertal growth spurt is a milestone to monitor in both sexes, while delayed menarche in girls indicates inadequate control and increased plasma testosterone concentrations. In adults, regular menses and ovulation in the female and normal spermatogenesis in the male are reliable clinical indicators of adequate control.

Some of the tests listed in Table 3 are used as additional markers of control. There is a marked diurnal rhythm in 17OH-progesterone so that single random measurements are inadequate to monitor control. A daily profile is a useful measure of control, especially as capillary blood spot and saliva assays are available. Androstenedione can also be used as a marker of control. Random plasma testosterone measurements are useful to monitor control in infants, children, and adult females, but not in pubertal boys and adult males because of testosterone secretion by the testis. Serum electrolytes are an insensitive index of the adequacy of mineralocorticoid replacement, but renin measurement and blood pressure recordings should be undertaken routinely after infancy. An elevated plasma renin indicates the need for 9a-fludrocortisone treatment even if there has been no overt salt loss. Salt losers invariably like a salty diet even when adequately replaced with mineralocorticoid.

Outcome in treated 21-hydroxylase deficiency

The survival rate for the salt-wasting form of 21-hydroxylase deficiency has improved in recent years. However, an unequal sex incidence suggests that male infants still die in infancy from an unrecognized adrenal crisis. Achieving normal growth is a problem in management and patients rarely reach their predicted adult height. A recent clinical trial of lowering the glucocorticoid dose by blocking the action of androgen with an antiandrogen and the conversion of androgen to oestrogen with an aromatase inhibitor is showing promising results for improved growth.

Fertility is reduced in adult females. Contributory factors include inadequate vaginal introitus, and anovulatory cycles from increased progesterone concentrations acting as a 'mini-pill'. These problems are remediable and pregnancy rates are now improving. Nevertheless, there is evidence of lower maternalism and heterosexuality in adult females. Those who do become pregnant need careful monitoring to maintain steroid levels within the pregnancy-related range. Delivery is usually by caesarean section, and the offspring are normal even if testosterone levels increase slightly during pregnancy. Adult males who stop taking glucocorticoid replacement may develop oligospermia; this is usually reversible if treatment is restarted. Testicular tumours may also occur from ACTH hyperstimulation of testicular adrenal-rest cells. Laparoscopic adrenalectomy is a radical form of treatment in patients recalcitrant to medical management, particularly females with persistent signs of virilization.

Genetics of 21-hydroxylase deficiency

Congenital adrenal hyperplasia is an autosomal recessive condition; the *CYP21* gene is closely linked to the major histocompatibility complex on the short arm of chromosome 6. Studies of HLA haplotypes show an association between the uncommon A3, Bw47, DR7 haplotype in the classical salt-losing form, whereas in the non-classical late-onset form, there is a strong association with HLA-B14, DR1.

Two genes, *CYP21* and a pseudogene, *CYP21P*, were identified within the class III region of the HLA complex on chromosome 6p21.3 and are approximately 30 kb apart. They are adjacent to, and in tandem repeat with *C4A* and *C4B* genes which encode for the fourth component of serum complement (Fig. 2). *CYP21P* is functionally inactive because of a series of deleterious mutations, but is 97 per cent homologous with the active gene. Each gene comprises 10 exons. Misalignment and unequal crossing over between sister chromatids during meiosis leads to a major gene deletion. This is always associated with the severe, salt-losing form of congenital adrenal hyperplasia. The frequency of gene deletions as a cause of 21-hydroxylase deficiency is about 25 per cent and is highest in northern European populations. Another frequent genotype is associated with gene conversion events in which there is non-reciprocal transfer of multiple mutations from *CYP21P* to the active *CYP21* gene. Such large-scale conversions may account for a further 10 to 15 per cent of cases, all manifesting with the severe, salt-losing form. The majority of gene conversion events are small scale in nature. Several point mutations have now been identified while linked microsatellites are useful for prenatal diagnosis when the family genotype has previously been ascertained.

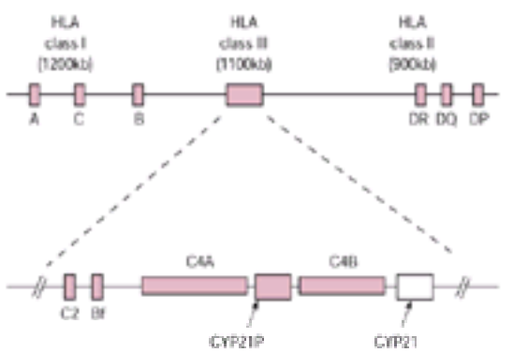

Fig. 2 Schema of the HLA gene region on chromosome 21p. The active 21-hydroxylase gene is *CYP21*, the inactive pseudogene, *CYP21P*. The two genes are in tandem repeat with complement C4A and C4B genes.

A sufficient number of alleles have now been studied to indicate general concordance between genotype and phenotype. The mutations which cause more than 90 per cent of cases of 21-hydroxylase deficiency are shown in Fig. 3 in relation to the expected phenotype. The most common mutation in classic 21-hydroxylase deficiency affects mRNA splicing due to a nucleotide base change (A/C to G) in the second intron. A stretch of nucleotides which is normally spliced out is retained, so that the translational reading frame is altered and an inactive protein synthesized. Most patients with this mutation have the salt-losing form of congenital adrenal hyperplasia, but some patients who are homozygous for this mutation are salt replete. Presumably, enough normally spliced mRNA is generated to produce some enzyme activity. Other examples leading to salt loss are shown in Fig. 3. *In vitro* functional assays of wild type and mutant CYP21 enzymes using progesterone and 170H-progesterone as substrate show total absence of enzyme activity for mutations leading to salt loss. A specific mutation associated with non-salt-wasting occurs in exon 4, changing isoleucine to an asparagine (Ile172Asn). This mutation results in an enzyme with about 1 per cent of normal activity, sufficient for adequate aldosterone production.

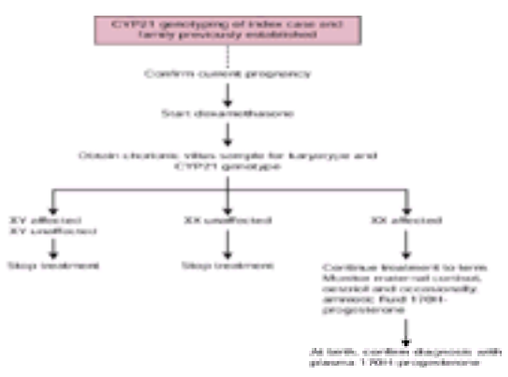

Fig. 3 Genotype: phenotype correlations for the 10 most frequent causes of 21-hydroxylase deficiency. E6 cluster refers to three mutations (Ile 236 Asp, Val 237 Glu, Met 239 Lys) in exon 6.

The non-classical or late-onset form of 21-hydroxylase deficiency is associated with a mutant enzyme which has 50 per cent and 20 per cent of normal activity *in vitro* with substrates 17OH-progesterone and progesterone, respectively. An example is Val251Leu in exon 7 which is associated with the haplotype HLA-B14, DR1. This single mutation accounts for the majority of non-classical cases of congenital adrenal hyperplasia, and is most frequently found in East European Jews. Genetic studies in 21-hydroxylase deficiency show that many patients are compound heterozygotes. In general, the phenotype reflects the less deleterious mutation.

Prenatal diagnosis and treatment

Chorionic villus sampling and molecular analysis of the *CYP21* gene has enabled an earlier and more reliable diagnosis to be made. Furthermore, there is the option of offering prenatal treatment to prevent virilization of an affected female fetus. Figure 4 outlines the current protocol used for the prenatal diagnosis and treatment of 21-hydroxylase deficiency.

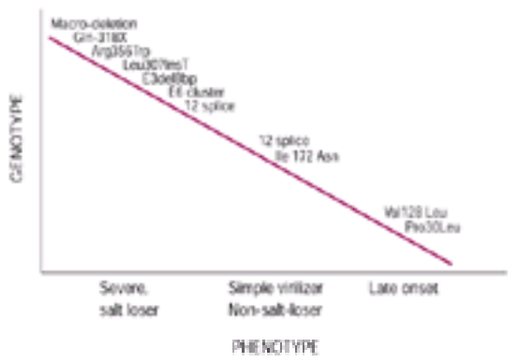

Fig. 4 Outline protocol for prenatal management of 21-hydroxylase deficiency.

Maternal dexamethasone treatment is started early as fetal adrenal steroidogenesis is established by the eighth week of gestation. *CYP21* genotyping of the index case, parents, and unaffected siblings should have been performed previously. DNA analysis is then more reliable, especially if the straightforward technique of linked microsatellite markers is used. Dexamethasone is chosen as the glucocorticoid since, unlike hydrocortisone and prednisolone, this steroid is not inactivated by placental 11b-hydroxy-steroid dehydrogenase. The conventional starting dose is 20 µg/kg per day based on prepregnancy bodyweight, administered in three divided doses. Once the diagnosis has been confirmed by molecular genetic analysis, treatment is only continued to term in the case of an affected female fetus. Thus, seven out of eight fetuses will be exposed unnecessarily to dexamethasone for about 6 weeks during early gestation. Fetal adrenal suppression is monitored by serial measurements of maternal plasma or urinary oestriol concentrations. This steroid metabolite is formed as a result of placental aromatization of weak androgen substrates produced uniquely by the fetal adrenal gland. More direct evidence of adrenal suppression can be obtained by collecting amniotic fluid for measurement of 170H-progesterone and testosterone.

The outcome of prenatal treatment is satisfactory in the majority of cases when treatment is started early and continues uninterrupted to term. Thus, the external genitalia in affected females are completely normal or so mildly affected that surgery is not required. There have been isolated reports of other abnormalities in treated infants but no specific pattern is emerging to suggest that prenatal dexamethasone treatment is detrimental to postnatal growth and development. This treatment to prevent a congenital malformation is still experimental and should be undertaken as part of a clinical trial which includes long-term outcome surveillance. Maternal side-effects of the treatment include excessive weight gain, striae formation, hypertension, and glucose intolerance.

Other forms of congenital adrenal hyperplasia

P450scc deficiency

This extremely rare form of the condition has also been variously called cholesterol desmolase deficiency and lipoid adrenal hyperplasia. The production of all classes of steroid hormones is deficient in gonadal as well as in adrenal tissue. Affected males have female external genitalia because of failure to synthesize testosterone. Affected 46XX females have developed puberty spontaneously suggesting the enzyme deficiency is less severe in the ovary compared with the testis.

The gene encoding P450scc is designated *CYP11A* and it was assumed that mutations in this gene caused lipoid adrenal hyperplasia. However, no mutations were found in several cases studied. Furthermore, adrenal tissue studied from an affected patient showed normal P450scc cDNA. When the human StAR gene was cloned, subsequent studies identified deleterious StAR mutations in patients with this form of congenital adrenal hyperplasia. The disorder is most common in the Japanese population; a premature stop codon at amino acid 258 substituting for glutamine is a frequently reported mutation. The StAR gene is expressed in the adrenals and gonads, but not the placenta, explaining why congenital lipoid adrenal hyperplasia is not a lethal disorder. Further analysis of the P450scc gene in a patient with lipoid adrenal hyperplasia who had a normal StAR gene, revealed a heterozygous mutation. The child had survived 4 years before developing an acute adrenal crisis.

3b-Hydroxysteroid dehydrogenase deficiency

3b-Hydroxysteroid dehydrogenase/isomerase (3bHSD) is a non-P450 membrane-bound enzyme which converts ‡^{5} to ‡^{4} steroids in the adrenals and gonads. Hence it is needed for the synthesis of glucocorticoids, mineralocorticoids, progesterone, androgens, and oestrogens. Two highly homologous genes, *HSD3B1* and *HSD382*, control the expression of two human isoenzymes. Type I enzyme is expressed predominantly in the placenta and peripheral tissues, whereas type II is expressed in the adrenals and gonads. Deficiency of 3bHSD activity also causes severe glucocorticoid and mineralocorticoid deficiency. Genital abnormalities occur, mainly in males because of the production of weak androgens by the testis. Diagnosis is confirmed by an elevated ratio of ‡ ^{5} (170H-pregnenolone) to ‡^{4} (170H-progesterone) steroids and analysis of urinary steroid metabolites.

Molecular studies show the majority of patients have missense mutations in the *HSD3B2* gene. Nevertheless, there is significant conversion of ‡ ^{5} to ‡^{4} steroids in peripheral tissues through the action of type I 3bHSD. Consequently, some patients have elevated levels of ‡ ^{4} steroids (17OH-progesterone, androstenedione), which has led to a mistaken diagnosis of 21-hydroxylase deficiency. Extraglandular steroid synthesis accounts for 40 per cent of androgen production in adult males and most oestrogen production in prepubertal and postmenopausal females. Spontaneous onset of puberty and menarche are reported in females with 3bHSD deficiency.

17a-Hydroxylase deficiency

A single P450c17 enzyme catalyses 17a-hydroxylase and 17,20-lyase reactions. Both are required for the synthesis of sex hormones (C19 steroids), whereas only 17a-hydroxylase activity is required to synthesize cortisol (C21, 17-hydroxysteroids). Mineralocorticoid biosynthesis is not dependent on the presence of the P45017a enzyme, so that ACTH-stimulated, low renin hypertension is a typical feature of P45017a hydroxylase deficiency due to excess production of C21, 17-deoxysteroids such as aldosterone. There is an accompanying hypokalaemic, metabolic alkalosis. Inadequate androgen in affected males causes a phenotype ranging from female genitalia to an ambiguous appearance or features of a hypospadic male. Females lack breast development and have primary amenorrhoea. The P450c17 enzyme operates as a qualitative regulator of steroidogenesis using pregnenolone as substrate.

Increased corticosterone, deoxycorticosterone, and progesterone and decreased levels of testosterone, oestradiol, and renin characterize this enzyme defect.

Measurements of steroid metabolites delineate patterns indicative of 17a-hydroxylase or 17,20-lyase deficiency alone, or combined. Most patients have a mutant P450c17 which leads to loss of both enzyme activities.

The 6.5-kb human *CYP17* gene comprises eight exons. A frequent mutation is a 4-bp duplication in exon 8 which, as a result of altering the reading frame, leads to a shortened carboxy-terminal sequence. Expression studies of the mutant protein show absence of both 17a-hydroxylase and 17,20-lyase activities. This is consistent with biochemical findings and a clinical female phenotype in affected males and females. The differential catalytic activity of this enzyme is manifest at adrenarche with the development of the zona reticularis and increased 17,20-lyase activity. This causes increased concentrations of dehydroepiandrosterone (DHEA) and its sulphate (DHEAS), independent of any change either in ACTH or cortisol levels. The increase in adrenal androgens may lead to early onset of pubic and axillary hair, body odour, and a moderate advance in skeletal maturation. Premature adrenarche must be differentiated from late-onset congenital adrenal hyperplasia or an adrenal tumour. Studies on the regulation of 17,20-lyase activity suggests a role for P450c17 phosphorylation in mediating the increased differential enzyme activity occurring at the time of adrenarche.

11b-Hydroxylase deficiency

Deficiency of 11b-hydroxylase activity accounts for about 5 per cent of cases of congenital adrenal hyperplasia. The enzyme is required for the terminal conversion of 11-deoxycortisol to cortisol and deoxycorticosterone to corticosterone. Consequences of increased ACTH stimulation are salt and water retention, low-renin hypertension, and virilization secondary to the increased production of deoxycorticosterone and adrenal androgens. Newborn females and infant males are more profoundly virilized than is the case with 21-hydroxylase deficiency. Prepubertal breast development is another specific and unexplained feature. Hypertension can develop in early childhood, the severity not necessarily correlating with plasma levels of deoxycorticosterone.

The diagnosis is confirmed by elevated concentrations of 11-deoxy-cortisol and deoxycorticosterone in plasma and their tetrahydro metabolites in urine. Plasma concentrations of androstenedione and testosterone are increased. Moderately elevated levels of 17OH-progesterone may lead to an erroneous diagnosis of 21-hydroxylase deficiency. Treatment requires only glucocorticoid replacement, although transient salt-wasting may follow an initial fall in levels of the potent mineralocorticoid, deoxycorticosterone. Antihypertensive treatment may be necessary if hypertension has been long-standing. Milder or late-onset deficiency occurs and manifests similar features to the late-onset form of 21-hydroxylase deficiency.

11b-Hydoxylase activity is a function of the *CYP11B1* gene which comprises nine exons and is located on chromosome 8q22. The gene is highly expressed in the adrenals; transcripts are controlled by ACTH and to a lesser extent, by angiotensin II. Located on the same chromosome, at a distance of about 40 kb, is the highly homologous *CYP11B2* gene which encodes aldosterone synthase (also referred to as corticosterone methyloxidase II) which catalyses the conversion of corticosterone via 18OH-corticosterone to aldosterone.

Mutations throughout the *CYP11B1* gene cause 11b-hydroxylase deficiency. The majority are missense mutations with some clustering occurring in exons 2, 6, 7, and 8. The highest incidence of this form of congenital adrenal hyperplasia occurs in an inbred population of Sephardic Jews in Morocco. A single amino acid substitution (Arg448His) is the cause. This alters the haeme-binding sequence which is a unique and conserved feature of all cytochrome P450 enzymes. Prenatal treatment with dexamethasone has also been used successfully in this form of congenital adrenal hyperplasia to prevent virilization of an affected female fetus. The late-onset or non-classic form of 11b-hydroxylase deficiency has been found in one study to be associated with compound heterozygote mutations of the *CYP11B1* gene. Studies of hirsute women with marginally elevated levels of 11-deoxycortisol have not revealed mutations in the *CYP11B1* gene.

12.8.1 Ovarian disorders

H. S. Jacobs

Approach to the patient with ovarian disorders

Synchronization of the changes in the ovary and uterus and the hypothalamic–pituitary unit is complex and, not surprisingly, the ovulatory cycle is vulnerable to disturbances at any of the levels of endocrine organization. Ovarian cyclicity may also be disrupted by a deterioration in general health, a protective mechanism that avoids reproduction occurring in circumstances adverse to fetal development.

In obtaining the history, information about the regularity of the menstrual cycle is relevant in women concerned about fertility because the chance of conception is directly related to the rate of ovulation. If a woman ovulates only six rather than the usual 12 to 13 times a year, it will take her twice as long to conceive as a woman of the same age with a regular monthly cycle. Oligomenorrhea (interval between menstrual periods of more than 6 weeks but less than 6 months) is usually a consequence of the polycystic ovary syndrome (see later); amenorrhoea (no periods for more than 6 months) has a broader spectrum of causes (Table 1 and Table 2). The duration of a menstrual disturbance is relevant both to its cause and its consequences. For example, a history of delayed menarche implies that the disturbance was present from the age of 12, a common finding in women with polycystic ovary syndrome. A history of weight fluctuation is important because weight loss, often in the context of mild (and denied) anorexia nervosa, is a common cause of amenorrhoea and weight increase a common precipitant of the clinical expression of polycystic ovary syndrome. Bulimia may complicate either of the above conditions and, like anorexia nervosa, requires specialist management in its own right. It is always relevant to inquire about a family history of the patient's complaint since an increasing number of mono- and polygenic causes of reproductive disturbance are now recognized.

The association of amenorrhoea with galactorrhoea implies hyperprolactinaemia and an association with symptoms of oestrogen deficiency (flushing and sweating attacks and/or vaginal dryness and discomfort during intercourse) implies an increased risk of osteoporosis. Symptoms of hyperandrogenism (seborrhoea, acne, and excessive hair growth) imply increased production of androgens, which, in most cases, is caused by polycystic ovary syndrome. It is preferable to use the term 'unwanted hair' rather than 'hirsutism' to avoid provoking a debate with the patient about what is and what is not excessive. On the other hand, whether the unwanted hair is severe enough to be helped by present methods of treatment is a matter for the physician's judgement. Some women express a concern, which should not be trivialized, that the development of unwanted hair means they are turning into a man. They need a clear explanation of the underlying disorder and reassurance that treatment is available.

If the patient has previously used an oral contraceptive, one should determine whether it was primarily for contraception or had been prescribed to correct a menstrual disturbance. In the latter case, it is important to appreciate that treatment with an oral contraceptive does not cure such problems, which are therefore likely to recur when it is stopped. Oral contraceptives do not cause amenorrhoea after discontinuation. Amenorrhoea occurring after discontinuation of an oral contraceptive therefore needs the same investigation as amenorrhoea temporally unrelated to previous use of an oral contraceptive.

Most women with menstrual disturbances want reassurance about their present or future fertility. Their age is clearly of great importance in this evaluation which will also have to determine the extent to which failure to ovulate is an adequate explanation of the failure to conceive. Many older women need advice about the long-term effects of oestrogen deficiency and the wisdom of hormone replacement therapy.

Amenorrhoea

While the classification is usually into primary (the patient has never had a menstrual period) or secondary amenorrhoea (interval between periods exceeds 6 months) most of the common causes can present as either, as seen in Table 1 and Table 2. With the exception of structural abnormalities, such as an absent uterus, differences between primary and secondary amenorrhoea are outweighed by similarities so here they are considered primarily in terms of their aetiology.

In young women with primary amenorrhoea there may have been congenital abnormalities in the development of the ovaries, genital tract, or external genitalia or a perturbation of the normal process of puberty (Chapter 12.9.3). Investigation is appropriate when menstruation has not occurred by the age of 16 in the presence of normal secondary sexual development or by the age of 14 in its absence.

Developmental abnormalities

Developmental abnormalities of the mullerian duct, external genitalia, and the problems of intersexual abnormalities are dealt with elsewhere.

Gonadal dysgenesis

The commonest cause of gonadal dysgenesis is Turner's syndrome, in the severest form of which a 45XO karyotype is associated with a characteristic phenotypic appearance. Typically patients are of short stature, with cubitus valgus, webbed neck, low hairline, shield chest, and widely spaced nipples. The palate is often arched and the fourth metacarpal short. Lymphoedema, multiple pigmented naevei, and hearing loss are common. Coarctation of the aorta occurs in 10 to 20 per cent and hypertension independent of that abnormality occurs more commonly than in the normal population. The condition occurs in about 1 in 2500 female births. Spontaneous and, indeed, ovulatory cycles occasionally occur, particularly if there is chromosomal mosaicism, but in the long term premature ovarian failure is inevitable. It is important to determine the karyotype as the presence of a Y chromosome in an individual with gonadal dysgenesis means residual gonadal tissue must be removed because of an increased risk of malignancy.

Serum gonadotrophin concentrations are elevated compared with those of normal girls of the same age and may approach the menopausal range. Oestrogen levels are low, the uterus is small and bone densitometry shows skeletal decalcification; a history of spontaneous fracture is common. In addition to cardiovascular and renal assessment, autoimmune thyroiditis and diabetes mellitus should be excluded.

Management includes initiation of low-dose oestrogen therapy (starting with no more than 5 µg of ethinyl oestradiol per day) to promote breast development without prejudicing linear growth. The dose is gradually raised over 12 to 18 months. Maintenance therapy is with a cyclical oestrogen–progestogen preparation (such as an

oral contraceptive), as regular withdrawal bleeding is necessary to prevent endometrial hyperplasia and the risk of malignancy. While it is now possible to provide fertility to women with Turner's syndrome through ovum donation, shortage of oocytes remains an important and usually critically limiting factor. Given the prevalence of hypertension and cardiovascular disorder, careful medical assessment before referral is required.

Hypothalamic causes of amenorrhoea

Hypothalamic hypogonadotrophic hypogonadism may be functional or organic and can occur in an isolated form or in association with more widespread endocrine disorders, as in patients with infiltrating (sarcoidosis, tuberculosis), expanding (craniopharyngioma), or traumatic (head injury) lesions of the hypothalamus. Hypogonadotrophic hypogonadism that is potentially reversible occurs in primary and secondary iron overload syndromes and is a frequent presenting feature of juvenile haemochromatosis. Lesions of the pituitary stalk are increasingly recognized.

Idiopathic hypogonadotrophic hypogonadism is characterized by low serum levels of gonadotrophins and gonadal steroids in the absence of structural defects of the hypothalamic–pituitary axis. Idiopathic hypogonadotrophic hypogonadism usually results from a congenital defect of secretion of gonadotrophin-releasing hormone, although mutations of the gene encoding the gonadotrophin-releasing hormone receptor have also been described.

Hypogonadism with anosmia. In a number of idiopathic hypogonadotrophic hypogonadism pedigrees mis- and non-sense mutations and partial and complete deletions have been identified in a gene located in the distal part of the short arm of the X chromosome (Xp22.3). These mutations are associated with hypogonadotrophic hypogonadism and anosmia, as features of Kallman's syndrome in boys and men. This (*KAL*) gene lies next to the steroid sulphatase locus, so patients may exhibit a contiguous gene syndrome comprising complete X-linked Kallman's syndrome and ichthyosis. The *KAL* gene encodes a molecule with similarities to proteins involved in neural cell adhesion and axonal pathfinding. X-linked Kallman's syndrome arises from a defect of embryonic migration of olfactory and gonadotrophin-releasing hormone producing neurones from the anlage of the olfactory lobes into the hypothalamus. In affected females the disorder is usually inherited as an autosomal recessive or dominant trait, generally with incomplete penetrance. The molecular cause in these cases is not known.

In women Kallman's syndrome presents with delayed puberty and primary amenorrhoea. Characteristically the patient cannot smell curry or the difference between tea and coffee. There are signs of marked oestrogen deficiency, usually amounting to sexual infantilism. Adult stature is normal. Mirror movements, in which voluntary movements of one limb are associated with involuntary, non suppressible and homologous mirror movements of the contralateral limb, occur in 85 per cent and unilateral renal agenesis in 31 per cent of X-linked cases.

Investigations reveal subnormal serum gonadotrophin and oestradiol concentrations, on pelvic ultrasound the uterus and ovaries are small, and bone densitometry reveals skeletal demineralization (Fig. 1). Renal imaging may show an absent kidney; MRI of the brain shows absent or abnormal olfactory bulbs and sulci, with a normal pituitary gland.

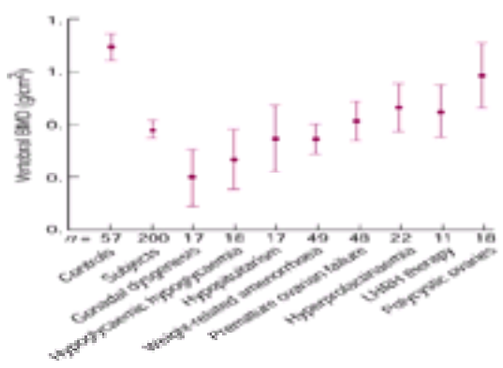

Fig. 1 Vertebral bone mineral density measurements in 200 young women with amenorrhoea, arranged by diagnosis. With the exception of the bone mineral density measurements in the women with polycystic ovary syndrome, the bone mineral density measurements of all other groups were significantly below those of the controls.

Management of idiopathic hypogonadotrophic hypogonadism involves induction of pubertal maturation, initially with small doses of oestrogen (not more than 5 µg/day of ethinyl oestradiol) to optimize breast development. Delay in recognition and treatment impairs full development and so has important psychosocial implications. Surgical referral for breast augmentation is appropriate if development remains inadequate after a year's treatment with gradually increasing doses of oestrogen. Maintenance hormone treatment is with an oral contraceptive preparation. Bone densitometry should be repeated to ensure that the dose of oestrogen is adequate. While an increase of 5 to 6 per cent per year for 2 to 3 years is expected, delay in diagnosis may result in failure to attain normal peak bone mass. Treatment with pulsatile gonadotrophin-releasing hormone or gonadotrophin injections allows an excellent prognosis for fertility.

Functional hypogonadotrophic hypogonadism

Weight-related amenorrhoea

Amenorrhoea is usual when the body fat content falls below 17 per cent or the body mass index falls below 19 kg/m ^{2}. The latter figure assumes an average amount of exercise; for competitive athletes, particularly those in track events, the figure would be higher. Depending on the age of onset, the patient may present with primary or secondary amenorrhoea.

The neuroendocrine mechanisms that signal this critical level of nutritional reserve are uncertain but centre on reduced secretion of leptin which results in impaired secretion of gonadotrophins, particularly luteinizing hormone. Serum insulin and insulin-like growth factor 1 levels are low so there is also reduced insulin drive to the ovaries. The consequent anovulation is protective because it avoids reproduction occurring in adverse circumstances. Quite apart from the obstetric evidence of premature delivery of immature babies to women who are underweight, there is also a link between deficient fetal nutrition and an increased prevalence in adults of cardiovascular and pulmonary disease.

Self-imposed starvation

The cause is often anorexia nervosa (Chapter 26.5.5). In patients presenting with amenorrhoea, loss of appetite is usually denied and the patient often draws attention to what she regards as a normal pattern of eating. These women characteristically maintain a good appetite which they have to suppress. In contrast, some women lose weight as a feature of the anorexia of depression, occasioned perhaps by the breakup of a relationship; in this condition the patient does lose her appetite. The prognosis for a return of normal weight and spontaneous menstrual cycles is much better than that in women with anorexia nervosa.

Exercise-related amenorrhoea

Amenorrhoea is common in ballet dancers and high-performance athletes, particularly during phases of intensive training and performance. The amenorrhoea is associated with reduced body weight and body fat content. Psychological stress is unlikely to be a major determinant because amenorrhoea is not common in Olympic swimmers, who, though as competitive as track athletes, have a normal body fat content.

Involuntary starvation

Worldwide, the most important causes of starvation are social disintegration, famine, and war. Increasingly we recognize that the deleterious physical effects of starvation are passed to the next generation, *inter alia*, through the adverse effects of fetal malnutrition on adult health.

Altered absorption

In patients with malabsorption, for instance in women with cystic fibrosis, amenorrhoea is associated with reduced body mass index and body fat content and resolves when nutrition improves.

Investigation of weight-related amenorrhoea

The diagnosis is made in part by identifying that the patient's weight is subnormal for her height, bearing in mind the effect of high-performance training on replacing body fat with more dense muscle. It is also made by exclusion, because self-imposed weight loss is common in young women and may coexist with other conditions.

Women with weight-related amenorrhoea have subnormal serum gonadotrophin (particularly luteinizing hormone) and oestradiol concentrations, with small ovaries and a small uterus on ultrasound scanning. Skeletal demineralization is the rule, except in those with coexisting polycystic ovaries (see later). Serum markers of bone resorbtion are low, indicating that, in contrast to the osteoporosis of oestrogen deficiency, this is a 'low-turnover' osteoporosis. The most likely cause is reduced osteotrophic stimulation by insulin-like growth factor 1 and leptin.

Management involves explanation, identification of psychiatric conditions for which specialist advice is needed, and correction of oestrogen deficiency. Optimally the latter is achieved through weight gain. Oestrogen deficiency may, however, be so severe that if the patient is unable to put on weight, it may be preferable for her to take oestrogen rather than have the clinician adopt a purist position. Bone mineral density, however, only improves when the patient gains weight: oestrogen treatment is ineffective. So far as fertility is concerned, medical induction of ovulation should be eschewed until the patient's weight has returned to normal so that nutritional risks to the unborn child (and adult) have been minimized. In the event, when the body mass index returns to normal, induction of ovulation is rarely required.

Pituitary causes of amenorrhoea

While a non-functioning pituitary tumour sometimes causes amenorrhoea, the commonest pituitary cause is hypersecretion of prolactin. The subject is discussed further in Chapter 12.2.

Ovarian causes of amenorrhoea

Primary ovarian failure

Primary ovarian failure occurs normally at the menopause ('age appropriate primary ovarian failure') because of the process of atresia (Fig. 2) that results in almost complete depletion of oocytes and follicles by about the age of 50. If the rate of atresia is faster than normal, the causes of which are discussed below, depletion of oocytes and follicles occurs prematurely and 'age inappropriate' or 'premature' ovarian failure develops.

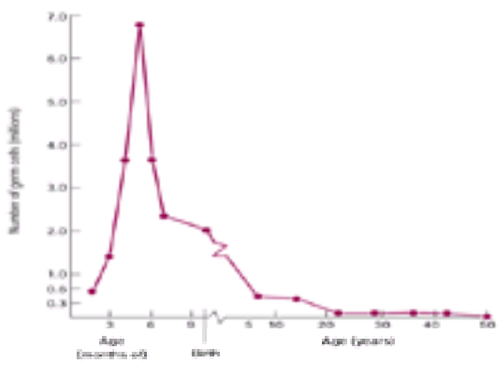

Fig. 2 The number of oocytes in the gonads in relation to age. Note that the maximum rate of atresia occurs before birth. (After Baker TG (1963). *Proceedings of the Royal Society (Biology)* **158**, 417)

Oocytes do not divide once they have been laid down in the ovary. Thus unlike the testis, the ovary has a finite complement of germ cells. Oocytes 'used' in the process of ovulation account for a minute proportion of those that are lost, and it can be seen from Fig. 2 that most atresia occurs during intrauterine life when endocrine influences are least important. The apoptotic process of atresia is controlled genetically. Loss of the second X chromosome, as in 45XO Turner's syndrome, accelerates the rate. This observation, together with the occurrence of familial cases of premature ovarian failure, has prompted the search for genes critical for normal ovarian development. Three loci on the X chromosome appear to be vital: the first is Xp22, which contains a series of genes that escape X inactivation, among which is the *ZFX* gene. Premature ovarian failure is one of the features of the transgenic mouse with this gene 'knocked out'. The *SOX3* gene (mapped to Xq26–27.2), the homologue of the *SRY* gene on the Y chromosome that determines testicular development, also escapes X inactivation and fulfils several of the criteria for a candidate gene. The third region of interest is Xq13–22 because several women with premature ovarian failure and break points in this region have been described. Familial premature ovarian failure also occurs without cytogenetic abnormality and autosomal dominant, autosomal recessive, and X-linked patterns of inheritance have been described. The condition may be present in families with galactosaemia, blepharophimosis, and fragile X syndrome. The presentation is particularly intriguing in the last case because the association is specifically with the premutation, until recently thought not to have a phenotype other than the risk of transmitting fragile X syndrome.

Destruction of genetic material by ionizing irradiation, anticancer chemotherapy, and viral infections, such as mumps oophoritis, can cause premature ovarian failure (Table 3). The association of premature ovarian failure with thyroiditis, adrenalitis, and diabetes mellitus has led to the hypothesis that in many cases the cause is autoimmune. While reliable tests are not widely available, autoantibodies to ovarian cells, oocytes, or gonadotrophin receptors have been reported in up to 80 per cent of cases, a result consistent with the author's finding of thyroid and adrenal autoantibodies in more than half of the patients remaining after those with chromosomal causes had been excluded. Finally, the presence in follicular fluid of toxic pollutants from tobacco smoke, such as cotinine, a congener of nicotine, may account for the earlier menopause that occurs in women who smoke cigarettes.

The symptoms of primary ovarian failure are those of oestrogen deficiency, together with infertility. Investigation reveals subnormal oestradiol and raised serum gonadotrophin concentrations. While the serum luteinizing hormone is often elevated in patients with polycystic ovary syndrome, a rise in the concentration of follicle-stimulating hormone always suggests primary ovarian failure. Autoantibodies should be sought because their presence alerts the clinician to the possible development of pluriglandular endocrine failure. Pelvic ultrasound shows undetectable or small ovaries and a small uterus. Bone densitometry usually reveals significant demineralization.

Patients with premature ovarian failure usually require hormone replacement therapy, the indications, precautions, etc. being the same as those for women in whom the menopause has occurred at a normal age. In some women there may be a spontaneous return of ovulatory menstrual cycles, albeit usually temporary, and therefore pregnancies do sometimes occur. Treatment with glucocorticoids or immunolytic drugs for women with autoimmune ovarian failure has occasionally proven successful but formal controlled trials are lacking and these treatments are not recommended. The ovaries do not respond to further stimulation with gonadotrophins so the only chance of childbearing for most women is through ovum donation. The problems of supplies of donor oocytes are formidable.

Resistant ovary syndrome

This ill-defined syndrome refers to women with amenorrhoea and elevated serum gonadotrophin concentrations in whom, paradoxically, oestrogen levels are well maintained. The persistent secretion of oestradiol suggests persistence of ovarian follicular activity, an implication occasionally confirmed histologically or by ultrasound assessment of the ovaries and by the occasional and unpredictable occurrence of pregnancy. The ovaries do not respond to further stimulation with

exogenous gonadotrophins. While both cause and prognosis remain obscure the condition is most easily understood as a transitional phase on the way to primary ovarian failure.

Polycystic ovary syndrome

A full description of polycystic ovary syndrome is given later. Its clinical expression, typically dating from the time of puberty, involves a menstrual disorder (usually oligomenorrhoea but amenorrhoea in 26 per cent of cases) hyperandrogenization, and weight increase.

The indications for treatment of amenorrhoea in women with polycystic ovary syndrome depend upon the patient's needs. For women who wish to conceive, induction of ovulation is required, combined with attempts to reduce insulin drive to the ovaries by diet, exercise, and insulin-sensitizing drugs such as metformin (see later). For women needing contraception, an oral contraceptive is appropriate, the choice of preparation depending on the degree of associated unwanted hair. An oral contraceptive is also appropriate for women troubled by the lack or unpredictability of menstruation. For the remainder, it is acceptable to remain amenorrhoeic, provided annual ultrasound scans of the endometrium shows that overstimulation has not occurred.

Investigation of amenorrhoea

The patient's stature, nutritional status, the presence of unwanted hair (male pattern or the lanugo of anorexia nervosa) or acanthosis nigricans, and the physical stigmata of oestrogen deficiency are important parts of the physical examination. Pelvic ultrasound reveals the ovarian dimensions and whether they have the characteristic internal echoes of polycystic ovaries and the size of the uterus and degree of endometrial thickening. Hormone assays reveal subnormal serum oestradiol levels associated with elevated (primary ovarian failure) or subnormal (hypogonadotrophic hypogonadism) gonadotrophin concentrations. Serum ferritin measurements are conducted to screen for excessive iron storage in patients with low gonadotrophin concentrations. Assessment of white blood cell karyotype and measurement of autoantibodies is undertaken in patients with primary ovarian failure. Bone densitometry may reveal demineralization of spine and hips. Radiological assessment of the pituitary is undertaken in patients with hyperprolactinaemia.

Treatment of amenorrhoea

In addition to correcting the cause whenever possible, management is directed at minimizing the long-term complications of oestrogen deficiency. When the cause cannot be corrected oestrogen replacement therapy, usually in the form of an oral contraceptive, is appropriate. Outcome should be monitored by ensuring that sufficient oestrogen is administered to cause withdrawal bleeds and that there is an improvement in bone density if skeletal demineralization has been demonstrated.

Hyperandrogenization

Normal hair growth and androgen production in women

At birth the fetus is covered in lanugo hair which rapidly disappears and is not seen again unless anorexia nervosa develops, although very rarely such hair appears as a non-metastatic complication of malignancy. The follicles in the skin of prepubertal children grow soft, short, and fair vellus hair, which, together with scalp, eyebrow, and eyelash hair, is known as non-sexual hair. In response to the secretion of adrenal androgens at puberty, both boys and girls develop terminal hair in the axillae and lower pubic triangle (ambosexual hair). Terminal hair is long, pigmented and coarse. In boys the further increase of (testicular) androgen secretion leads to the development of terminal hair in the upper pubic triangle and on the face, chest, abdomen, and arms and legs—that is, male pattern hair.

Perception of hairiness depends in part on its distribution and in part on its character and pigmentation. While there is racial variation in the density of hair follicles (Native Americans and Orientals having few and women from the Mediterranean littoral having many follicles per unit area of skin) it is the development of male pattern hair in women which constitutes hirsutism.

The sources of androgens in normal women are shown in Fig. 3 from which it can be seen that 50 per cent of directly secreted and 75 per cent of peripherally derived testosterone normally originates from the adrenal cortex. Testosterone circulates specifically bound to sex hormone binding globulin, from which it disassociates and diffuses into target tissues where it is either 5a reduced to a more powerful androgen, dihydrotestosterone, or aromatized to oestradiol. The dihydrotesterone–nuclear protein receptor complex associates with the specific DNA receptor to cause androgen-specific protein synthesis and the expression of androgen action.

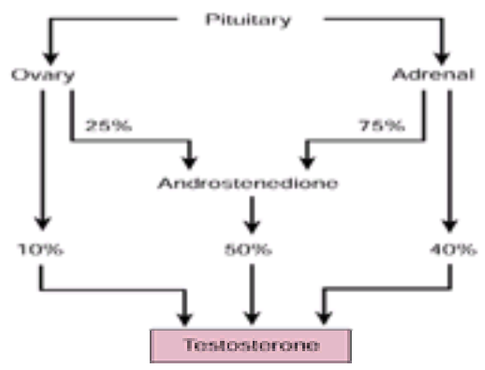

Fig. 3 Sources of androgens in normal women.

Synthesis of sex hormone binding globulin, whose concentration largely determines the total serum testosterone concentration, takes place in the liver, stimulated by thyroxine and inhibited by insulin and to a lesser extent by androgens. The rate of clearance of sex hormone binding globulin is reduced by oestrogen.

Clinical hyperandrogenization

Hyperandrogenization in women is manifest as seborrhoea, persistent acne, and the development of a male pattern of distribution and quality of hair. Male pattern hair loss may also occur, particularly in women with male family members who are bald. Clitoromegaly and increased muscle bulk are signs of severe and usually long-standing overexposure to androgens.

Although defects in adrenal steroid biosynthesis (congenital and late onset adrenal hyperplasia), Cushing's syndrome, and adrenal androgen secreting tumours may all cause oversecretion of androgens and therefore present with hirsutism, the commonest cause by far is polycystic ovary syndrome, in which condition there is an increase in the direct ovarian secretion of androgens.

Polycystic ovary syndrome

Polycystic ovaries are readily identified by pelvic ultrasound, because they are larger than normal (average volume three times that in normal women) and have a highly echodense central stroma in which cysts of 2 to 6 mm diameter are arranged around the circumference (Fig. 4). When ovaries with this appearance are detected in women complaining of specific symptoms, the term polycystic ovary syndrome is used (Table 4). Defined in this way, the polycystic ovary syndrome corresponds to the condition described over 50 years ago by Stein and Leventhal.

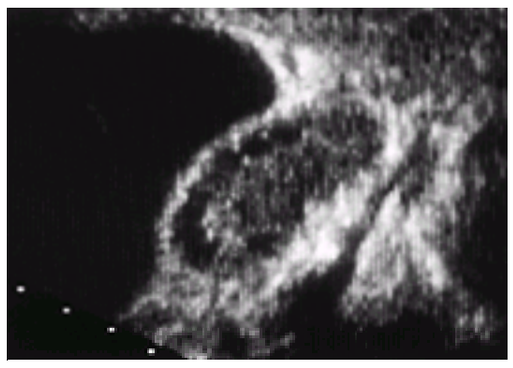

Fig. 4 Transabdominal ultrasound image of a polycystic ovary. Note the enlarged ovary with the echodense central stroma and the necklace of cysts around the circumference.

Patients with this condition commonly present in their late teens or early twenties, complaining of the consequences of hyperandrogenization or of a menstrual disturbance (Table 4). There is often a family history of similar complaints but even when that is absent an ultrasound scan usually reveals polycystic ovaries in first-degree relatives. Infertility is caused by failure of ovulation, although hypersecretion of luteinizing hormone is also important in this regard. Obesity, often associated with an increase in the ratio of waist to hip circumference, is the third classical feature.

Endocrine features

The classical profile is of hypersecretion of luteinizing hormone and androgens with normal circulating follicle-stimulating hormone, prolactin, and thyroxine concentrations. In fact a spectrum of endocrine findings occurs, reflecting the phenotypic heterogeneity of the polycystic ovary syndrome. In a study of more than 1500 cases, 44 per cent had an elevated serum luteinizing hormone and 22 per cent an elevated serum total testosterone concentration. Levels of luteinizing hormone were raised most commonly in the women complaining of infertility and of testosterone in those complaining of hirsutism.

The nature of the primary disturbance underlying these findings is uncertain. A central problem is failure of the polycystic ovary to convert androgens, made in excessive amounts by the abundant theca and interstitial cells of the hyperplastic ovarian stroma, into oestrogens. The androgens (predominantly androstenedione and testosterone) are released into the circulation and converted in the skin to dihydrotestosterone. In liver and fat tissue, they are converted into oestrogens at a rate which increases with the degree of obesity. The high levels of oestrogen (predominantly oestrone) inhibit secretion of follicle-stimulating hormone and may stimulate secretion of luteinizing hormone. The former effect contributes to persistent anovulation and the consequent lack of progesterone (which in the normal luteal phase limits the proliferative action of oestradiol) means that the action on the uterus of the normally weak oestrogen oestrone is unopposed. These patients are consequently at risk from endometrial hyperplasia and neoplasia. The raised levels of luteinizing hormone stimulate the excessive numbers of theca and interstitial cells to oversecrete androgens. Exposure of the ovaries to high levels of luteinizing hormone at inappropriate times of the cycle may also impair fertility through an action on the developing oocyte.

The above model does not explain the variable clinical presentation of polycystic ovary syndrome. It is likely that environmental factors lead to expression of the underlying, probably inherited, condition.

Many patients with polycystic ovary syndrome, particularly those who are anovulatory, are resistant to the action of insulin. While several types of insulin resistance are currently recognized (Chapter 12.11), in women with polycystic ovary syndrome the resistance is specifically to insulin-mediated extrasplanchnic disposal of glucose. As a consequence, euglycaemia can only be maintained through compensatory hypersecretion of insulin, the clinical clue to which is the development of acanthosis nigricans (see Plate 1). The insulin resistance spares the liver (the fasting glucose concentration is normal, serum sex hormone binding globulin and high-density lipoprotein concentrations are suppressed), the skin, and the ovary. Ovarian dysfunction results, in direct proportion to the intensity of compensatory hyperinsulinism.

A specific defect in transduction of the insulin signal has been described in women with polycystic ovary syndrome. In addition, as children enter puberty, insulin resistance develops in response to the increase of growth hormone secretion that underlies the acceleration in growth at this age. Obesity itself, present in some 40 per cent of women with polycystic ovary syndrome, worsens insulin resistance and so causes further deterioration of ovarian function. Should the patient come from a family with diabetes mellitus, there is the added risk of developing the insulin resistance of non-insulin-dependent diabetes mellitus.

Hypersecretion of insulin inhibits hepatic synthesis of sex hormone binding globulin which, particularly in obese patients, results in an apparent disparity between circulating testosterone concentrations and the degree of hirsutism. In these women the concentration of unbound testosterone, and by implication the rate of production of testosterone, is very high despite serum total testosterone concentrations which may be within the normal range. Hypersecretion of insulin also has non-reproductive adverse effects in patients with polycystic ovary syndrome. Thus an inverse relation of the cardioprotective high-density lipoprotein to cholesterol concentration and the fasting serum insulin concentration has been demonstrated, together with subnormal total high-density lipoprotein concentrations (Fig. 5). These data, together with reports of an increased incidence of coronary heart disease, hypertension, and diabetes in follow-up studies of patients with histologically verified polycystic ovaries, indicate the clinical importance of hypersecretion of insulin and its control in patients with polycystic ovary syndrome.

Fig. 5 Serum high-density lipoprotein concentrations in lean and obese women with polycystic ovary syndrome. Note that despite maintaining a normal body mass index, slim women with polycystic ovary syndrome have a statistically significant depression of their fasting high-density lipoprotein cholesterol concentration. The high-density lipoprotein falls even further in women with polycystic ovary syndrome who are obese.

The familial nature of polycystic ovary syndrome has led to extensive investigation of its genetics. Thus far linkage with genes involved in the steroid biosynthetic pathway (*CYP11A*) and the control of insulin secretion have been identified and confirmed. *CYP11A* encodes the side chain cleavage enzyme which converts cholesterol to pregnenolone, a rate limiting step in steroid biosynthesis. Presumably a mutation causing upregulation of this enzyme could result in an increase in androgen secretion, a cardinal feature of the syndrome. The linkage described with the large class III alleles of the insulin gene variable number tandem repeats (*INS VNTR*) also occurs with type 2 diabetes mellitus. Class III *INS VNTR* promotes insulin secretion, perhaps resulting in insulin resistance as a secondary event. The effects of these and other candidate genes may be expressed in fetal development or through obesity in later life.

Other ovarian causes of hirsutism

Hyperthecosis

Characterized pathologically by the presence of islands of luteinized theca cells within the ovarian stroma at a distance from follicles, the clinical features include very marked hypersecretion of androgens and of insulin. The condition is probably most easily regarded as a severe form of the polycystic ovary syndrome.

Ovarian tumours

Androgen secreting tumours of the ovary are derived from sex cord or stromal cells and include Sertoli–Leydig cell tumours (arrhenoblastomas), hilar cell tumours, lipoid cell tumours, and adrenal rest tumours. Other non-hormone secreting tumours (Brenner, cystadenoma, and cystadenocarcinoma) have been reported to stimulate androgen secretion by the surrounding ovarian stroma. These conditions are all very rare causes of hirsutism.

Diagnosis of hyperandrogenism

Adrenal causes of hyperandrogenism are discussed in Section 12.7 but hypersecretion of androgens by polycystic ovaries is much more common. While an ovarian tumour is suggested by a short history of rapidly advancing hirsutism, amenorrhoea, and a serum testosterone concentration in the male range, such lesions are in fact rare. A serum testosterone exceeding 10 nmol/litre is more commonly associated with polycystic ovary syndrome and severe insulin resistance, as suggested clinically by the presence of acanthosis nigricans, than with the development of an ovarian tumour.

Pelvic ultrasound will detect polycystic ovaries or an ovarian tumour. The serum total testosterone concentration reflects in part the rate of production of testosterone and in part the serum concentration of sex hormone binding globulin; it should be interpreted in the light of the patient's body weight and a concentration within the normal range should not therefore be dismissed in women who are overweight. Serum luteinizing hormone concentrations are often raised but with a normal level of follicle-stimulating hormone. Serum prolactin concentrations are modestly elevated (up to 2500 mu/litre) in 15 per cent of patients with polycystic ovary syndrome. About half of these cases have a microadenoma detected by MRI scan.

A small number of patients with hirsutism have no diagnosable cause for their cutaneous virilism. Labelled 'idiopathic hirsutism', these patients may have enhanced sensitivity of androgen-dependent tissues, perhaps caused by increased dermal activity of the 5a reductase enzyme.

Management of hirsutism

Medication reduces the rate of hair growth but cosmetic treatment is required to remove existing unwanted hair. Hair can be camouflaged by bleaching and removed by plucking, waxing, electrolysis, or laser. The latter two methods offer the possibility of long-term hair removal. Laser treatment works by selective thermolysis and, with present equipment, is only suitable for removal of dark hair from a fair skin.

In the United Kingdom the preferred drug for treatment of hyperandrogenization is cyproterone acetate. This steroid is a peripheral antiandrogen, a progestogen, and a mild glucocorticoid. In combination with oestrogen, it suppresses secretion of gonadotrophin and so reduces the secretion of ovarian androgens. It is also contraceptive. Its glucocorticoid activity may reduce secretion of adrenal androgens. Finally, it blocks uptake of the dihydrotestosterone–protein complex by the DNA acceptor protein in the nucleus of androgen sensitive cells, so acting as a peripheral antiandrogen.

Treatment is administered cyclically, together with oestrogen, given most conveniently in the form of Dianette (Fig. 6). Seborrhoea and acne usually clear up in about 6 weeks but it takes 12 to 18 months to realize the maximum improvement of unwanted hair. Cosmetic treatment is continued while on the medication, the impact of therapy being indexed by a reduction in the number of treatments required.

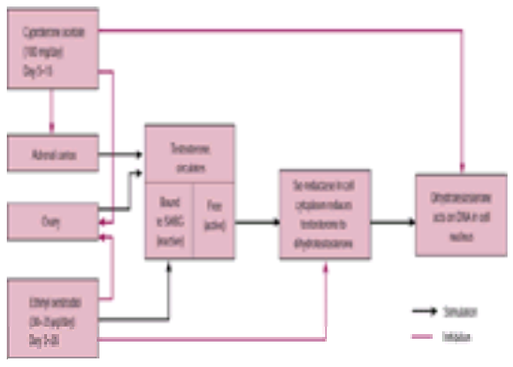

Fig. 6 The use of cyproterone acetate and ethinyloestradiol in the treatment of hirsutism. In the author's practice, ethinyloestradiol is usually replaced with Dianette®, a conveniently packaged formulation of ethinyloestradiol (35 µg) and cyproterone acetate (2 mg). (After *Medicine International* (1989))

Adverse reactions, contraindications, and surveillance are essentially those advised for treatment with the oral contraceptive pill. As symptoms remit, the dose of cyproterone acetate is reduced until the patient is taking the lowest dose compatible with symptomatic relief. Eventually treatment with Dianette alone is usually sufficient for maintenance. In patients not responding to this regimen, other antiandrogens, such as aldactone and flutamide, may be tried. Inhibition of the type II 5a reductase enzyme with finasteride has similar efficacy. Indeed the major difference between the available medications is in the pattern of adverse effects rather than in efficacy. Since these drugs are not contraceptive the patient must be warned of possible feminizing effects on a male fetus if they are taken inadvertently during pregnancy. They are therefore optimally prescribed with an oral contraceptive.

Infertility

Infertility can be defined as absence of conception after a year of unprotected intercourse, but it is most logically evaluated in relation to normal fertility. The maximum conception rate per ovulation is 25 to 30 per cent, so that the best cumulative conception rates are about 60 per cent after 6 months and 85 per cent after a year. Other than mechanical bars to conception (for example gynaecological problems such as occluded fallopian tubes) the important factors that reduce a woman's fertility are her age and any process that reduces the number of ovulations per unit time. The central strategy of medical management of female infertility is therefore the diagnosis and treatment of the causes of anovulation. An additional strategy is to ensure that ovulation, and thus conception, occurs in as favourable an environment as possible.

Ovulation is only proven by the occurrence of pregnancy, so indirect methods of detection are required. In practice, ovulation is usually inferred retrospectively by detection of a corpus luteum, indexed endocrinologically either by measurement of serum progesterone concentrations or indirectly by the effects of progesterone on basal body temperature or endometrial histology. Ovulation can be predicted ultrasonically by detecting the development of a preovulatory follicle of average diameter 20 to 22 mm, followed by its collapse and replacement by a solid structure, i.e. visualization of a corpus luteum. The preovulatory surge of luteinizing hormone can be detected by the patient herself using one of a number of commercially available immunological urine tests. These methods are used to determine whether anovulation can account for a couple's infertility and whether treatment has actually resulted in ovulation; prediction of ovulation is helpful for timing investigations and maximizing the chance of conception by ensuring intercourse around the time of ovulation.

Conception rates after the age of 35 are only half of those before the age of 25. Demographic changes in northern Europe (median maternal age at first birth in the United Kingdom is now 27 years) have resulted in a steady increase in the number of couples requesting consultations for infertility.

The causes of amenorrhoea are discussed above. All except primary ovarian failure are correctable (and that condition is treatable by oocyte donation) so the fertility prognosis for this group of patients is excellent. The commonest cause of oligomenorrhoea is polycystic ovary syndrome and while patients with this condition usually

ovulate readily in response to treatment, in about 40 per cent hypersecretion of luteinizing hormone impairs fertility, despite the occurrence (spontaneously or as a result of treatment) of otherwise normal ovulation. The mechanism is uncertain but may involve an adverse effect of the high levels of luteinizing hormone on completion of the final stages of oocyte maturation.

Failure to ovulate despite (more or less) regular menstrual cycles is an unusual but recognized cause of infertility.

Infertility not explained by ovulatory failure is usually treated by *in vitro* fertilization and embryo transfer.

Induction of ovulation

Table 5 shows the agents commonly used and the endocrine level at which they exert their actions. Anti-oestrogens enhance hypothalamic secretion of gonadotrophin releasing hormone by competing with oestrogen receptors, thus simulating oestrogen deficiency. The drug is taken for 5 days and provokes gonadotrophin secretion and thence follicular development. The most commonly used preparation is clomiphene, which is a racemic mixture, one isomer having oestrogenic and the other anti-oestrogenic activity. Most slim patients with polycystic ovary syndrome ovulate in response to clomiphene. Obese patients, who are usually hyperinsulinaemic, can be treated with metformin, which in a dose of 500 mg three times per day will often result in ovulation or enhance the response to treatment with clomiphene.

In patients not responding to the above treatments, pituitary secretion of gonadotrophins can be enhanced by injection of gonadotrophin releasing hormone. It is administered in a pulsatile fashion, usually by the subcutaneous route, the injections being given at 90 min intervals by a portable miniaturized pump.

For patients with structural lesions of the pituitary, gonadotrophin secretion can be replaced by injections of gonadotrophins. The preferred preparations are those synthesized by recombinant technology. Follicular development is induced by the injection of follicle-stimulating hormone (together with luteinizing hormone in those patients with hypogonadotrophic hypogonadism); ovulation is triggered and the corpus luteum maintained by a single injection of human chorionic gonadotrophin which has luteinizing hormone-like bioactivity and a very long half-life.

The objective of treatment is unifollicular ovulation with full-term delivery of a single infant. The response is monitored by ultrasound assessment of the ovaries and uterus and by measurement of plasma oestradiol concentrations. Human chorionic gonadotrophin is administered according to strict criteria (not more than three follicles of diameter equal to or greater than 16 mm, or six follicles equal to or greater than 14 mm diameter).

Complications of ovulation induction include multiple births (the perinatal mortality of twins is three times that of singletons) and the ovarian hyperstimulation syndrome. The latter condition occurs almost entirely in women with polycystic ovary syndrome who have received high-dose and inadequately monitored gonadotrophin therapy. It results from massive follicular luteinization and so only occurs after ovulation has been triggered by human chorionic gonadotrophin or, very rarely, by a spontaneous surge of luteinizing hormone. Symptoms usually appear 5 to 10 days after administration of human chorionic gonadotrophin. In its mildest form it consists of ovarian enlargement and discomfort but in the more severe forms abdominal distension, nausea, vomiting, and diarrhoea develop. As a result of increased vascular permeability, protein-rich fluid accumulates in the peritoneal and sometimes the thoracic cavity; hypovolaemia develops, associated with haemoconcentration, decreased central venous pressure, low blood pressure, and tachycardia. The patient develops a tense ascites, respiration is embarrassed, and urine formation is suppressed. A hypercoagulable state may develop with the risk of cerebral and peripheral venous thrombosis and embolism.

In managing this syndrome, its self-limiting nature should be borne in mind. Treatment is designed first to maintain blood volume while correcting fluid and electrolyte balance, second to avoid thromboembolic phenomena (by full heparinization if severe hypercoagulability is detected), and third to relieve abdominal and pulmonary symptoms (by paracentesis under ultrasound control).

12.8.2Disorders of male reproduction

F. C. W. Wu

Physiology of the hypothalamic–pituitary–testicular axis

The adult testis performs two functions—the production of androgens and spermatozoa (Fig. 1). These functions are dependent on trophic hormones from the hypothalamus and anterior pituitary which are responsive to the negative feedback action of testicular hormones, thus forming a closed-loop functional axis (Fig. 2).

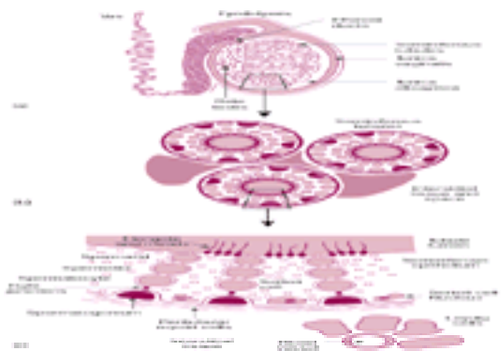

Fig. 1 (a) Human testis, epididymis, and vas deferens showing efferent ducts leading from the rete testis to the caput epididymis and the cauda epididymis continuing to become the vas deferens. (b) Cross-section through a seminiferous tubule showing central lumen, seminiferous epithelium, and interstitial space containing Leydig cells. (c) Anatomical relationships in the seminiferous epithelium between germ cells (spermatogonia, spermatocytes, and spermatids), Sertoli cells, peritubular myoid cells, and Leydig cells.

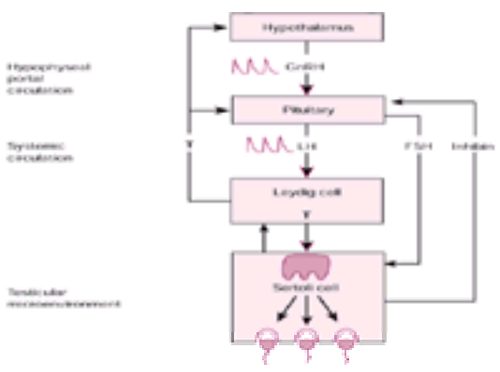

Fig. 2 Functional relationships in the hypothalamic–pituitary–testicular axis and testicular microenvironment. Gonadotrophin releasing hormone (GnRH) is secreted into the hypophysial circulation in an episodic manner which is reflected by an luteinizing hormone (LH) pulse in the systemic circulation. Open arrows represent positive stimulation and closed arrows negative feedback.

Gonadotrophin releasing hormone (GnRH) is synthesized in neurosecretory neurones in the hypothalamus and then released episodically into the pituitary portal circulation at a frequency of 1 to 2 hourly. GnRH stimulates synthesis and secretion of both luteinizing hormone (LH) and follicle stimulating hormone (FSH) in the gonadotrophs of the anterior pituitary gland. Each episode of GnRH secretion elicits an immediate release of gonadotrophins into the systemic circulation. The pulsatile pattern of LH secretion is more clearly defined, with its rapid release and shorter circulating half-life than FSH (Fig. 2). This intermittent mode of GnRH stimulation avoids desensitization of the pituitary gonadotrophs by continuous GnRH exposure, and is therefore obligatory for maintaining normal gonadotrophin secretion. Pituitary FSH secretion can also be modulated by locally produced activin, a peptide hormone of the inhibin family which stimulates FSH.

LH stimulates biosynthesis of androgenic steroids by binding to specific surface membrane receptors on the Leydig cells. This activates the cyclic AMP/ protein kinase and the steroidogenic acute regulatory protein which mobilizes cholesterol substrate, transfers cholesterol from the outer to inner mitochondrial membrane where it is converted to pregnenolone by splitting the side-chain at position C21. Figure 3 shows the principal steps in the steroidogenic pathway in which the carbon skeleton of the parent compound, cholesterol, is progressively hydrolysed to form various androgenic steroids. Testosterone is the main end product of the biosynthetic pathway in adult Leydig cells. The daily testicular production rate of testosterone is between 3 and 10 mg. As the principal circulating androgen secreted by the adult testes, testosterone exerts the major negative feedback action on gonadotrophin secretion by restricting the frequency of GnRH release from the hypothalamus and by reducing the amplitude of LH response to GnRH. Androgens are essential for the differentiation, growth, and function of the male genital ducts (epididymis) and accessory glands (seminal vesicles and prostate), male secondary sexual characteristics, and sexual potency (Table 1). Testosterone circulates in plasma bound to sex hormone binding globulin (SHBG) and albumin. In man, 60 per cent of circulating testosterone is bound to SHBG, 38 per cent to albumin, and 2 per cent is free. Free and albumin-bound testosterone constitute the bioavailable fractions of circulating testosterone. Androgen action is mediated through specific binding to intranuclear androgen receptors which increase transcription of specific androgen-responsive genes in target cells. In target organs, such as the fetal external genitalia, prostate, and facial hair follicles, full activation requires the local metabolism of testosterone by the enzyme 5a-reductase to 5a-dihydrotestosterone, an androgen which is several-fold more potent than testosterone (Fig. 3).

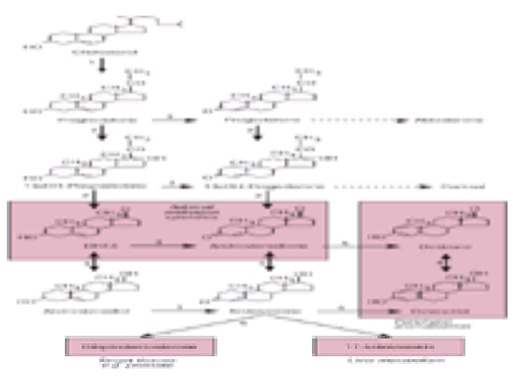

Fig. 3 Steroidogenic pathway from cholesterol to testosterone and further conversion of testosterone: (1) cholesterol side-chain cleavage; (2)

17a-hydroxylase/17,20-lyase; (3) 3b-hydroxysteroid dehydrogenase; (4) 17b-hydroxysteroid dehydrogenase; (5) aromatase; (6) 5a-reductase.

Recently described males with mutant oestrogen receptor (oestrogen resistance) and *CYP19* gene encoding aromatase (oestrogen deficiency), and the corresponding gene-knockout mouse models, have revolutionized our understanding of the role of oestrogens in men. An increasing variety of androgen-dependent functions in males are now known to be mediated by the oestrogen receptors a and b via conversion of testosterone to oestradiol by the widely distributed P450 aromatase in target tissues. These include pubertal growth spurt, skeletal maturation, fusion of epiphyses at the end of puberty, bone mass accrual and maintenance, some aspects of male-specific behaviour (in mouse models), fluid resorption from the testicular efferent ducts, and FSH feedback regulation. Much of the action of circulating testosterone is therefore regulated or refined locally at many different target tissues by 5a-reductase and aromatase expression. The relative contribution of circulating (endocrine action) compared with locally-produced (paracrine or intracrine action) hormones and the balance between androgen and oestrogen receptor activation are crucial to the physiological effects of androgens in man.

The endocrine (androgen synthesis) and gametogenic (spermatogenesis) functions of the testis are closely interlinked. Although testosterone is important as the principal circulating androgen, its local (paracrine) action within the testis is crucial, together with FSH, for the initiation and maintenance of normal spermatogenesis and hence fertility (Fig. 1 and Fig. 2). Since germ cells do not possess receptors for FSH or testosterone, these hormone signals are transduced through the Sertoli and peritubular cells. Sertoli cells create an insular microenvironment in the seminiferous tubules by providing the physical framework and elaborating an ever-changing chemical myriad of growth factors and cytokines for the developing germ cells enmeshed in their cytoplasm (Fig. 1). Sertoli cells also secrete inhibin B, a glycoprotein hormone, which inhibits FSH secretion by the pituitary (Fig. 2).

Spermatogenesis is a complex, repetitive series of cytodifferentiation processes in the seminiferous epithelium whereby cohorts of undifferentiated diploid germ cells (spermatogonia) proliferate and transform into greatly expanded populations of haploid spermatozoa (Fig. 1). The human testes produce around 200 million spermatozoa per day. Mitotic divisions of spermatogonial stem cells form subpopulations of spermatogonia which, at regular intervals of 16 days, differentiate into primary preleptotene spermatocytes to initiate meiosis. Meiotic reduction divisions of spermatocytes generate round spermatids which then transform (spermiogenesis) into compact, virtually cytoplasm-free, elongated spermatids. Condensed nuclear DNA forms the sperm head with an overlying Golgi-derived acrosome cap and a tail (containing nine pairs of microtubules arranged around a central pair) capable of propelling, flagellar movements. Mature spermatozoa are released from Sertoli cell cytoplasm into the tubular lumen some 74 days after their initial development from spermatogonia. The control systems regulating germ cell divisions and development remain poorly understood.

Male reproductive disorders

Male hypogonadism is a descriptive term for the clinical complex associated with androgen deficiency due to the failure of Leydig cell function. Concomitant impairment of spermatogenesis is likely since the seminiferous tubules will also be androgen deficient or directly involved by the same pathological process. However, infertility is usually an isolated abnormality of spermatogenesis where patients seldom show any clinical evidence of androgen deficiency. In the last 10 years, an increasing number of specific genetic defects have been identified, by genomic DNA mapping, to be associated with abnormal gonadal function and development. This has greatly improved our understanding of the pathogenesis of these conditions.

Male hypogonadism

Aetiology

A large number of pathological conditions can lead to destruction or malfunction of the hypothalamic–pituitary–testicular axis (Table 2). It is important to identify the underlying cause of hypogonadism and distinguish between pituitary-hypothalamic (secondary or hypogonadotrophic hypogonadism) and testicular (primary or hypergonadotrophic hypogonadism) disorders. The causal lesion may require specific treatment e.g. pituitary tumour, haemochromatosis. Hypogonadotrophic conditions are amenable to treatment aimed at inducing or restoring spermatogenesis while primary testicular failure, which is usually irreversible, is not.

Diagnosis

General clinical features of hypogonadism

The age of onset of androgen deficiency critically influences the manifestation of hypogonadism (Table 1). Prepubertal onset of testosterone deficiency gives rise to sexual infantilism and patients will present with delayed puberty. Eunuchoidal body proportions (arm span greater than height and heel–pubis exceeding crown–pubis lengths by at least 5 cm; Fig. 2) develop due to the continued growth of long bones (growth hormone-mediated) allowed by the delayed closure of their epiphyses and lack of the testosterone/oestradiol-induced spinal growth in late puberty.

Postpubertal onset of testosterone deficiency leads to regression of spermatogenesis, diminished sex drive and erection, loss of ejaculation, muscle atrophy, poor stamina, and decreased secondary sexual hair and shaving frequency. However, no change is observed in body and penile proportions or voice (Table 1). Symptoms and signs of hypogonadism usually develop and progress insidiously. It is therefore common for patients to present only after many years following the onset of hypogonadism. Furthermore, young patients who has never been adequately androgenized may not be aware, or even deny, that secondary sexual function is subnormal. In contrast, after surgical or traumatic/inflammatory castration, adults may experience hot flushes from acute withdrawal of androgens. Fetal onset of defective androgen action due to androgen receptor abnormalities or steroidogenic enzyme deficiency cause failure of masculinization of the genitalia resulting in intersexual states (Table 2).

Clinical findings associated with hypogonadism

Hypothalamic–pituitary tumours are suggested by headache, impairment of visual acuity or visual field loss, polyuria and polydipsia, or evidence of pituitary hormone excess such as Cushing's disease, acromegaly, and hyperprolactinaemia. Hyperprolactinaemia causes loss of sex drive even in the presence of normal testosterone. Primary testicular failure is suggested by a history of orchitis, testicular trauma, surgery, torsion, irradiation, or chemotherapy. An increasing number of chronic systemic diseases (Table 2) are associated compromised hypothalamic–pituitary–testicular function. With improved survival resulting from specific treatment, the role of gonadal dysfunction in the quality of life of these patients is increasingly important.

The use of recreational drugs and medications which interfere with pituitary–testicular function or androgen action should be sought (Table 2). Evidence of alcohol abuse should be noted. Ethanol causes a lowering of plasma testosterone through a direct toxic effect on Leydig cell steroidogenesis. Testicular atrophy and gynaecomastia, found in 50 per cent of men with hepatic cirrhosis, are due to altered androgen steroid metabolism, increased sex-hormone-binding globulin, and increased oestrogen production. These changes are usually irreversible.

Neurological diseases can be associated with hypogonadism. Postpubertal atrophy of the seminiferous tubules occurs in 80 per cent of patients with dystrophia myotonica, an autosomal dominant disorder characterized by myotonia, distal muscle atrophy, lens opacities, and premature frontal balding. Variable degrees of androgen deficiency also exist. Hypogonadotrophic hypogonadism is associated with familial cerebellar ataxia, Laurence–Moon, Bardet–Biedl, and Prader–Willi syndromes. Defective spermatogenesis is common in paraplegia or quadraplegia following spinal injury because of the inability to maintain a low scrotal temperature.

Specific condition

Klinefelter's syndrome is the commonest cause of male hypogonadism with an incidence of 2 per 1000 live births. It is a developmental disorder of the testis resulting from the presence of an extra X chromosome derived from the non-disjunction of parental (maternal origin in two-thirds of cases) germ cells during meiosis. The most common karyotype is 47 XXY (80–90 per cent) but rarer variants include 46 XY/47 XXY mosaic, multiple X + Y, and the so-called XX male syndrome. Accelerated atrophy of germ cells before puberty and hyalinization of the seminiferous tubules gives rise to sterility and small, firm testes. Leydig cells appear relatively hyperplastic but cell mass is in fact normal. The degree of Leydig cell steroidogenic defect (mechanism of which remains uncertain) is very variable ranging from the virilized, adult male presenting with infertility (see below) to the eunuchoidal youth who fails to complete sexual maturation. In midadulthood, 80 per cent of patients have reduced testosterone with elevated LH, FSH, and oestradiol. Other features include gynaecomastia, reduced body hair, long legs, tall stature, learning (verbal

and cognitive) difficulties, poor school performance, behavioural disturbances, and autoimmune endocrinopathies including diabetes mellitus. There is also an increased incidence of osteopenia, breast tumour, testicular and extratesticular (especially mediastinal and retroperitoneal) germ cell tumours, varicose veins, and leg ulcers. Mental retardation is associated with higher order X chromosome polysomy.

Kallmann's syndrome, with an incidence of 1 in 7500 males, is a sporadic or familial (X-linked or autosomal) form of congenital hypogonadotrophic hypogonadism associated with a number of somatic congenital abnormalities including anosmia or hyposmia (defective smell sense), red–green colour blindness, synkinesis, nerve deafness, cleft-lip or palate, and renal malformations. The X-linked variety is caused by deletion or mutation in the *KAL-1* gene in Xp22.3 encoding an cell adhesion protein. Faulty embryonic migration of GnRH-secreting neurones from their site of origin in the nose to the hypothalamus prevents normal axonal secretion into the pituitary portal circulation in the median eminence. GnRH is thus unable to target the gonadotrophs in the anterior pituitary. The same migratory defect affects the olfactory neurones in the nose, resulting in aplasia of the olfactory bulb and anosmia.

Total and free testosterone declines gradually but variably with age in men from the age of 40 years onwards. This is amplified by the age-related increase in SHBG and exacerbated by concomitant non-gonadal diseases and medications. In some elderly men, testosterone may fall below the young adult physiological range. Differentiation of non-specific symptoms of ageing, such as frailty, decreased muscle strength, lack of stamina, and decline in libido, from those of mild hypogonadism is difficult. Whether these functional changes, normally accepted as part of healthy ageing, are causally related to alterations in circulating testosterone is unclear. The existence and prevalence of a male climacteric remains controversial.

Investigation

Confirmation of hypogonadism

The clinical suspicion or diagnosis of hypogonadism must be confirmed by demonstration of low circulating testosterone before replacement therapy is commenced. Samples obtained between 8 and 9 a.m. avoid the physiological, diurnal trough levels of testosterone later in the day. In the presence of background changes in SHBG, such as in ageing, obesity, anticonvulsant medications, diabetes, thyrotoxicosis, and liver disease, free testosterone can be calculated from the total testosterone and SHBG concentrations. Free testosterone assays are technically demanding and result obtained by commercial kits can be misleading.

Assessment of the hypothalamic–pituitary–testicular axis and target tissue resistance

Measurement of LH, FSH, and prolactin is required to differentiate between primary and secondary hypogonadism. The physiological basis for differentiating between hypogonadotrophic and hypergonadotrophic hypogonadism is illustrated in Fig. 1. Pathologies in the hypothalamus and pituitary will give rise to low or low–normal gonadotrophins and low testosterone, that is a state of hypogonadotrophic hypogonadism or secondary testicular failure where the potential for stimulating testicular function by exogenous gonadotrophin or GnRH replacement is maintained. Conditions affecting the testes will interrupt normal testicular negative feedback. This results in elevated gonadotrophin levels with low testosterone, characteristic of hypergonadotrophic hypogonadism or primary testicular failure. Failure of spermatogenesis with reduced testicular size is commonly associated with a rise in FSH alone. The value of circulating inhibin B and mullerian inhibiting hormone for diagnostic purposes is currently being assessed. Patients with androgen insensitivity syndromes have elevated testosterone with high LH but normal to low FSH. Increased LH or FSH is associated with the very rare LH and FSH resistance syndromes.

Human chorionic gonadotrophin (hCG) stimulates Leydig cell steroidogenesis and plasma testosterone increases over 4 to 7 days. It is useful for detecting the presence of functional testicular tissue in patients with impalpable testes, assessing functional reserve of the testes prior to treatment with exogenous gonadotrophin or GnRH, and in differentiating hypergonadotrophic hypogonadism from rare cases who produce immunologically detectable, but biologically inactive, LH in excess.

Stimulation tests of gonadotrophin secretory reserve using clomiphene and GnRH seldom give additional information and has become largely obsolete, especially with the improved sensitivity and range of modern gonadotrophin immunoassays.

Assessment of the pituitary

Patients with hypogonadotrophic hypogonadism without the stigmata of Kallmann's syndrome should undergo full pituitary functional and anatomical assessment to exclude an underlying pituitary tumour. They require pharmacological tests of growth hormone and ACTH reserve, thyroid function tests, visual field charting, and MR or CT scanning of the pituitary and hypothalamus.

Other investigations

Suspected Klinefelter's syndrome should be confirmed by chromosome karyotyping on peripheral blood lymphocytes. Ultrasound and MR scan are useful in locating ectopic or intra-abdominal testes. DNA analysis can help confirm the diagnosis of androgen resistance syndromes and an increasing number of rare causes of hypogonadism (Table 2) such as haemochromatosis.

Treatment objectives

Treatment objectives are to:

1. relieve the symptoms of androgen deficiency;
2. prevent the long-term consequences of androgen deficiency such as osteopenia;
3. reproduce physiological, circulating, and tissue levels of plasma testosterone, dihydrotestoerone, and oestradiol;
4. induce fertility, if required, in hypogonadotrophic patients;
5. treat any specific underlying diseases.

The mainstay of treatment of the hypogonadal male is androgen replacement. Although hypogonadotrophic patients have the potential for fertility, gonadotrophin and pulsatile GnRH therapy should only be employed when there is a requirement for fertility because of the expense and complexity of these regimens. Previous testosterone treatment does not jeopardize subsequent response to gonadotrophin so that younger hypogonadotrophic subjects should be treated by testosterone in the same manner as hypergonadotrophic patients to initiate and maintain virilization and sexual function.

Androgen replacement

The circulating half-life of free testosterone is short (10 min) due to rapid degradation by the liver. To achieve sustained physiological circulating concentrations, testosterone has to be administered in a modified form or by a parenteral route so that its rate of metabolism or absorption is retarded.

Injectable testosterone esters are the commonest first-line androgen preparations. A mixture of four different testosterone esters (propionate, phenylpropionate, isocaproate, and decanoate) (Sustanon, Organon, Oss, the Netherlands), 250 mg 2 to 3-weekly, and testosterone enanthate (Primoteston depot, Schering, Berlin, Germany), 200 mg 2-weekly, are the most popular. Whilst undoubtedly effective, these preparations inevitably give rise to high supraphysiological peak testosterone levels within the first week which then fall sharply to lower limits of normal before the next dose. Some patients are disturbed by fluctuations in libido, mood, and stamina associated with the repeated rise and fall of testosterone levels as well as the painful, deep, intramuscular injections.

Crystalline testosterone compressed into cylindrical pellets, surgically implanted subcutaneously under local anaesthesia, provide a depot source of testosterone for several months. Peak testosterone levels are achieved after 2 to 4 weeks, followed by a gradual decline over subsequent months. A total dose of 800 mg (4 × 200 mg implants) can maintain physiological concentrations of testosterone over 6 months, which some patients find more convenient than more frequent injections. The implantation procedure can be complicated, though rarely, by haemorrhage and infection. Even in experienced hands, 10 per cent of implanted pellets are extruded. Implants should only be used as maintenance therapy for patients who have already shown satisfactory tolerance to androgen effects of shorter-acting preparations.

Testosterone undecanoate is administered orally and absorbed from the gut through intestinal lymphatics. Low bioavailability (<0.5 per cent), variable absorption, multiple daily dosing, and higher costs has restricted the use of testosterone undecanoate despite the obvious appeal of oral administration. To maintain testosterone

consistently within the physiological range, two to three times daily administration of 80 mg (2 × 40 mg capsules) of testosterone undecanoate is required. Intestinal 5a-reductase action gives rise to a disproportionate and unphysiological increase in dihydrotestosterone relative to testosterone. Oral testosterone undecanoate is useful in the induction of puberty in adolescents where lower doses are preferable, and as second line treatment in adults who are intolerant of injections or implants.

17a-alkylated androgens are relatively weak androgens but some may have more potent anabolic effects. 17a-alkylated compounds cause cholestatic jaundice in a reversible and dose-related manner while long-term treatment is associated with peliosis hepatis (haemorrhagic cysts in the liver) and liver tumours. Consequently, 17a-methyl testosterone, oxymetholone, and fluoxymesterone have now been withdrawn from the market in many countries. As a group, 17a-alkylated androgens are not recommended for clinical use but they are the most commonly abused anabolic steroids. Mesterolone, which is not hepatotoxic, is a weak androgen with low clinical efficacy but remains commercially available.

Transdermal testosterone preparations offer the advantages of stable physiological levels of testosterone without peaks and troughs, painless self-administration, minimal risk of overdosing and low potential for abuse. A 60 cm^2 translucent membrane (Testoderm™, ALZA, Palo Alto, United States) applied to the scrotum delivers testosterone at a rate of 4 or 6 mg per day. Daily renewal of Testoderm™ in the morning maintains plasma testosterone within the adult physiological range with a normal diurnal profile. 5a-Dihydrotestosterone levels are elevated because of abundant 5a-reductase activity in genital skin. This does not seem to have any adverse consequences even after several years of treatment. Local skin irritation is negligible. A non-scrotal transdermal system (Androderm™ or Andropatch™ SmithKline Beecham, Welwyn Garden City, United Kingdom) delivers testosterone at 2.5 mg (6.5 cm diameter) or 5 mg (13 cm diameter) daily. At a dose of 5 mg daily applied at bedtime, plasma testosterone, dihydrotestosterone, and oestradiol are maintained within the physiological range throughout 24 h with a small diurnal variation. While clinical efficacy is satisfactory, the major drawback of Andropatch™ is skin reaction at the application sites, which occurs in 60 to 70 per cent of cases. A new, non-scrotal testosterone (Testoderm TTS™, ALZA, Palo Alto, United States) has recently become available and is said to have a lower incidence of skin irritation.

Many novel androgen preparations are currently under clinical investigation or being developed. Most promising are testosterone gel, cyclodextrins, buccal preparations, and esters with long half-lives (testosterone undecanoate or decanoate in castor oil for intramuscular injection 2 to 3-monthly) and selective androgen receptor modulators such as 7a-methy-19-nortestosterone (MENT).

The choice of preparations depends on age of the patient, the patient's own preference, facilities for injections, and available experience for surgical implants. Many boys with constitutional delayed puberty will spontaneously enter or progress in puberty after short courses of testosterone, for example intramuscular testosterone enanthate 50 mg monthly or oral testosterone undecanoate 40 mg daily for 3 to 6 months. The low doses of testosterone will stimulate linear growth and promote virilization without premature epiphyseal fusion. In patients with no evidence of spontaneous progression, gradually increasing doses of testosterone over 3 to 4 years will ensure full virilization except for testicular growth. They can be maintained on adult replacement doses subsequently if hypogoandotrophic hypogonadism appears to be permanent. Testosterone treatment can be safely started after the age of 14. Indeed, delayed treatment can be associated with permanently impaired peak bone mass.

The invasive nature of the implantation procedure and the long duration of action make them less than ideal for the induction of puberty in adolescents and the initiation of treatment in androgen-naive young adults where a more gradual and flexible increase in dose is desirable. For these reasons, testosterone implant is usually reserved for maintenance treatment in young adults, replacement having been initiated with intramuscular or oral preparations. Almost all adult patients respond well to testosterone enanthate 200 mg 2-weekly, 300 mg 3-weekly or Sustanon 250 mg 2 to 3-weekly. In the absence of a satisfactory biological marker for androgen action, monitoring of treatment is best gauged by clinical response and documenting plasma testosterone within the low–normal range immediately before the next dose so that appropriate adjustments of dosing intervals can be made.

Hypogonadal patients over the age of 50 starting testosterone for the first time should be checked for pre-existing, occult prostatic cancer with digital rectal examination and prostate-specific antigen (PSA) measurement. These should also be repeated in the first 3 to 6 months after initiating treatment to ensure that there is no deterioration. Subsequent monitoring for prostatic disease should not differ from eugonadal men of comparable age since there is no increased relative risk in hypogonadal patients on long-term testosterone replacement.

Testosterone replacement therapy is safe and side-effects are rare. They may include acne, transient priapism, gynaecomastia, fluid retention, increase in haematocrit, obstructive sleep apnoea, and exacerbation of pre-existing behavioural disturbances. Testosterone is contraindicated in patients with known prostatic cancer and breast cancer. In older patients with benign prostatic hyperplasia, sleep apnoea, polycythaemia, dyslipidaemia, cardiac failure, liver disease, and renal failure, a cautious approach with reduced doses of testosterone, careful dose titration, and close supervision or specific management of the coexisting problems usually allow patients to benefit from androgen replacement.

Infertility

Infertility is defined as the inability of a couple to initiate a pregnancy after 12 months of unprotected intercourse. Some 8 to 15 per cent of married couples experience involuntary infertility. Of these, male factors alone are estimated to be responsible in 30 per cent and contributory in a further 20 per cent of subfertile couples. Thus, male infertility may affect 5 per cent of men of reproductive age. A secular trend of declining semen quality (sperm density) in men over the last 50 years has been reported in some but not other regions of Europe. This, together with a concurrent increase in incidence of testicular cancer, hypospadias, and cryptorchidism, has raised the question of possible environmental endocrine disruptors with oestrogenic or antiandrogenic actions influencing prenatal or neonatal testicular and genital tract development. The concern prompted the recent development of sensitive techniques for monitoring potential deleterious reproductive effects of environmental chemicals. However, there is currently no evidence that the incidence of male infertility is increasing.

Aetiologies

Male infertility, comprising a heterogeneous group of disorders (Table 2), represents the male partner's contribution to a couple's failure to conceive. This implied failure to fertilize normal ova is usually associated with defective spermatogenesis giving rise to absent (azoospermia) or low sperm output (oligozoospermia: <20 million/ml) and/or abnormal spermiogenesis giving rise to spermatozoa with poor motility (asthenozoospermia:<50 per cent of spermatozoa showing progressive motility) and abnormal morphology (teratozoospermia: <15 per cent normal forms). The pathogenic basis of defective spermaotgenesis or spermiogenesis remains poorly understood. Testicular histology may show quantitative reduction in all germ cell types (hypospermatogenesis), Sertoli cells only, or maturation arrest at the primary spermatocyte (premeiotic) or spermatid (postmeiotic) stage.

Idiopathic azoospermia/ oligozoospermia

By far the commonest form of male infertility (60 per cent) is idiopathic azoo/oligozoospermia, usually associated with asthenozoopermia and teratozoospermia. This probably represents the end result of a multitude of ill-defined pathologies which disrupt normal seminiferous tubular functions. However, recent molecular analyses have revealed that a substantial proportion of these cases hitherto classified as idiopathic have discrete gene defects associated with impaired spermatogenesis (see below).

Asthenozoospermia

Reduced velocity or vigour of sperm motility may be due to metabolic/ functional defects or ultrastructural malformations in the axonemal complex of the sperm tail usually associated with oligozoospermia or a high percentage of dead and abnormally-shaped sperm. The latter finding may indicate a recently-recognized condition, epididymal necro/asthenozoospermia. Testicular spermatozoa are normal, the defects occurring during epididymal transit. Rarely, complete asthenozoospermia (with normal sperm density) may result from absence of dynein arms (sites of Na/K ATPase activity) linking individual microtubules. This is associated with similar defects in respiratory cilia and a history of chronic respiratory infection, bronchiectasis, and sinusitis (immotile cilia syndrome). In addition, some of these patients have situs inversus (Kartargener's syndrome). Absence of the central pair of microtubules in the sperm tail is an even rarer cause of complete asthenozoospermia—the 9+0 syndrome.

Teratozoospermia

An extreme example of abnormal sperm morphology is the failure of acrosome cap development in the sperm head leading to formation of round-headed spermatozoa (globozoospermia) which are unable to bind to the zona pellucida of ova, a prerequisite for fertilization.

Chromosome disorders

Chromosome abnormalities identified by cytogenetic studies of blood lymphocyte are found in 15 per cent of azoospermic patients; 90 per cent of these have Klinefelter's syndrome. Other chromosomal abnormalities encountered include reciprocal X or Y autosomal translocations, XYY and XX males, reciprocal and robertsonian autosomal translocations, supernumerary autosomes, and inversion of autosomes.

Klinefelter's (47XXY) patients are azoospermic. Spontaneous pregnancies have been reported in Klinefelter's patients with 46XY/47XXY mosaicim. The mechanism by which an extra X chromosome gives rise to spermatogenic failure is not known. Inactivation of the X chromosome in primary spermatocytes is necessary for spermatogenesis to proceed normally through meiosis. Hyalinized seminiferous tubules devoid of germ cells are pervasive in the atrophic testes. Occasionally, isolated foci of tubules with preserved spermatogenesis can be identified in testicular biopsy of 47 XXY patients.

Y chromosome microdeletions

A major breakthrough in the understanding of the molecular genetics of male infertility is the recent characterization of three non-overlapping regions (designated azoospermic factors AZFa, ASFb, and AZFc) on the long arm of the Y chromosomes (Yq11) which contain multiple genes involved in spermatogenesis. Microdeletions in these AZF loci, identifiable only by PCR amplification of DNA but not routine karyotyping, have been found in 3 to 37.5 per cent of patients previously considered to have idiopathic azoospermia and severe oligozoospermia but not in fertile control populations. Larger deletions (involving more than one AZF locus) are associated with more severe testicular phenotypes and the incidence of microdeletions is highest amongst azoospermic patients with Sertoli cell-only histology. AZFc is by far the most frequently encountered deletion. Y chromosome microdeletions are emerging as the second most common specific aetiology of male infertility (after varicoceles).

Several cloned genes have been mapped to each of the AZF intervals. At least one strong candidate gene is associated with each deletion cluster— *DFFRY* in AZFa, *RBMY* in AZFb, and *DAZ* in AZFc. These are multicopy gene families scattered in both arms of the Y chromosome with the latter two being expressed only in the testis. The specific products of these candidate genes and their functional significance remain unclear. Male infertility associated with microdeletions of Y chromatin is probably attributable to reduced copy number of more than one of these gene families. Other, as yet unidentified, genes important in spermatogenesis within or outside the AZF loci of the Y chromosome are highly likely. A significant proportion of patients with microdeletions of the Y chromosome is oligozoospermic and not azoospermic. Transmission of specific Y chromosome microdeletions to male offspring by assisted conception techniques has been clearly documented.

Defects in target tissue

Mutations in the ligand binding or DNA binding domains of the androgen receptor cause defects in androgen action and varying degrees of failure of masculinization during primary sexual development (androgen insensitivity syndromes) despite raised levels of testosterone being produced by inguinal or intra-abdominal testes. These defects are, in descending order of severity:

- Complete testicular feminization—female phenotype and female external genitalia with absent uterus and Fallopian tubes. Presents with primary amenorrhoea.
- Incomplete testicular feminization—female phenotype and female external genitalia with minimal virilization such as clitoral hypertrophy and partial fusion.
- Reifenstein's syndrome—ambiguous genitalia with perineoscrotal hypospadias, poor penile development, bifid scrotum, and gynaecomastia at puberty.

In contrast to the above, expansion of CAG polyglutamine repeats to greater than 40 in the N-termial domain of the androgen receptor causes X-linked spinal bulbar muscular atrophy (Kennedy's disease) associated with gynaecomastia, poor virilization, and azoospermia due to 'late-onset' androgen resistance. Expansion of CAG glutamine repeats to between 25 to 40 is associated with a four-fold increased risk of oligozoospermia or azoospermia without clinical evidence of neuromuscular degeneration. This may represent a exclusively testicular form of androgen insensitivity.

5a-reductase-2 deficiency–deficient 5a-dihydrotestosterone action in the genital tract causes clitoral hypertrophy with perineoscrotal hypospadias and blind-ending pseudovagina, inguinal testes with epididymis and vas. Usually raised as girls, these patients dramatically virilize at puberty without gynaecomasita.

Males with oestrogen resistance and aromatase deficiency are normally virilized at birth and have normal pubertal development except for non-fusion of epiphyses resulting in extreme tall stature and osteoporosis in adulthood. Effects on spermatogenesis and fertility are currently unclear.

Cryptorchidism

Cryptorchidism has a prevalence of 2.5 to 5 per cent at birth which declines to 1 per cent by 1 year. Spontaneous descent rarely occurs after this age. Undescended testes can be a feature of many hypogonadotrophic conditions, and intersexual and dysgenetic states such as androgen insensitivity syndromes and Noonan's syndrome. The persistent mullerian duct syndrome is caused by defects in antimullerian hormone (AMH) production or action during fetal development. The presence of Fallopian tubes and uterus obstructs testicular descent. The lower temperature in the scrotum is a prerequisite for normal spermatogenesis. Undescended testes are therefore exposed to the harmful effects of the higher temperature in the abdomen and inguinal region. The testis which is not permanently in a low scrotal position by the age of 2 years will have sustained permanent damage to the seminiferous epithelium. Orchidopexy after 2 years of age for undescended testes does not improve fertility. For these reasons, treatment should ideally be undertaken between 1 and 2 years of age. hCG or intranasal GnRH are currently being increasingly used for early initial treatment of cryptorchidism. If hormonal treatment is unsuccessful, orchidopexy can be carried out by the age of 2 years. The risk of testicular tumour in a patient with a history of undescended testis, whether successfully treated by orchidopexy or not, is four to five-fold higher than the general population.

Testicular tumours

It is important to remember that infertility can be a presenting symptom of testicular tumours, the commonest malignancy in young adult men. With increasing use of testicular ultrasound, it has become clear that there is a significantly higher risk of testicular tumours in infertile men (in the absence of cryptorchidism) compared to the general population. Carcinoma *in situ*, an obligatory precancerous state, is occasionally encountered incidentally in diagnostic testicular biopsies. Without treatment, 50 per cent of carcinomata *in situ* progress to malignant seminoma or non-seminomatous germ cell tumours.

Varicocele

Varicocele is a dilatation of the scrotal portion of the pampiniform plexus due to reflux of blood in the internal spermatic veins, usually involving the left side from the renal vein. It usually gives rise to a reduction in ipsilateral testicular volume but varying degrees of hypospermatogenesis are often seen in both testes. Although a varicocele is clinically detectable in up to 40 per cent of male partners of infertile couples, its significance in male infertility remains controversial. Increased scrotal temperature, hypoxia, and exposure of the testes to adrenal metabolites have been postulated as possible mechanisms by which spermatic vein reflux can induce seminiferous tubular damage. Since varicoceles can be detected clinically in 15 per cent of fertile young men, it must not be assumed that this condition is invariably or solely responsible for infertility without actively excluding other possible aetiologies including those in the female partner.

Sperm autoimmunity

Immunological infertility is a specific disorder caused by sperm membrane-bound IgA antibodies found in around 5 per cent of men presenting with infertility. Conditions predisposing to sperm autoimmunity include vasectomy, testicular injury/inflammation, genital tract infection/obstruction, and family history of autoimmune disease. Male patients with significant antisperm antibody titres usually have severely suppressed fertility potential due to sperm agglutination, poor sperm transit through cervical mucus, and blocked sperm–oocyte fusion.

Genital tract infection

Infection in the lower genital tract is a major cause of male infertility in the global context. Chlamydia, gonococcus, Gram-negative enterococci, and tubercle bacillus are the usual pathogens. If not treated by appropriate antibiotics promptly, inflammation of the accessory glands and excurrent ducts may give rise to disturbed

function, formation of sperm antibody, and permanent structural damage with obstruction in the outflow tract. Asymptomatic prostatitis due to occult and usually focal infection is best diagnosed by transrectal ultrasound examination of the prostate.

Excurrent duct obstruction

Vasectomy and previous genitourinary infections, usually sexually transmitted or tuberculous, are the most common causes of obstructive azoospermia. Congenital bilateral agenesis of the wolffian duct-derived structures, corpus/cauda epididymis, vas deferens and seminal vesicles (CBAVD) characterized by impalpable scrotal vasa, distended caput epididymis, acidic non-coagulating semen of reduced volume (<2 ml) devoid of fructose and sperm is present in 95 per cent of males with cystic fibrosis. They carry homozygous or compound heterozygous mutations in the cystic fibrosis transmembrane regulator (*CFTR*) gene. More commonly (6 per cent of azoospermic men and 1–2 per cent of infertile males), patients present with CBAVD without frank respiratory tract disease or pancreatic insufficiency. They have milder heterozygous mutations and/or the 5T variant in intron 8 of the *CFTR* gene, giving rise to a predominantly genital phenotype of cystic fibrosis. Renal and urinary tract abnormalities are common in these patients. In Young's syndrome, progressive epididymal obstruction is due to progressive inspissation of amorphous secretion in the lumen. In these patients, the high incidence of chronic sinopulmonary infection from childhood and bronchiectasis is presumably the consequence of the same abnormality in the respiratory tract. Epidemiological data has recently raised the possibility of mercury poisoning in this condition.

Coital disorders

Inadequate coital frequency, technique (including the use of vaginal lubricants with spermicidal properties), and faulty timing of intercourse may contribute to continuing infertility but are rarely the only aetiological factor in the infertile couple.

Diagnosis

History

Particular attention should be paid to the following aspects. Previous surgery such as herniorrhaphy in childhood, trauma, or torsion suggests possible damage to the vas or testis. History of cryptorchidism and genitourinary infections are important aetiological factors. Delayed onset of puberty may suggest the possibility of gonadotrophin deficiency. A history of recurrent chest infection, sinusitis, or bronchiectasis may be obtained in patients with epididymal obstruction (Young's syndrome), immotile cilia syndrome, and CBAVD associated with cystic fibrosis. Chronic disorders such as renal failure, liver disease, malignancy, diabetes, and multiple sclerosis are associated with a variety of testicular and sexual dysfunctions. Each patient should be asked about episodes of pyrexia within the past 12 weeks because of transient suppression of spermatogenesis. Careful enquiry should also be made about occupational or environmental exposure to testicular toxins, radiation, current medications, previous treatment, or recreational drugs. Painful ejaculation, haemotospermia, and pain in the perineum are symptoms suggestive of chronic infection in the prostate and seminal vesicles. It is important to establish that vaginal intercourse takes place with appropriate frequency and timing without the use of vaginal lubricants.

Examination

Assessment of height, weight, body habitus, and secondary sexual development should be carried out in all patients. Measurement of testicular volumes by comparison with Prader's orchidometer provide a convenient clinical index of seminiferous tubular mass. Normal adult testicular volume is between 15 and 35 ml. Testicular volume is a key finding in differentiating between azoospermia due to seminiferous tubular failure (reduced volumes) and that arising from excurrent duct obstruction (normal volume). Testicular size is also a useful indicator of the degree of testicular development in hypogonadotrophic patients. If not in the scrotum, the lowest position of the testes should be defined with the patient upright. Irregular contour, induration, or abnormal consistency of the testis suggest previous orchitis, surgery, or malignancy. Special attention should also be paid to the palpation of the epididymis and scrotal vas. An enlarged and tense caput epididymis may be palpable in cases of obstructive azoospermia. Irregularity and induration of the epididymis and vas suggest previous infection. In congenital agenesis of wolffian duct-derived structures, the scrotal vasa are either impalpable or extremely thin. The patient should be examined standing so that varicoceles can become visible (grade 3) or palpable (grade 2), or detected as a venous impulse in the spermatic cord during valsalva manoeuvre (grade 1). Rectal examination may reveal irregular contour or abnormal consistency and tenderness in the prostate in the presence of chronic prostatitis and enlarged seminal vesicles due to ejaculatory duct obstruction.

Investigations

Conventional parameters of the semen analysis such as sperm density, percentage of motile sperm, quality of sperm movements, and sperm morphology provide a semiquantitative index of fertility potential. Although a variety of tests of sperm function, such as computer-aided sperm movement analyses, cervical mucus penetration, acrosome reaction, sperm-zona binding, and hamster oocyte penetration, have been devised, none are sufficiently reliable and accurate to be used routinely in clinical practice. Infertile men with oligozoospermia produce spermatozoa harbouring abnormal DNA with strand breaks and redundant cytoplasm which may produce excessive reactive oxygen species. Chromatin structure and cytoplasmic enzyme (LDH-X or CK-M) assays are being applied to assess functional integrity of spermatozoa. They may provide more reliable quantitative biochemical measures of male fertility to guide management in the future.

Measurement of plasma FSH is useful in distinguishing primary from secondary testicular failure and in identifying patients with obstructive azoospermia. In the presence of azoospermia or oligozoospermia, an elevated FSH, particularly with reduced testicular volume, is presumptive evidence of severe and usually irreversible seminiferous tubular damage. Low or undetectable FSH (usually associated with low LH and testosterone with clinical evidence of androgen deficiency) is suggestive of hypogonadotrophism. Conversely, azoospermia with normal FSH and normal testicular volume usually indicates the presence of bilateral genital tract obstruction. The potential role of inhibin B measurement as a circulating marker of Sertoli cell function in routine diagnostic workup of male infertility is currently being evaluated. Testosterone and LH measurements are only indicated in the assessment of the infertile male when there is clinical suspicion of androgen deficiency, Klinefelter's syndrome, or sex steroid abuse. A high LH and testosterone should raise the possibility of abnormalities in androgen receptors while low LH and testosterone suggest gonadotrophin deficiency. Hyperprolactinaemia is not a recognized cause of male infertility but prolactin measurement should be undertaken if there is clinical evidence of sexual dysfunction (particularly diminished libido) or pituitary disease leading to secondary testicular failure. Oestradiol measurement is rarely indicated except in the presence of gynaecomastia.

Chromosome analysis by karyotyping or fluorescent *in situ* hybridization (FISH) should be carried out in patients with azoospermia, testicular atrophy, and elevated FSH, primarily to confirm the diagnosis of Klinefelter's syndrome. Screening for Y chromosome microdeletions should be considered in all patients with sperm density less than 5 million/ml by an appropriate number of PCR-based DNA markers and confirmed by Southern blotting. The need for testicular biopsy has largely been superseded by the use of plasma FSH in recent years to differentiate between primary testicular failure and obstructive lesions. Undetectable or very low levels of seminal fructose is used to confirm the clinical diagnosis of vasal and seminal vesicle agenesis or blocked ejaculatory ducts in the presence of obstructive azoospermia. An increase in number (more than 1 million/ml) of peroxidase-positive or monoclonal antibody-detected leucocytes in the semen may indicate genital tract infection. Semen culture for pathogens are difficult because of the bactericidal properties of seminal plasma and urethral and skin commensals. Antisperm antibodies are detected by the mixed agglutination reaction where sheep red blood cells or polyacrylamide beads are coated with rabbit antibodies to specific classes of human Igs. These will attach to motile spermatozoa carrying specific IgA on the surface of the sperm head or tail. Ultrasound examination of the testis has become a routine investigation for infertile males with non-obstructive azoospermia or severe oligospermia to detect occult testicular tumours. In patients with persistent or treated cryptorchidism, testicular ultrasound should be carried out annually. Ultrasound of the urinary tract is indicated in patients with CBAVD. Transrectal ultrasound can aid the diagnosis of asymptomatic chronic prostatitis.

Management

Pregnancies can occur in subfertile couples without treatment albeit with a much reduced probability depending on the duration of infertility, age, and coexisting subtle abnormalities in the female partner in addition to the defects in sperm quality. Since the majority of patients with male infertility present no recognizable or reversible aetiologies, management remains largely empirical.

Subfertility due to idiopathic hypospermatogenesis

Although a wide variety of empirical medical treatments, including gonadotrophins, androgens, and antioestrogens, have been tried in attempts to improve fertility in subfertile men, none have been shown to be effective when assessed in randomized, controlled therapeutic trials and are therefore not recommended. Instead,

assisted conception techniques are increasingly applied to overcome idiopathic male infertility. This is based on the premise that placing a large number of 'prepared' motile spermatozoa in close proximity to ovulated or retrieved oocytes *in vivo* or *in vitro* can enhance the probability of fertilization. Intrauterine insemination (IUI) of more than 1 million washed, motile spermatozoa (freed of seminal plasma, leucocytes, and abnormal/ dead spermatozoa) is a relatively simple and inexpensive technique with few complications. Pregnancy rates of 5 to 10 per cent per cycle can be expected. This can be combined with controlled ovarian stimulation of the female using gonadotrophins but the risk of multiple pregnancies increases. *In vitro* fertilization (IVF) involves more intensive gonadotrophin stimulation of the female, suppression of spontaneous ovulation, and collection of multiple oocytes by laparoscopy or transvaginal-ultrasound-guided ovarian puncture which are then coincubated with prepared spermatozoa in culture medium. In patients with moderate oligozoospermia, average fertilization rates of 30 per cent and live birth rates of 5 to 12 per cent per treatment cycle can be expected. In those with severe and multiple defects in semen parameters, standard IVF is less effective. For these cases, microinjection of single live spermatozoon directly into harvested oocytes (intracytoplasmic sperm injection, ICSI) has become the treatment of choice. This bypasses the sperm–oocyte interactions normally required for fertilization in natural conception or IVF and can achieve a remarkably high fertilization and live birth rates ((55 and 26 per cent per cycle respectively) even with the most severely abnormal samples. Since only a few spermatozoa are required, ICSI has revolutionized management of extreme oligozoospermia and azoospermia irrespective of aetiology. Non-obstructive azoospermia is often intermittent and careful examination of centrifuged deposits of semen to detect and harvest occasional ejaculated spermatozoa for ICSI should be attempted repeatedly before resorting to alternatives. Even in patients with persistent azoospermia, isolated foci of spermatogenesis may be preserved so that testicular sperm extraction via multiple biopsies can often yield viable testicular spermatozoa (including several patients with Klinefelter's syndrome) for ICSI.

In obstructive azoospermia, epididymal spermatozoa can be aspirated by an open procedure or percutaneous needle puncture of the proximal epididymis. In these circumstances, cryostorage of harvested spermatozoa for subsequent ICSI is required; this does not appear to compromise efficacy. In children born after successful ICSI treatment, the incidence of major congenital abnormalities is not increased compared to natural pregnancies but there is a small increase in sex chromosome aneuploidy in some series. Concern regarding the developmental potential of children born after ICSI has been raised. Long-term follow-up of children from ICSI births is indicated.

Specific treatable conditions

Removal or withdrawal from antispermatogenic agent or drug exposure may lead to improvement in fertility. This is most commonly seen in patients with inflammatory bowel diseases changing treatment from sulfasalazine to 5-aminosalicylic acid which removes the offending moiety, sulfapyridine. Withdrawal from anabolic steroid abuse invariably leads to recovery of spermatogenesis although this may take many months because of the long half-lives of some preparations. Cryopreservation of semen should be offered to all male patients of reproductive ageing before commencing anticancer chemotherapy or testicular irradiation.

When patients with hypogonadotrophic hypogonadism desire fertility, they can discontinue exogenous androgen replacement and start on human chorionic gonadotrophin (hCG 2000 IU, subcutaneous, twice weekly) for 6 to 12 months. This should maintain normal testosterone levels. Patients with postpubertally-acquired gonadotrophin deficiency (e.g. from pituitary tumour) where spermatogenesis has previously been established, usually respond to hCG treatment alone to reinitiate germ cell development. If there is no spermatozoa in the ejaculate at the end of 12 months, human menopausal gonadotrophin (hMG), which contain both FSH and LH, or recombinant FSH should be added at 75 to 150 IU, subcutaneous, thrice weekly. Combined treatment may be required for a further 12 months. Most patients with congenital forms of hypogonadotrophic hypogonadism will require FSH to stimulate Sertoli cell division and initiate spermatogenesis. In general, around 70 per cent should show active spermatogenesis and 50 per cent could be expected to achieve spontaneous pregnancies even if sperm densities remain in the oligozoospermic range. Patients with hypothalamic GnRH deficiency, can be treated by pulsatile GnRH delivered 2-hourly by a battery-driven portable infusion minipump. Many find this form of chronic therapy impractical and too demanding. The outcome of treatment is similar to that obtained with exogenous gonadotrophin therapy.

Active infection in the genital tract should be treated by appropriate antibiotics (erythromycin, doxycycline, or norfloxacin) for 4 weeks for the patient and his partner.

Obstructive azoospermia due to epididymal obstruction can be treated by microsurgical epididymovasostomy. High pregnancy rates can only be achieved by a few experienced microsurgeon. A more feasible alternative is to obtain spermatozoa from the caput epididymis or efferent ducts proximal to the site of obstruction by direct needle aspiration (microepididymal sperm aspiration or percutaneous epididymal sperm aspiration) for use in assisted fertilization procedures (usually ICSI). In patients with CBAVD, *CFTR* mutation screening of the partner and genetic counselling should be undertaken beforehand because of the risk of cystic fibrosis in offspring.

Sperm antibody can be treated by immunosuppression with high-dose prednisolone 0.75 mg/kg per day or prednisolone 20 mg twice daily on days 1 to 10 and 5 mg on days 11 and 12 of the partner's cycle for three to six cycles. Side-effects are common, including irritability, sleeplessness, arthralgia, muscle weakness, peptic ulceration, glucose intolerance, and bilateral aseptic necrosis of femoral heads. Results of controlled trials of glucocorticoid treatment are conflicting. IVF and ICSI are increasingly being applied to manage immunological male infertility.

Varicocele can be treated either by open surgical ligation or transfemoral embolization of the internal spermatic veins. Results of treatment of varicocele from eight prospective, controlled therapeutic trials are confusing. Coexisting female factors contributing to infertility, insufficient samples size, high dropout rates, and lack of randomization/ blinding or sham procedures are some of the more important confounding variables which typify difficulties of treatment trials in male infertility. Nevertheless, the Royal College of Obstetricians and Gynaecologists recently concluded that treatment of varicocele in oligozoospermic, but not normospermic, subfertile men can significantly improve semen quality and pregnancy rate. The cost of varicocele treatment per live birth is less with surgical ligation (and embolization) than for assisted conception techniques.

Retrograde ejaculation can be treated medically with a-adrenergic, anticholinergic agents or imipramine. If unsuccessful, spermatozoa can be recovered from bladder catheterization and irrigation with culture medium for artificial insemination or IVF. Semen can be obtained by masturbation, vibrators, or electroejaculation from patients with various coital dysfunctions.

Untreatable sterility

Patients with persistent, non-obstructive azoospermia without retrievable postmeiotic germ cells, unable to undergo or failed to be helped by ICSI should be counselled regarding the options of continuing childlessness, adoption, and donor insemination.

Genetic screening and counselling

This has become important with the realization that genetic disorders could account for an increasing proportion of infertility previously believed to be idiopathic and that there is a high probability of transmitting infertility to male offspring if assisted reproductive treatment is successful. Furthermore, the long-term health of the ICSI offspring remains an unsettled question. Counselling should therefore be carried out in all couples considering microassisted fertilization techniques. It is also recommended that chromosome karyotyping and Y chromosome screening be performed in patients with azoospermia and severe oligozoospermia (less than 5 million/ml) regardless of the coexistence of other clinical abnormalities such as varicocele or cryptorchidism. This not only allows a firm diagnosis to be made but also encourages the clinician to forego empirical treatment and couples who conceived by assisted reproduction techniques may inform their son at a suitable age that he is likely to have fertility problems. Patients with obstructive azoopsermia due to CBAVD and their partners should undergo *CFTR* gene screening followed by genetic counselling if positive.

Erectile impotence

Erectile failure may be caused by neurological disorders such as autonomic neuropathy (usually complicating diabetes), multiple sclerosis and spinal injuries, vascular disease involving pelvic vessels, retroperitoneal and bladder neck surgery, medications (commonly a and b-adrenergic antagonists, psychotropic agents), alcohol abuse, severe systemic disease, psychological dysfunctions (including depression), relationship problems, androgen deficiency, and hyperprolactinaemia. Loss of libido characterizes androgen deficiency and hyperprolactinaemia, while normal spontaneous morning erection is suggestive of psychogenic impotence. Testosterone deficiency is uncommon (less than 5 per cent) in patients who present with erectile dysfunction without loss of libido. Management should aim to correct any reversible underlying disease (e.g. prolactinoma) or substitute offending medications. Androgen replacement is only indicated in patients with total or free plasma testosterone in the hypogonadal range. The use of phosphodiesterase inhibitor (PGE5 inhibitors), such as sildenafil, to enhance the neurovascular cGMP-mediated nitric oxide synthesis in penile vasculature has been remarkably successful in a treating a wide variety of erectile dysfunction. This has largely superseded the use of vacuum devices and intracavernosal injection of vasodilator agents such as papaverine or prostaglandin E1. These are reserved for cases with severe neurogenic

impotence unresponsive to PGE5 inhibitors.

12.8.3The breast

H. S. Jacobs

Gynaecomastia

Gynaecomastia is defined as benign enlargement of the male breast caused by proliferation of the glandular components. Clinically the distinction from enlargement by fat tissue is made by examining the patient in the supine position, the breast being held between thumb and forefinger and the fingers gently moved towards the nipple. A firm or rubbery mobile disc-like mound of tissue arising concentrically from beneath the nipple and areola indicates the presence of gynaecomastia. The most important condition that needs to be excluded is carcinoma of the male breast. Cancer usually presents as a unilateral eccentric mass that is hard and fixed to underlying tissue; it may be associated with skin tethering, nipple discharge, or axillary lymphadenopathy. Mammography and fine needle aspiration are helpful in the differential diagnosis but if doubt remains biopsy is appropriate. While cancer of the male breast is rare, it has to be recognized that it is 16 times more common in Klinefelter's syndrome than in other men. Other causes of gynaecomastia are not, however, associated with an increased risk of breast cancer.

Pathogenesis

Microscopically breast tissue in both sexes appears identical at birth. It remains quiescent until puberty when, in boys, the ducts and surrounding mesenchymal tissue transiently proliferate, only to involute and ultimately to atrophy. Gynaecomastia is characterized by initial proliferation of the fibroblastic stroma and ductal system. Progressive fibrosis and hyalinization then occur in association with regression of the epithelial components. These regressive changes occur even if the stimulus (for example oestrogen treatment) continues. When gynaecomastia has been present for more than a year, clinical regression is rarely complete because the fibrosis persists even when the cause has been removed.

Since oestrogens stimulate and androgens inhibit development of breast tissue, gynaecomastia arises whenever there is an imbalance between these hormones. An alteration in the ratio of free androgen to free oestrogen, rather than a specific concentration of either, is thought to underlie most cases of gynaecomastia.

In men 98 per cent of testosterone is directly secreted by the testes, whereas the origin of oestrogen is more complex (Fig. 1): thus only about 15 per cent of oestradiol and less than 5 per cent of oestrone are directly secreted. In both cases the remainder is produced by extraglandular conversion (aromatization) of androgenic precursors in peripheral tissues such as adipose tissue, liver, and muscle. There is also substantial interconversion of oestrone and oestradiol. Treatment of normal men with human chorionic gonadotrophin results in an increase of directly secreted oestradiol in proportion to the increase of testosterone, so that while directly secreted oestradiol in normal men rarely amounts to more than 6 µg/day, when levels of luteinizing hormones are persistently high substantial amounts of oestradiol may be directly secreted by the testis.

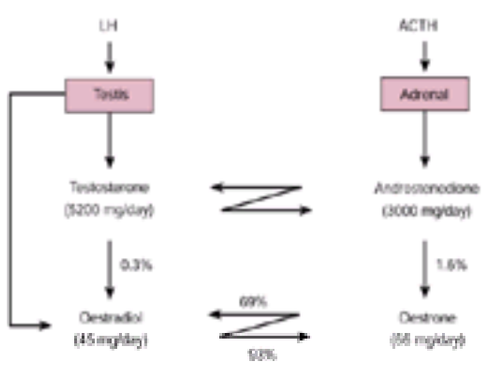

Fig. 1 Sources of oestrogen in men.

Causes

Gynaecomastia may be physiological or pathological. Physiologically it occurs at three times of life: the first is neonatally in response to transplacental passage of oestrogens, the second is during puberty for reasons that are not at all clear, and the third is in elderly men, probably because of the decline in Leydig cell function that occurs normally with age.

Pathological gynaecomastia is caused by a deficiency of testosterone formation or action, enhanced production of oestrogen, drugs, and unknown causes.

Testosterone deficiency

The commonest cause is Klinefelter's syndrome, about half the cases of which develop gynaecomastia at the time of puberty. The serum testosterone is usually about 50 per cent of normal, the gonadotrophin concentrations are raised, and the serum oestradiol is above normal. The diagnosis is suspected clinically and confirmed by white blood cell karyotype. Congenital causes of testosterone deficiency include defects in testosterone biosynthesis and congenital anorchia. Acquired causes include viral orchitis (usually mumps), trauma, neurological disease (myotonia dystrophica and spinal cord lesions), and renal failure. Androgen resistance syndromes are associated with high rates of secretion of testosterone and oestradiol; because of the large amounts of precursor (testosterone) there is also excessive extragonadal conversion of androgens to oestrogens.

Increased secretion of oestrogen

Testicular tumours, such as Leydig and Sertoli cell tumours, may secrete androgens and oestrogens autonomously; gonadotrophin secretion is therefore suppressed and azoospermia is common. They may be too small to be detected clinically but ultrasound can be very helpful. Some testicular tumours, for example choriocarcinomas, secrete human choionic gonadotrophin which then stimulates oestrogen secretion by the contralateral testis. Human choionic gonadotrophin may also be secreted by non-testicular tumours such as a bronchogenic carcinoma.

True hermaphroditism may be associated with gynaecomastia because of oestrogen secretion by the ovotestis.

Increased extragonadal production of oestrogens

Adrenal disease

Congenital adrenal hyperplasia caused by 2,1-hydroxylase or 3b or 17b steroid dehydrogenase deficiencies results in increased availability of adrenal androgen for peripheral aromatization. Adrenal carcinoma may be associated with massive oestrogen production, usually caused by extraglandular aromatization of the enormous amounts of androgen secreted by the tumour but occasionally directly secreted.

Liver disease

Cirrhosis, particularly alcoholic cirrhosis, is typically associated with gynaecomastia, testicular atrophy, and impotence. Plasma and urinary excretion of oestrogen is increased. The mechanism is in part decreased hepatic extraction of androstenedione and consequently an increase in its extrasplanchnic aromatization and partly reduced testosterone secretion by the testes. The gynaecomastia of starvation and refeeding may also be related to disturbed liver function.

Drugs

Oestrogens and oestrogen-like drugs

The most familiar use of oestrogen is in the treatment of advanced carcinoma of the prostate, indeed it is the development of gynaecomastia in this situation that has provided the model for most of our understanding of the evolution of the histological changes in the breast in gynaecomastia. Oestrogen residues in food (via injected animals) and cosmetic products have been reported as a cause of gynaecomastia.

Treatment with digitalis glycosides may cause gynaecomastia, the drug acting either as an oestrogen or as an oestrogen precursor.

Drugs that enhance oestrogen secretion

Treatment with human chorionic gonadotrophin and clomiphene can cause increased oestrogen secretion. The development of gynaecomastia in men treated with human chorionic gonadotrophin usually means that the dose used has been too high.

Drugs that inhibit testosterone secretion

Ketoconazole, an antifungal agent that is also used in the management of certain forms of Cushing's syndrome, blocks steroid synthesis in Leydig cells and, if a high dose is maintained, gynaecomastia may result.

Spironolactone causes gynaecomastia in as many as 50 per cent of men treated with 150 mg/day. The drug suppresses testosterone synthesis (by inhibiting 17,20-desmolase) but it also acts as a peripheral antiandrogen.

Drugs that block testosterone action

Cyproterone acetate and flutamide are two antiandrogens used in the management of advanced prostatic disease which usually produce gynaecomastia. Cimetidine, but not ranitidine, is antiandrogenic and is associated with a significant risk of gynaecomastia.

Whereas in most series between 50 and 75 per cent of cases of gynaecomastia are labelled idiopathic because no endocrinopathy can be identified, there are increasing reasons to suspect that environmental pollution, either with oestrogens or antiandrogens, is responsible for many of the cases.

Diagnosis

The history should include enquiry about drugs as well as possible environmental exposure to oestrogens and antiandrogens. Examination should include the testes. While small firm testes are characteristic of Klinefelter's syndrome, asymmetrical enlargement suggests a Leydig cell tumour (most readily diagnosed by ultrasound). Evaluation of alcohol intake and liver function is appropriate. Endocrine assessment should include measurement of testosterone, oestradiol, gonadotrophins, and dehydroepiandrosterone sulphate (high levels suggest adrenal disease) concentrations.

Treatment

Once gynaecomastia has been present for about a year medical treatment is unlikely to lead to a reduction in breast size because of the fibrosis which usually develops by this time. Consequently surgery is the mainstay of treatment. The psychological effects of persistent breast development in adolescent boys may be severe and surgery should be considered at an early stage: temporizing rarely produces resolution. Medical therapy with androgens or anti-oestrogens produces uncertain effects and can only be expected to have much benefit if administered early in the course of the disorder. Gynaecomastia caused by oestrogen treatment, as in the treatment of prostatic disease, can be prevented by pretreatment with low-dose irradiation of the breasts.

Galactorrhoea

Galactorrhoea is defined as a persistent discharge of milk or milk like secretion in the absence of parturition or beyond 6 months postpartum in a non-nursing mother. Galactorrhoea is not a sign of breast cancer and not a risk factor for it.

There are essentially two types of galactorrhoea—spontaneous galactorrhoea or galactorrhoea present on expression only. In the latter case the menstrual cycle is usually intact and an endocrine cause is rarely found. It is spontaneous galactorrhoea that is significant in endocrine terms and which is usually associated with amenorrhoea. It is in this situation that hyperprolactinaemia occurs.

In the puerperium there is a clear correlation between the amount of prolactin released in response to suckling and the volume of milk secreted. In contrast, in inappropriate lactation, that is, in galactorrhoea, no such relation exists, presumably because the breasts have not been prepared for lactation by the oestrogen- and progesterone-rich environment of pregnancy. When this observation is considered in relation to the ease and widespread availability of prolactin measurements, one can readily appreciate that the physical sign of galactorrhoea has ceased to have much diagnostic significance. In women with amenorrhoea caused by hyperprolactinaemia, for example, only about 20 per cent have galactorrhoea. Thus the evaluation of galactorrhoea nowadays is essentially the evaluation of hyperprolactinaemia.

Management

The essential investigation is the measurement of serum prolactin. The management of hyperprolactinaemia is outlined in Chapter 12.2. For women with non-hyperprolactinaemic galactorrhoea the important advice is first to stop expressing the milk, the second is the reassurance that it is not a sign of cancer, or a risk factor for it, and third is a trial of drug therapy with bromocriptine. In the author's experience, after they have received appropriate reassurance, patients with non-hyperprolactinaemic galactorrhoea rarely need drug therapy. Such patients are, however, very sensitive to the adverse effects of the drug and side-effects are common, even with low doses.

12.8.4 Sexual dysfunction

Raymond C. Rosen and Irwin Goldstein

Introduction

Sexual dysfunction is a common complaint in men and women and is associated with a broad range of medical, psychological, and interpersonal causes. Despite significant progress in basic research and clinical therapeutics in recent years, sexual problems remain among the most frequently overlooked and mismanaged patient complaints. Patient–physician communication difficulties, lack of knowledge, and inadequate reimbursement are frequently cited reasons for these shortcomings. Few physicians are adequately trained in the diagnosis and treatment of sexual dysfunction, and many patients seek assistance from inappropriate or unqualified providers. This trend is particularly unfortunate, since sexual problems frequently impact on patients' interpersonal functioning and quality of life. Moreover, new treatment options are available which offer significant therapeutic potential for many individuals.

Sexual problems are generally classified according to the four-phase model of sexual response originally proposed by Masters and Johnson. These include: (i) sexual desire disorders (hypoactive sexual desire disorder, sexual aversion disorder); (ii) sexual arousal disorders (erectile dysfunction, female arousal disorder); (iii) orgasmic disorders (female orgasmic disorder, premature or delayed ejaculation); and (iv) sexual pain disorders (dyspareunia, vaginismus). The specific dysfunctions and corresponding phases of the sexual response cycle are shown in Table 1.

Although public and professional attention has focused predominantly on erectile dysfunction, other sexual problems (e.g. hypoactive sexual desire, premature ejaculation) are more commonly reported in community-based surveys. Sexual dysfunction is more prevalent in women than men; recent British and American studies have found that about 40 per cent of women and 30 per cent of men have had one or more sexual problems in the past. Less than 10 per cent of these problems are typically brought to the attention of a physician or other health-care provider.

Medical management of sexual dysfunction should always begin with a thorough history and physical examination. In appropriate clinical contexts, at least one question regarding sexual function ought to be included in the initial examination of every patient, regardless of age or gender (such as 'Are you satisfied with your current sexual functioning or relationship?'). A physical examination and laboratory testing are important, since sexual problems are frequently associated with underlying medical illnesses or risk factors (such as diabetes, cardiovascular disease). The role of depression or other psychiatric disorders should also be considered, as well as possible iatrogenic effects of prescription or non-prescription drugs. It is also important to evaluate relationship and lifestyle factors in all cases. Finally, the patient's needs and expectations, as well as cultural or family issues should be taken into account.

Male sexual dysfunction

Male sexual dysfunction may be divided into erectile dysfunction, premature ejaculation, hypoactive sexual desire, and priapism.

Erectile dysfunction

Epidemiology

Erectile dysfunction is a significant and common medical problem, with recent epidemiological studies suggesting that approximately 10 per cent of men aged 40 to 70 have severe or complete erectile dysfunction, defined as the total inability to achieve or maintain erections sufficient for sexual performance. An additional 25 per cent of men in this age category have moderate or intermittent erectile difficulties. The disorder is highly age-dependent, as the combined prevalence of moderate to complete erectile dysfunction rises from approximately 22 per cent at age 40 to 49 per cent by age 70 (Fig. 1). Although less common in younger men, erectile dysfunction still affects 5 to 10 per cent of men below the age of 40. Findings from these studies show that erectile dysfunction impacts significantly on mood state, interpersonal functioning, and overall quality of life.

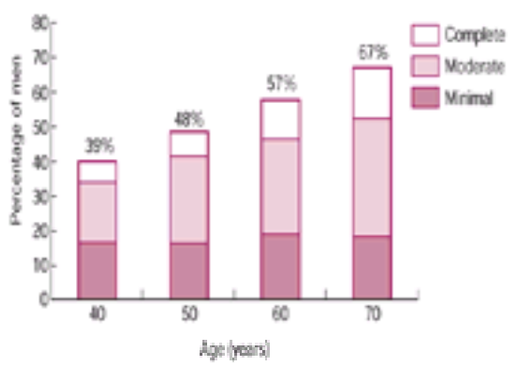

Fig. 1 Prevalence of erectile dysfunction (Feldman HA *et al.*, 1994).

Clinical context

Erectile dysfunction is strongly related to both physical and psychological health. Among the major risk factors are diabetes mellitus, heart disease, hypertension, and decreased high-density lipoprotein levels. Medications for diabetes, hypertension, cardiovascular disease, and depression may also cause erectile difficulties. In addition, there is a higher prevalence of erectile dysfunction among men who have undergone radiation or surgery for prostate cancer, or who have a lower spinal cord injury or other neurological diseases (such as Parkinson's disease, multiple sclerosis). Lifestyle factors, including smoking, alcohol consumption, and sedentary behaviour are additional risk factors. The psychological correlates of erectile dysfunction include anxiety, depression, and anger. Despite its increasing prevalence among older men, erectile dysfunction is not considered a normal or inevitable part of the ageing process. It is rarely (in fewer than 5 per cent of cases) due to ageing-related hypogonadism, although the relationship between erectile dysfunction and age-related declines in androgen remains controversial.

Pathophysiology

Basic research on neurovascular mechanisms has contributed greatly to our understanding of normal and pathological processes of erection. There is increasing evidence that the state of trabecular smooth muscle contractility is regulated by a delicate balance between neurotransmitter and vasoactive substances mediating erectile tissue contraction (consistent with flaccidity) and relaxation (consistent with erection). The neurotransmitter nitric oxide (NO) has been found to play a major role in inducing trabecular smooth muscle relaxation, as shown in Fig. 2: cGMP binds to cGMP-dependent protein kinases (PKG) and to cGMP-dependent ion channels, leading to lowering of intracellular calcium concentration and activation of myosin light-chain phosphatases, resulting in inhibition of smooth muscle contractility and enhancement of penile erection (Fig. 2).

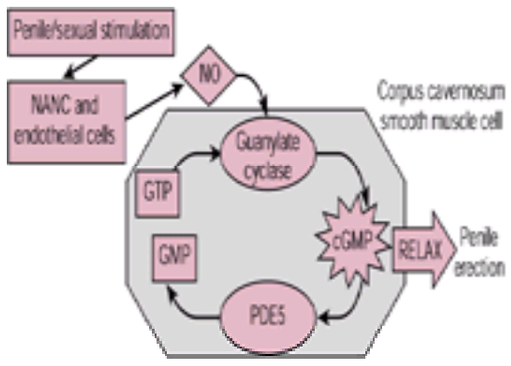

Fig. 2 Penile erection: the nitric oxide–cGMP mechanism. cGMP, cyclic guanosine monophosphate; GTP, guanosine triphosphate; NANC, non-adrenergic non-cholinergic neurones; NO, nitric oxide; PDE5, phosphodiesterase type 5.

Multiple vasoactive agents, including vasoactive intestinal polypeptide, prostaglandin E_1, forskolin, phosphodiesterase inhibitors, and a-adrenergic receptor antagonists affect smooth muscle contractility, each via a specific mechanism. Ultimately, all act by changes in intracellular calcium and modulation of specific smooth muscle myosin light-chain kinases and myosin light-chain phosphatases. These enzymes rapidly change the state of myosin phosphorylation and result in either smooth muscle contraction (flaccidity) or relaxation (erection). The role of central nervous system and spinal mechanisms has also been elucidated in recent studies. Understanding of these biochemical and neural mechanisms regulating erection has permitted the rational development of new pharmacological strategies for the management of erectile dysfunction.

Diagnosis and evaluation

Guidelines for diagnosis and evaluation were recently established by the 1st International Consultation on Erectile Dysfunction (Table 2). According to these guidelines, the first step in the process is the taking of a comprehensive sexual, medical, and psychosocial history. In obtaining a sexual history, special attention should be paid to personal or cultural sensitivities. History taking should be aimed at characterizing the severity, onset, and duration of the problem, and evaluating the need for specialized testing. A physical examination and selected laboratory testing should be performed on all patients with complaints of erectile dysfunction. Although not different from a routine physical examination, special emphasis is placed on review of genitourinary, endocrine, vascular, and neurological systems. The physical examination may corroborate aspects of the medical history (such as poor peripheral circulation), and may occasionally reveal unsuspected physical findings (such as Peyronie's plaques, small testes, prostate cancer). The physical examination also provides an opportunity for patient education and reassurance regarding normal genital anatomy.

Selective laboratory testing should be performed in all cases. This includes investigation of the hypothalamic–pituitary–gonadal axis via assessment of androgenic status, particularly if sexual desire is reduced. There is disagreement about the relative value of the various testosterone assays, including total, free, and bioavailable testosterone. However, strong consensus exists that at least one of these assays should be performed. A serum prolactin determination may be obtained in selected cases. Standard serum chemistries, full blood count, and lipid profiles may be of value and should be obtained, if not performed in the past year. Determination of serum thyroid-stimulating hormone may also be of value, as both hyper- and hypothyroidism are associated with erectile difficulties. Finally, measurement of serum prostatic specific antigen may be indicated based upon the patient's age and relative risk status.

Specialized diagnostic procedures, such as nocturnal penile tumescence and rigidity testing or other specialized vascular or neurological techniques, may play a role in selected cases. For example, CT and MR imaging, penile Doppler ultrasound, penile arteriography, cavernosal/pudendal/sphincter electromyography, or other tests may be of value in evaluating young patients with pelvic or penile trauma who may be candidates for reconstructive vascular surgery. Patients with complicated diabetes or other endocrinopathies may benefit from further endocrinological studies. Similarly, patients with complicated psychological or relationship problems may be suitably referred to a mental health or sex therapy specialist. Finally, patients with a history of cardiac disease or significant cardiovascular risk factors should be evaluated for potential cardiac risk associated with sexual activity: consensus guidelines have recently been established (Table 3).

Treatment

Results of the initial evaluation and specialized testing should be carefully reviewed with the patient and (if possible) their partner prior to initiating therapy. Potentially modifiable risk factors, such as cigarette smoking or alcohol abuse, should be addressed. Prescription drugs such as antihypertensives or antidepressants may be implicated in the patient's erectile difficulties, and should be altered when medically possible. Patients with specific endocrine deficiencies such as hypogonadism should be placed on hormone replacement therapy prior to initiation of direct therapies for erectile dysfunction. Sexual problems in the partner, such as a lack of lubrication, hypoactive sexual desire, or dyspareunia (painful intercourse) should also be addressed. Patients and partners should be fully informed about the range of treatment options available and the risks and benefits associated with each.

Direct therapies for erectile dysfunction can be stratified according to the mechanism of action, degree of invasiveness, ease of administration, reversibility, and relative costs associated with each (Table 4).

Sexual counselling and education

First-line options include sexual counselling or education, and oral agents (such as sildenafil). These options can be used alone or in combination. Brief sexual or couple's counselling is aimed at resolving specific psychological or interpersonal causes, such as relationship distress, sexual performance concerns, dysfunctional communication patterns, and comorbid sexual dysfunctions (such as hypoactive sexual desire). Advantages of sexual counselling include its non-invasiveness and relatively broad applicability. The major disadvantages are the lack of acceptability for many patients and uncertain efficacy.

Oral therapies

Sildenafil citrate (Viagra) is the first oral drug to be widely approved for the treatment of erectile dysfunction. It is a potent and selective inhibitor of type 5 phosphodiesterase, the primary form of the enzyme found in human penile erectile tissue (Fig. 2), thereby preventing the breakdown of cyclic guanosine monophosphate (cGMP), the intracellular second messenger of nitric oxide. Because nitric oxide is released following sexual stimulation, sildenafil only works when a man is sexually stimulated. Its mechanism of action is entirely peripheral and includes direct effects on smooth muscle relaxation and vasodilation of the penile arterioles. Sildenafil is administered 'on demand' in dosages of 25, 50, or 100 mg, and is effective in approximately 30 to 60 min, requiring ongoing sexual stimulation to be effective. Cardiac safety does not appear to be a major concern, except for patients receiving nitrates in any form, or those who have other cardiac risk factors associated with sexual activity itself (Princeton Consensus). Sildenafil is contraindicated for men receiving nitrate therapy, including short- or long-acting agents delivered by oral, sublingual, transnasal, or topical administration. Efficacy has been reported at 43 to 82 per cent, depending upon aetiology and severity of erectile dysfunction. The drug's side-effects include headaches, flushing, dyspepsia, and nasal congestion. A small percentage of men (2 to 3 per cent) may also experience mild alterations in colour vision (blue hue), visual brightness or sensitivity, or blurred vision.

Other oral agents are in development at the time of writing: some of these are based on a similar mechanism of action to sildenafil (i.e. PDE-5 inhibition), whereas others depend upon central dopaminergic activity, the dopamine–oxytocin pathway that originates from the hypothalamus and pituitary areas in the brain, or peripheral and/or central sympathetic inhibition. Some of these agents are in advanced clinical trials, but none has received regulatory approval yet in the United States or Europe. Combination oral agents are also being evaluated in some trials, and may play an important role in the future.

Local therapies

Injectable, intraurethral, or topical agents are classified as second-line therapies for erectile dysfunction according to recent guidelines. These should be selected based upon: (i) failure, insufficient response, or adverse side-effects associated with one or more of the first-line therapies, or (ii) patient/partner preferences. These interventions consist of intraurethral administration or intracavernosal injection of alprostadil. Vacuum pump devices can also be included in this category. Although widely utilized, these treatments are associated with variable efficacy, a high patient discontinuation rate, possible risk of side-effects, and moderately high costs.

Intracavernosal injection therapy

Prior to the approval of sildenafil, intracavernosal self-injection was the most common medical therapy for erectile dysfunction. Different forms of prostaglandin are used primarily for this purpose: alprostadil sterile powder and alprostadil alfadex are both synthetic formulations of prostaglandin E_1. Injection therapy is effective in most cases of erectile dysfunction, regardless of aetiology. It is contraindicated in men with a history of hypersensitivity to the drug employed, in those at risk for priapism (e.g. sickle-cell disease, hypercoagulable states), and in men receiving monoamine oxidase inhibitors. The effective therapeutic range is between 1 and 60 µg with the majority of responders (85 per cent) requiring less than 20 µg. In general, intracavernosal injection therapy with alprostadil is effective in 70 to 80 per cent of patients, although discontinuation rates are high in most studies. Side-effects include prolonged erections or priapism, penile pain, and fibrosis with chronic use. In addition to single-agent injection therapy, various combinations of alprostadil, phentolamine, and/or papaverine are widely employed in urological practice. Intracavernosal injections have been shown to be effective in about 70 to 80 per cent of men who fail first-line therapy with sildenafil.

Intraurethral alprostadil

Alprostadil may be administered intraurethrally in the form of a semi-solid pellet inserted by means of a special applicator. To obtain an effective concentration of alprostadil in the corpora cavernosa, 125 to 1000 µg of the drug are required. In a mixed group of patients with organic erectile dysfunction, 65 per cent of men receiving intraurethral alprostadil responded with a firm erection when tested in the office, and 50 per cent of administrations to that subset resulted in at least one episode of successful intercourse in the home setting. Side-effects associated with the intraurethral administration of alprostadil include penile pain and hypotension. Prolonged erections and penile fibrosis are rare, although the clinical success rate is low.

Vacuum constriction device therapy

The use of vacuum constriction device (**VCD**) therapy is a well-established, non-invasive treatment that has recently been approved by the United States Food and Drug Administration for over-the-counter distribution. It provides a useful treatment alternative for patients for whom pharmacological therapies are contraindicated, or who do not desire other interventions. Vacuum constriction devices apply a negative pressure to the flaccid penis, thus drawing venous blood into the penis, which is then retained by the application of an elastic constriction band at the base of the penis. Efficacy rates of 60 to 80 per cent have been reported in most studies. Like intracorporal injection therapy, VCD treatment is associated with a high rate of patient discontinuation. The adverse events occasionally associated with VCD therapy include penile pain, numbness, bruising, and delayed ejaculation.

Surgical treatments

Surgical implantation of a penile prosthesis, which was at one time the mainstay of treatment for erectile dysfunction, is now performed only in rare or special cases. For select cases of severe, treatment-refractory erectile dysfunction, for patients who fail pharmacological therapy or who prefer a permanent solution for the problem, surgical implantation of a semi-rigid or inflatable penile prosthesis is available. Various types of surgical prostheses have been described in the literature. The inflatable penile prosthesis provides a more aesthetic erection and better concealment than semi-rigid prostheses, although there is an increased rate of mechanical failure and complications (5 to 20 per cent) with the former. Despite the cost, invasiveness, and potential medical complications involved, penile implant surgery has been associated with high rates of patient satisfaction in previous studies. It should be noted, however, that these studies were conducted prior to the advent of newer forms of therapy (e.g. sildenafil).

Premature ejaculation

Definition and epidemiology

Premature ejaculation is difficult to define precisely. In part, it depends on the timing or speed of the partner's response, and whether satisfactory intercourse has been achieved. The preferred definition currently is that offered by DSM-IV: 'Persistent or recurrent ejaculation with minimal sexual stimulation or before, upon, or shortly after penetration and before the person wishes it'. In making the diagnosis, clinicians should consider the circumstances of the problem, including the degree of associated distress in the male and his partner. Some authors distinguish between primary or life-long premature ejaculation, and secondary or situational forms of the disorder. Other aspects of sexual functioning should be carefully evaluated, particularly since premature ejaculation can develop as a secondary reaction to erectile dysfunction. Otherwise, little is known about either the pathophysiology or aetiology of the disorder.

Premature ejaculation is a common disorder, affecting approximately 25 to 40 per cent of adult men at some time. In the National Health and Social Life Survey, approximately one-third of men in each age cohort reported problems with ejaculating too rapidly. Despite its greater prevalence, premature ejaculation has attracted less attention among health professionals and the lay public than erectile dysfunction. This may be due, in part, to the fact that men are able to function sexually (i.e. to perform intercourse) despite a mild or moderate degree of premature ejaculation. In the most severe cases, however, the male ejaculates before penetration is achieved. Far fewer men with premature ejaculation seek professional help for their problem, including those with the most severe forms of the disorder. This is unfortunate, since simple and effective therapies are widely available.

Treatment

Treatment of premature ejaculation consists of either behavioural/sex therapy training or pharmacological treatment. Masters and Johnson popularized the most widely used 'Stop–Start' technique in the 1970s. The method involves direct stimulation of the male until premonitory sensations are experienced just prior to orgasm. All stimulation is stopped at this point. After repeated practices over 4 to 8 weeks, the male becomes more aware of these anticipatory sensations and is able to delay or control his ejaculation to a much greater degree. This conditioning technique is often effective when practiced regularly by the male and his partner. However, it demands significant motivation on the part of the couple, and treatment efficacy is not always maintained over time.

The use of new pharmacological treatments, particularly the serotonin-uptake inhibiting drugs (**SSRIs**), has grown considerably in recent years. Among the specific drugs used for this purpose, sertraline and paroxetine have been most extensively studied. Clomipramine, which is not a true serotonin-uptake inhibitor, although

highly serotonergic, appears the most potent inhibitor of ejaculation to date, but can cause unpleasant side-effects, such as drowsiness or light-headedness, and may also cause decreased sexual desire or loss of erectile ability in some patients. Some authors recommend initial use of one of these agents on a daily basis, and then as needed during subsequent weeks. In one study, rapid ejaculation resumed shortly after withdrawal of clomipramine therapy that had been administered for the previous 8 weeks. To guard against this, patients should be encouraged to practice conditioning exercises along with use of the medication, and a combination of drug and non-drug therapies for premature ejaculation are currently recommended by most authors, although no controlled studies have been performed.

Hypoactive sexual desire

Hypoactive or low sexual desire is reported by about 10 to 15 per cent of men in population-based or community studies. It may be due to a variety of causes, including endocrine disorders (such as hypogonadism), other medical conditions (such as renal insufficiency), psychiatric illnesses (such as depression), or psychological factors. Various prescription (such as SSRIs) and non-prescription drugs (such as alcohol) can temporarily suppress sexual desire, as can partner conflicts or other sexual problems (such as erectile dysfunction).

Men with chronic low desire should receive a thorough medical and endocrine examination, including evaluation of the hypothalamic–pituitary–gonadal axis. Treatment should be based on identification of the relevant aetiological cause, wherever possible. Currently, there are no pharmacological agents which are safe and effective for treatment of hypoactive desire disorders in men.

Priapism

Priapism is a pathological condition defined by a persistent penile erection, greater than 4 to 6 h in duration, which persists after the cessation of sexual stimulation. Priapism is distinguished from prolonged erection, defined by a penile erection lasting up to 4 h, that spontaneously undergoes detumescence. There are two forms of priapism, veno-occlusive priapism, also referred to as low-flow or ischaemic priapism, and arterial priapism. It is essential to distinguish veno-occlusive from arterial priapism since the former is an emergency urological condition.

Veno-occlusive priapism

Introduction

Veno-occlusive priapism, the more common form of the disorder, typically presents as painful, tender, and persistent penile erection. Unless treated, it may cause irreversible damage to the erectile tissue, corporal fibrosis, and permanent erectile dysfunction. Veno-occlusive priapism is the consequence of a failure to regulate corporal veno-occlusion and is a 'closed-compartment syndrome' associated with absent cavernosal arterial inflow. The pathophysiology is based on unremitting corporal venous outflow obstruction, similar to other closed-compartment syndromes in the arms and legs.

Veno-occlusive priapism typically develops in stages. At first, in the presence of complete corporal veno-occlusion, cavernosal arterial inflow persists while intracavernosal pressures are lower than cavernosal artery systolic perfusion pressures. The presence of persistent cavernosal arterial inflow without corporal venous outflow results in intracavernosal pressure and volume increasing until maximal values of each are achieved.

In the next stage, intracavernosal pressure approximates cavernosal artery systolic pressure, thereby preventing further cavernosal arterial inflow. The consequences of absent cavernosal arterial inflow over time include: (i) an increase in corporal PCO_2, (ii) a decrease in corporal pH, and (iii) a decrease in corporal PO_2. The development of corporal tissue acidosis and hypoxia in this stage of veno-occlusive priapism results in adverse biochemical and cellular changes in the corporal tissue, which act to perpetuate the completeness of corporal veno-occlusion. A partial reversal of this process may occur during this phase with pharmacological or surgical intervention, when intracavernosal pressure lower than the cavernosal artery systolic pressure is transiently achieved. However, unless the primary aetiological cause is addressed, veno-occlusion and prolonged erection will probably recur. Over time, the intracavernosal blood will again become acidotic and hypoxic. Individuals in the intermediary second stage will either resolve the veno-occlusive priapism or progress to the third and final stage.

In the final stage of veno-occlusive priapism, irreversible changes to erectile tissue result from persistent exposure to acidotic and hypoxic corporal blood, which is clinically described as black, crankcase oil in appearance. It is not yet known when irreversible erectile tissue changes occur in an individual patient. It is likely that many factors contribute to the conversion from reversible stage II to irreversible stage III veno-occlusive priapism.

Aetiology

The main causes of venous priapism are listed in Table 5. Failure to regulate corporal veno-occlusion may be secondary to extraluminal or intraluminal obstructive pathophysiologies of the subtunical venules. Classic extraluminal obstructive mechanisms include pharmacological agents that induce persistent corporal smooth muscle relaxation, such as a-blockers and drugs with a-adrenergic effects (trazodone, clozapine), or intracavernosal/intraurethral agents (papaverine, prostaglandin E_1). Androgen administration may also cause priapism, perhaps related to facilitation of nitric oxide synthase (NOS) enzyme activity. Other extraluminal obstructive pathophysiologies are related to persistent neurological stimuli from central nervous system disorders such as spinal stenosis, as well as from erectile tissue infiltration with metastatic or local invasive tumours. Common intraluminal obstructive mechanisms include hyperviscosity, haematological disorders (sickle-cell disease, leukaemia), 20 per cent lipid administration in total parenteral nutrition, or fat embolism (pelvic fractures).

Management

A precise diagnosis should be established in all cases of priapism prior to therapeutic intervention. Veno-occlusive priapism can be diagnosed either by obtaining blood gas values (PO_2, pH, PCO_2) or determining cavernosal artery Doppler flow (absent in veno-occlusive priapism; present and bounding in arterial priapism). Aspects of the patient's history, particularly the presence or absence of penile pain, may also be of value in distinguishing veno-occlusive from arterial priapism. In patients with intact sensory nerves (i.e. excluding spinal cord injury, diabetes, etc.) veno-occlusive priapism is inevitably painful because of absent arterial inflow and resulting ischaemia. Arterial priapism is rarely associated with significant penile pain, although discomfort may be reported, particularly in the perineum—often the site of trauma. Since priapism may result in irreversible erectile dysfunction, it is important to establish the premorbid erectile function of the patient.

Other important aspects of the history include the occurrence and duration of previous episodes of prolonged erection or priapism, and response to previous therapies. Individuals with previous episodes of prolonged erection, often referred to clinically as 'stuttering' priapism, should be assessed for the presence of haematological conditions, such as sickle-cell disease or trait. Past or current use of intracorporal vasorelaxants (papaverine, prostaglandin E_1), psychotropic agents (trazodone, clozapine), a-blockers (prazosin), anticoagulants (heparin, coumarin), recreational drugs (cocaine), and over-the-counter adrenergic agonists (phenylephrine) should also be carefully assessed. Other aetiological factors include: penile or perineal trauma, such as falling on to a bicycle bar; haematological neoplasms such as leukaemia; metastatic or locally infiltrating neoplasms such as renal, bladder, or prostate carcinoma; neurological conditions such as spinal cord compression or acute lumbosacral disc prolapse; coagulopathy, such as disseminated intravascular coagulopathy; and elevated intravascular fat levels such as during total parenteral nutrition or following a fat embolism.

The goal of treatment for veno-occlusive priapism is to restore normal cavernosal arterial inflow. When appropriate, based on the duration and severity of the priapism, initial treatment may consist of non-specific medical management. This will involve aspiration of intracavernosal blood and/or interval saline lavage of the corpora cavernosa with large-bore butterfly needles (bilateral if indicated), with or without a penile block (1 per cent lidocaine without adrenaline). If cavernosal arterial blood flow is not re-established, intracavernosal adrenergic agonist therapy may be initiated to induce corporal smooth muscle contraction pharmacologically and thus initiate detumescence. Interval intracavernosal irrigation with large-bore butterfly needles may also be used. When administering intracavernosal adrenergic therapy, consideration for cardiovascular monitoring should be considered, especially if the agent selected has significant b_1-activity and the patient has a history of cardiovascular disease.

When veno-occlusive priapism is related to a specific aetiology, full resolution typically requires specific medical management. Such patients include those who have utilized pharmacological agents which have induced persistent corporal smooth muscle relaxation, who have a neurogenic pathophysiology, erectile tissue infiltration, or intraluminal obstructive mechanisms such as sickle-cell disease, leukaemia, or 20 per cent lipid administration in total parenteral nutrition. All remediable causes of priapism should be managed with disease-specific therapy. This may include discontinuation of the drug causing the persistent smooth muscle relaxation (cocaine, trazodone, etc.), irradiation (leukaemia), hydration and exchange transfusion (sickle-cell disease), appropriate therapy for any neurological condition, or substituting

10 per cent for 20 per cent lipids in total parenteral nutrition.

Surgical treatment should be considered if the erection recurs despite repeated adrenergic agonist administration, thereby resulting in loss of cavernosal arterial inflow. This may consist of a Winter's procedure, which involves the development of percutaneous shunts between the corpus spongiosum and the corpora cavernosa. Should a percutaneous shunt not restore arterial inflow in the cavernosal arteries, an Al Ghorab (distal) shunt is indicated. A transverse incision is fashioned in the glans penis 1 cm proximal to the corona. Blunt dissection allows exposure and excision of the distal portions of the corpora cavernosa. The glans is then closed, creating an open fistula between the corpora cavernosa and corpus spongiosum. Several proximal shunting procedures have been described for the management of recalcitrant veno-occlusive priapism, including cavernovenous (cavernosaphenous and cavernodorsal vein) and proximal cavernosal–spongiosal (Quackles). The role of these procedures and their indications are not clearly defined.

Arterial priapism

Arterial priapism is a rare condition involving the inability to regulate arterial inflow, the usual cause being trauma to the perineum or penis. Such trauma can result in a lacerated cavernosal artery that sends arterial blood directly to the lacunar spaces, bypassing physiological helicine arteriolar resistance mechanisms. An arterial–lacunar fistula can often be identified on duplex Doppler ultrasonography (usually located in the perineum) and selective internal pudendal arteriography. Clinical presentation is with a painless, non-tender, moderately (not fully) rigid penile erection.

Arterial priapism is not a medical emergency since the condition does not involve absent cavernosal arterial inflow with resultant erectile tissue ischaemia. Management involves 'watchful waiting'. For patients who wish to undergo treatment, surgical ligation of the cavernosal artery fistula or arterial embolization is typically performed.

Female sexual dysfunction

Introduction

Female sexual dysfunctions are broadly defined as alterations or disturbances in sexual functioning in women that are associated with subjective dissatisfaction or distress. These consist primarily of disorders of sexual desire, arousal, orgasm, and/or sexual pain (Table 6). While each of these disorders is uniquely defined, there is often significant overlap in affected patients. As noted above, about 40 per cent of adult women in community-based studies complain of one or more sexual dysfunctions in the past year. There has been limited investigation of the anatomy, physiology, and molecular biology of female sexual response, and the aetiology and pathophysiologies of specific sexual dysfunctions in women are not well understood. Stimulated in part by advances in male sexual dysfunction, there is increasing interest in basic science and clinical management aspects of female sexual dysfunction.

Anatomy and physiology

There are multiple anatomical structures which comprise the internal and external female genital tract, including the clitoris, labia minora, and corpus spongiosum (vestibular) erectile tissue, periurethral glans, urethra, anterior fornix, pubococcygeus muscle, and cervix. There are also multiple non-genital peripheral anatomical structures involved in female sexual response, such as salivary and sweat glands, cutaneous blood vessels, and nipples.

Internal and external genitalia

The vagina consists of a cyclindrical sheath of autonomically innervated smooth muscle (longitudinal outer, inner circular layer) lined by stratified squamous epithelium and a subdermal layer rich in capillaries. The vaginal wall consists of an inner glandular mucous-type stratified squamous cell epithelium supported by a thick lamina propia. This epithelium undergoes hormone-related cyclical changes, including slight keratinization of the superficial cells during the menstrual cycle. Deep to the epithelium lies the smooth muscle of the muscularis. There is a surrounding deeper fibrous layer above the muscularis, which provides structural support to the vagina and is rich is collagen and elastin, to allow for expansion of the vagina during sexual stimulation. Three sets of skeletal muscles surround the vagina, including the ischiocavernosum, bulbocavernosus, transverse perinei and levator ani, and pubococcygeus muscles.

The main arterial supply to the vagina flows to its superior aspect and arises from vaginal branches of the uterine artery. The middle portion of the vagina receives blood from the inferior vaginal artery, a branch of the hypogastric artery. The middle haemorrhoidal and the clitoral arteries send branches to the distal aspect of the vagina.

Autonomic efferent innervation of the vagina originates from the hypogastric plexus and the sacral plexus. These give rise to the uterovaginal nerves that contain both parasympathetic and sympathetic fibres, travelling within the uterosacral and cardinal ligaments to supply the proximal two-thirds of the vagina and the corporal bodies of the clitoris. Somatic afferent innervation is provided by the pudendal nerve, which reaches the perineum through Alcock's canal. There is an abundance of nerve fibres in the distal and anterior aspect of the vagina: these play a major role in sexual function and can easily be injured during pelvic surgery, or from blunt perineal trauma.

The vulva includes the labia minora, labia majora, the clitoris, the urinary meatus, the vaginal opening, and the corpus spongiosum erectile tissue (vestibular bulbs) of the labia minora. The labia majora are fatty folds covered by hair-bearing skin that fuses anteriorly with the mons veneris, or anterior prominence of the symphysis pubis, and posteriorly with the perineal body or posterior commissure. The labia minora are smaller folds covered by hairless skin laterally and by vaginal mucosa medially, and which fuse anteriorly to forms the prepuce of the clitoris, and posteriorly in the fossa navicularis. The perineal branch of the pudendal nerve innervates the labia. The main arterial supply arises from the inferior perineal branch of the internal pudendal, and by branches of the femoral artery.

The corpus spongiosum erectile tissues are paired structures located beneath the skin of the labia minora. The arterial supply is by the bulbar and posterior labial branches of the internal pudendal artery. The corpus spongiosum terminates in the glans clitoris. The corpora cavernosa of the clitoris measure up to 13 cm in length. The body of the clitoris consists of two paired erectile chambers composed of endothelial-lined lacunar spaces, trabecular smooth muscle, and trabecular connective tissue (collagen and elastin) surrounded by a fibrous sheath, the tunica albuginea. The arteries include the dorsal and clitoral cavernosal arteries, which arise from the iliohypogastric pudendal bed. The autonomic efferent motor innervation occurs via the cavernosal nerve of the clitoris, arising from the pelvic and hypogastric plexus.

As described above, the sexual response cycle in both men and women occurs in four stages: desire, arousal, orgasm, and resolution. The mechanisms underlying sexual response are less well understood in women than in men, particularly the role of central nervous system and hormonal processes. Sexual arousal responses in the genital and non-genital peripheral anatomical structures are largely the product of spinal cord reflex mechanisms. The spinal segments are under descending excitatory and inhibitory control from multiple supraspinal sites. The afferent reflex arm is primarily via the pudendal nerve; the efferent reflex arm consists of co-ordinated somatic and autonomic activity. One spinal sexual reflex is the bulbocavernosus reflex involving sacral cord segments S2, 3, and 4 in which pudendal nerve stimulation results in pelvic floor muscle contraction. Another spinal sexual reflex involves vaginal and clitoral cavernosal autonomic nerve stimulation and results in clitoral, labial, and vaginal engorgement.

In the unstimulated state, clitoral corporal and vaginal smooth muscles are under contractile tone. Following sexual stimulation, neurogenic- and endothelial-mediated release of nitric oxide (NO) plays a key role in clitoral cavernosal artery and helicine arteriolar smooth muscle relaxation. This leads to clitoral engorgement, a rise in clitoral cavernosal artery inflow, and an increase in clitoral intracavernosal pressure. The result is extrusion of the glans clitoris and enhanced sensitivity.

In the basal state the vaginal epithelium reabsorbs sodium from the submucosal capillary plasma transudate. Following sexual stimulation, neurotransmitters including NO and vasoactive intestinal peptide modulate vaginal and vaginal arteriolar smooth muscle relaxation. A dramatic increase in capillary inflow in the submucosa overwhelms sodium reabsorption leading to 3 to 5 ml of vaginal transudate, enhancing lubrication essential for pleasurable coitus. Vaginal smooth muscle relaxation results in increased vaginal length and luminal diameter, especially in the distal two-thirds. Vasoactive intestinal polypeptide is a non-adrenergic non-cholinergic neurotransmitter that plays a key role in enhancing vaginal blood flow, lubrication, and secretions.

Hormones

Steroid hormones play an important role in the regulation of female sexual function. Symptoms associated with diminished oestrogen include vaginal dryness, irritation, and pain, as well as causing complaints regarding sexual function such as decreased sexual arousal, decreased genital sensation, and difficulty achieving orgasm. Oestrogen replacement in postmenopausal or surgically menopausal women restores clitoral and vaginal pressure thresholds to premenopausal levels. Oestrogens have also vasoprotective and vasodilatory effects, which result in increased vaginal and clitoral blood flow, preventing atherosclerotic compromise of the iliohypogastric arterial bed. Thickness and rugae of the vaginal wall, as well as vaginal lubrication, are both oestrogen dependent. Oestrogen also improves integrity of vaginal mucosal tissue and has beneficial effects on vaginal sensation, vasocongestion, and secretions. By contrast, oestrogen deprivation leads to decreased pelvic blood flow resulting in clitoral fibrosis, thinned vaginal epithelial layers, and decreased vaginal submucosal vasculature.

In addition to conventional hormone replacement therapy and topical oestrogen creams, exogenous water- and oil-based lubricants have been used for alleviating symptoms of vaginal irritation and dryness. Although some of these agents have properties similar to vaginal fluid, they are limited by application time and duration of effectiveness. Oestrogen replacement therapy and oestrogen creams are effective for relieving symptoms of vaginal dryness in many women, but they are not a viable alternative for all women.

Low testosterone levels are often associated with a decline in sexual arousal, genital sensation, libido, and orgasm. Testosterone administration in women with decreased desire has been successful, although there are no currently approved testosterone preparations for this purpose. It has also been shown that menopausal women respond better to parental oestrogen–androgen than oestrogen alone in restoring sexual desire, energy, and sense of well being.

Specific sexual dysfunctions in women

Hypoactive sexual desire disorder

Hypoactive sexual desire disorder is defined as chronic or persistent deficiency of sexual interest or desire. It is distinguished from sexual aversion disorder, which is characterized by persistent or recurrent phobic aversion to, and avoidance of, sexual contact with a partner. Hypoactive sexual desire disorder is the most commonly reported sexual problem in women, affecting approximately 20 to 30 per cent of those aged 30 to 70 years. It is age-related and strongly associated with other medical and psychiatric disorders, particularly chronic illnesses and depression. It may be related to the use of prescription drugs, particularly antidepressants (e.g. SSRIs), alcohol abuse, or hormonal changes. Low sexual desire in women is also frequently associated with partner conflicts or the presence of other sexual dysfunctions (such as erectile dysfunction, anorgasmia). The degree of personal distress associated with the disorder varies widely and should be taken into account in making the diagnosis.

Female sexual arousal disorder

Female sexual arousal disorder refers to a chronic or persistent lack of subjective or physical arousal during sexual stimulation. This is characterized by an inability to achieve an adequate lubrication–swelling response of the vagina and labia for the completion of sexual activity, or a lack of subjective arousal during sexual activity. Although women with sexual arousal disorder may perform intercourse, the lack of adequate lubrication may result in pain or vaginal irritation. Findings from the National Health and Social Life Survey in the United States showed that approximately 20 per cent of women aged 18 to 59 reported difficulty in lubrication during sexual stimulation. Similar prevalence estimates were reported in a large-scale British study, which also found that sexual arousal difficulties became commoner with agieng, and that marital difficulties, anxiety, and depression were all significant risk factors.

Orgasmic disorder

Orgasmic disorder in women is a persistent or recurrent difficulty, delay in, or absence of orgasmic attainment despite adequate sexual stimulation and arousal. Primary anorgasmia refers to the woman who has never experienced orgasm through any means, whereas secondary orgasmic dysfunction occurs when a woman is unable to have orgasm with a particular partner or by means of specific stimulation (i.e. sexual intercourse). Both types of orgasmic dysfunction are common, affecting 10 to 20 per cent of women in population-based studies and associated with medical or psychiatric illnesses, use of prescription or non-prescription drugs, and specific neurological disorders (such as spinal cord injury). Relationship conflicts were also found to be significantly associated with the occurrence of orgasmic difficulties in women in a recent British study.

Dyspareunia

Dyspareunia, or pain associated with sexual intercourse, is common in women. The pain may occur before, during, or after intercourse. In most cases it is caused by a lack of lubrication or other physical cause. According to the National Health and Social Life Survey, about 15 per cent of women have experienced pain during sexual activity during the past year. In postmenopausal women, the prevalence of dyspareunia may be even higher. A wide variety of medical or organic conditions are associated, including hymenal scarring, pelvic inflammatory disease, and vulvar vestibulitis. However, dyspareunia is not reliably associated with any particular medical disorder. Moreover, anatomical or physiological factors that may have caused the original pain may not be the same factors responsible for maintaining it. Accordingly, some authors have recommended an interactive or multidimensional model of physical and psychological determinants of dyspareunia.

Vaginismus

Vaginismus, or involuntary spasms of the musculature of the outer third of the vagina, is a significant cause of penetration difficulties in women. The disorder is often seen in sex therapy clinics, occurring in approximately 15 to 17 per cent of women presenting for treatment who often complain of secondary dyspareunia in addition to other sexual dysfunctions. Women with primary or generalized vaginismus typically avoid gynaecological examinations and tampon use, in addition to sexual intercourse. Vaginismus can occur in association with vaginal pain due to various medical conditions, although it is more frequently related to psychological or interpersonal factors.

Management of female sexual dysfunction

Diagnostic assessment

There is no consensus on the routine diagnostic assessment of the woman with sexual dysfunction. Common features of the work-up typically include history (sexual, psychosocial, and medical), physical examination (external genitalia, internal genitalia), and laboratory testing (oestrogen, testosterone, glucose, full blood count, creatinine, liver function tests, cholesterol, urine analysis, vaginal cultures as appropriate). Specialized tests, such as vaginal photoplethysmography, have been reported in the literature, but are not used in routine clinical practice. Other specialized investigations may include: (i) neurological (somatosensory evoked potential, electromyography), (ii) hormonal, and (iii) psychological (depression, anxiety).

Treatment

There are limited data on safety and efficacy of the various primary psychological and hormonal treatments that have been used for female sexual dysfunction.

Psychological therapy has demonstrated efficacy in sexual desire, orgasmic disorders, vaginismus, and sexual pain disorders. Oestrogen and/or androgen replacement hormonal therapy may be useful in sexual desire, arousal, orgasmic, and dyspareunia sexual pain disorders. Oestrogen replacement is indicated in menopausal women to relieve hot flushes, prevent osteoporosis, lower the risk of cardiovascular disease, improve clitoral sensitivity, and decrease pain and burning during intercourse. In combination with oestrogen, methyl testosterone is used to treat symptoms of inhibited desire, dyspareunia, and lack of vaginal lubrication, as well as for its vasoprotective effects.

Other treatment options with scant efficacy and safety evaluations include vaginal lubricants, vasodilator agents such as sildenafil citrate, vaginal dilators, pelvic floor rehabilitation using biofeedback electromyography, and Kegel exercises.

Patient and partner education is an essential component in the management of female sexual dysfunction and should be a continuous element at each phase in the process of care. Modification of known risk factors (hypertension, hyperlipidaemia, prescription drugs, cigarette smoking, and alcohol abuse) and self-destructive

behaviours is part of good clinical practice.

Summary

Female sexual dysfunction is age-related and common, affecting 30 to 50 per cent of women. Improved understanding of both normal and dysfunctional sexual response in women is the keystone to enhanced management. A collaborative and comprehensive evaluation, patient and partner education, modification of reversible causes, and an individualized treatment plan should be the standard management of women with sexual dysfunction.

Basic science and clinical research in female sexual function and dysfunction are needed to overcome the gender gap, achieve a more balanced therapeutic perspective between psychological and physiological factors, and offer female patients enhanced opportunity for relief of a persistent or recurrent sexual condition that causes significant personal distress.

12.9.1 Normal and abnormal sexual differentiation

M. O. Savage

Introduction

Disorders of sexual differentiation are characterized by an abnormality in the formation of the internal or external genital structures. Most are genetically determined and are associated with an ambiguous appearance of the external genitalia. During the past three decades, the study of intersex disorders has changed in orientation. The emphasis has moved away from descriptive clinical syndromes towards the biochemical and molecular nature of the defects that cause them. If such an aetiological approach is to be used, a fundamental understanding of normal sexual differentiation is required. This provides the basis for the classification, investigation, and management of patients with abnormal sexual differentiation.

Physiology of fetal sexual differentiation

In the male, it is established that the castrated embryo develops as a female, indicating that the fetal testis is essential for male development. The chromosomal sex of the embryo, established at conception, directs the development of either ovaries or testes. In the male, specific genes on the short arm of the Y chromosome, known as the sex-determining region of the Y chromosome, code for testis determination, and hence contribute to testicular differentiation. Testicular Leydig cells synthesize and secrete testosterone from 8 weeks of gestation, aided by stimulation with placental human chorionic gonadotrophin (hCG). Testosterone diffuses locally to maintain and virilize the wolffian ducts which become the vas deferens, seminal vesicles, and epididymis. Antimüllerian hormone, or müllerian-inhibitory factor, is a glycoprotein which is secreted during the same time period by testicular Sertoli cells to inhibit the formation of the uterus, fallopian tubes, and upper vagina from the müllerian structures.

In androgen-dependent tissues, testosterone is converted to dihydrotestosterone which virilizes the external genitalia. Peripheral androgen action depends on the binding of the androgen in the target tissues to a receptor coded by an X chromosome.

In the female, ovarian development occurs in the presence of two X chromosomes and external gonadal development occurs spontaneously. Genital development in both sexes is completed by 20 weeks of fetal life. In the male, growth of the formed penis is dependent upon continued testicular testosterone secretion under stimulation by pituitary gonadotrophins.

Classification of intersex states

The classification that forms the basis of clinical assessment and management depends on gonadal morphology (Table 1). Female pseudohermaphroditism describes genital ambiguity resulting from abnormal virilization of a female with normal ovaries. The male counterpart—male pseudohermaphroditism—is the result of incomplete virilization of a male with differentiated testes. Thirdly, the true hermaphrodite possesses both ovarian and testicular tissue.

Female pseudohermaphroditism

Female pseudohermaphrodites have 46 XX karyotypes with normal ovaries and müllerian structures, but the external genitalia are virilized. The aetiology of female pseudohermaphroditism is given in Table 2. The degree of genital ambiguity can range from enlargement of the clitoris or fusion of the posterior labia to a completely male appearance, depending on the timing of androgen production and the concentration of androgens in the fetal circulation. Virilization may be caused by excessive production of either fetal or maternal androgens.

Virilization by fetal androgens

Congenital adrenal hyperplasia (see also Chapter 12.7.2)

The commonest cause of ambiguous genitalia in the newborn female is a recessively inherited enzyme defect of cortisol synthesis, with diversion of intermediates to androgen production. A reduction in steroid 21-hydroxylase or absence of 11b-hydroxylase or 3b-hydroxysteroid dehydrogenase can be the cause of this condition. These enzymes are part of the steroid biosynthetic pathways which link cholesterol with cortisol, aldosterone, and androgens. In the absence of, or lowered potential for, cortisol production, there are high adrenocorticotrophic hormone (ACTH) levels leading to adrenal hyperplasia and excess androgen production.

21-hydroxylase deficiency

This form of congenital adrenal hyperplasia accounts for 90 per cent of cases of female pseudohermaphroditism, and should be excluded before proceeding to assign other causes for ambiguous genitalia. The degree of virilization can be variable (Fig. 1). In Europe, 60 per cent of all cases will develop salt depletion due to decreased production of aldosterone in the first 2 weeks of life. Usually, there is enlargement of the clitoris associated with a degree of posterior labial fusion and the formation of a hypoplastic lower vagina which may open into the urethra.

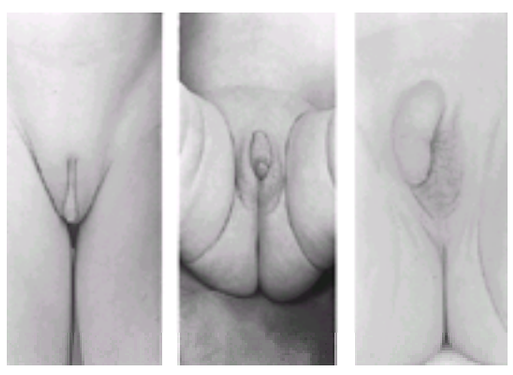

Fig. 1 Variation in degree of virilization in three female infants with 21-hydroxylase deficiency.

17-Hydroxyprogesterone is a biosynthetic precursor of cortisol, and plasma levels are elevated in 21-hydroxylase deficiency. After the third day of life, there is good discrimination between plasma levels of 17-hydroxyprogesterone in affected cases (100–800 nmol/l) and those of normal infants (less than 15 nmol/l). Measurement of plasma renin activity and aldosterone help to define the extent of mineralocorticoid deficiency. Analysis of urine steroid excretion using chromatography and mass spectrometry can provide a reliable diagnostic profile from day 3 after birth. A variant of 21-hydroxylase deficiency, due to a milder defect, is the non-classical form of the disease, characterized by absence of neonatal genital ambiguity but development of other signs of androgen excess such as hirsutism.

11b-hydroxylase deficiency

This defect probably accounts for about 5 per cent of all cases of congenital adrenal hyperplasia. The disorder is caused by mutations of the *CYP11B1* gene which abolish enzyme activity. The virilization may be severe, with affected females sometimes raised as males. The plasma concentration of 11-deoxycortisol (compound S) is elevated, and may exceed 1000 nmol/l. The urine steroid pattern will show high excretion of 6-hydroxytetrahydro-11-deoxycortisol as well as of tetrahydro-S.

3b-hydroxysteroid dehydrogenase deficiency

This rare defect was originally described in male infants with incomplete virilization. However, a paradoxical androgen affect may be seen in female infants due to a very high level of dehydroepiandrosterone, the steroid precursor immediately proximal to the enzyme block. A non-classical or attenuated form of 3b-hydroxysteroid dehydrogenase deficiency has been described which presents with virilization in postadrenarchal or peripubertal females.

Virilization by maternal androgens

Virilization of the external genitalia by a maternal ovarian or adrenal androgen-secreting tumour is a rare but well-recognized cause of female pseudohermaphroditism. The degree of virilization may be striking.

Other causes of fetal virilization

Female pseudohermaphroditism due to maternal administration of progestogen preparations became recognized about 30 years ago. A number of dysmorphic childhood syndromes may also be associated with virilized female genitalia.

Male pseudohermaphroditism

Male pseudohermaphroditism arises as a result of a disturbance of male genital development in patients with testes and a 46 XY karyotype. The genital anomaly can vary from apparently female to male external genitalia with a small penis or perineal hypospadias. The three main aetiological groups (Table 3) are impaired Leydig cell activity, peripheral androgen insensitivity, and deficient testosterone and antimüllerian hormone production by incompletely differentiated testes.

Impaired testicular secretion of testosterone

Inborn errors of testosterone biosynthesis

These rare disorders (Fig. 2) lead to defective testosterone synthesis during the critical period of fetal sexual differentiation. The result is inadequate testosterone secretion, either locally to virilize the wolffian ducts to form the vas deferens, seminal vesicles, or epididimis, or peripherally to virilize the external genitalia. Synthesis of antimüllerian hormone, being a glycoprotein rather than a steroid, is unaffected. When the enzyme deficiency, inherited as an autosomal recessive trait, is situated early in the biosynthetic pathway, adrenal steroid synthesis may also be affected.

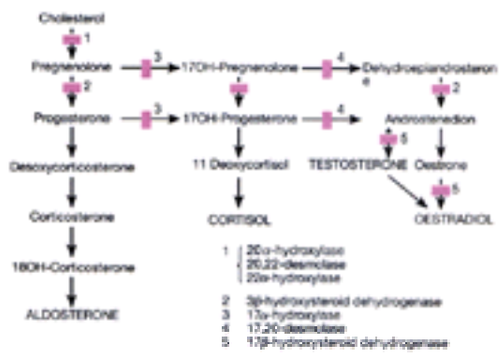

Fig. 2 Enzyme defects in testosterone biosynthesis.

Deficient formation of pregnenolone

Three closely related microsomal enzymes (20a-hydroxylase, 20,22-desmolase, and 22a-hydroxylase) are necessary for the conversion of cholesterol to pregnenolone. Deficiency of one of these enzymes leads to impaired synthesis of cortisol, aldosterone, and testosterone. Accumulation of cholesterol has been demonstrated in the hyperplastic adrenal leading to the term congenital lipoid adrenal hyperplasia. Recently, the gene responsible for the disorder has been cloned and validated by the demonstration of a non-sense mutation. The gene encodes for a protein named StAR (steroidogenic acute regulatory protein).

Deficiency of 3b-hydroxysteroid dehydrogenase

Male patients with this enzyme deficiency are poorly virilized and usually develop salt loss and adrenal failure in infancy. Some subjects have survived puberty, which has been characterized by virilization and gynaecomastia. Urinary pregnenetriol and plasma dehydroepiandrosterone are elevated, as is plasma renin activity. Several mutations of the type II 3b-hydroxysteroid dehydrogenase enzyme have been reported.

Deficiency of 17a-hydroxylase

This defect in cytochrome P450c17 results in decreased cortisol synthesis by the adrenal cortex and testosterone by the fetal testes, resulting usually in a omplete lack of virilization. Several different mutations of the *CYP17* gene have been reported. The disorder is identified biochemically by demonstrating high serum and urinary levels of progesterone and corticosterone. A compensatory increase in ACTH leads to excess mineralocorticoid secretion, causing hypertension, hypokalaemia, and low plasma renin activity.

Deficiency of 17,20-desmolase

This rare defect is related to 17-hydroxylase deficiency as both enzyme activities are coded by the same gene. Impaired virilization may be variable in degree. Biochemically, identification of the defect relies on elevation of plasma 17-hydroxyprogesterone, 17-hydroxypregnenolone, and urinary pregnanetriolone.

Deficiency of 17-ketosteroid reductase (17b-hydroxysteroid dehydrogenase)

Patients with this defect are born with female-looking external genitalia and a phallus closely resembling a normal clitoris. There are three types of 17b-hydroxysteroid dehydrogenase enzyme. Abnormalities of the type 3 enzyme, which has specific testicular expression, causes this disorder and several different mutations of the

respective gene have been described. There is a high prevalence of this disorder within the Arab population of the Gaza Strip. The enzyme defect interferes with conversion of androstenedione to testosterone, adrenal steroid synthesis being unaffected. There is elevation of the androstenedione to testosterone ratio, particularly after hCG stimulation. Subjects are usually raised as girls; however, gender conversion to male has been described, coinciding with the marked virilization which occurs at puberty.

Androgen insensitivity syndromes

Mechanisms of androgen action

Testosterone, the principal androgen secreted by the testis, circulates bound to two proteins, sex hormone binding globulin and albumin. The protein-bound steroid is in dynamic equilibrium with the free hormone. Free testosterone enters the target cell by a passive mechanism (Fig. 3). Inside the cell, testosterone can be reduced to dihydrotestosterone by the enzyme 5a-reductase. Testosterone or dihydrotestosterone binds with high affinity to specific receptor proteins to form an androgen–receptor complex. This complex enters the cell nucleus and, after transformation into a DNA binding state, binds to specific nucleotide sequences which promote transcription of messenger RNA, resulting in clinical virilization. The gene encoding the human androgen receptor has recently been cloned.

Fig. 3 Scheme of intracellular androgen action (adapted from Hughes and Pinsky, 1989). T, testosterone; DHT, dihydrotestosterone; R, receptor.

Although testosterone and dihydrotestosterone bind to the same receptor, the two hormones perform different roles in androgen physiology (Fig. 4). Testosterone regulates secretion of luteinizing hormone, virilizes the wolffian ducts during fetal life, and may be essential for spermatogenesis. Dihydrotestosterone is responsible for formation of the external genitalia and prostate, and for most secondary sexual effects, such as hair growth and enlargement of the genitalia.

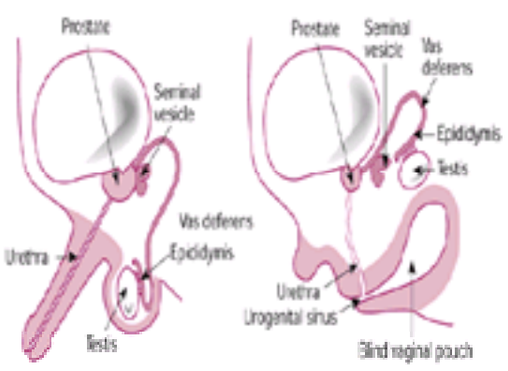

Fig. 4 Roles of testosterone and dihydrotestosterone in male sexual differentiation in the normal male (left) and the patient with 5a-reductase deficiency (right). Testosterone, heavy shading; dihydrotestosterone, light shading.

Clinical features of androgen insensitivity

Abnormalities of androgen action may have a severe effect on male sexual differentiation, resulting in incomplete virilization during fetal life and at puberty. The syndromes of androgen insensitivity probably account for the majority of cases of male pseudohermaphroditism. There are three main forms. The most important numerically is an X-linked cystolic androgen receptor defect. This may be manifested by a broad clinical spectrum from complete androgen insensitivity to a virtually normally formed male with infertility. The second form is known as receptor-positive resistance, where a similar spectrum of clinical defects is associated with apparently normal receptor function. Thirdly, 5a-reductase deficiency is an autosomally inherited enzyme defect resulting in impaired conversion of testosterone to dihydrotestosterone in the target cell.

Androgen receptor defects

These defects may be expressed clinically as a spectrum of deficient formation of the male internal and external genitalia.

Complete androgen insensitivity

The typical patient with presents after puberty with primary amenorrhoea, or before puberty with inguinal hernias and palpable testes. The phenotype and psychosexual orientation is female. Breasts develop as in a normal woman, but pubic and axillary hair is scanty and the vagina is blind-ending due to regression of müllerian structures, which are virtually always absent. Wolffian structures are usually absent and the gonads show Leydig cell hyperplasia with no spermatogenesis. There is a significant risk of gonadal malignancy occurring after puberty, when gonadectomy is recommended.

Incomplete androgen insensitivity

Here there is a range of impaired virilization from clitoral enlargement and labial fusion to small external genitalia, usually with hypospadias. At puberty, feminization may be dominant, with gynaecomastia a feature in some patients.

The endocrine features of androgen insensitivity are essentially similar in the range of clinical defects. Testicular androgen secretion is normal or increased. Plasma testosterone may be elevated in infancy but is normal during the remainder of the prepubertal period. At puberty, plasma testosterone, oestradiol, and sex hormone binding globulin levels are elevated. Plasma gonadotrophins are normal in childhood but both luteinizing hormone and follicle stimulating hormone levels are consistently elevated during and after puberty, due to insensitivity of the hypothalamic androgen receptor. Patients are usually infertile.

5a-Reductase deficiency

This autosomal recessive disorder is characterized by impaired conversion of testosterone to dihydrotestosterone in androgen-dependent target cells. It was first described in the Dominican Republic, and occurs principally in areas of high consanguinity. The clinical features can be summarized as showing male internal genital structures and female external genitalia (Fig. 4). Fetal dihydrotestosterone-dependent development is abnormal, resulting in a rudimentary phallus and absent prostate. The wolffian structures develop normally, and the testes differentiate with spermatogenesis capable of progressing to the spermatozoa stage. Most subjects

are raised as females but gender conversion to male occurs at puberty, coinciding with striking virilization of body habitus (Fig. 5) and male psychosexual orientation. Virilization during and after puberty, however, is incomplete, as the penis remains small and body and facial hair is sparse.

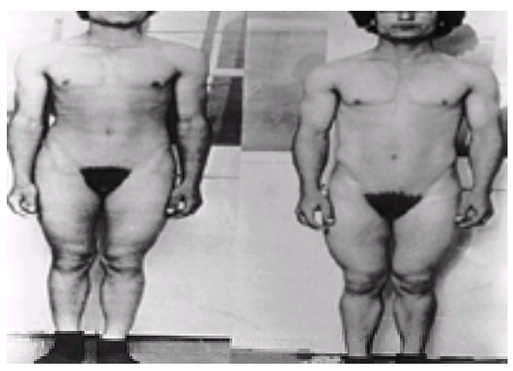

Fig. 5 Two Greek Cypriot brothers with 5a-reductase deficiency.

The endocrine features comprise low plasma dihydrotestosterone with normal testosterone and an elevated testosterone to dihydrotestosterone ratio. This abnormal ratio is the cardinal diagnostic feature. There is also elevation of the ratio of 5b : 5a androgen metabolites (i.e. aetiocholanolone to androsterone) in urine.

Male pseudohermaphroditism related to abnormal testicular differentiation

Incomplete differentiation of the fetal testes due to a defect of the Y-chromosomal genes responsible for testicular determination may cause genital ambiguity. Incompletely formed or dysgenetic testes secrete insufficient testosterone and antimüllerian hormone for normal male development. A number of clinical syndromes exist in this category.

Dysgenetic male pseudohermaphroditism

In this syndrome there are bilateral dysgenetic testes, persistent müllerian structures, cryptorchidism, and poorly virilized external genitalia.

Mixed gonadal dysgenesis

Here there is asymmetrical gonadal differentiation with a testis present on one side and a streak gonad on the other. The internal structures are also asymmetrical, reflecting the endocrine function of the ipsilateral gonad. Many patients have a mosaic XO/XY karyotype and features of Turner's syndrome.

Drash syndrome

This syndrome combines dysgenetic testes, genital ambiguity, glomerulonephritis, and Wilms' tumour.

True hermaphroditism

The diagnosis of true hermaphroditism is made when ovarian as well as testicular tissue is present in the same individual. Van Niekerk has published an extensive review of the literature, including a large personal series. The most common presenting symptoms are abnormal appearance of the external genitalia. Most patients have a 46 XX karyotype: about half are pure 46 XX and about a third are mosaics or chimeras with 46 XX cell lines, that is 46 XX/46 XY. A few patients with a pure 46 XY karyotype have been reported. Occasional familial cases of true hermaphroditism have been described in the literature.

Other 46 XX intersex states

Pure gonadal dysgenesis

This disorder, which may be familial, is usually associated with female external genitalia. Clitoromegaly is sometimes present. The gonads are streaks and the karyotype may be 46 XX or XY. 46 XY gonadal dysgenesis, inherited as an X-linked recessive or male-limited autosomal dominant condition, has also been described.

XX male

A number of XX males have been described. These are normal-appearing males with normal intelligence and male psychosexual orientation. Gynaecomastia, sparse facial hair, small genitalia, and hypospadias may occur in this syndrome. The testes are small and resemble Klinefelter testes histologically. There is absence of spermatogenesis, leading to sterility. Families have been reported containing both an XX male and a 46 XX true hermaphrodite.

Gonadal neoplasia and intersex states

It is now established that a number of intersex disorders carry an increased risk of gonadal tumours. Two important risk factors are the presence of dysgenetic gonadal tissue and a Y chromosome. Intra-abdominal gonads are more susceptible than scrotal glands. The commonest tumour is a gonadoblastoma which is a premalignant lesion but can progress to an invasive tumour.

Clinical and laboratory assessment of patients with intersex states

The assessment of patients with intersex states may be considered from the point of view of the paediatrician assessing an infant with ambiguous genitalia. The same principles apply to the older child or adult. It must be emphasized that the general appearance of the external genitalia, while important in deciding the appropriate gender for the child, is of very little help in defining the aetiology of the disorder.

Clinical assessment

The principles of clinical assessment are shown in Table 4. A history of a similar disorder in other family members may shed light on the likely diagnosis. Many of these conditions are genetically determined. Examination for other anomalies which could point to a dysmorphic syndrome known to be associated with abnormal genital development is also relevant. The most important aspect of the examination, however, is careful palpation of the gonads.

If no gonads are palpable, the most likely diagnosis is female pseudohermaphroditism due to congenital adrenal hyperplasia, and this is virtually certain if symptoms of salt loss develop. Other possible disorders are true hermaphroditism or male pseudohermaphroditism with intra-abdominal gonads. When both gonads are palpable in the scrotum or labial folds, the patient is likely to be a male pseudohermaphrodite, and measurement of plasma androgens will indicate whether the aetiology is a testicular or peripheral defect. A true hermaphrodite with bilateral ovotestes may also present in this way. The presence of only one palpable gonad or asymmetry of the perineum is suggestive of mixed gonadal dysgenesis; true hermaphroditism with asymmetrical gonads is the other differential diagnosis.

Laboratory assessment

A similar scheme may be devised as a guide to confirming the aetiology biochemically (Table 5). In all intersex patients a karyotype is indicated. If no gonads are palpable, determination of plasma 17-hydroxyprogesterone will confirm or exclude 21-hydroxylase deficiency. In 11b-hydroxylase deficiency the plasma 11-deoxycortisol concentration is elevated. The infant with two palpable gonads needs an hCG stimulation test to assess testicular androgen secretion. Numerous hCG regimens exist, of which two examples are 1000 IU daily for 3 days or a single injection of 1500 IU/m ^{2} body surface area. Basal and poststimulatory concentrations of testosterone, dihydrotestosterone, and androstenedione should distinguish a disorder of testosterone biosynthesis from a syndrome of androgen insensitivity.

If one gonad is palpable, gonadal biopsy may be helpful, particularly if ovarian tissue is suspected. Pelvic ultrasonography or exploratory laparotomy for identification of internal genital structures may also be indicated. In any patient with incomplete virilization, urethrography should be performed to identify a vaginal cavity communicating posteriorly with the urethra.

Medical management

Choice of gender

Parents are usually shocked to learn that there is doubt as to the sex of their child; they are often under the impression that the child may grow up to be neither male nor female. Temptation to give a provisional opinion should be avoided until the nature of the disorder is known and an informed answer can be given. The decision as to the appropriate sex-of-rearing is based mainly on the appearance of the external genitalia and on the likely pattern of secondary sexual development at puberty. This decision should be taken jointly by the endocrinologist, urologist, and the parents. The gender should be assigned as soon as possible; however, in some cases of severe ambiguity, there is a case for waiting to assess the effect of early treatment with depot testosterone (25–50 mg at monthly intervals) on phallic growth as a guide to androgen responsiveness.

The concept that, once established, gender identity and role are more or less fixed has now been questioned. Although change of gender may be extremely difficult, the possibility of gender conversion should be viewed with an open mind in the individual subject who, because of spontaneous virilization or feminization at puberty, finds existence in their original gender intolerable.

Sex hormone therapy

Long-term treatment with androgens to promote phallic growth in early childhood has rightly fallen into disrepute because of the acceleration of bone maturation, which leads to loss of ultimate growth potential. While standard testosterone treatment is effective for inducing pubertal development in males with androgen-responsive syndromes, it is of limited value in patients with androgen insensitivity. Induction of full masculization in these patients is still very unsatisfactory. It has, however, been demonstrated that some further virilization in adult patients may be effectively induced using supraphysiological doses of depot testosterone (500 mg weekly). Effects, albeit slow to appear, were seen specifically in penile length and facial and body hair growth.

12.9.2Normal growth and its disorders

M. A. Preece

The normal curve of growth

The upper panel of Fig. 1 shows the curve of height attained (or distance) for a typical male from birth to 18 years of age. It contains all the relevant information about growth in height of an individual child. In the lower panel the growth data have been converted to height velocity in cm/year. This is calculated from the distance data by dividing the difference between two height measurements (as close to 1 year apart as possible) by the exact time elapsed between them. The calculated velocity is plotted at the midpoint of the time interval over which it is measured. This representation of growth is particularly useful as it emphasizes the dynamic nature of the growth process.

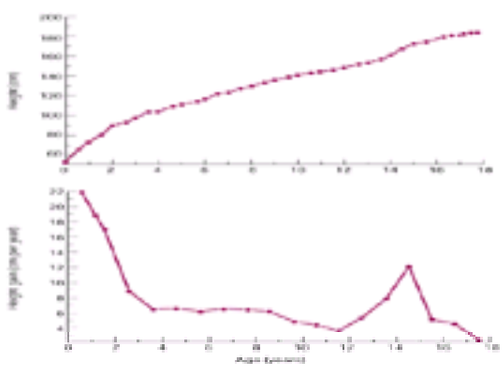

Fig. 1 The growth in height of an individual boy from birth to 18 years of age. The top panel shows the height attained or distance curve and the lower panel shows the data replotted as height gain or growth velocity. (Reproduced from Tanner JM (1962). *Growth at adolescence*, Blackwell, Oxford, with permission.)

The growth velocity in any one year is a more sensitive measure of events occurring in that year than is the coincident height distance datum, which is a measurement summating all previous growth. Thus, the more sensitive measures of the velocity curve may show rather dramatic change in growth during disease or during treatment, where the simpler distance curve would be less sensitive.

There are three epochs of growth: early, rather fast growth before the age of 2 years; relatively slow steady growth during the preschool and primary school years; and then the period around puberty when the adolescent growth spurt dominates the growth pattern.

Epochs of growth

Infancy

During the first year of life the infant has an average height velocity of about 25 cm/year. However, since this is a time when the velocity is changing dramatically, measurement over shorter time periods should be considered. The velocity during the first 3 months is equivalent to 3.3 cm/month in boys and 3.0 cm/month in girls, dropping to 1.2 cm/month and 1.3 cm/month respectively by the last 3 months of that year. During the next 3 years there is a further deceleration to a velocity of 0.5 cm/month, or 6 cm/year, which is the average through much of middle childhood. This continues with gentle slowing until puberty.

The first 3 years are also the time of increased channelling of the growth curve. At birth, the length of the baby is determined mostly by the fetal environment which, in turn, is much dependent on maternal size; the father's height is poorly correlated with the child's. During the next 2 to 3 years, the influence of the father's genetic make-up increases progressively until there is equal influence from both parents. This phenomenon can result in some rather bizarre growth patterns where mother and father have very different heights. For example, when the child is born to a tall mother but short father, the initially rather large baby will tend to grow unusually slowly until the genetically expected channel is achieved.

Middle childhood

Although in healthy children growth is a moderately steady process, there are fluctuations that occur in the short and middle term, the most striking of which are related to seasonal changes. Most children grow faster in spring and summer, with relatively slow periods in the autumn and winter; a few children show a reversed pattern, and others no regular pattern at all. There is a rather constant, but small, growth spurt at 6 to 7 years of age in both boys and girls, with no sexual dimorphism; it has been attributed to the onset of adrenal androgen secretion that occurs at about that age.

Puberty

There is little difference in growth rates between males and females before 10 years of age. Then the typical female starts her adolescent growth spurt and, for a few years, is taller than a male of the same age. About 2 years later the male starts his spurt and by the age of 14 is the taller. The major difference in adult height between males and females (14 cm in the United Kingdom) is established at puberty. About 11 cm comes from the extra 2 years of prepubertal growth of boys and 3 cm from their more intense growth spurt.

Sexual dimorphism in height during puberty is reflected in many other body dimensions. At this time there is a more dramatic growth spurt in males for most body dimensions, occurring about 2 years later than in females. A major exception is the more dramatic and sustained growth spurt of the female pelvis. There are also associated changes in soft tissues, leading to the greater muscularity of the male.

Metabolic and endocrine factors controlling growth

Each of the epochs of growth described above is associated with particular metabolic or hormonal factors which exert their effects in an almost sequential manner. These distinctions should not be overstated, however, and are only useful as a general guide to the most important factors at a given age. In essence, infant growth is dominated by nutritional considerations, the childhood period by growth hormone, and puberty by the sex hormones, but nutrition has an important role throughout and growth hormone is important in early infant growth, as shown by the reduced size at birth of children with congenital growth hormone deficiency. Thyroid hormone is also important throughout the growing period. Throughout growth the actions of growth hormone and possibly other hormonal and nutritional factors are in part

mediated by the insulin-like growth factors and their binding proteins.

Disorders of growth

Growth disorders are predominantly problems of childhood, and patients seen by the adult physician are inevitably left with a legacy of events which have occurred before maturity. In many cases where the condition was successfully treated during childhood there may be no residual problem with stature in adult life. In contrast, there are many situations when this happy outcome is not achieved and there is still a persistent problem requiring attention in the adult clinic. Thus the importance of the various disorders is different and what follows reflects this.

Short stature

Definition

What is considered as short (or for that matter tall) stature is essentially arbitrary. It is usually considered as a height that falls below the second centile for the relevant population; these values for adults are given in Table 1. This is easy when the discrepancy is severe but difficulties arise with patients whose height lies close to this limit. In this situation the perceptions of the patient may greatly colour the situation and its management. The most important decision is whether the apparent short stature is a symptom of a disorder that requires attention, and therefore most stress is placed upon diagnosis.

Classification of short stature

The major categories of short stature are shown in Table 2. The process of attributing such labels to an individual patient is largely one of clinical assessment, including critical appraisal of the pattern of growth combined with appropriate confirmatory investigations.

Familial short stature

This relatively common condition is among the most difficult to manage. It is sometimes referred to as normal or idiopathic short stature. Patients usually present in childhood with heights clustered around the second centile. The parents are usually of comparable size and the child's stature is simply reflecting the genetic inheritance. This apparently straightforward situation is made difficult because of the considerable social pressures that now exist; parents and their children simply find it hard to accept the situation and want it changed.

Diagnosis

The clinical picture is clear: the child will be at or below the second centile for height with a normal growth velocity measured over 1 year. The height will be appropriate for the family and it is critical that parental heights are properly taken into account. The simplest way to do this is to measure both parents and then determine their height centiles. The child's predicted adult height is calculated by an appropriate method that takes into account skeletal maturity; this predicted adult height should lie within a range of 10 cm above or below the midparental height centile, which represents the 2nd to 98th centiles for that family.

The general medical picture is of good health, apart from the usual childhood illnesses. Similarly, apart from short stature, no abnormalities are found on general examination. In this situation no investigations are necessary other than the assessment of skeletal maturity for the prediction of adult height.

Management

The main problem is to persuade the patient and the family that there is no medical problem. Even when this is achieved, there is often a wish to change the prognosis for height. In recent years there have been many clinical trials of human growth hormone in this situation. While definitive data are still scarce, there is increasing evidence that although a short-term acceleration of height velocity is almost always achieved, this is not maintained, and adult height is relatively unchanged. When such treatment is started after the age of 11 years this is moderately certain, but there remains some uncertainty if the human growth hormone is started at younger ages (6 to 8 years). Even if this is more successful, there remains a considerable debate about the ethics and cost-effectiveness of such treatment of normal healthy children.

Constitutional delay of growth and/or puberty

This problem is largely covered elsewhere (see Chapter 12.9.3). Here comment is restricted to noting that in many cases the delay in maturation is evident well before puberty when the presentation is purely of short stature associated with delayed skeletal maturation. There is often an associated element of familial short stature; the delay is amenable to treatment with anabolic steroids or androgens, whereas the familial element is unaffected.

Intrauterine growth retardation

This comprises a relatively large group of children who share the common feature of being born inappropriately small for gestational age, usually assessed in terms of birth weight. Many show a sustained period of accelerated or 'catch-up' growth and reach the normal centiles for height and weight. However, a significant number fail to do this and remain below the 2nd centile although growing at a normal velocity. In some cases this clinical picture is part of a more general dysmorphic or genetic syndrome, but it may occur alone.

Diagnosis

Traditionally intrauterine growth retardation is diagnosed when a baby is born with a birth weight more than two standard deviations below the mean for gestational age, maternal height, and parity. However, this criterion is changing to reflect intrauterine diagnosis by fetal ultrasound measurements.

In addition to the birth characteristics, the growth curve is typical and there are a number of other clinical features. The facies are small and triangular with a normal sized cranium which, compared with the small face, can give the impression of hydrocephalus. The general habitus is very lean and there may be a degree of limb asymmetry in about 50 per cent of cases. There are often other minor dysmorphic features.

Many children have severe feeding problems in the first few years of life, which may compound the lean appearance and create further anxieties for the families. There may be a degree of delayed skeletal maturation, but this is very variable. General and endocrine investigations are unhelpful.

Management

In all but the most severely affected children growth velocity is normal as long as the intrauterine growth retardation is not part of a more generalized dysmorphic syndrome. However, the long-term prognosis for height is usually rather worse than appears in childhood. This is because puberty tends to be prompt and the adolescent growth spurt attenuated, so that less growth is achieved in the teenage years than might be expected.

The only active treatment that is being pursued at present is the use of human growth hormone, but this is still under clinical trial. Early results suggest short-term benefit, but predicted mature height is little changed, as in the case of familial short stature.

Environmental short stature

Over the past 30 years it has become clear that children's growth may be adversely affected by their environment other than by malnutrition or infection. This effect may be due to emotional or physical abuse or neglect and may sometimes present in the most bizarre of ways, often imitating other organic disorders such as growth hormone insufficiency. It is most common in young children but may rarely present in young teenagers and, strikingly, may present in a single child in a family where

the other children thrive.

Diagnosis

This is a diagnosis which is notoriously easy to miss. In its most classical form it presents as an apparently straightforward diagnosis of growth hormone insufficiency although there will often be additional features of bizarre eating habits, behavioural abnormalities, or other evidence of abnormal family dynamics. In many cases where an initial diagnosis of growth hormone insufficiency is made, treatment with human growth hormone is started, often with early success. However, the accelerated growth soon falters and during the subsequent reappraisal the real diagnosis is uncovered.

As the above suggests, endocrine investigations are often misleading. Once the suspicion is raised the only way to confirm the diagnosis is a period of time away from the family environment, either by a hospital admission or by short-term fostering. A period of accelerated growth (initially weight gain followed by increase in height) makes the diagnosis. There is then the need for a detailed social and psychiatric appraisal of the family.

Management

Once the diagnosis is made the management is predominantly that of manipulation of the family circumstances, either by extensive social and psychiatric support for the family with the child *in situ*, or more commonly by removing the child from the family and placement elsewhere by fostering or adoption.

With proper management in childhood those who have suffered from environmental short stature should not present medical problems in adult life. However, it is highly likely that there may be continuing psychological problems and particularly the possibility of subsequent abuse of one or more of their own children.

Chronic paediatric disease

Any child with a longstanding chronic disease will show some degree of growth disorder if the primary activity of the underlying condition is less than optimally controlled. This may be due to the disease itself or to its treatment; the use of high doses of systemic corticosteroids is a particularly important example of the latter. However, it is very unusual for such a child to present with short stature as the primary symptom because the underlying disease is usually evident at an earlier stage. Notable exceptions to this rule are some gastrointestinal diseases, especially coeliac and inflammatory bowel disease. Irrespective of the primary disease, a degree of delayed skeletal maturation is prominent and may be the first feature of disordered growth to appear.

Management is targeted at the primary disease wherever possible. Adjunctive therapies, such as human growth hormone in chronic renal failure, are being studied within clinical trials. The long-term benefits of such treatments remain unclear at the present time.

Endocrine disease

The endocrine causes of short stature form the main group of readily treated growth disorders. Many of the details will have already been covered in the chapters on the relevant endocrine glands and only a brief summary is given here.

Hypothyroidism

Inadequately treated congenital or acquired juvenile hypothyroidism is always associated with marked growth failure. Congenital disease ought to be diagnosed by neonatal screening programmes, such that growth is never a problem, although some delay in initiating thyroid replacement may lead to the more serious problems of intellectual impairment. On the other hand, juvenile hypothyroidism, usually due to autoimmune thyroiditis, can be far more insidious and often presents with growth failure as the sole symptom.

Diagnosis

In any undiagnosed short child consideration should always be given to the possibility of juvenile hypothyroidism. The classical features of adult disease such as constipation and intellectual impairment are usually absent and poor growth may be the only abnormality. Most typically the child grows with a very low velocity, rapidly crossing centiles downwards. General medical examination may be quite normal unless the disease is long established and severe; such symptoms and signs as may be present are no different from those in adults. A goitre may be present, depending upon the stage of the disease.

A striking delay in skeletal maturation is often seen; to the unwary this may lead to an incorrect diagnosis of constitutional delay of growth and/or puberty, as the degree of maturational delay will usually be sufficient to apparently explain the height deficit. For this reason thyroid function tests should be undertaken early and will confirm or deny the diagnosis without ambiguity. Serum T_3 or T_4 will be low, with an elevated serum concentration of thyroid-stimulating hormone.

Management

Thyroid replacement with L-thyroxine is relatively straightforward, with an initial dose of 100 µg/m ^{2}/day; this is fine-tuned according to growth response, clinical examination, and maintenance of a suppressed thyroid-stimulating hormone concentration with either a normal serum T_3 concentration or serum T_4 in the upper normal range. The prognosis for height is generally very good, except in those diagnosed and treated well into puberty, when the outcome is less satisfactory.

Growth hormone insufficiency

Growth hormone insufficiency may occur as an isolated disorder of uncertain aetiology, as part of more complex diseases and developmental anomalies, or as part of more extensive hypothalamopituitary disease. A list of such conditions is given in Table 3. Recently, it has become clear that there are a number of genetic causes of growth hormone insufficiency and wider pituitary malfunction. Deletions or mutations of the structural growth hormone gene on chromosome 17 is now well recognized as are the cascade of homeobox genes responsible for pituitary development including *PIT1*, *PROP1* and *HESX1*.

The principal differences between the congenital and acquired forms are that the onset of the growth failure occurs differently. In the first case there is failure of normal growth from a very early age which can usually be detected within the first year of life. In contrast, acquired growth hormone insufficiency can lead to abnormally slow growth at any age before maturity. In the latter situation the assessment of height velocity assumes far greater importance as height may remain within the normal centiles for several years before the child becomes overtly short and below the third centile.

Particularly noteworthy is the pattern of growth in children receiving cranial or craniospinal irradiation as this may be rather different from other causes of growth hormone insufficiency. In both cases there may be associated early puberty, particularly with radiation doses below 2400 cGy, leading to a rather confusing picture as the early but rather attenuated adolescent growth spurt may mask the onset of growth hormone insufficiency. When the spine is involved in the radiation field there may be a combination of growth hormone insufficiency and direct damage to the spinal epiphyses, with subsequent failure of spinal growth which is not due to the endocrine abnormalities and is not responsive to endocrine replacement.

Diagnosis

Children with growth hormone insufficiency grow with a slow height velocity and, depending on whether the insufficiency is congenital or acquired later, fall progressively further below the second centile or cross height centiles downwards. The degree of short stature can range from relatively mild to very severe, depending on the degree of insufficiency, the age of onset, and parental heights. As in many short stature disorders, the parents' heights still modify the expression of the disorder such that children with growth hormone insufficiency born to tall parents will tend to be more normal in height for longer than those with equivalent disease born to shorter parents.

Other clinical features include a rather young appearance, with immature facies and sometimes a quite striking degree of frontal bossing. There is usually an excess of subcutaneous fat, giving a rather cherubic appearance, and in boys there may be hypoplastic genitalia not necessarily due to associated gonadotrophin deficiency

but caused by a severe growth hormone insufficiency in the intrauterine or neonatal perod.

The diagnosis is confirmed by a variety of endocrine measurements (see Chapter 12.2). Growth hormone is secreted in an episodic manner such that measurement in single serum samples is valueless. It is most commonly measured in several samples following pituitary stimulation by a provocative agent, of which the most important are listed in Table 4. The definition of a normal response is still rather arbitrary, but is usually set at a peak of more than 7 mg/l at some point following the administration of the provocative agent. It is important that the characteristics of different growth hormone assays are taken into account and centres carrying out these tests should establish their own cutoff values. The place of growth hormone releasing hormone is uncertain; it tests the integrity of the hypothalamopituitary axis but does not detect primary hypothalamic disease, which is probably the most important cause of growth hormone insufficiency.

Additional aids to diagnosis are the measurement of growth hormone concentrations in serial blood samples taken frequently (every 15 to 20 min) over 24 h, or the measurement of basal serum concentrations of insulin-like growth factor I together with insulin-like growth factor binding protein 3. The former approach is laborious and labour intensive and is probably unhelpful except in some rare situations where an assessment of physiological growth hormone secretion is required. Measurement of insulin-like growth factor I and its binding protein is rather too insensitive for routine clinical use.

Growth hormone insufficiency may be isolated or part of a wider constellation of pituitary hormone deficiencies, and it is important to check thyroid and adrenal function at an early stage. Gonadotrophin deficiency is relatively common but difficult to confirm prior to the age of puberty, and it may not be until puberty fails to occur spontaneously that suspicion is raised (see Chapter 12.9.3).

Having confirmed the diagnosis of growth hormone insufficiency, isolated or otherwise, it is important to determine the underlying aetiology and, in particular, seek an intracranial space-occupying lesion. Craniopharyngioma is the most important lesion and the use of modern imaging techniques, cranial computed tomography or magnetic resonance imaging, is mandatory. These lesions are most commonly associated with multiple pituitary hormone deficiencies, although these may take some years to become manifest (see Chapter 12.2).

Management

The treatment of growth hormone insufficiency is the same whatever the underlying aetiology: human growth hormone, 5 to 10 mg/m^2/week (0.2–0.4 mg/kg/week; 1 mg pure protein = 3 IU), by daily subcutaneous injection. The growth velocity is the best indicator of response and it should show a clear acceleration, usually to 10 cm/year or more. A poor response indicates the need to review the diagnosis. It is essential that any coexisting pituitary hormone deficiencies (such as deficiency of thyroid-stimulating hormone leading to secondary hypothyroidism) are adequately treated with appropriate replacement.

Treatment is continued until growth is complete and may therefore last for many years. For this reason it is particularly important to review dosage as growth occurs and ensure that injection sites are cared for adequately.

Growth hormone receptor deficiency

This is a very rare disorder whose importance lies in the ability to mimic the much more common severe growth hormone insufficiency. The clinical phenotypes may be indistinguishable but in the case of growth hormone receptor deficiency there is excessive secretion of growth hormone by the pituitary gland; the fault lies in the growth hormone receptor, which is either absent or non-functioning, leading to a deficiency of insulin-like growth factor I. The abnormality is due to one of several mutations in the receptor gene, which is inherited according to an autosomal recessive pattern. Until now it has been untreatable but clinical trials of recombinant insulin-like growth factor I look promising.

Adrenocortical excess (see also Chapter 12.7.1)

An excess of circulating corticosteroids is a potent cause of growth failure, whether due to endogenous overproduction or exogenous medication. In the former case, the aetiology may be hypothalamopituitary or adrenal in origin, as in adults. The diagnosis of Cushing's disease in childhood is rare and taxing to make, although once considered, the approach does not differ from that in adults. Iatrogenic glucocorticoid excess is much more common and is most often related to overuse of topical steroids for atopic disease; inhaled steroids for asthma and powerful dermatological preparations for eczema are particularly important. The management of the growth failure is entirely dependent on reducing the glucocorticoid load usually by the introduction of an alternative non-steroidal treatment for the underlying condition.

Genetic/chromosomal disorders, dysmorphic syndromes, and bone dysplasias

For the purposes of this book these last three categories can be considered together. For the main part they are individually rare, but are so many and varied that together they make a significant contribution to the causes of short stature. The approach to diagnosis depends heavily on clinical suspicion backed up by chromosomal and radiological investigation.

Turner syndrome

This is the only condition that will be discussed in any detail as it is relatively common (about 1 in 2500 to 3500 female births), surprisingly easy to miss, and amenable to useful treatment. Turner syndrome tends to present in two distinct age groups: birth or infancy and mid childhood. The young girls usually have a number of the classical features, including coarctation of the aorta leading to early clinical suspicion. However, a large number of affected girls only have subtle clinical signs, and in these patients short stature is virtually the only significant feature. Diagnosis is confirmed by chromosomal analysis, which may reveal a 45X karyotype with complete absence of one X chromosome, a more subtle structural abnormality of one X, such as an isochromosome, or a mosaic combination of cells with different chromosomal complements.

Untreated girls with Turner's syndrome reach adult heights of between 134 and 156 cm but this is dependent on their parents' heights; girls from tall families will be relatively tall for the diagnosis, even reaching into the lower part of the normal range. Puberty is usually, but not always, absent.

Treatment for both the short stature and the lack of puberty is possible. The latter requires the use of oestrogen and progestogens. A typical regimen would be the slow introduction of ethinyl oestradiol at about 12 to 13 years of age in a dose of 1 µg/day increasing to doses of 20 to 30 µg/day over 2 years. It should be given continuously at first but when adult doses are reached it should be omitted for one week in every four, when a withdrawal bleed will occur, mimicking menstruation. At the same time it is important that a progestogen, such as norethisterone 5 mg/day, is introduced for the last week of the cycle. More recently, clinical trials have shown that moderate growth benefit can be achieved by the combined use of human growth hormone (7–10 mg/m^2) and the mild anabolic steroid, oxandrolone (1.25–2.5 mg/day).

Tall stature

The causes of excessive growth are far fewer than those of short stature. Most common are variants of normal, usually with tall parents; pathological causes of tall stature are very rare.

Definition

This can be defined in a complementary way to short stature (see above); it is equally arbitrary. In practical terms, boys find difficulty in accepting heights above 200 cm, whereas most girls find 185 cm the limit.

Classification

The principal causes of tall stature are familial tall stature, pituitary gigantism, Sotos syndrome, Marfan syndrome, and homocystinuria; only the first will be discussed in any detail.

Familial tall stature

This is more or less the mirror image of familial short stature which is discussed above. There is often an element of advanced maturation with a skeletal age that exceeds chronological age by several years and early pubertal development. The diagnosis is made by clinical appraisal, including knowledge of parental heights and the demonstration that predicted adult height is appropriate for the family. Exclusion of other potential causes is often possible on clinical grounds, but the exclusion of excessive growth hormone secretion may be necessary.

Management

The calculation of a predicted adult height, which because of the advanced skeletal maturation is often less than the family fears, may be all that is necessary as the expected height is then acceptable. If this is not the case, then other pharmacological treatments may need discussion. At present these are unsatisfactory, although in girls it may be possible to curtail final height by induction of puberty early using physiological doses of ethinyl oestradiol, if they present early enough. In the past high-dose ethinyl oestradiol (100–300 µg/day) has been advocated in an attempt to accelerate skeletal maturation. However, the benefits are far from certain, there may be quite unpleasant side-effects, and the long-term safety is unclear.

The use of testosterone in boys, in an analogous manner to the use of oestrogen in girls, is of even less value and is probably contraindicated.

Other causes of tall stature

Pituitary gigantism with excessive growth hormone secretion is extremely rare but does occasionally require specific exclusion, usually by demonstration of normal suppression of growth hormone secretion to undetectable levels by oral glucose (1.75 g/kg). Serum concentrations of insulin-like growth factor I will usually be high but may overlap the normal range.

Marfan syndrome is characterized by disproportionately long limbs and digits (arachnodactyly), and is usually associated with a high-arched palate and pectus excavatum. It is an important diagnosis to make because of the risk of eye problems and dissection of the aortic root and arch. Ultrasound examination of the heart and aorta should be a regular routine.

Sotos syndrome and the other dysmorphic causes of tall stature are even rarer and can usually be diagnosed on other criteria. They are not considered further here.

12.9.3 Puberty

R. J. M. Ross and M. O. Savage

Introduction

Puberty, as defined by the *Concise Oxford dictionary*, is 'the state of being functionally capable of procreation' through the natural development of reproductive organs. The word is derived from '*puber*' meaning adult, and not 'pubic', which refers to the lower part of the abdomen, the pubes. There is a popular misconception that the onset of puberty is heralded by the development of pubic hair, but breast budding is usually the first sign of puberty in girls and an enlargement in testicular size in boys. A clear understanding of normal pubertal development is essential for the management of patients with disordered puberty, as in many cases counselling and reassurance is all that is required.

Sexual differentiation takes place at two stages of life: the first *in utero* extending to the perinatal period, and the second occurring at puberty. Between these two stages is the 'quiescent period'. The physiological changes that accompany sexual differentiation and the hormonal factors that control these changes are well defined, but what determines the duration of the 'quiescent period' and the onset of puberty remains to be established. What is known is that puberty is centrally driven, and this is well illustrated by the failure of pubertal development in children with Kallmann's syndrome and the changes that occur in anorexia nervosa. In Kallmann's syndrome there is a failure in the migration of gonadotrophin-releasing hormone (**GnRH**) neurones to the hypothalamus during fetal life. Affected patients present with hypogonadotrophic hypogonadism associated with anosmia. When puberty is delayed or arrested by anorexia nervosa it may be induced by the pulsatile administration of GnRH. The GnRH pulse generator is therefore essential for normal puberty, and the cues that switch it to pubertal mode include, most importantly, age and maturation of the central nervous system, environmental factors such as stress, social factors (probably the reason for an earlier onset of puberty in Western countries), and metabolic factors such as nutrition, body composition, and leptin.

The onset of puberty is characterized by an increase in basal luteinizing-hormone (**LH**) levels and in the amplitude and frequency of LH pulses independent of gonadal changes. Gonadal activation stimulated by the rise in gonadotrophin (LH and follicle-stimulating hormone (**FSH**)) secretion results in rising levels of the sex steroids. Apart from their action on sexual maturation, gonadal steroids have a direct effect in stimulating skeletal growth and also a central action in stimulating increased growth-hormone (**GH**) production. A consistent pattern of hormonal changes results in a relatively constant pattern of growth and pubertal development, characterized in girls by the development of breasts, pubic hair, and the onset of menstruation, and in boys by an increase in testicular volume, genitalia size, and the appearance of pubic hair. This is best appreciated by plotting a child's development on growth and development records. A loss of the normal pattern of development suggests pathology. For instance, a boy who at 8 years has a height above the 97th centile, stage 3 genitalia, and pubic hair, but testes less than 4 ml is likely to have an abnormal source of androgens, such as an androgen-secreting tumour or congenital adrenal hyperplasia.

Timing of puberty

Disorders of puberty can be classified by the timing of the onset of sexual characteristics into either precocious or delayed puberty. Precocious puberty is characterized by signs of sexual maturation appearing less than 2.5 standard deviations (**SD**) from the mean: before 8 years of age in a girl and before 9 years in a boy. In Western society puberty is considered delayed when there are no signs of pubertal maturation in a girl aged 13.4 years (2 SD) or a boy aged 13.8 years. As a simple working rule, investigation should be considered if there are no signs of puberty at 14 years of age. These ages are guidelines as they vary between populations and over time.

Precocious puberty

Precocious puberty can be classified into true (pituitary gonadotrophin-dependent) or pseudo (pituitary gonadotrophin-independent) precocious puberty (Table 1). In true precocious puberty, as in normal puberty, there is activation of the hypothalamopituitary axis and thus the normal pattern of puberty is preserved (complete precocious puberty). In pseudo precocious puberty, for example that caused by an adrenal adenoma, the normal pattern of puberty is lost (incomplete precocious puberty). Pseudo precocious puberty may be isosexual, with appropriate male or female puberty, or heterosexual, when there is virilization of a girl (as in congenital adrenal hyperplasia), or feminization of a boy (as in an oestrogen-producing Leydig cell tumour). Two conditions do not fit clearly into this classification: isolated thelarche and isolated pubarche.

Isolated thelarche and isolated pubarche

Breast enlargement in the absence of other signs of puberty is called premature thelarche. It is most common under the age of 2 years and may persist from neonatal breast enlargement. There is usually spontaneous regression and later a normally timed puberty. Isolated pubarche is the early appearance of pubic hair with or without axillary hair. It is more commonly seen in girls than boys and characteristically between 4 and 6 years of age. It is associated with adrenarche, an increase in adrenal androgen secretion seen in middle childhood. There can be a slight growth spurt and advance in bone age, but this is part of normal development. It can be differentiated from abnormal forms of virilization, including adrenal tumours and congenital adrenal hyperplasia, by measuring the sex steroid hormone profile, including dehydroepiandrosterone-sulphate (**DHEA-S**), and demonstrating normal suppression of adrenal androgens by dexamethasone. It has been suggested that premature adrenarche may be a precursor of the polycystic ovarian syndrome in girls, and some clinicians advocate long-term follow up for these patients.

Precocious puberty

Precocious puberty presents much more commonly in girls than boys, and in the majority of girls no organic cause is found and it is idiopathic and sporadic. In contrast, in boys idiopathic precocious puberty is rare and, although there are families with familial true precocious puberty, most commonly it is due to CNS tumours, either hypothalamic hamartomas or gliomas, or dysgerminomas (Table 1).

The clinical investigation of precocious puberty is first directed towards distinguishing between a true, pseudo, isosexual, or heterosexual condition. History and examination will help to establish whether there is a normal pattern of pubertal development, as in true precocious puberty, or an abnormal pattern as seen in pseudo precocious puberty. In girls, ultrasound of the pelvis will demonstrate the effect of oestrogens on uterine size and define the appearance of the ovaries. Measurement of the gonadotrophin response to GnRH should be made, as should basal measurements of b-human chorionic gonadotrophin, adrenocorticotrophic hormone, adrenal steroids (including cortisol, 17-hydroxyprogesterone, DHEA-S, and androstenedione), testosterone, oestrogen, and thyroid hormones. Steroid profiles may also be made on urine collections. Skeletal maturation should be determined by measuring bone age.

True precocious puberty

In true precocious puberty the gonadotrophins will show a pubertal response to GnRH with a greater rise of LH than FSH. In the normal prepubertal child there is only a small rise in the gonadotrophins and the response of FSH is greater than that of LH. In pseudo precocious puberty the gonadotrophins are usually suppressed unless true puberty has also been initiated, which may occur due to excessive sex-steroid secretion from any cause. Acquired hypothyroidism is associated with increased levels of FSH and may result in breast development and menstruation in girls and testicular enlargement in boys. These patients usually have stunted growth and the diagnosis is easily made by the measurement of thyroid stimulating hormone levels. Once a diagnosis of true precocious puberty is made, appropriate

scanning of the hypothalamopituitary axis should be performed using magnetic resonance imaging (**MRI**).

Pseudo precocious puberty

The further investigation of pseudo precocious puberty depends on the findings of the original screening tests. Adrenal tumours will be associated with an increased production of adrenal steroids which is not suppressed by a low-dose dexamethasone suppression test. Imaging will pick up adrenal carcinomas (usually greater than 6 cm in diameter) and most adenomas, although on occasion venous catheter sampling is required. Congenital adrenal hyperplasia in girls usually presents early with virilization and ambiguous genitalia; however, it may present later in boys with virilization and tall stature, but prepubertal testes. There is a typical urinary steroid profile, and in the commonest form there is 21-hydroxylase deficiency, with levels of ACTH and 17-hydroxyprogesterone raised, and low levels of cortisol. Ovarian tumours are best detected by ultrasound scanning, as are testicular tumours. The McCune–Albright syndrome (polyostotic fibrous dysplasia) is an unusual cause of precocious puberty due to postzygotic activating mutations in the gene encoding the G protein, G alpha s, resulting in activation of the signal-transduction pathway generating cyclic AMP. Girls usually present with autonomous ovarian activity, but this may be succeeded by true precocious puberty. Patients have patches of *café-au-lait* pigmentation with a ragged border and fibrous dysplasia of the bones. Testotoxicosis is an unusual inherited disorder due to activating mutations of the gene for the LH receptor. It is characterized by pubertal levels of testosterone, pubertal-sized testes, and a suppressed hypothalamogonadal axis. Tumours producing human chorionic gonadotrophin (**hCG**) can be detected by measuring hCG and scanning appropriate sites, including the gonads, liver, and pineal gland.

Treatment

There are four aims in the treatment of precocious puberty:

1. to remove the primary cause;
2. to treat the psychosocial consequences;
3. to allow a normal puberty; and
4. to promote normal growth.

Children with precocious puberty appear much older than they are, and this can result in considerable psychological difficulties and behavioural problems. Growth is stimulated both by a direct action of sex steroids on skeletal maturation and by the induction of GH secretion. This early maturation of the skeleton results in early fusion of the epiphysis, and although the child is initially tall, his or her ultimate height may be very short.

Girls with only slightly advanced pubertal development often require no treatment because puberty only advances slowly, and they do not have a significant loss in their height potential. GnRH analogues are now the treatment of choice in true precocious puberty. They act by downregulating the GnRH receptor and switching off the secretion of LH and FSH. GnRH analogues have been produced as nasal sprays, daily injections, and monthly depot injections. In our experience, depot injections have proved the most effective (goserelin 3.6 mg/month). GnRH may produce an initial period of stimulation, which can be prevented by giving concomitant treatment with cyproterone acetate (100 mg/m^2 once a day for the first 6 weeks). Occasionally the acute suppression of oestrogen production at the start of treatment will precipitate an oestrogen-withdrawal bleed.

In pseudo precocious puberty removal of the primary cause is the mainstay of treatment for patients with tumours, and treatment with glucocorticoids for patients with congenital adrenal hyperplasia. In patients with congenital activating mutations of receptors or residual disease after treatment of tumours, cyproterone acetate, a peripherally acting antiandrogen, at a dose of 50 to 100 mg daily is effective in halting the progress of the physical features of puberty, and is useful in suppressing menstruation. Cyproterone acetate is a weak glucocorticoid and may suppress ACTH and the adrenal glands. Testolactone, and a combination of this with spironolactone and GnRH analogues, has proven effective in improving height prediction.

Any effective treatment of precocious puberty will slow the growth rate through the consequent reduced secretion of sex steroids and GH. Patients treated to arrest puberty will have longer to grow, but their reduced growth rate and already reduced growth potential mean that, despite the use of GnRH analogues, they will not achieve the height of which they were originally capable. The addition of GH treatment for 2 to 3 years during conventional therapy with GnRH analogues may improve the height prognosis in children with a low growth velocity.

Delayed puberty

The causes are summarized in Table 2. The individual conditions which may cause it are discussed in other parts of this book. Here, discussion is limited to the management of constitutional delay of growth and adolescence.

Constitutional delay of growth and adolescence (CDGA)

CDGA occurs in otherwise normal adolescents who have relatively short stature, delayed puberty and bone age, and a height prognosis appropriate in relation to their parents. It presents far more commonly in boys than girls and is the commonest cause of delayed puberty in boys, with Turner's syndrome being the commonest in girls. CDGA needs to be distinguished from isolated gonadotrophin deficiency, but this is rarely easy as gonadotrophin levels are low, with a low or prepubertal response to GnRH in both conditions. A positive family history may indicate CDGA, and associated anosmia suggests Kallmann's syndrome. If in doubt and if treatment is indicated, then the patient should be reassessed after therapy (see below) to see if puberty then progresses without treatment.

Psychological problems are common in children with delayed puberty and short stature. Recent studies have suggested that delayed puberty may be associated with a reduced spinal bone density, putting adults at risk of bone fracture later in life. Thus, there are good reasons for treating this condition, which may be considered as a variant of normal growth.

Intervention with sex steroids or anabolic steroids is a safe treatment that brings forward the timing of the growth spurt without reducing the height potential. The object of treatment is to stimulate normal puberty and maximize linear growth. In boys a reasonable starting dose of testosterone esters is 25 to 50 mg monthly, increasing gradually to 250 mg every 4 weeks, although puberty may be induced more rapidly over a 6-month period and the course of treatment may be as short as 3 months. Oral Oxandralone (unlicensed, but available on a named-patient basis from Searle, UK), 2.5 mg daily, will similarly increase growth velocity.

In girls, ethinyloestradiol at an initial dose of 2 to 10 µg daily can later be increased to between 10 and 20 µg daily, with the addition of progesterone when the oestrogen dose has reached 20 µg (for example, medroxyprogesterone acetate 5 mg on days 1–14 of the calendar month).

12.10 Non-diabetic pancreatic endocrine disorders and multiple endocrine neoplasia

P. J. Hammond and S. R. Bloom

Pancreatic endocrine tumours

Pancreatic endocrine tumours (islet cell tumours, gastroenteropancreatic tumours) are rare, the most frequent, insulinomas and gastrinomas, occurring with an annual incidence of 1 per million, with others having an incidence of less than 1 per 10 million. Functioning tumours usually present with the symptoms of hormone excess. They may secrete the pancreatic hormones insulin, glucagon, and somatostatin, or ectopic hormones such as gastrin, vasoactive intestinal polypeptide (VIP), or parathyroid hormone related peptide (PTHrP) (see Chapter 12.6). Non-functioning tumours can reach a large size in an apparently well patient, as characteristically these tumours cause little non-endocrine systemic upset. They were once often mistakenly identified as adenocarcinomas, but are now increasingly diagnosed as a result of detection of their secretion of functionally inactive peptides, such as pancreatic polypeptide and neurotensin, or immunohistochemical staining for neuroendocrine markers, such as chromogranin and neurone-specific enolase. They probably account for 50 per cent of all pancreatic endocrine tumours. This section will initially consider aspects of tumour biology, diagnosis, and management common to all tumours, before describing each syndrome.

Natural history

These tumours were originally described as APUDomas because it was thought that they had a common origin from neural crest cells with the ability to perform amine precursor uptake and decarboxylation (APUD). However, this theory has since been disproved, and it has been proposed that the neuroendocrine and mucosal endocrine cells of the gastroenteropancreatic axis are derived from a common, bipotential endoplacal stem cell.

The genetic basis for the development of sporadic pancreatic endocrine tumours is largely unknown. However, about 25 per cent of them, particularly gastrinomas and insulinomas, occur as part of the familial autosomal dominant multiple endocrine neoplasia type 1 (MEN1) syndrome (see below), in which there is a mutation in the *menin* gene in the q13 region of chromosome 11, and loss of heterozygosity for this region has been demonstrated in some patients with sporadic gastrinoma and insulinoma.

Islet cells are pluripotential with respect to peptide production. Thus 70 per cent of tumours are associated with elevated pancreatic polypeptide levels, and in a small proportion of cases other hormones, particularly gastrin, may become elevated and cause secondary syndromes during the course of the disease. Altered processing of peptide precursor molecules may result in a variety of molecular weight forms of the same peptide being secreted, and not all the immunoreactive peptide is bioactive. This can have clinical implications; for example large molecular forms of glucagon (enteroglucagon) can cause villous hypertrophy and slowed intestinal transit, and large forms of somatostatin have been reported to cause hypoglycaemia, rather than the hyperglycaemia usually associated with the somatostatinoma syndrome.

Most pancreatic endocrine tumours are slow-growing and prolonged survival is often possible, even in the presence of metastatic spread, the median survival being about 5 years. However, some patients have aggressive, rapidly spreading disease, particularly those with non-functioning tumours, whose median survival is little over 2 years. Early in the disease, morbidity and mortality result from the effects of peptide hypersecretion rather than tumour bulk. The unpredictable nature of these tumours makes it difficult to give an accurate prognosis, occasional patients surviving for decades, and, combined with their rarity, this has made it difficult to assess the efficacy of different therapeutic strategies.

Diagnosis

Pancreatic endocrine tumours can usually be diagnosed by hormonal radioimmunoassay of a single fasting plasma sample, and for certain syndromes a small number of confirmatory tests. Several conditions other than tumour are associated with increased circulating gut hormone levels (Table 1), particularly renal failure, but the elevations are usually more modest than those associated with tumour syndromes. Gut hormone radioimmunoassays are not well standardized, and the use of different antibodies and assay techniques in different laboratories can give different values on the same sample. However, concentrations are usually of the same order of magnitude in all assays and show a similar percentage increase above normal.

Most glucagonomas, non-functioning tumours, and pancreatic VIPomas and somatostatinomas are large (greater than 2 cm) tumours, which may be calcified and have metastasized to the liver in the majority of cases. Such tumours are easily localized by abdominal computed tomography (CT) scanning and ultrasonography. However, localization of tumours producing more active hormones, which are therefore detected earlier in their lifecycle, may be very difficult; for example 40 per cent of gastrinomas and insulinomas are microadenomas, less than 1 cm in diameter. Insulinomas often occur in the distal two-thirds of the pancreas, and over 90 per cent of gastrinomas are found in the gastrinoma triangle, bounded by the third part of the duodenum, the neck of the pancreas, and the porta hepatis, about 20 per cent of these being in the duodenum. CT scanning and meticulous, highly selective angiography (Fig. 1) will localize 70 per cent of these microadenomas. Magnetic resonance imaging (MRI) may be more sensitive at detecting small pancreatic lesions than CT scanning, but this method requires further evaluation. Transhepatic percutaneous portal venous sampling is a sensitive method of detecting hormone gradients, but cannot give accurate enough resolution to assist the surgeon in most cases, and is an expensive procedure not without risk. In experienced hands, endoscopic ultrasonography may be more sensitive than conventional imaging, with a resolution of 2 mm and a detection rate of over 75 per cent for tumours in the pancreatic head (Fig. 2), but visualization is poorer for lesions of the pancreatic tail and duodenum. Intraoperative ultrasonography has a sensitivity of over 90 per cent for pancreatic tumours, and endoscopic transillumination of the duodenum may allow the surgeon to detect an occult gastrinoma. Functional radiological localization has been described for both insulinomas and gastrinomas. Injection of calcium or secretin into the artery supplying the tumour causes a marked rise in insulin or gastrin levels, respectively, in the hepatic vein, and allows equivocal lesions to be verified, or the site of unlocalized lesions to be more accurately predicted, and can be used to confirm tumour resection intraoperatively. Somatostatin receptor scintigraphy with radiolabelled somatostatin analogues has proved useful in demonstrating the extent of metastatic disease (Fig. 3), and may assist in the localization of extrapancreatic VIPomas, but is less effective in detecting microadenomas. There is controversy as to whether invasive imaging, usually angiography with provocative testing, or non-invasive imaging, principally endoscopic ultrasonography and somatostatin receptor scintigraphy, is the preferred option for localization of small tumours, but the choice will probably be determined by local expertise.

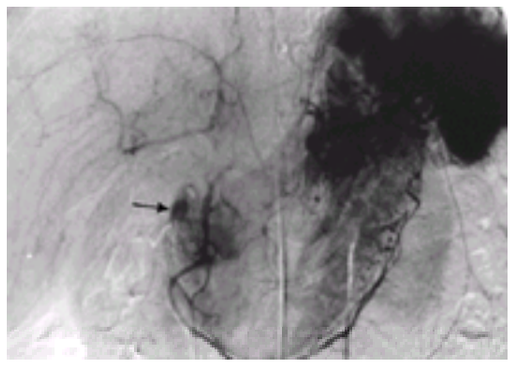

Fig. 1 Venous phase of coeliac axis angiogram demonstrating gastrinoma blush in duodenal wall (arrowed).

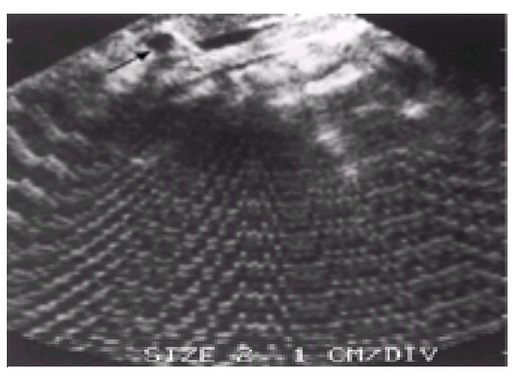

Fig. 2 Endoscopic ultrasound showing a 0.7 cm insulinoma in the head of the pancreas (arrowed).

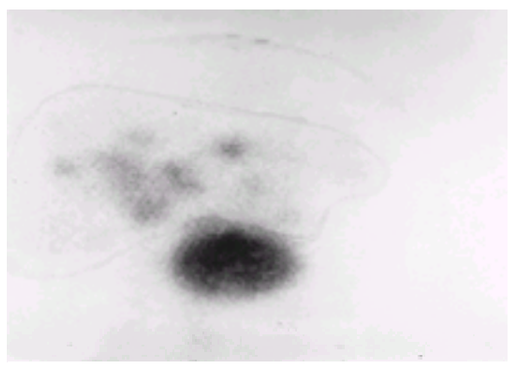

Fig. 3 ^{111}Indium-labelled somatostatin analogue scan showing the large primary tumour and diffuse hepatic metastases in a patient with a pancreatic glucagonoma.

Confirmation of the diagnosis can be made by immunocytochemical analysis of resection specimens or liver biopsies, in addition to conventional histology. Antisera against non-specific markers, such as chromogranins, provide evidence for a neuroendocrine origin, while antisera to different peptides identify the specific tumour type.

Treatment

Surgery offers the only hope of cure for pancreatic endocrine tumours, and all sporadic tumours without evidence of metastatic spread should be resected if possible. Surgical cures have been reported for a few patients with hepatic metastases amenable to enucleation, and, recently, liver transplantation has been successfully performed in patients with metastatic disease confined to the liver.

In the majority of patients, surgical cure is not possible and the aim of treatment in these cases is symptomatic palliation. Until the terminal stages of the disease, this is directed at reducing the symptoms of hormone excess in those with functional tumours. This can be achieved by reducing tumour bulk or inhibiting hormone secretion or action. Reduction of tumour bulk surgically is usually precluded by the operative morbidity. A variety of chemotherapy regimens have been reported as effective, although it is difficult to demonstrate that a particular regimen prolongs survival due to the small numbers of patients for analysis and the unpredictable nature of the tumours. The standard regimen consists of streptozotocin and 5-fluorouracil, with response rates of 80 per cent for functioning tumours, VIPomas responding particularly well, and about 50 per cent for non-functioning tumours. The combination of doxorubicin and streptozotocin has been reported to be more effective, preventing progression of disease for long periods and probably prolonging survival, and other studies have combined doxorubicin, streptozotocin, and 5-fluorouracil. Other agents advocated are dacarbazine for glucagonomas, and cisplatin and etoposide for anaplastic tumours. Another effective means of reducing tumour load in patients with extensive hepatic disease is embolization of the hepatic arterial supply to the metastases, a patent portal vein being needed to support the normal liver parenchyma. Response rates with this procedure are between 60 and 80 per cent. Additional benefit may be gained by chemoembolization, where chemotherapy is delivered via the catheter during the procedure.

Inhibition of hormone release and action is achieved by using the subcutaneous somatostatin analogue, octreotide. Native somatostatin inhibits multiple endocrine functions, acting particularly by blocking hormone effects on the target tissue, but has a half-life in circulation of only 3 min. Octreotide has a half-life of 2 h in the circulation and can be given in three doses daily. The clinical sequelae of peptide hypersecretion are often greatly diminished 24 h after the first injection, although patients become progressively resistant to its effects over many months or years, in part due to continued tumour growth. Recently, long-acting formulations of octreotide have become available, meaning that injections need only be given every 2 to 6 weeks, depending on the response.

Tumour syndromes

Gastrinoma

Gastrinomas are the commonest pancreatic endocrine tumour. Sixty per cent are malignant, 50 per cent of patients having metastases at the time of diagnosis, and up to 30 per cent of patients have the multiple endocrine neoplasia type 1 (MEN1) syndrome. The majority of tumours are pancreatic, but between 20 and 40 per cent are duodenal, and these are usually microadenomas, as little as 1 mm in diameter. Sporadic duodenal microgastrinomas are solitary, but in those patients with MEN1 they are usually multiple and associated with pancreatic microadenomas. Primary lymph node gastrinomas have been described but may represent metastases from duodenal microgastrinomas.

The gastrinoma syndrome was first described in 1955 by Zollinger and Ellison, who reported the triad of fulminating ulcer diathesis, recurrent ulceration with a poor response to therapy, and pancreatic non-b-cell islet tumours. The syndrome is the result of excess gastrin-stimulated gastric acid secretion. This causes severe, multiple peptic ulcers, which are usually duodenal, but may occur in the oesophagus and jejunum, and are often associated with complications such as haemorrhage, perforation, and stricture formation. Diarrhoea and steatorrhoea, due to acid inactivation of small bowel enzymes and mucosal damage, may be prominent features,

frequently preceding ulcer disease by 12 months or more.

The diagnosis of the gastrinoma syndrome requires the demonstration of a raised fasting gastrin concentration, associated with increased basal gastric acid secretion. The patient should, ideally, not take H_2 blockers for 3 days or omeprazole for 2 weeks before the test. Hypergastrinaemia and raised acid output may also arise from retained antrum following partial gastrectomy or the rare condition of G-cell hyperplasia. The intravenous secretin test distinguishes these conditions from gastrinoma and can aid diagnosis when other investigations are equivocal. In the presence of a gastrinoma, gastrin levels are elevated by at least 50 per cent following secretin, while there is no such increase in association with G-cell hyperplasia or retained antrum. Furthermore, gastrin levels are increased in response to a test meal in the latter conditions but not in association with a gastrinoma. Endoscopy may be valuable in demonstrating oesophageal and duodenal ulceration and hypertrophy of the gastric mucosa, while immunocytochemical analysis of antral biopsies may demonstrate G-cell hyperplasia. Localization of microgastrinomas may be aided preoperatively by endoscopic ultrasound or selective arterial secretin injection, or intraoperatively by ultrasonography or duodenotomy with transillumination and careful palpation. Small tumours often secrete gastrin rapidly and store little peptide so that histological diagnosis may only be possible by *in situ* hybridization to demonstrate synthesis of gastrin messenger RNA.

Since all gastrinomas may have the potential to metastasize, localized non-metastatic tumours should be resected, and regular attempts at localization should be made for occult tumours. In the past, the morbidity and mortality of the gastrinoma syndrome resulted from the severe peptic ulceration and associated complications. The best treatment for this was total gastrectomy to remove the source of acid hypersecretion. The H2-blockers provided relief of symptoms for many patients but often failed to suppress acid secretion adequately. The introduction of proton-pump inhibitors, which almost completely inhibits gastric acid production in all cases, has transformed the management of these patients, and offers the best palliation for those with metastatic disease. Most experience has been gained with omeprazole, but there is evidence that the newer agents are equally effective. Omeprazole is acid-labile and so initially should be administered with an H2-blocker. Since the introduction of proton-pump inhibitors, morbidity and mortality now occur much later and result from tumour bulk. Chemotherapy is effective in less than 50 per cent of cases, but hepatic embolization may be beneficial in the remainder.

VIPoma

VIPomas arise in the pancreas in 90 per cent of cases. The remaining tumours are mainly gangliomas or ganglioneuroblastomas originating in the sympathetic chain or adrenal medulla, and these tumours are especially common in children. Most extrapancreatic tumours are benign, but 50 per cent of pancreatic VIPomas have metastasized at the time of diagnosis, usually to local lymph nodes and the liver.

The features of the VIPoma (Verner–Morrison, pancreatic cholera) syndrome (Table 2) reflect the known biological actions of VIP. Large-volume diarrhoea without steatorrhoea is the cardinal symptom, most patients excreting more than 3 litres daily, with volumes of over 20 litres described. It is often intermittent at first, but in severe crises the volume loss coupled with the vasodilatory effects of VIP and the associated hypokalaemia may precipitate cardiovascular collapse.

Hypokalaemia results from loss in stools and activation of the renin–angiotensin system, and may be profound. The loss of bicarbonate in the stool leads to acidosis, which may mask the true potassium deficit. Achlorhydria or hypochlorhydria occurs in over 50 per cent of patients and distinguishes this diarrhoeal syndrome from that associated with gastrinoma, but its absence in a proportion of patients makes the acronym WDHA (watery diarrhoea, hypokalaemia, and achlorhydria) syndrome inappropriate. In up to 50 per cent of cases there is glucose intolerance as a result of the glucagon-like actions of VIP. Other features include: hypercalcaemia, probably due to PTHrP secretion and exacerbated by the dehydration; hypomagnesaemia due to loss in stools; and flushing of the head and neck, which can occur on tumour palpation and may be associated with a marked fall in systemic blood pressure. In advanced cases, extreme weight loss may occur.

VIPomas are usually associated with markedly raised plasma VIP concentrations, but because the half-life of VIP in circulation is only 2 min, the diagnosis is best confirmed by the finding of elevated circulating peptide histidine–methionine, which is produced from the prepro-VIP molecule, is more stable in plasma, and is cosecreted by VIPomas. Pancreatic polypeptide levels are elevated in 75 per cent of cases and neurotensin in 10 per cent. Ganglioneuroblastomas may secrete noradrenaline and adrenaline and so be associated with elevated urinary catecholamines and catecholamine metabolites.

VIPomas are usually large and so localization is rarely a problem. Occasionally, angiography may be necessary to detect small pancreatic lesions, or radiolabelled somatostatin or *m*-iodobenzylguanidine (MIBG) scanning to identify extrapancreatic tumours.

Resection specimens from pancreatic tumours show the structural and secretory patterns of epithelial endocrine tumours, while those from ganglioneuroblastomas show neurones and nerve fibres, together with Schwann cells. Immunocytochemistry detects VIP and peptide histidine–methionine, and electron microscopy shows poorly granulated tumours, with characteristic, small secretory granules.

Patients with non-metastatic disease should have surgical resections, and this is feasible in the majority of ganglioneuroblastomas. Chemotherapy provides very effective palliation for those with metastatic disease, and the excellent response to the comparatively non-toxic regimen of streptozotocin and 5-fluorouracil makes the use of other advocated agents, particularly a-interferon, unnecessary. Similarly, hepatic embolization is not usually indicated for metastatic VIPomas. Acute VIPoma crises should be managed with fluid and electrolyte support, and monitoring of central venous pressure is usually required. A number of drugs, including prednisolone, indomethacin, metoclopramide, lithium carbonate, and opiates, have been used with varying degrees of success to treat the diarrhoea. These have now been superseded by the somatostatin analogue, octreotide. Ninety per cent of patients respond to octreotide, with reduction of diarrhoea almost to normal and resolution of the electrolyte imbalance within 48 h, and it may be life-saving in an acute crisis. Unfortunately, the median duration of response to octreotide alone is less than 1 year, and so its use is probably best combined with chemotherapy.

Glucagonoma

Glucagonomas are a-cell tumours of the pancreas which secrete various forms of glucagon and other peptides derived from the preproglucagon molecule. They have an estimated annual incidence of 1 in 20 million, with a marginal female preponderance, and invariably present in adulthood. Over 70 per cent of patients have metastases at the time of diagnosis.

The characteristic feature of the glucagonoma syndrome is the rash of necrolytic migratory erythema, which occurs in almost all patients, although it often remains undiagnosed for many years (Plate 1). It usually starts in the groins and perineum, migrating to the distal extremities. The initial lesions are erythematous patches, which become raised and may be associated with bullae. These lesions break down and gradually heal, often leaving an area of hyperpigmentation, only to recur in another site. All mucous membranes may be involved, commonly leading to angular stomatitis, cheilitis, and glossitis. The cause of the rash is unknown. A direct effect of glucagon on the skin, glucagon-induced prostaglandin release, amino acid or free fatty acid deficiency, or zinc deficiency, due to the similarity with acrodermatitis enteropathica, have all been proposed as the underlying mechanism. The rash has been reported in a few patients without glucagonomas, who either had coeliac disease or cirrhosis, both of which may have led to elevation in glucagon and glucagon-like peptides. Other common features of glucagonomas include: impaired glucose tolerance, and occasionally mild diabetes requiring insulin therapy; progressive weight loss, which is occasionally severe enough to be fatal; venous thrombosis, which may be life-threatening; normochromic normocytic anaemia, probably as a result of direct bone marrow suppression by glucagon; bowel disturbance and nail dystrophy. Mental slowness, depression, and paraneoplastic neurological syndromes have also been described.

The diagnosis of glucagonoma is confirmed by demonstrating raised fasting plasma glucagon concentrations by radioimmunoassay; the elevation is usually 10- to 20-fold. Localization is almost never a problem, since tumours are invariably large and pancreatic, with metastases in the majority of cases. Barium studies often show thickened jejunal and ileal mucosa due to the trophic effects of large forms of glucagon on the small bowel. The tumour tissue contains large quantities of extractable glucagon which is localized to a-cells. Electron microscopy shows dense-core secretory granules and the core is often eccentric. Fifty per cent of tumours produce pancreatic polypeptide and coproduction of gastrin and insulin has been described. Skin biopsies show necrolysis of the stratum Malpighi of the epidermis in early lesions, but only a non-specific dermatitis at later stages.

Surgical cure of glucagonomas is rarely possible, although it has been claimed for patients with resectable metastatic disease; recently, successful liver transplantation for patients with metastatic glucagonomas has been reported. Surgery is complicated by the tendency to venous thrombosis, the catabolic effects of glucagon, and anaemia. A significant proportion of glucagonomas fail to respond to the combination of streptozotocin and 5-fluorouracil, and in these cases dacarbazine or hepatic embolization may be necessary. Octreotide is particularly effective in treating the rash, with resolution usually occurring within the first month of treatment and persisting for at least 6 months, but it has little impact on the other features of the syndrome. Other simple treatments for the rash which are worth using in all cases are topical or oral zinc and a high-protein diet. Amino acid infusions and blood transfusion may also be effective, but the tendency of the rash to spontaneous remission, often following hospitalization, throws doubt on the value of such procedures. The thrombotic tendency, which can result in fatal pulmonary

emboli, is refractory to conventional anticoagulation, but aspirin or dipyridamole may be of benefit.

Somatostatinoma

Somatostatinomas are extremely rare, with an estimated annual incidence of about 1 in 40 million. Fifty per cent of these tumours are pancreatic, the remainder arising in the duodenum. Approximately 50 per cent of duodenal somatostatinomas occur in association with neurofibromatosis type I (von Recklinghausen's disease) and these tumours are usually periampullary. Pancreatic tumours usually present late with hepatic metastases, but duodenal tumours are frequently identified earlier as a result of local effects.

The somatostatinoma syndrome is characterized by the triad of cholelithiasis, diabetes mellitus, and steatorrhoea, the latter occurring in almost all patients with pancreatic tumours. These features result from the inhibitory actions of somatostatin on gallbladder contraction and secretion, insulin secretion, and pancreatic exocrine secretions. Hypoglycaemia has occasionally been described, possibly due to larger molecular forms of somatostatin having a greater inhibitory effect on counter-regulatory hormones than on insulin. Other features of the syndrome include hypochlorhydria, anaemia, postprandial fullness, and weight loss. The full syndrome is rarely seen in association with duodenal somatostatinoma, gallbladder disease being the only common manifestation. These tumours usually present as a result of effects on local structures, such as obstruction of the ampulla of Vater causing jaundice or pancreatitis, or intestinal obstruction or haemorrhage.

Circulating levels of somatostatin are usually elevated greater than 10-fold in association with pancreatic tumours, but duodenal tumours are associated with much lower levels, probably because they are usually about one-tenth the size of the pancreatic lesions. Multiple molecular weight forms of somatostatin may be demonstrated by column chromatography of plasma or tumour extracts, and these may explain unusual clinical features. Localization is rarely a problem as barium examinations or endoscopy will identify duodenal lesions. Duodenal somatostatinomas are classified histologically as duodenal carcinoids. Duodenal carcinoids have the usual features of neuroendocrine tumours but often contain psammoma bodies. Those associated with neurofibromatosis type I are more likely to be pure somatostatinomas and to contain psammoma bodies.

Surgical resection of duodenal somatostatinomas is usually curative, although a Whipple's procedure may be needed to ensure clearance of periampullary tumours. Pancreatic tumours have almost always metastasized by the time of diagnosis and so palliation with chemotherapy or hepatic embolization are the only therapeutic options.

Pancreatic polypeptide, neurotensin, and other hormones

Pancreatic polypeptide (PP) can be extracted from almost all pancreatic endocrine tumours and is secreted by up to 75 per cent of them. The finding of elevated circulating pancreatic polypeptide in association with other tumour syndromes indicates a pancreatic tumour source. However, pancreatic polypeptide itself has no recognized physiological role and no associated tumour syndrome, and pure PPomas can be regarded effectively as non-functioning tumours. Similarly neurotensin, which is elevated in 10 per cent of VIPomas, does not cause a characteristic syndrome. Interestingly, neurotensin is produced by fibrolamellar hepatomas.

Hypercalcaemia is a feature of the VIPoma syndrome and may also occur in association with pancreatic endocrine tumours without other hormone syndromes. Secretion of parathyroid hormone related peptide (PTHrP) by pancreatic endocrine tumours has now been reported in a number of cases, and synthesis of PTHrP messenger RNA in normal and tumorous islets has been described. It is highly probable, therefore, that almost all cases of hypercalcaemia in association with pancreatic endocrine tumours are mediated by PTHrP. In these patients the hypercalcaemia responds to both octreotide and bisphosphonates.

The hypothalamic hormone, growth hormone releasing hormone (GHRH), was originally isolated from a pancreatic endocrine tumour, and there have been subsequent reports of patients with acromegaly and gigantism as a result of GHRH secretion by pancreatic endocrine tumours. Treatment options for these patients have included surgical resection, octreotide therapy, and liver transplantation.

Another hypothalamic releasing factor, corticotrophin releasing hormone, may be produced by pancreatic endocrine tumours, but this only causes Cushing's syndrome when the tumour also secretes corticotrophin. One patient with an enteroglucagon-secreting tumour of the right kidney, causing villous hypertrophy and slowed intestinal transit, steatorrhoea, and mild diabetes, has been reported, and there has been one case of acromegaly due to a growth hormone secreting pancreatic endocrine tumour. Other peptides produced by islet-cell tumours include neuropeptide Y, neuromedin B, calcitonin gene-related peptide, bombesin, and motilin, but these are not associated with recognized clinical syndromes.

Non-functioning tumours

Tumours not associated with a recognized hormonal syndrome may account for half of all pancreatic endocrine tumours. They usually present late with symptoms attributable to tumour bulk, such as anorexia and weight loss, or to effects on local structures, such as obstructive jaundice or intestinal obstruction or haemorrhage. They are often mistakenly diagnosed as adenocarcinomas, but the presence of elevated circulating gut hormones, such as pancreatic polypeptide or neurotensin, and the use of immunocytochemical analysis, can point to the correct diagnosis. Non-functioning tumours usually respond poorly to chemotherapy, but hepatic embolization may be beneficial. They have a poor prognosis as a result of their late presentation and lack of response to therapy.

Multiple endocrine neoplasia

The multiple endocrine neoplasia syndromes (MEN1 and MEN2) are familial conditions with an autosomal dominant pattern of inheritance and a high degree of penetrance. The genetic defect has been identified for both types of MEN—the MEN1 gene, *menin*, on chromosome region 11q13, and the MEN2 gene, *ret*, on chromosome region 10q11.2. In MEN2 there have been few mutations identified, so that rapid mutation screening is possible, and genotype–phenotype correlations have been identified. In MEN1 many different mutations have been identified, often occurring in only one kindred, and mutation detection can only be done by formal gene sequencing. Identification of specific gene defects in these syndromes may provide novel therapeutic options for tumour prevention in affected individuals.

Multiple endocrine neoplasia type 1 (MEN1)

MEN1 is characterized by the association of parathyroid hyperplasia, pancreatic endocrine tumours, and pituitary adenomas. This association was first described by Underdahl in 1953, and the autosomal dominant inheritance was first proposed in 1954 by Wermer, whose name provided the eponym for the syndrome. The prevalence of the condition has been estimated at about 1 in 10 000. The affected gene has been termed *menin* and is found on the 11q13 region of the long arm of chromosome 11. It encodes a nuclear protein which interacts with the JunD component of the transcription factor AP-1. The development of tumours fits the 'two-hit' model proposed by Knudson and demonstrated by familial retinoblastoma, whereby there is a germline mutation of the MEN1 gene on one chromosome 11, followed by a somatic deletion of the same region on the other chromosome, leading to loss of heterozygosity for that allele and subsequent tumour formation. A substantial proportion of MEN1 cases arise through sporadic mutations, and these patients present between the third and fifth decades, while familial cases can be identified earlier through screening, usually biochemical but increasingly genetic once the mutation affecting a kindred has been sequenced.

Parathyroid hyperplasia and adenomas

Hyperparathyroidism is the presenting feature of MEN1 in the majority of patients, and occurs in almost all cases. Patients present either with asymptomatic hypercalcaemia on biochemical screening or with the features of sporadic hyperparathyroidism. All four glands are diffusely hyperplastic and there may be nodule formation. Whether true adenomas develop remains controversial, but it is assumed that the presence of a capsule indicates adenomatous change. All patients should be operated on to prevent later morbidity from hypercalcaemia and there are two surgical approaches. Subtotal parathyroidectomy may be performed, but hyperparathyroidism will almost always recur, necessitating excision of the remaining parathyroid tissue. However, most surgeons would perform total parathyroidectomy, either with autotransplantation of one gland to the forearm, which can later be removed if hyperparathyroidism recurs, or with immediate replacement therapy with 1a-hydroxycholecalciferol.

Pancreatic endocrine tumours

Pancreatic endocrine tumours occur in about 70 per cent of patients with MEN1, and usually present between the ages of 15 and 50 if not identified by screening. They account for most of the morbidity and mortality of the MEN1 syndrome. Over 60 per cent of tumours are gastrinomas and about 30 per cent are insulinomas, the two coexisting in about 10 per cent of cases. VIPomas have rarely been described and there are only isolated reports of glucagonomas, but non-functioning tumours

may occur frequently. Diffuse hyperplasia of the pancreas is usually seen, similar to the parathyroid, and in the majority of cases there are multiple adenomas, most of which are less than 1 cm in diameter. Duodenal microgastrinomas are very common, probably accounting for almost half of all MEN1-associated gastrinomas, and are usually multiple, with up to 15 separate tumours described.

The surgical approach to pancreatic endocrine tumours in MEN1 is controversial. Surgical cure is best achieved by removing the pancreas and duodenum with adjacent lymph nodes, but such an aggressive approach is only justified in families in which the pancreatic disease has been extremely malignant, and in these kindreds it should be performed only when pancreatic disease is biochemically apparent. An alternative, potentially curative, approach is to perform a subtotal pancreatectomy with enucleation of palpable tumours in the head and careful exploration for duodenal lesions, which should also be resected. A more conservative strategy is to enucleate gross lesions to reduce the risk of developing metastatic disease, although size dose not necessarily correlate with metastatic potential, and then control hormonal syndromes with appropriate medical therapy. The latter approach may be appropriate for gastrinomas because proton-pump inhibitors are such an effective treatment, but for insulinomas, where medical therapy is often unsuccessful and symptoms usually recur after enucleation alone, more aggressive surgical management may be the best option. The treatment of metastatic disease is the same as in sporadic cases.

Pancreatic endocrine tumours associated with MEN1 are less malignant than sporadic tumours and carry a better prognosis, with a median survival of 15 years compared to 5 years for patients with sporadic tumours. This may reflect more indolent disease or earlier diagnosis.

Pituitary adenomas

The true incidence of pituitary adenomas in MEN1 is disputed. They are detected by screening in 30 per cent of patients, but are found at autopsy in over 50 per cent of patients. Unlike the pancreas and parathyroid, there does not appear to be diffuse pituitary hyperplasia, and loss of heterozygosity for the MEN1 locus is much less common in pituitary tumours than in parathyroid and pancreatic lesions.

Prolactinomas are the commonest tumours, occurring in about two-thirds of cases, with acromegaly accounting for about 30 per cent, and other functioning tumours being rare. Treatment is the same as for sporadic pituitary tumours (see Chapter 12.6).

Other lesions

Lesions in other tissues have been reported in association with MEN1, but their relationship to the syndrome remains controversial. Carcinoid tumours of the foregut, midgut, and thymuta occur in about 10 per cent of cases, and are often found in the pancreas, but are rarely symptomatic. Lipomas occur in a significant proportion of patients and act as a marker for affected individuals. Adrenal lesions are common autopsy findings in normal individuals, but do appear to occur more frequently in MEN1, with an incidence of up to 40 per cent. Furthermore, *menin* gene mutations have been demonstrated in individuals with atypical familial endocrine syndromes including phaeochromocytoma. Histology of adrenal lesions associated with MEN1 usually demonstrates nodular hyperplasia and there is no associated excess hormone secretion. Loss of heterozygosity of the MEN1 locus is not found in these lesions and it has been proposed that there may be a circulating adrenal growth factor, possibly secreted by the pancreas, since there is a strong correlation with pancreatic tumours, particularly insulinomas. MEN1-associated adrenal tumours showing loss of heterozygosity for 11q13 have been reported but are very rare. Thyroid disease has been reported in association with MEN1, but does not appear to occur more frequently than in the normal population.

Screening

The screening of first- and second-degree relatives of patients with MEN1 is aimed at early detection of parathyroid, pancreatic, or pituitary lesions in gene carriers, to reduce the associated morbidity. There is no evidence that screening reduces mortality, although the identification of affected individuals in 'malignant' kindreds with aggressive pancreatic disease may allow curative surgery which would be expected to prolong survival. Screening lowers the age of detection of the syndrome by about 20 years.

The most useful screening investigations are a serum calcium, fasting gastrin, and prolactin, although in practice a full gut hormone screen is usually performed. It has been suggested that the most sensitive markers of pancreatic disease are basal and test-meal-stimulated pancreatic polypeptide and gastrin, and basal insulin and proinsulin, identifying lesions at least 3 years before there are any radiological abnormalities. Since pancreatic tumours are the only life-threatening manifestation of the syndrome, such a screening protocol may be warranted. The MEN1 syndrome rarely develops before the age of 5 or after the age of 70, and so screening should be performed annually from 5 to 65, and at longer intervals thereafter. Eighty per cent of affected individuals will have been identified by the fifth decade. Screening of patients with apparently sporadic pancreatic endocrine tumours for evidence of MEN1 is probably justified, especially in those with gastrinomas or insulinomas. There is little evidence to support screening in those with sporadic pituitary tumours. MEN1 is present in 15 per cent of all patients with hyperparathyroidism, but hypercalcaemia may be associated with elevated fasting gastrin and pancreatic polypeptide, and, whereas in those at risk of MEN1 this finding would be highly significant, in those with sporadic hyperparathyroidism this very rarely indicates pancreatic disease, so screening of all patients is not warranted.

Genetic mutation analysis can be used to screen for affected individuals in kindreds where the gene mutation has been identified, but if this is not the case biochemical screening is still needed.

Multiple endocrine neoplasia type 2 (MEN2)

Multiple endocrine neoplasia type 2 is the association of medullary cell carcinoma of the thyroid (MTC) and phaeochromocytoma. The association was first recognized in 1932, but it was not until 1961 that it was noted that the risk of phaeochromocytoma in patients with MTC was increased 14-fold. MEN2 has since been subdivided: in MEN2A, or Sipple's syndrome, parathyroid hyperplasia may occur; MEN2B is associated with mucosal neuromas and marfanoid habitus. In addition, there is a familial form of MTC without other features. Germ line mutations of the *ret* proto-oncogene, a receptor tyrosine kinase, have been identified in all three syndromes. In MEN2A and familial MTC, mutations occur in the extracellular domain, whilst in MEN2B mutation in the tyrosine kinase domain has been demonstrated. The MEN2 phenotypes reflect the expression of *ret* in different tissues. Tumours in affected individuals are heterozygous for the *ret* mutation, and so it is the only known dominantly inherited proto-oncogene. It is likely that activation of *ret* leads to hyperplasia in affected tissues and that a somatic mutation in another oncogene is required for carcinogenesis. Thus loss of heterozygosity for the short arm of chromosome 1 has been described in phaeochromocytomas and MTC associated with MEN2. New mutations are uncommon in MEN2A, and probably account for less than 10 per cent of cases, whereas new mutations account for about 50 per cent of cases with MEN2B. Those patients with MEN2A not identified by screening usually present in the fourth and fifth decades, while those with MEN2B present much earlier due to their characteristic phenotype.

Medullary cell carcinoma of the thyroid (MTC)

MTC is a tumour of the C cells of the thyroid (see Chapter 12.4 and Chapter 12.5), which secrete calcitonin, and this acts as a tumour marker. Twenty-five per cent of cases are familial. The incidence of MTC in MEN2 is probably 100 per cent. Familial MTC alone is the most benign form of MTC, while MTC in association with MEN2B is the most malignant form of the disease. In MEN2, the initial thyroid lesion is C-cell hyperplasia, which has been found as early as the age of 3 years in MEN2A and may be present at birth in MEN2B. Over the subsequent 5 to 10 years, microscopic MTC develops and finally gross tumours become apparent. Metastases are invariably present when tumours are already palpable, but there is speculation that they may occur with clinically occult disease. All forms of hereditary MTC are bilateral, with multifocal tumours, usually occurring at the junction of the upper third and lower two-thirds of the thyroid.

In MEN2A, MEN2B, and familial MTC genotype screening has largely replaced biochemical screening for MTC using pentagastrin-stimulated calcitonin, with over 95 per cent of kindreds with MEN2 and over 80 per cent of those with familial MTC having germline mutations of the *ret* gene, 99 per cent of MEN2 kindreds having a mutation in codon 918. In families with a known *ret* mutation it has been recommended that a positive genotype should result in a total thyroidectomy with lymph node clearance by the age of 2 years in MEN2B kindreds and at age 3 in MEN2A and familial MTC kindreds. In MEN2B MTC has been reported as early as 15 months of age with metastases by the age of 3 years. Prior to thyroidectomy those with a positive genotype should be screened biochemically for phaeochromocytoma, which, if confirmed, should be resected first. In those patients with MTC not identified by screening, thyroidectomy should still be performed, unless distant metastases, usually to lung or liver, are present. It is probable that in all patients with palpable disease, metastases to local lymph nodes will be present, so a central lymph node dissection should also be performed, probably with lateral node sampling to look for further spread. The prognosis is poor in this group, with recurrent disease in about 20 per cent of patients with clinically occult but macroscopic MTC and in over 60 per cent of those with palpable MTC. It is particularly poor in individuals with

MEN2B who present with clinically apparent MTC. Their 10-year survival is about 50 per cent, and death from metastatic disease in the mid-twenties is common.

Phaeochromocytoma

Phaeochromocytoma is familial in 5 per cent of cases, 20 per cent of whom have MEN2. Fifty per cent of individuals with MEN2 develop phaeochromocytoma. About 70 per cent are bilateral, almost all are benign, and they are rarely extra-adrenal. The initial lesion, similar to that in the thyroid, is adrenal medullary hyperplasia, followed by nodule formation and, subsequently, development of multiple, multifocal phaeochromocytomas (see Chapter 15.16.2.4).

Symptoms and biochemical abnormalities are rare during the stage of medullary hyperplasia. MEN2-associated phaeochromocytomas are characterized by excessive adrenaline secretion, so that palpitation and other b-adrenergic symptoms predominate initially, with hypertension a late feature, although often present by the time of diagnosis. A urine adrenaline: noradrenaline ratio of greater than 0.15 in a patient with MEN2 indicates medullary hyperplasia or phaeochromocytoma. The treatment for adrenal medullary hyperplasia or phaeochromocytoma is bilateral adrenalectomy, since the incidence of bilateral disease is high, and the mortality from phaeochromocytoma in MEN2 about 15 per cent, usually due to sudden death. If an adrenal lesion is identified at the same time as MTC, the adrenalectomy should be performed first.

Other features of MEN2A

Parathyroid hyperplasia occurs in up to 80 per cent of patients with MEN2A, but less than 20 per cent have hypercalcaemia, the remainder being identified at the time of thyroidectomy. Parathyroidectomy should be performed in those with hypercalcaemia and in the remaining patients grossly enlarged glands should be removed at the time of thyroidectomy.

Cutaneous lichen amyloidosis, often preceded by intense pruritus, has been described in two kindreds with MEN2A and provides a phenotypic marker for the syndrome.

Other features of MEN2B

The characteristic phenotype of marfanoid habitus and mucosal neuromas (Fig. 4) identifies affected individuals with MEN2B and allows early intervention, since these features usually predate MTC and phaeochromocytoma. Neuromas are commonly ocular and oral, causing whitish-yellow or pink nodules on the anterior aspect of the tongue, lips, and eyelids, with thickening of the mucosa and often eversion of the lower lids. The nasal bridge may be broadened, pedunculated neuromas are found on cheek mucosa, and the corneal nerves are thickened and medullated. Involvement of peripheral motor and sensory nerves can cause a peroneal muscular atrophy type picture. Intestinal ganglioneuromatosis affects about 75 per cent of cases. Neuromas involve the autonomic nerves of both the myenteric and submucosal plexi and can cause poor suckling with failure to thrive, altered bowel habit, recurrent pseudo-obstruction, toxic megacolon, and occasionally dysphagia and vomiting, possibly due to achalasia. Almost all patients have a marfanoid habitus, usually associated with skeletal abnormalities, particularly slipped femoral epiphyses. Delayed puberty is another common feature of the syndrome.

Fig. 4 (a) Characteristic phenotype of MEN2B showing facial appearance. (b) Characteristic phenotype of MEN2B showing mucosal neuromas on tongue.

Screening

Screening to identify affected individuals by genotyping and for early biochemical detection of adrenal disease reduces both morbidity and mortality in MEN2. A positive genotype identifies individuals for thyroidectomy. If a kindred's genotype has not been identified an elevated pentagastrin-stimulated calcitonin but normal basal calcitonin identifies individuals at the stage of C-cell hyperplasia or microscopic MTC. Where it is indicated biochemical screening in MEN2A or familial MTC should commence at age 3 and be performed annually. In MEN2B individuals with the phenotype do not need screening, as they should have a thyroidectomy before the age of 2 years. Urinary metanephrines and catecholamines identify at least 95 per cent of phaeochromocytomas. Urinary vanillylmandelic acid levels are less useful, being associated with a high number of false positives and negatives. MIBG and/or CT scanning or measurement of plasma catecholamines may identify phaeochromocytomas missed by urinary assays. Serum calcium should be measured at the annual screening to identify overt hyperparathyroidism. In families where a mutation has been characterized, affected individuals can be identified by mutation screening.

Other syndromes associated with endocrine neoplasia

There are other syndromes which overlap with the multiple endocrine neoplasia syndromes and gene mutation analysis can identify those which are true variants of MEN1 or MEN2. Phaeochromocytomas may be associated with pancreatic islet-cell tumours alone, or in combination with other syndromes: von Hippel–Lindau syndrome is associated with a high incidence of phaeochromocytomas, islet-cell tumours, cerebellar haemangioblastomas, retinal angiomas, and renal cell carcinoma; neurofibromatosis type I (von Recklinghausen's syndrome) is often associated with phaeochromocytoma and, rarely, with duodenal somatostatinoma and medullary thyroid carcinoma; and phaeochromocytoma may be associated with prolactinoma as a mixed MEN syndrome.

12.11.1

Diabetes

Gareth Williams

Diabetes mellitus can be defined as a state of chronic hyperglycaemia sufficient to cause long-term damage to specific tissues, notably the retina, kidney, nerves, and arteries.

This functional label gives little insight into the long and colourful history of this disease, its clinical and scientific importance, or its immense personal and socio-economic impact. Diabetes was recognized in antiquity, and its clinical features (with empirical treatment guidelines) were recorded over 3500 years ago in the Egyptian 'Ebers' papyrus. Our understanding of the disease has advanced greatly, especially during the last two decades, but many aspects of its management remain imperfect.

Diabetes is and will remain a threat to global health. In the United Kingdom, at least 2 per cent of the population (over 1 million people) are diabetic and the disease absorbs 5 to 10 per cent of the total health budget. Worldwide, diabetes probably affects 150 million people and its prevalence is predicted to double by 2015.

Diagnosis of diabetes

Blood glucose concentrations are is normally tightly regulated: fasting values lie between 3.5 and 5.5 mmol/l and even large carbohydrate loads do not raise the concentration above 8 mmol/l. It is logical to define diabetes by the blood glucose concentrations which cause the chronic complications of the disease but the choice of the diagnostic glucose levels has been contentious (and has stirred up much passion among epidemiologists). One difficulty is that some diabetic complications show a 'threshold' effect with the risk rising above a cutoff level (for example fasting plasma glucose of 6 to 7 mmol/l for retinopathy), whereas macrovascular disease (atheroma) does not (see later). Another problem is that even the current criteria are not self-consistent: for example, 30 per cent of newly diagnosed type 2 diabetic patients will have a 'normal' fasting plasma glucose, while another 30 per cent will have a 'normal' value 2 h after an oral glucose tolerance test.

The current diagnostic criteria for diabetes and other hyperglycaemic states (Fig. 1) have been approved by the World Health Organization and most national diabetes associations. All values refer to venous plasma glucose concentrations:

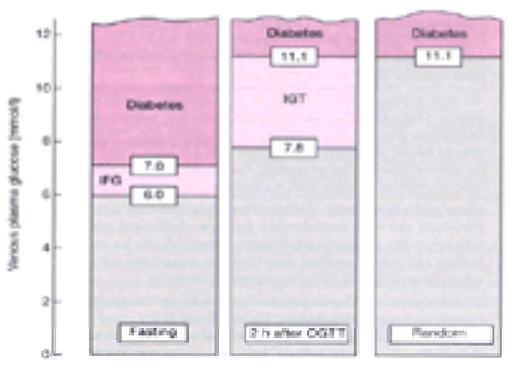

Fig. 1 Diagnostic thresholds for diabetes, impaired glucose tolerance (IGT), and impaired fasting glucose (IFG). From the Expert Committee on the Diagnosis and classification of diabetes mellitus (1997). *Diabetes Care* **20**, 1183–97. For conversion to mg/dl, multiply values in mmol/l by 18.

1. Diabetes mellitus: fasting glucose more than 7.0 mmol/l and/or a value exceeding 11.1 mmol/l, either at 2 h during an oral glucose tolerance test or in a random sample. The corresponding levels in non-SI units are 126 and 200 mg/dl respectively. The diagnostic fasting glucose level was lowered from the previous value of 7.8 mmol/l to reflect more accurately the risk of developing diabetic retinopathy.
2. Impaired glucose tolerance: fasting glucose less than 7.0 mmol/l and 2-h oral glucose tolerance test value between 7.8 and 11.1 mmol/l.
3. Impaired fasting glucose: fasting glucose 6.1 to 6.9 mmol/l (110 to 124 mg/dl).

Impaired glucose tolerance (**IGT**) and the recently distinguished impaired fasting glucose (**IFG**) are intermediate categories of hyperglycaemia that carry definite risks and so require follow-up and risk-factor management (see below). They are often transient stages and overlap to some extent: about one-third of subjects with

impaired fasting glucose also have impaired glucose tolerance, while one-quarter of those with impaired glucose tolerance also show impaired fasting glucose.

The new criteria put much emphasis on the fasting plasma glucose concentration. However, the time-consuming oral glucose tolerance test is still required in some cases with borderline fasting hyperglycaemia, because the 2-h oral glucose tolerance test value in such patients may be high enough to put them at risk of microvascular complications. Moreover, the oral glucose tolerance test remains the only way to define impaired glucose tolerance.

Practical screening and diagnostic procedures

Figure 2 shows an algorithmic approach to screening for and diagnosis of diabetes and its associated hyperglycaemic states. Certain high-risk groups need to be actively screened for type 2 diabetes, which may be present (and causing complications) for several years before it is noticed. These include subjects predisposed to develop type 2 diabetes through genotype and/or phenotype, those affected by diabetogenic conditions such as pregnancy, endocrine disorders or certain drugs, and those with other cardiovascular risk factors in whom hyperglycaemia must not be missed.

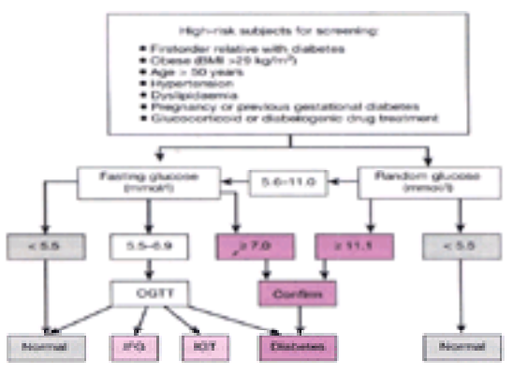

Fig. 2 Screening algorithm for diagnosing diabetes, impaired glucose tolerance, and impaired fasting glucose. All glucose values relate to venous plasma (mmol/l). Adapted from data in Shaw JE and Zimmet P (2000). Do we know how to diagnose diabetes and do we need to screen for the disease? In: Gill GV, Pickup JC, Williams G, eds. *Difficult diabetes*, pp 3–21. Blackwell Science, Oxford.

Diabetes is not a trivial diagnosis, and certain practical points must be carefully observed:

1. Glucose should be measured in venous plasma using a quality-controlled laboratory method. Capillary (finger-prick) samples contain higher glucose levels than venous blood, from which glucose has been extracted by the tissue bed; whole-blood glucose levels are lower than in plasma, because red cells actively metabolize glucose and so contain only low concentrations. These differences may reach 0.5 to 1.0 mmol/l. Portable glucose meters correlate well with laboratory glucose methods, but because of potential technical errors they should not be used to make or refute the diagnosis.
2. An oral glucose tolerance test is indicated for borderline hyperglycaemia (Fig. 2). After an overnight fast, the subject drinks 75 g of anhydrous glucose dissolved in 250 ml water (or 394 ml Lucozade); venous blood is sampled at baseline and 2 h later. Food intake should be normal during the preceding few days: poor nutrition can cause delayed hyperglycaemia with a raised 2-h value (the 'lag' curve).
3. Abnormal values need confirmation. Postchallenge glucose levels in particular can vary considerably. Because of this and possible laboratory error, the diagnosis of diabetes should ideally be verified using a further sample on another day. Obvious exceptions are grossly raised values in seriously ill patients, especially children.
4. Diabetes must not be diagnosed from indirect measures of hyperglycaemia such as raised glycated haemoglobin (HbA_{1c}) or fructosamine levels in blood, or glycosuria. HbA_{1c} and fructosamine reflect average blood glucose concentrations, but the measurements are not sufficiently sensitive or standardized (several different methods are in use) to be used diagnostically. Glycosuria depends on the renal threshold for glucose reabsorption and its presence does not necessarily indicate hyperglycaemia; conversely, glucose may be absent from the urine in diabetic subjects who also have a high renal threshold. However, abnormal results with any of these tests suggest diabetes and indicate the need for formal blood glucose screening.

Impaired glucose tolerance (IGT)

Impaired glucose tolerance is a metastable state: within 5 years, about 25 per cent of subjects with impaired glucose tolerance deteriorate into type 2 diabetes, while a further 25 per cent revert to normoglycaemia. The degree of hyperglycaemia in impaired glucose tolerance falls, by definition, below the threshold for microvascular complications but is enough to predispose to cardiovascular disease (see later).

Subjects found to have impaired glucose tolerance must be followed up because of the hazards of both diabetes and macrovascular disease. An oral glucose tolerance test should be repeated at least annually, and dietary and lifestyle advice given to decrease metabolic and cardiovascular risks; increased physical activity, a low-fat diet and weight loss convincingly reduce both the progression to type 2 diabetes and cardiovascular events. Risk factors such as smoking, hypertension, dyslipidaemia, and obesity should be managed actively. Specific antihyperglycaemic treatments (with metformin or thiazolidinediones, to improve insulin sensitivity) are currently being evaluated.

Impaired fasting glucose (IFG)

As with impaired glucose tolerance, the 5-year risk of progressing to type 2 diabetes appears to be about 25 per cent, and IFG predisposes to cardiovascular disease. Long-term monitoring and management should therefore be as for impaired glucose tolerance.

Metabolic basis of diabetes

Diabetes is due to inadequate production of insulin and/or 'resistance' to the glucose-lowering and other actions of insulin. To put this in context, key aspects of normal metabolism will be briefly reviewed.

The islets of Langerhans

There are about 1 million islets of Langerhans in the normal adult: insulin is produced by the b (B) cells, which make up the bulky core of each islet; b cells also synthesize the peptide known as amylin or islet-associated polypeptide. The other islet cell types, mostly surrounding the b-cell core, are the a (A) cells that produce glucagon, the † (D) cells that produce somatostatin, and the PP cells that synthesize pancreatic polypeptide. All islet cells are derived embryologically from the buds of gut endoderm which also give rise to the exocrine pancreatic tissue.

The various islet cell types communicate with each other through the hormones they secrete into the islet's rich capillary plexus and probably by paracrine effects on adjacent cells; these interactions presumably regulate hormone secretion. Insulin inhibits release of glucagon, while glucagon powerfully stimulates insulin secretion—an action exploited in the testing of b-cell reserve (see below). Somatostatin suppresses the secretion of insulin and glucagon. Amylin can inhibit insulin secretion under experimental conditions but its physiological role is uncertain. Amylin also polymerizes outside the b cell to produce fibrils of amyloid material, which have been implicated in the progressive b-cell damage of type 2 diabetes.

Insulin

Insulin has a molecular weight of 5800 Da; it is made up of an A chain (21 amino acid residues) and a B chain (30 residues), joined covalently by two disulphide bridges. The precursor molecule, proinsulin, consists of the A and B chains linked end-to-end through a connecting (C) peptide which is cleaved off during insulin processing. In the circulation, insulin is monomeric but in crystals and more concentrated solutions (for example in the insulin vial and the subcutaneous injection

site), six insulin molecules self-associate around a central Zn^{2+} ion. Self-association influences the pharmacokinetic properties of subcutaneously injected insulin: the rate-limiting dissociation of hexamers into monomers slows the absorption of even 'fast-acting' insulin.

Insulin regulates metabolism in birds, fish, and reptiles as well as mammals, and its structure is remarkably well conserved across the phyla. Three species of insulin are used therapeutically; the human sequence differs from porcine at a single residue (B30) and from bovine at two others. These differences affect the pharmacokinetic and immunogenic characteristics of the insulins (see below). The physicochemical behaviour of insulin has been successfully manipulated in synthetic 'designer' insulins that have improved absorption profiles: modification of the C terminus of the B chain, a region crucial for self-association, produces analogues that remain in the monomeric state and are therefore absorbed faster than the native soluble insulin (see below).

Insulin biosynthesis and processing

Insulin is a product of the preproinsulin (*INS*) gene, located on the short arm of chromosome 11, whose coding region contains three exons. Translation of *INS* mRNA in the rough endoplasmic reticulum produces preproinsulin, which is successively cleaved during its passage through the Golgi vesicles and secretory vesicles to yield first proinsulin and finally insulin and C peptide. Proinsulin is converted into insulin by the proteolytic excision of the C-peptide chain; the two intermediate cleavage products (with either end of the C peptide remaining attached to insulin) are called 'split products' of proinsulin. Normally, almost all proinsulin is processed through this 'regulated' pathway to yield equimolar amounts of insulin and C peptide. However, a 'constitutive' pathway may predominate in dysfunctional b cells (for example in type 2 diabetes and insulinoma), when processing is not complete and large quantities of proinsulin and split products may be released into the circulation.

C peptide is generally regarded as an inert byproduct of insulin production. However, its structure is also conserved across species and it may have vasoactive and other properties.

Insulinopathies are point mutations in the *INS* gene which either produce a mutant insulin (for example, insulin Chicago: a phenylalanine for leucine substitution at residue B25) or interfere with one of the cleavage sites of proinsulin so that the mutant split product cannot be further processed (for example, proinsulin Tokyo). These conditions are inherited as autosomal dominant traits; circulating insulin-like or proinsulin-like immunoreactivities may be extremely high but glucose intolerance is often surprisingly mild.

Insulin secretion

Glucose is the main insulin secretagogue; this action of glucose is modulated by other ingested nutrients, by hormones released by the islets and the gut, and by the autonomic innervation of the islet. The process gives insight into the mode of action of the sulphonylureas and related drugs, and the cause of maturity onset diabetes of the young (see below).

Glucose-stimulated insulin secretion

The amount of insulin released by the normal b cell is tightly coupled to blood glucose levels and begins to increase immediately when blood glucose rises. The ability of the b cell to sense ambient glucose levels accurately and rapidly depends on the glucose transporter isoform GLUT-2 and the glucose metabolizing enzyme glucokinase, while insulin release hinges on depolarization of the b-cell membrane which is controlled by a specific ion channel, the ATP-sensitive K^+ channel. The characteristics of GLUT-2 allow glucose at physiological concentrations to freely enter the b cell, where it is immediately converted by glucokinase into glucose-6-phosphate—the point of entry into the glycolytic pathway which ultimately yields ATP; ATP production within the b cell is therefore proportionate to extracellular glucose.

ATP binds to and closes the ATP-dependent K^+ channel; when open, this channel allows K^+ ions to leave the b cell along their concentration gradient and thus helps to maintain the negative charge inside the b-cell membrane. ATP-induced closure of the channel therefore causes K^+ ions to accumulate within the cell and the membrane to depolarize, which triggers the opening of specific (voltage-gated) Ca^{2+} channels in the membrane. Ca^{2+} ions then flood into the b cell from the outside and activate the contractile proteins which drag the secretory vesicles containing insulin and C peptide to the cell surface. Here, the vesicles fuse with the cell membrane and release their contents into the extracellular space (exocytosis), from where insulin and C peptide enter the islet capillaries.

Other factors affecting insulin secretion

Sulphonylureas induce insulin secretion by closing the same ATP-sensitive K^+ channel as glucose: they bind to a specific sulphonylurea receptor (SUR-1) linked to the K^+ channel protein (called Kir 6.2). Repaglinide also closes this K^+ channel, but binds to a different site from the sulphonylureas. By contrast, diazoxide locks the channel open, hyperpolarizing the b-cell membrane and inhibiting insulin secretion—hence its use in treating insulinoma.

Glucagon and glucagon-like peptide-1 7–36 amide (**GLP-1**; a gut peptide with insulin secretagogue (incretin) actions), both stimulate insulin secretion by raising cytosolic Ca^{2+} concentrations; binding to their receptors increases generation of cyclic AMP which blocks removal of Ca^{2+} into intracellular organelles. Conversely, somatostatin and possibly amylin act to decrease production of cyclic AMP and inhibit insulin secretion. Arginine stimulates insulin secretion, possibly by depolarizing the b-cell membrane as it enters the cell (it is cationic).

The autonomic nervous system is an important modulator of insulin secretion; it is stimulated by the parasympathetic (vagal) outflow and inhibited by the sympathetic. Vagal stimulation is mediated by acetylcholine acting via muscarinic receptors, while the inhibitory sympathetic neurotransmitter is noradrenaline, interacting with a_2 adrenoceptors.

Diseases due to defects in insulin secretion in perhaps 10 per cent of pedigrees is due to mutations affecting glucokinase (glucokinase-dependent maturity onset diabetes of the young). These impair ATP production from glucose, blunting the insulin response of the b cell to rising glucose and resulting in variable hyperglycaemia (see below). By contrast, familial neonatal hyperinsulinism is caused by mutations in *SUR-1* that close the ATP-sensitive K^+ channel, leading to sustained insulin secretion and severe hypoglycaemia soon after birth.

Normal pattern of insulin secretion

Insulin concentrations in peripheral blood show basal levels of about 10 mU/l that tend to fall overnight, on which are superimposed prandial peaks reaching 80 to 100 mU/l, roughly proportionate to the amount eaten. The prandial peaks are elicited by the insulin secretagogue effects of glucose and other nutrients, augmented by incretin gut peptides (such as GLP-1) and the vagal outflow (the early cephalic phase of insulin release).

Very frequent sampling (every minute) shows that 'basal' insulin secretion is in fact pulsatile, with clear but low-amplitude peaks every 9 to 13 min. This may help to keep the target tissues sensitive to insulin; loss of this pulsatility is an early sign of b-cell dysfunction in type 2 diabetes. An acute insulin secretagogue challenge (for example an intravenous glucose bolus) induces a sharp 'first-phase' insulin peak, loss of which is another early abnormality in type 2 diabetes.

The insulin response elicited by eating is larger than when an equivalent nutrient load is given intravenously. This is because glucose entering the gut stimulates neuroendocrine cells in the gut wall to release 'incretin' hormones which act on the b cell to enhance insulin secretion (the 'enteroinsular axis': see Chapter 14.8). An important incretin appears to be GLP-1, a product of alternative processing of the preproglucagon gene (glucagon itself is not produced, in contrast to the islet a cell). GLP-1 released from the small intestine augments insulin release in the presence of glucose, an effect being explored in the treatment of type 2 diabetes.

Peripheral insulin levels are lower than those in the portal vein, into which the islets drain, because up to 30 per cent of insulin is removed on its first pass through the liver—one of the main targets for insulin action. The kidney also actively clears and degrades insulin; the circulating half-life is only a few minutes.

C peptide provides a robust measure of residual b-cell function, because it is cleared more slowly than insulin and its plasma concentrations are therefore more stable. C peptide is generally measured after intense b-cell stimulation with the powerful insulin secretagogue glucagon; alternatives are a heavy oral load of carbohydrate, or simply the measurement of 24-h secretion of C peptide in urine (it is cleared largely intact through the kidneys). In normal subjects and most with type 2 diabetes, peak C-peptide concentrations at 6 min after 1 mg of intravenous glucagon are 1 to 4 nmol/l, whereas type 1 diabetic individuals are typically

'C-peptide negative', with peak levels less than 0.6 nmol/l.

The insulin receptor and signal transduction

The insulin receptor belongs to the family that also includes the insulin-like growth factor 1 receptor. Insulin receptors are found in the obvious insulin target tissues (fat, liver, and skeletal muscle) but also in unexpected sites, such as the brain and gonads, in which glucose uptake does not depend on insulin.

The insulin receptor is a 400-kDa heterotetramer composed of two a and two b glycoprotein subunits, interconnected by disulphide bridges (Fig. 3). Both a and b subunits are encoded within a complex gene (22 exons) on chromosome 19q. The a subunit (135 kDa) lies entirely extracellularly, while the b subunit (95 kDa) spans the cell membrane and extends into the cytoplasm. Part of the intracytoplasmic tail functions as a tyrosine kinase, attaching phosphate groups from ATP to tyrosine residues elsewhere on the receptor (autophosphorylation) and on other intracellular proteins. This tyrosine kinase activity is essential for insulin signalling and for insulin to exert its many effects on its target tissues. Insulin binds to a site on the extracellular a subunits, and binding triggers a conformational change in the receptor which activates the tyrosine kinase domain of the b subunits.

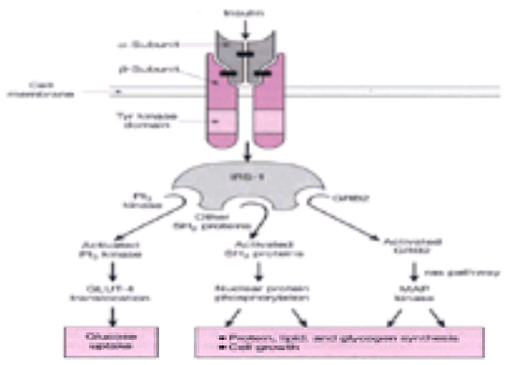

Fig. 3 The insulin receptor and signal transduction pathways within insulin's target cells. Binding of insulin to the extracellular a subunits of the receptor activates the tyrosine (Tyr) kinase domain of the intracellular b subunit. This phosphorylates insulin receptor substrate 1 (IRS-1) and the related IRS-2, which in turn phosphorylate other signalling proteins. These activated proteins then trigger other reactions that result in the biological actions of insulin, including enhanced glucose uptake, anabolic effects, and cell growth. PI_3 kinase, phosphatidylinositol 3 kinase; MAP kinase, mitogen-activated protein kinase.

Postreceptor mechanisms

The activated receptor phosphorylates tyrosine residues on specific intracellular proteins which initiate the signal transduction pathway within the target cell. One protein is the large (130 kDa) insulin receptor substrate 1, which has numerous phosphorylation sites that can accept other proteins possessing specific 'SH2' domains. 'Docking' and activation (phosphorylation) of these proteins by insulin receptor substrate 1 begins a cascade of intracellular reactions that lead ultimately to the effects of insulin on glucose, lipid, and protein metabolism and its many other actions. The details remain elusive, but the mitogen-activated protein kinase pathway is involved in glycogen synthesis, while the phosphatidylinositol 3 kinase pathway mediates glucose transporter translocation (see Fig. 3).

Receptor turnover

Receptors that bind insulin are 'internalized', i.e. taken up into the target cell by an invagination of the cell membrane that is coated with the protein clathrin. Bound insulin is degraded in the lysosomes, while most of the insulin receptors are carried back to the cell surface and reinserted into the membrane. The density of receptors on the cell surface is therefore a dynamic quantity, regulated partly by new receptor synthesis and partly by receptor recycling, which in turn is determined by insulin binding. Prolonged exposure to high insulin concentrations increases the proportion of internalized receptors and so decreases the density of receptors available on the cell surface. This 'downregulation' of receptors reduces the sensitivity of the target tissue to insulin.

Disorders due to insulin receptor defects

Many mutations have now been described in the insulin receptor, including point mutations that cause single-residue substitutions or truncation of the a or b subunits. Mutations affecting the tyrosine kinase domain interfere with insulin signalling and can lead to severe insulin resistance and glucose intolerance, sometimes with serious mental and physical abnormalities (for example in 'leprechaunism') which confirm the importance of insulin in fetal development.

Antibodies may develop against the insulin receptor and usually cause insulin resistance with variable hyperglycaemia (the 'type B' insulin resistance syndrome); rarely, hypoglycaemia results from antibodies that activate the receptor (analogous to thyrotoxicosis induced by antibodies to the thyroid-stimulating hormone receptor in Graves' disease).

Metabolic actions of insulin

Insulin functions as an anabolic hormone, favouring the uptake, utilization, and storage of glucose, the storage of lipids as triglyceride, and preventing the breakdown of protein.

Effects on carbohydrate metabolism

Insulin lowers blood glucose in two main ways (Fig. 4). At low basal concentrations (overnight and between meals) it shuts off the production of glucose by the liver, which is the main determinant of fasting glycaemia. Hepatic glucose output is fuelled by both glycogen breakdown (glycogenolysis) and gluconeogenesis (i.e. glucose synthesis from substrates including lactate, glycerol, and alanine and other amino acids); the rate-limiting enzymes for these processes are powerfully inhibited by insulin. Conversely, insulin stimulates glycogen synthesis.

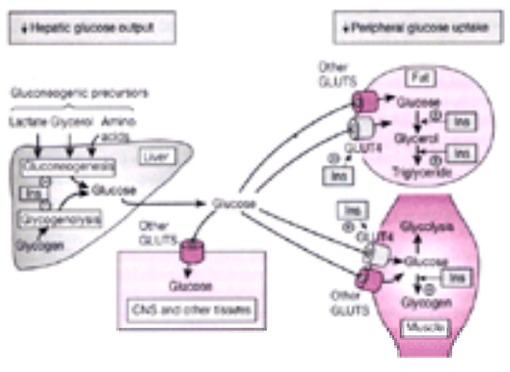

Fig. 4 Effects of insulin on glucose homeostasis. Insulin inhibits gluconeogenesis and glycogen breakdown in the liver, thus decreasing hepatic glucose output. Blood glucose is also lowered by increased glucose uptake into fat and skeletal muscle, mediated by the insulin-stimulated glucose transporter, GLUT-4. (Non-insulin mediated glucose uptake is effected by other GLUT proteins.)

At higher concentrations, such as after meals, insulin also stimulates glucose transport into skeletal muscle (where it is utilized to provide energy via glycolysis, or stored as glycogen) and into fat (where it is used to synthesize triglycerides). In both these tissues, insulin enhances glucose uptake through a specific glucose transporter protein, GLUT-4 (Fig. 4). Insulin causes GLUT-4 units to be translocated rapidly to the cell surface and inserted into the membrane: there, GLUT-4 units act as hydrophilic pores through which glucose can cross the otherwise impermeable membrane into the cell, following its concentration gradient. Insulin also stimulates GLUT-4 synthesis. Overall, insulin acting via GLUT-4 can increase glucose uptake into muscle and fat by up to 40-fold over the basal 'non-insulin mediated' glucose uptake. Non-insulin mediated glucose uptake occurs through other glucose transporter isoforms that operate in the absence of insulin, notably GLUT-1 in peripheral tissues and erythrocytes and GLUT-3 in brain.

Effects on lipid metabolism

Insulin inhibits triglyceride breakdown (lipolysis), while promoting its synthesis (lipogenesis). Lipolytic enzymes that split triglyceride into glycerol and free fatty acids are powerfully inhibited by insulin, even at low basal insulin concentrations. Profound insulin deficiency, such as in untreated type 1 diabetes, is therefore required before uncontrolled lipolysis occurs and generates enough free fatty acids to cause ketoacidosis (see below).

Effects on protein metabolism

Insulin inhibits protein catabolism and thus reduces the generation of amino acids which can act as gluconeogenic precursors to enhance glucose production by the liver and kidney. Insulin also promotes protein synthesis and cellular and tissue growth.

Other actions of insulin

These include vasodilatation, mediated by endothelial production of nitric oxide; growth and differentiation of the fetal nervous system; and enhanced tubular reabsorption of Na^+ ions by the kidneys.

Measurements of insulin action

Glucose lowering is the most easily tested biological action of insulin, and forms the basis for most measurements of 'insulin resistance'. Several methods are used in the research setting; theoretically, the simplest could be used in clinical diabetes care, to identify patients with marked insulin resistance who might benefit particularly from insulin-sensitizing drugs such as the thiazolidinediones.

1. *Homeostatic model assessment* (HOMA) is an index derived by mathematical modelling of the relationship between the fasting glucose and insulin concentrations: with decreasing insulin sensitivity, insulin secretion increases in an attempt to maintain euglycaemia, resulting in compensatory hyperinsulinaemia. Homeostatic model assessment can be performed on a single fasting blood sample and compares well with the insulin–glucose clamp.
2. *Insulin–glucose (hyperinsulinaemic–euglycaemic) clamp*. Insulin is infused intravenously to achieve constant high concentrations and a separate infusion of glucose is adjusted to maintain blood glucose 'clamped' at a normal value. The more glucose required, the greater is the insulin sensitivity. The clamp is generally regarded as the 'gold standard' method but demands blood glucose measurements every few minutes and takes some hours to perform.
3. *Intravenous glucose tolerance test*. An intravenous glucose bolus stimulates insulin release, and mathematical modelling of the relationship between the insulin peak and the decay in blood glucose levels can yield indices of both insulin secretion and insulin sensitivity.

Insulin resistance

Insulin resistance (or insensitivity) is a poorly defined term signifying decreased biological activity of insulin, and which is usually equated with impaired glucose-lowering.

There is no universal normal range for insulin sensitivity, because the ability of insulin to lower glucose varies considerably between and within individuals—it is influenced, for example, by levels of physical activity and fitness. Subjects with 'insulin-resistant' conditions such as type 2 diabetes or essential hypertension commonly show reductions of 40 to 60 per cent in glucose disposal (measured by the clamp technique), as compared with matched healthy controls, yet many apparently normal subjects also have comparable decreases in insulin sensitivity. There is no argument about extreme examples of insulin resistance: in some patients with so-called 'leprechaunism', over 20 000 U/day of insulin have failed to control hyperglycaemia and ketosis. A working definition of clinically relevant insulin resistance in insulin-treated diabetic patients is a daily requirement of more than 1.5 U/kg.

Causes of insulin resistance

Inherited causes

Inherited causes include the very rare mutations affecting the insulin receptor or postreceptor signalling pathways which can lead to extreme insulin resistance; milder polygenic defects contribute to the insulin resistance of type 2 diabetes (see below). Insulin receptor mutations cause clinically distinct syndromes, often with acanthosis nigricans and, in women, features of polycystic ovary disease and masculinization; hyperglycaemia is variable. Specific syndromes include the speculatively named 'leprechaunism' and various inherited lipodystrophies in which fat is lost from subcutaneous and other depots in defined but unexplained anatomical patterns (see Chapter 10.5). Recently, mutations affecting the *PPAR-g* gene (the target for the thiazolidinedione drugs; see below) have been shown to modify insulin sensitivity.

Obesity

Obesity induces insulin resistance, especially in skeletal muscle, while weight loss can improve insulin sensitivity in the obese. Insulin resistance is particularly associated with truncal (central) obesity, where fat is deposited in and around the abdomen; both the subcutaneous and intra-abdominal (visceral) fat depots have been implicated to various degrees that may reflect ethnic and other differences.

It is still not clear how an increased fat mass can decrease whole-body insulin sensitivity, but circulating fat-derived products are presumed to be responsible. Intra-abdominal fat depots would secrete potentially diabetogenic mediators into the portal circulation—where they would be delivered directly to the liver—and this may explain the association of visceral adiposity with insulin resistance. Possible candidates include free fatty acids and the cytokine tumour necrosis factor-a; both are secreted by adipocytes and, under experimental conditions at least, interfere with aspects of insulin action. Levels of free fatty acids are raised in obese subjects, apparently because lipolysis is enhanced, and free fatty acids may cause hyperglycaemia by competing with glucose metabolism in liver and muscle. In liver, free fatty acids enhance gluconeogenesis by stimulating the rate-limiting enzyme pyruvate carboxylase and so increase hepatic glucose production. In muscle, free fatty acids inhibit glycolysis at the level of phosphofructokinase and glucose oxidation via pyruvate dehydrogenase, causing a decrease in glucose utilization and a secondary reduction in glucose uptake (the 'glucose–fatty acid' or Randle cycle). *In vitro*, tumour necrosis factor-a inhibits the tyrosine kinase activity of the insulin receptor that is crucial for insulin signalling. Production of tumour necrosis factor-a by adipose tissue is increased in obesity but its role as a mediator of insulin resistance in human obesity is uncertain. Recently, a novel adipocyte product, adiponectin, has been shown to enhance insulin sensitivity in rodents; intriguingly, circulating adiponectin concentrations are decreased in human obesity.

Physical inactivity strongly predisposes to obesity and also promotes insulin resistance which can be reversed by regular exercise. The mechanism is unknown but physical training is known to stimulate translocation of GLUT-4 glucose transporters to the surface of muscle cells independently of insulin.

Other acquired causes

There are several other acquired causes of insulin resistance. Intrauterine growth retardation may contribute (see the 'Barker–Hales' hypothesis below). Physiological states of insulin resistance, due to the appropriate oversecretion of the counter-regulatory hormones whose metabolic actions oppose those of insulin, are puberty and pregnancy (see gestational diabetes, Chapter 13.10). Endocrine diseases that induce insulin resistance and can cause glucose intolerance and overt diabetes through excessive production of anti-insulin hormones include acromegaly (prevalence of diabetes and impaired glucose tolerance each around 25 per cent),

Cushing's disease (diabetes around 30 per cent), thyrotoxicosis, and the very rare glucagonoma (diabetes in more than 90 per cent of cases). In these disorders, diabetes is mostly non-ketotic, although insulin may be needed to control hyperglycaemia.

Intercurrent illnesses, for example myocardial infarction, stroke, or severe infections, induce the secretion of counter-regulatory stress hormones that can cause marked insulin resistance—insulin-treated diabetic patients may need twice their usual insulin dosages during such episodes. Many drugs decrease insulin sensitivity, including glucocorticoids, b_2 adrenoceptor agonists (ritodrine, salbutamol), and certain oral contraceptive pills containing high-dose oestrogen or levonorgestrel; glucocorticoid-induced hyperglycaemia commonly requires insulin treatment.

The 'type B' insulin resistance syndrome is due to the development of autoantibodies against the insulin receptor which interfere with insulin binding and/or signalling. Most patients are young women, usually with pre-existing autoimmune diseases such as lupus erythematosus, and masculinization often occurs. Acquired lipodystrophies are also associated with insulin resistance, sometimes severe. 'Immune insulin resistance' describes insulin-treated patients with very high insulin requirements (sometimes several thousand U/day) because of high titres of insulin-binding antibodies that bind and inactivate administered insulin. This has become very rare since the introduction of highly purified human-sequence insulin preparations with low immunogenicity (see below).

Metabolic and clinical features of insulin resistance

The metabolic disturbance due to insulin-resistant syndromes ranges from subclinical glucose intolerance to severely symptomatic hyperglycaemia, sometimes with ketosis. A crucial determinant is the capacity of the individual's b cells to secrete insulin in response to the rises in blood glucose that are due to impaired insulin action. The resulting hyperinsulinaemia is extremely variable, with plasma insulin levels ranging from twice normal in many obese subjects to 500 times normal in patients with defects of insulin receptors. Near-normoglycaemia can be maintained as long as hyperinsulinaemia can compensate for the underlying defect in insulin signalling; diabetes occurs when b-cell failure supervenes and insulin secretion falls below a critical level. In the total absence of functional insulin receptors (for example in 'leprechaunism'), massive endogenous hyperinsulinaemia or administration of industrial insulin dosages cannot prevent severe diabetes, although very high insulin concentrations may exert some metabolic actions through 'cross-talk' with the insulin-like growth factor-1 receptor.

Acanthosis nigricans, a characteristic skin manifestation of severe insulin resistance, may be due to high insulin concentrations activating growth factor receptors (perhaps the insulin-like growth factor-1 receptor) that drive the proliferation of keratinocytes and melanocytes. Hyperplasia of these cells leads to a velvety thickening and variable darkening of the skin, especially in the axillae, groin, and nape of the neck (see Chapter 23.1). Widespread acanthosis nigricans can also accompany gut tumours, which may also secrete dermal growth factors.

Increased androgen concentrations may lead to hirsutism and occasionally virilization in women with severe insulin resistance; high insulin concentrations may stimulate androgen production by the ovaries, which often show a polycystic appearance. Insulin resistance is a feature of polycystic ovary syndrome, especially in obese patients (Chapter 12.8.1). Enhancing insulin sensitivity through weight loss or treatment with metformin or the thiazolidinediones can decrease androgen levels and improve hirsutism and menstrual dysfunction.

The 'insulin resistance syndrome', or 'metabolic syndrome X'

This term identifies the co-occurrence of insulin resistance and glucose intolerance (ranging from mild to overt type 2 diabetes), with truncal obesity, dyslipidaemia (raised triglycerides and a high low density lipoprotein:high-density lipoprotein ratio), and hypertension (see Fig. 5).

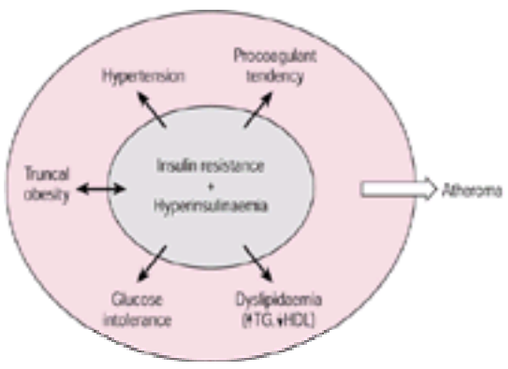

Fig. 5 Syndrome X, a constellation of atherogenic risk factors which may each be related to insulin resistance and/or the hyperinsulinaemia that accompanies insulin-resistant states. -TG, hypertriglyceridaemia; ¯HDL, reduced high-density lipoprotein cholesterol.

These abnormalities are all common in most westernized populations, and it is still not clear whether or not this constellation of cardiovascular risk factors represents a genuine syndrome with a common underlying cause. Reaven and others have argued that insulin resistance is the central abnormality, and that the key features can be explained either by loss of specific actions of insulin or by the effects of the compensatory hyperinsulinaemia on organs that remain relatively insulin sensitive. For example, raised insulin levels could contribute to hypertension by enhancing retention of Na^+ by the kidney; conversely, blood pressure could also be raised through loss of the direct vasodilator action of insulin. The pattern of abnormalities would therefore require 'insulin resistance' to affect certain tissues and specific actions of insulin but not others. Other proatherogenic defects identified in subjects with various features of syndrome X include increased coagulability of the blood (for example increased levels of plasminogen activator inhibitor 1) and impaired endothelial-mediated vasodilatation. The relationship of these abnormalities to insulin resistance is uncertain. Obesity, dyslipidaemia, hypertension, and glucose intolerance are all independent cardiovascular risk factors; any possible proatherogenic role of hyperinsulinaemia *per se* remains controversial.

The aetiology of syndrome X is unresolved. Adiposity, insulin sensitivity, and blood pressure show variable strengths of familial transmission that differ between populations and generally suggest polygenic inheritance of minor genes. On the other hand, Barker and Hales have suggested that fetal malnutrition programmes insulin resistance, hypertension, and dyslipidaemia in middle to late adult life. The underlying mechanisms remain elusive. Because obesity leads to insulin resistance and glucose intolerance, dyslipidaemia, hypertension, and atheroma, weight gain in middle age may be particularly hazardous in subjects who were underweight at birth.

Syndrome X is important clinically because it predisposes to atheroma formation and substantially increases the risk of dying prematurely from myocardial infarction or stroke. Treatment of syndrome X is currently based on correcting any factors (for example type 2 diabetes, hypertension, and dyslipidaemia) present in the individual patient. Lifestyle and dietary modification that achieves weight loss can improve most aspects of the syndrome, and specific insulin-sensitizing drugs such as the thiazolidinediones (see later) may prove beneficial.

Types and classification of diabetes mellitus

The current World Health Organization classification is based on aetiology (Table 1). Type 1 and type 2 diabetes together account for 90 to 95 per cent of cases and will be described in detail.

Type 1 diabetes

'Type 1' diabetes—now preferred to 'insulin-dependent' diabetes—is due to autoimmune killing of the b cells (the so-called 'type-1 process'). A similar clinical picture of insulin dependence can be caused by other forms of severe pancreatic damage.

Epidemiology and demographic features

Type 1 diabetes is considerably rarer than type 2, accounting for between 5 and 15 per cent of all diabetes and 30 to 50 per cent of insulin-treated cases in various populations. It appears predominantly in childhood, with a peak age at presentation of about 11 years in girls and 14 years in boys—hence the old description of 'juvenile-onset'. However, it can develop at any age, and about 5 per cent of newly diagnosed Caucasian diabetic patients over 65 years have type 1 diabetes.

The prevalence of type 1 diabetes varies considerably throughout the world. Incidence is highest in northern European countries (about 30 to 35 cases per 100 000 children per year in Scotland and Finland) and declines progressively towards the equator; there are some isolated 'hot spots' such as Sardinia, where the incidence is as high as in Finland. High susceptibility is found in European populations throughout the world, while African and Oriental populations are relatively spared (incidences of less than 1 per 100 000 per year). Superimposed on this geographical variation are time-related changes in incidence that hint at the importance of the environment in causing the disease. Type 1 diabetes presents more frequently during the winter months, particularly in children aged 10 to 14 years. In several countries (for example Sweden, Scotland, and Poland), there have been sharp 30 to 50 per cent increases in incidence over 10- to 20-year periods, although the explanation and significance of these secular trends are not clear.

Susceptibility to type 1 diabetes shows no gender bias.

Aetiology

Type 1 diabetes is an autoimmune, predominantly T-cell-mediated process that selectively destroys the b cells. Susceptibility is multifactorial, resulting from the impact of environmental agents in a genetically disadvantaged subject. Of these two components, the environment appears more important; genetic factors explain only 30 to 40 per cent of total susceptibility. Immunogenetic aspects are discussed in detail in Chapter 12.11.2.

Genetic factors

Over 20 genetic loci are associated with type 1 diabetes, although only two (*IDDM1* and *IDDM2*) account for most of the genetic predisposition.

IDDM1 lies within the major histocompatibility complex region on chromosome 6, that encodes several proteins intimately involved in immune responses. Of particular importance is the *DQB1* gene; this encodes the DQB1 peptide chain, which forms part of the cleft in the surface of the HLA class II molecule that is crucial in presenting peptide fragments of antigen to the T-helper lymphocyte. Changes in the structure of the DQB1 peptide could therefore influence the coupling between the class II molecule–peptide complex and the T-lymphocyte receptor, and thus modulate the immune response against the (auto)antigenic peptide. Specific *DQB1* polymorphisms have been shown to predispose to type 1 diabetes (for example DQB1*0302), whereas others (such as DQB1*0602) are protective—at least in certain racial groups. The relationships of these polymorphisms to the long-recognized influences of the DR3 and DR4 class II antigens (which increase several-fold the risk of type 1 diabetes) and of the protective DR2 are discussed further in Chapter 12.11.2.

IDDM2 corresponds to the insulin gene (*INS*), whose uniqueness as a b-cell product makes it an obvious candidate gene. As the insulin coding sequence is unchanged in type 1 diabetes, diabetogenic polymorphisms might affect the level of expression of the *INS* gene: variants which enhanced insulin expression could promote b-cell damage, because 'resting' the b cell (for example by giving exogenous insulin) in type 1 diabetic animals improves b-cell survival, in parallel with reduced expression of the putative autoantigen GAD65 (a specific isoform of the enzyme glutamic acid decarboxylase (**GAD**), expressed in the b-cell membrane).

Environmental factors

Viruses have long been popular candidates as a 'trigger' for diabetes. Some (for example mumps, coxsackie, cytomegalovirus, and rubella) infect the pancreas but normally damage the entire gland, particularly the exocrine tissue, rather than causing selective b-cell injury. Certain viruses target the b cell in animals (for example the Kilham rat virus) and can cause insulin-dependent diabetes, either though their direct cytolytic effects or by provoking a type 1-like autoimmune process. Important contenders in humans are coxsackie viruses (especially B4), rubella, and retroviruses.

Serological studies indicate that recent coxsackie B infections are relatively common among newly diagnosed patients with type 1 diabetes; these could represent the final insult in the disease's long natural history. Coxsackie viruses capable of damaging rodent b cells have also been isolated post-mortem from the islets of type 1 diabetic subjects. About 20 per cent of children who survive intrauterine rubella infection develop type 1 diabetes, with typical autoimmune markers. Retrovirus particles and RNA have recently been identified in b cells from type 1 diabetic patients, and two-thirds of newly diagnosed cases are reported to have antibodies against the protein encoded by the retroviral RNA.

Viruses could trigger or maintain autoimmune b-cell damage in various ways. Acute or persistent viral infection of b cells could release b-cell antigens that are normally sequestered beyond the reach of the immune cells. Certain viral proteins may elicit an immune response which crossreacts with specific b-cell antigens that happen to be similar ('molecular mimicry'): for example, peptide sequences of the P2-C capsid protein of coxsackie B viruses may crossreact with GAD65 in the b-cell membrane.

Other environmental factors are suggested to include bovine serum albumin from cows' milk and various toxins. Bovine serum albumin contains a peptide sequence that may crossreact with a b-cell surface protein (see below); this was suggested as an explaination for an apparent excess risk of type 1 diabetes among children fed with cows' milk in the neonatal period, although a protective effect for breast feeding remains controversial. Various toxins selectively damage b cells, including streptozotocin, a nitrosourea used to induce experimental diabetes in rodents. Related nitrosamine compounds have been blamed for the higher risk of type 1 diabetes in the children of women who eat fermented smoked mutton (a traditional delicacy in Iceland).

Autoimmune features

Type 1 diabetes has strong associations with endocrine and other autoimmune diseases, including Schmidt's syndrome (with hypothyroidism and adrenocortical failure) and the polyglandular autoimmune deficiency syndromes.

Most b-cell damage is probably inflicted by T lymphocytes. 'Insulitis'—infiltration of the islets with immune cells, mostly cytotoxic/suppressor (CD8+) T lymphocytes—is a pathognomic feature of the disease, and circulating T-helper lymphocytes can be identified that react against b-cell antigens including GAD65.

Various circulating autoantibodies also occur. Some target antigens unique to the b cell, while other autoantigens are shared by other islet cell types. Notable b-cell selective autoantibodies are those that recognize GAD65, a heat-shock protein (hsp60), and insulin itself. GAD catalyses the conversion of glutamic acid to g-aminobutyric acid (**GABA**), whose role in the b cell is uncertain. Studies in rodents with type 1 diabetes suggest that the level of GAD65 expression influences the intensity of the autoimmune attack on the b cells. The GAD67 isoform of the enzyme is also expressed in the central nervous system, and autoimmune damage of GABAergic neurones is presumed to explain the association of type 1 diabetes with the rare 'stiff man' syndrome (Section 24).

GAD65 antibodies are present in 70 to 90 per cent of newly diagnosed type 1 patients, and insulin autoantibodies in 40 to 70 per cent. Islet cell antibodies and islet cell surface antibodies are present in 80 to 90 per cent and 30 to 60 per cent respectively of newly diagnosed patients. Islet cell antibodies and islet cell surface antibodies recognize uncharacterized antigens that are common to b and non-b cells in the islets (which share the same embryological origin). These antibodies cannot explain the selective destruction of b cells, although some islet cell surface antibodies are complement-fixing and may target the b cell preferentially; islet cell antibodies and islet cell surface antibodies could be raised secondarily to b-cell damage.

High titres of each of these classes of antibodies have some value in predicting diabetes in high-risk individuals—a risk of about 50 per cent for GAD65 antibodies in first-order relatives of subjects with type 1 diabetes. However, they are clearly not the immediate cause of the disease: they are found in many subjects who do not go on to develop it, including a few per cent of the normal population. These antibodies are therefore general markers of autoimmunity against the b cell, rather than evidence of b-cell destruction, which is primarily cell mediated. Titres of all these antibodies tend to be high at presentation and (according to prospective studies of high-risk subjects) during the months leading up to this. Thereafter, antibody levels decline progressively and may even become undetectable, possibly through dwindling of the antigen load that perpetuates autoimmunity as any remaining b cells disappear.

Natural history of type 1 diabetes

b-cell damage might be initiated by direct viral attack, environmental toxins, and/or a primary immune attack against specific b-cell antigens such as GAD65, perhaps via molecular mimicry. T-helper lymphocytes (CD4+) are activated by b-cell antigens presented together with diabetogenic class II antigens by antigen-presenting cells (macrophages) and perhaps by b cells themselves ('aberrant' class II antigen expression may be induced in b cells by certain cytokines generated during the autoimmune process). Activated T-helper cells produce cytokines that attract T and B lymphocytes and encourage them to proliferate in the islet, leading to insulitis. B lymphocytes might then damage b cells by producing antibodies against released b-cell antigens, while cytotoxic (CD8+) T lymphocytes directly attack b cells carrying the target autoantigens. Insulitis is a patchy and unpredictable process that might flare up after encounters with new environmental triggers such as viral infections, but which can also fade and abort for unknown reasons.

Several years of progressive autoimmune damage usually precede the clinical onset of diabetes. This long prediabetic phase is asymptomatic, although careful testing (for example with the intravenous glucose tolerance test) reveals loss of the first phase, then increasingly obvious disturbances of insulin and C-peptide secretion, and eventually glucose intolerance. Finally, when the b-cell mass has been eroded to a critical level (probably 5 to 10 per cent of normal), falling insulin secretion can no longer restrain hyperglycaemia and clinical diabetes develops.

Residual b-cell mass is variable at presentation of type 1 diabetes: some newly diagnosed type 1 patients are C-peptide positive, and b-cell secretion may improve temporarily during the 'honeymoon period' that can follow the lowering of blood glucose when insulin treatment is started (see below). With continuing b-cell destruction, endogenous insulin production declines progressively, and more than 90 per cent of type 1 patients become permanently C-peptide negative within 5 years of presentation. Ultimately, insulitis burns itself out and the immune cells retreat, leaving islet remnants that are devoid of b cells but which still contain intact a, †, and PP cells.

The protracted prediabetic phase provides an opportunity to prevent subjects with active insulitis from developing clinical disease. A combination of autoantibody titres and genetic markers (HLA haplotypes) can be used to predict the chances of the disease developing in high-risk subjects, such as the siblings of children with type 1 diabetes; various immunosuppressive and immunomodulatory treatments are currently undergoing clinical trials.

Metabolic disturbances of type 1 diabetes

In untreated type 1 diabetes, insulin concentrations are generally 10 to 50 per cent of non-diabetic levels in the face of hyperglycaemia which would normally greatly increase insulin secretion. Such severe deficiency cannot sustain the normal anabolic effects of insulin and leads to runaway catabolism in carbohydrate, fat, and protein metabolism. Each of these processes accelerates hyperglycaemia, while the oxidation of excess free fatty acids generated by triglyceride breakdown can result in diabetic ketoacidosis.

Carbohydrate metabolism

Basal hyperglycaemia is due mainly to unrestrained production of glucose by the liver and is accentuated after eating by the failure of glucose to be cleared peripherally (see Fig. 4). Hepatic glucose output is boosted, especially by increased gluconeogenesis: the normal inhibition of the process by insulin is lost, while the supply of gluconeogenic precursors (glycerol from lipolysis, amino acids such as alanine from protein breakdown) is increased. Increased gluconeogenesis in the kidney may also contribute. Postprandial glucose uptake into muscle and fat, mediated by insulin and GLUT-4, is greatly decreased; this is partly offset by increased non-insulin dependent glucose uptake into peripheral tissues, via glucose transporters that do not require insulin.

The overall result is hyperglycaemia, commonly in the range of 15 to 25 mmol/l and higher after meals. Glucose concentrations of over 40 mmol/l are not uncommon during intercurrent illness and especially when insulin treatment is omitted or not increased sufficiently.

Fat metabolism

Lipolysis is stimulated by severe insulin deficiency, generating glycerol (a gluconeogenic precursor) and free fatty acids, the substrate for ketone formation. Ketogenesis is particularly enhanced by concomitant glucagon excess (see below). Mobilization of body fat contributes to weight loss in untreated type 1 diabetes.

Protein metabolism

Loss of the net anabolic effect of insulin encourages catabolism of proteins (primarily through the proteasome-mediated pathway), thus generating amino acids including gluconeogenic precursors such as alanine and glutamine. Muscle wasting may be prominent.

Role of counter-regulatory hormones

The effects of hypoinsulinaemia are compounded by the counter-regulatory hormones which are secreted in excess in response to stress (for example infections, myocardial infarction, trauma, surgery) and when circulating volume falls (for example in hyperglycaemic dehydrated patients). Insulin deficiency also leads to increased glucagon secretion because insulin normally inhibits the a cells.

Glucagon increases hepatic glucose production, both by driving glycogen breakdown and by increasing uptake of glucogenic amino acids by the liver and enhancing gluconeogenesis. It also stimulates ketogenesis by increasing entry of free fatty acids (as their fatty acyl-CoA derivatives) into liver mitochondria (see Fig. 8 below). Glucagon excess is an important factor that promotes diabetic ketoacidosis, acting synergistically with insulin deficiency (see below).

Cortisol and catecholamines enhance gluconeogenesis. Cortisol, catecholamines, and growth hormone oppose the lipogenic action of insulin and favour lipolysis, in the presence of hypoinsulinaemia. Cortisol is a powerful inducer of proteolysis, whereas growth hormone co-operates with insulin to stimulate protein synthesis.

Clinical features of type 1 diabetes

The classical presentation of untreated or poorly controlled type 1 diabetes reflects the consequences of catabolism and hyperglycaemia (Table 2). These features usually develop progressively and quite rapidly over a period of a few days to a few weeks.

Diuresis is due mainly to the osmotic effect of glucose remaining in the renal tubule, when its concentration exceeds the reabsorption threshold for glucose (corresponding generally to plasma glucose levels of about 10 mmol/l). The osmotic loads of urinary ketones and of electrolytes that are obligatorily lost with glucose also contribute. Urine output may reach several litres per day, causing polyuria, nocturia, and in children, enuresis.

Thirst generally parallels urine output and can be very intense; it is characteristically made worse by sugar-rich drinks. Taking water to bed at night is a useful sign of pathological thirst. A high fluid intake is an important homeostatic response to diuresis, and patients unable to drink (for example through nausea in ketoacidosis) can rapidly become dehydrated and hypovolaemic.

Weight loss, due to loss of fat and muscle and later to dehydration, can be dramatic and reach several kilograms over a few weeks. The energy deficit caused by catabolism and urinary losses of glucose can amount to several hundred calories per day. Appetite is often increased; the mechanism in humans is not known; falls in circulating leptin and insulin, both of which act on the central nervous system to inhibit feeding, are probably responsible for hyperphagia in diabetic rodents.

Systemic symptoms include tiredness, malaise, lack of energy, and muscular weakness.

Blurred vision is commonly due to changes in the shape of the lens due to osmotic shifts, typically causing longsightedness. Rarely, acute 'snowflake' cataracts develop because of reversible refractile changes, rather than the permanent denaturation of lens proteins in senile cataract.

Infections are often present because hyperglycaemia predisposes to infections and also because infections stimulate the secretion of stress hormones. Genital

candida infections, causing recurrent pruritus vulvae in women and balanitis in men, are frequent and should always prompt testing for diabetes. Pyogenic skin infections and urinary tract infections, sometimes complicated by severe renal damage, are also common, and certain rare infections have a particular predilection for diabetic people (see below).

Diabetic ketoacidosis presents with hyperglycaemic symptoms, which are usually severe, together with nausea and vomiting, acidotic (Kussmaul) breathing, the smell of acetone on the breath, and, especially in children, altered mood and clouding of consciousness that may progress to coma. Diabetic ketoacidosis is described in detail later.

Unlike type 2 diabetes, which is often present for several years before diagnosis, hyperglycaemia in newly presenting type 1 patients develops too acutely for chronic diabetic complications to appear. Because obvious symptoms appear quickly, very few cases are picked up fortuitously, although doctors who have forgotten to think of diabetes in their differential diagnosis of weight loss or hyperventilation may be surprised when hyperglycaemia is detected by routine screening.

Prognosis of type 1 diabetes

Before the introduction of insulin during the early 1920s, type 1 diabetes was invariably fatal, usually within months. With various semistarvation diets, hyperglycaemic symptoms could be improved somewhat and life extended by a few miserable months.

With modern insulin treatment, type 1 diabetic patients can be rescued from diabetic ketoacidosis, although one-third of deaths in diabetic children and young adults are still due to metabolic emergencies, notably ketoacidosis. The main threat to survival with type 1 diabetes is now chronic tissue damage, particularly renal failure from nephropathy, and vascular disease, notably myocardial infarction and stroke. Throughout adult life, the overall risk of dying within 10 years is about fourfold higher for patients with type 1 diabetes than for their non-diabetic peers.

There is encouraging evidence from Europe and the United States that the outlook for type 1 diabetes has improved over the last 10 to 20 years, with definite declines in the incidence of microvascular complications and extended survival—at least in countries able to afford effective diabetes care. This is partly attributable to tighter control of hyperglycaemia, which can reduce by 30 to 40 per cent the risks of nephropathy and retinopathy developing or progressing to a clinically significant degree (see below). Other measures have undoubtedly contributed, including better treatment of raised blood pressure and blood lipids.

Tragically, however, in many parts of the world patients with type 1 diabetes still die today as they did a century ago, simply because insulin is not available.

Type 2 diabetes

Type 2 diabetes is a heterogeneous condition, diagnosed empirically by the absence of features suggesting type 1 diabetes (Table 2) and of the many other conditions that cause hyperglycaemia (Table 1). Diagnostic accuracy may depend on the thoroughness of investigation: for example, up to 10 per cent of subjects with late onset diabetes show evidence of autoimmune b-cell damage and thus probably have slowly evolving type 1 diabetes.

The term 'type 2' replaces 'non-insulin dependent' which was both clumsy and confusing: many type 2 patients require insulin to control hyperglycaemia.

Epidemiology and demographic features

Type 2 diabetes accounts for 85 to 90 per cent of diabetes worldwide and is very common. It affects about 2 per cent of the Caucasian populations in most westernized countries, the prevalence rising with age to 10 per cent of those over 70 years. It is substantially commoner in certain immigrant populations in more affluent countries, for example 5 per cent or more of young and middle-aged adults in some Asian or Afro-Caribbean groups in the United Kingdom.

Type 2 diabetes is most commonly diagnosed in those over 40 years of age and the incidence rises to a peak at 60 to 65 years. However, much younger people are now presenting with type 2 diabetes, following the rapid rise in childhood obesity. Up to one-third of North Americans diagnosed as diabetic under 20 years of age have type 2 diabetes, Afro-Caribbeans and Mexicans being at particular risk. Maturity onset diabetes of the young, which commonly presents before 25 years of age, is now classified separately (see below for more details).

The prevalence of type 2 diabetes shows striking geographical variation—entirely different from that of type 1—and ranges from less than 1 per cent in rural China to 50 per cent in the Pima Indians of New Mexico. Prevalence is also rising rapidly and, worldwide, will double within 10 to 15 years. This pandemic is largely explicable by westernization (so-called 'Cocacolonization'), and is following in the wake of the obesity that is spreading throughout the world. The Pima Indians illustrate this process especially vividly, although most developed and developing countries are showing the same phenomenon albeit more slowly. Diabetes was rare while the Pimas led a frugal existence in desert conditions and were lean and physically active. Following urban resettlement and exposure to overnutrition and inactivity, there were rapid increases in the prevalence of obesity (currently 80 per cent of adult Pimas have a body mass index of over 30 kg/m^2) and later of type 2 diabetes. The Pimas' spectacular susceptibility to obesity and diabetes may be explained by the selection of 'thrifty' genes, i.e. those encouraging the storage of excess energy as fat, which would favour survival in their original harsh environment. In a setting of readily available food, cars, and television, the same thrifty genes would lead to obesity and ultimately diabetes (see below).

There is a 3:2 male preponderance among subjects with type 2 diabetes.

Aetiology

Type 2 diabetes is due to the combination of insulin resistance and b-cell failure, the latter preventing sufficient insulin secretion to overcome the insulin resistance. These two components vary in importance between different individuals, who may be clinically quite similar, and each has numerous possible causes. Susceptibility is determined by the interactions between genes and environment. The steeply rising prevalence of type 2 diabetes suggests that diabetogenic genes are common and are now enjoying an unparalleled opportunity to express themselves through the global spread of 'Cocacolonization' and obesity.

Genetic factors

Overall genetic susceptibility to type 2 diabetes is probably 60 to 90 per cent, rather less than was previously deduced from twin studies. Generally, transmission does not follow simple mendelian rules, and this polygenic pattern presumably reflects the inheritance of a critical mass of minor diabetogenic minor polymorphisms which interfere with insulin action and/or insulin secretion. Having a first-order relative with the disease increases by fivefold an individual's chances of developing it, representing a lifetime risk in Caucasians of about 40 per cent.

Genetic factors may partly determine both insulin resistance and b-cell failure, although to different degrees in different individuals. Insulin sensitivity appears to be largely genetically determined, at least in some populations. Genes leading to insulin resistance could encode regulators of energy balance, metabolic enzymes, or the proteins that signal insulin action, and presumably include 'thrifty' genes favouring fat deposition. Specific genes have not been firmly incriminated: particular polymorphisms associated with type 2 diabetes have been reported (for example the b_3 adrenoceptor implicated in lipolysis and energy expenditure, the insulin signalling protein insulin receptor substrate-1, and glycogen synthetase) but subsequently questioned. Mutations affecting the insulin receptor and glucose transporters do not appear to cause common type 2 diabetes, although mutations of insulin receptors can lead to severe insulin resistance (see above).

Diabetogenic genes leading to inadequate production of insulin could decrease insulin secretion in response to glucose, or impair b-cell viability. Mutations affecting glucokinase cause maturity onset diabetes of the young 2 (see below) and rare cases (less than 1 per cent) of apparently typical type 2 diabetes; otherwise, mutations in the known components of the b cell's glucose-sensing or insulin-secreting machinery are not responsible for common type 2 diabetes.

Environmental factors

These clearly play a critical part, because obesity and type 2 diabetes are spreading too rapidly to be explicable by changes in the genome; environmental factors are also important in practice because they may be modified to treat and prevent the disease. Known environmental diabetogenic factors mostly induce insulin resistance (for example obesity, pregnancy, intercurrent illness, certain drugs). Hyperglycaemia *per se* can both impair insulin sensitivity and inhibit insulin secretion (so-called

'glucotoxicity').

Specific risk factors for type 2 diabetes

Obesity, itself determined by both genes and environment, is one of the most important risk factors, apparently due to aggravation of insulin resistance (see above). The diabetogenic properties of excess fat depend not only on its bulk but also on its anatomical distribution and the time of life at which it is laid down. The risks of developing type 2 diabetes begin to increase steeply once the body mass index exceeds 28 kg/m ^{2}; some studies estimate the risk at a body mass index over 35 kg/m^2 to be 80-fold higher than for individuals with a body mass index of less than 22 kg/m ^{2}—a lifetime risk of about 50 per cent. Fat in the truncal (central) distribution is more diabetogenic than that deposited around the hips and thighs, and the visceral (intra-abdominal) depot is strongly associated with insulin resistance. Increasing adiposity after the early twenties, especially around the waist, aggravates the risk of high body mass index.

Physical inactivity, especially from the twenties onwards, is an independent predictor of diabetes in middle age, the risk increasing by about threefold for sedentary people as compared with regular athletes. This is due to worsening insulin resistance, which can be improved by physical training.

The still controversial Barker and Hales hypothesis suggests that poor fetal growth can 'programme' enduring metabolic and vascular abnormalities that are manifested in adult life, especially in people who were underweight at birth but then become obese. These abnormalities include key features of 'syndrome X' (hyperglycaemia, hypertension, dyslipidaemia), resulting in atheroma formation, myocardial infarction and stroke (see above). Evidence, mainly from animals, suggests that maternal and therefore fetal malnutrition during a critical early phase of fetal development can reduce b-cell mass and permanently impair insulin secretory reserve; deficiencies of sulphur-containing amino acids may be responsible in experimental animals but the relevance to humans is unknown. Other studies suggest that insulin sensitivity may also be reduced into adult life.

b-Cell failure in type 2 diabetes

b-Cell failure is an obligatory defect in the pathogenesis of type 2 diabetes: near normoglycaemia can be maintained even in severe insulin resistance (due for example to mutations in the insulin receptor), as long as the b cell can respond to the challenge and secrete enough insulin to overcome the resistance.

Subtle abnormalities of insulin secretion, including loss of the physiological pulses and of the first-phase response to intravenous glucose injection, are seen in normoglycaemic subjects who later develop the disease. These defects presumably indicate that the b cell is already stressed in trying to produce enough insulin to overcome insulin resistance. Normoglycaemic first-order relatives of type 2 diabetic subjects also show loss of pulsatility of insulin secretion which might indicate an inherited tendency to b-cell failure.

The mechanism of b-cell failure in human type 2 diabetes is not known. Histologically, the islets in type 2 diabetes show no features of type 1 autoimmune insulitis, and b-cell mass is not so dramatically reduced. Animal models of the disease suggest various causes, including synchronized b-cell apoptosis (possibly mediated by nitric oxide) in the Zucker diabetic fatty rat, and the deposition of amyloid fibrils (see above) in the rhesus monkey. Amyloid deposits are also prominent in the islets of some type 2 diabetic patients but may merely be due to dysfunctional b-cell hypersecretion rather than the cause of b-cell damage. Once hyperglycaemia is established, 'glucotoxicity' *per se* may further worsen both insulin secretion and insulin resistance.

In established type 2 diabetes, insulin secretion is unequivocally subnormal and tends to decline progressively with time, as illustrated by the long-term follow-up data from the United Kingdom Prospective Diabetes Study. Initially, plasma insulin levels may be higher than in non-diabetic subjects but are still inappropriately low, as the normal pancreas would produce much higher insulin concentrations in response to diabetic levels of blood glucose. Conventional radioimmunoassays may overestimate insulin levels in type 2 diabetic patients because of crossreaction with incompletely processed insulin precursors (proinsulin and its split products) released by the 'constitutive' pathway which operates in the malfunctioning b cell (see above). Many type 2 patients ultimately need insulin replacement; this indicates relatively severe insulin deficiency, although still not as profound as in type 1 diabetes. Some type 2 patients who require insulin early have autoimmune markers characteristic of type 1 diabetes, suggesting that they in fact have an indolent variant of type 1 diabetes.

Natural history

Longitudinal and cross-sectional studies indicate that insulin resistance develops first and that compensatory increases in insulin secretion can initially maintain near-normoglycaemia. Worsening insulin resistance is thought to drive the b cells towards maximal insulin output, a metastable stage that probably corresponds to impaired glucose tolerance (see above). Rescue is still possible if insulin resistance is decreased, for example through weight loss or insulin-sensitizing drugs: about 25 per cent of subjects with impaired glucose tolerance return to normoglycaemia within 5 years. However, if insulin resistance persists or worsens, the b cells fail and insulin production falls. At this point, the brake limiting hyperglycaemia is released and blood glucose rises into the diabetic range. The bell-shaped response of insulin secretion, initially increasing to compensate but ultimately failing, has been termed the 'Starling curve' of the b cells because it recalls the classical plot of cardiac output against preload in heart failure.

In common type 2 diabetes, these events usually take many years, and significant hyperglycaemia may have been present for several years at the time of diagnosis. The whole process can be greatly accelerated by acute increases in insulin resistance induced, for example, by steroid treatment or pregnancy.

Metabolic disturbances in type 2 diabetes

Hyperglycaemia is the most obvious abnormality, the extreme case being the hyperosmolar non-ketotic state. Lipid metabolism is also disturbed but true ketoacidosis occurs only exceptionally and is usually provoked by intercurrent events such as infections or myocardial infarction.

Blood glucose concentrations are raised both in the basal (fasting) state and after eating. This reflects the impairment of insulin action in both liver and skeletal muscle, where insulin respectively shuts off hepatic glucose production and stimulates glucose uptake after meals. Hepatic glucose output is increased, due mainly to unsuppressed gluconeogenesis, and this is largely responsible for hyperglycaemia overnight and before meals. In muscle, GLUT-4 activity and glycogen synthesis are especially decreased; this reduces insulin-stimulated glucose uptake into muscle after meals, although basal glucose uptake (non-insulin mediated glucose uptake; see above) is higher than in normal subjects because of the mass-action effect of hyperglycaemia. The degree of hyperglycaemia varies widely: many patients have fasting plasma glucose levels of 8 to 13 mmol/l with postprandial peaks of up to 20 mmol/l, while values exceeding 60 mmol/l are not uncommon in the hyperosmolar non-ketotic state.

Insulin deficiency is less profound than in type 1 diabetes, so mobilization of triglyceride (loss of body fat, ketoacidosis) and catabolism of protein (muscle breakdown) are not usually pronounced. Diabetic ketoacidosis may develop in patients with apparently typical type 2 diabetes who can subsequently be controlled by oral hypoglycaemic agents rather than insulin. Diabetic ketoacidosis is usually precipitated by severe intercurrent illness (for example myocardial infarction, stroke, or pneumonia) in which excessive secretion of counter-regulatory stress hormones exacerbates the metabolic disturbance caused by relative insulin deficiency.

Clinical features

Many cases present with classical symptoms of osmotic diuresis, blurred vision due to hyperglycaemia-related refractive changes in the lens, and genital candidiasis (Table 2).

Weight loss may occur but is generally less dramatic than with newly presenting type 1 diabetes, and may not be obvious because many type 2 patients—over two-thirds in the United Kingdom—are obese. Rapid or severe weight loss in patients who otherwise appear to have type 2 diabetes should be regarded with suspicion as it may point to an early need for insulin replacement (and possibly type 1 diabetes itself) or to coexisting illness: a well-recognized but unexplained association with recent onset type 2 diabetes is carcinoma of the pancreas.

The hyperosmolar non-ketotic state can present with confusion or coma (see below); as mentioned above, diabetic ketoacidosis is rare.

Chronic diabetic complications may be a presenting feature, because hyperglycaemia severe enough to cause tissue damage may already have been present for several years. Extrapolating the numbers of microaneurysms (which only develop at diabetic glucose concentrations) in type 2 patients at various intervals after

diagnosis suggests that significant hyperglycaemia is present for an average of 5 to 7 years before diagnosis. Common problems are arterial disease (myocardial infarction, stroke, and peripheral vascular disease), cataract—which are common in the older population—and retinopathy, especially maculopathy, which can damage central vision.

Increasing numbers of diabetics are detected by screening, either in high-risk groups such as the obese and those with cardiovascular disease, or at routine health checks. Many of these are nominally asymptomatic but will admit to symptoms such as nocturia or perineal irritation if asked directly.

Prognosis of type 2 diabetes

A long-held and prevalent misconception is that type 2 diabetes is 'mild'. Some patients do have relatively unexciting or asymptomatic hyperglycaemia but this can still be enough to cause complications which wreck the patient's life just as much as in type 1 diabetes. Moreover, hyperglycaemia can be as hard to control (even with insulin) as in type 1 patients.

Overall, life expectancy is shortened by up to a quarter in patients with type 2 diabetes presenting in their forties, with vascular disease (myocardial infarction and stroke) being the main cause of premature death. Renal failure from diabetic nephropathy is becoming more common in type 2 patients as their survival from vascular complications improves, and the disease is now the most frequent pathology among people waiting for renal replacement therapy in the United States and some European countries.

Type 2 diabetes is therefore an important threat to the patient's health and survival, and must be taken seriously by patients and their medical attendants, even if the blood glucose concentrations are not dramatically raised. Accordingly, treatment guidelines for the disease are rigorous (Table 3).

Maturity onset diabetes of the young (MODY)

In 1974, Tattersall described a rare familial form of non-insulin dependent diabetes that he distinguished from the generality of cases by its early age of onset, autosomal dominant inheritance, and apparently low risk of microvascular complications. MODY is now known to differ fundamentally from type 2 diabetes in its aetiology and is classified separately as type 3A. It probably accounts for about 1 per cent of non-insulin dependent diabetes and is diagnosed strictly by:

1. Early onset: diabetes is diagnosed before 25 years in the subject and in at least one other family member. Some cases with glucokinase mutations present before 5 years of age.
2. Absence of features of type 1 diabetes, with C-peptide positivity and no requirement for insulin within 5 years of diagnosis.
3. Autosomal dominant inheritance across at least three generations.

MODY is due to failure of the b cell to secrete enough insulin to maintain normoglycaemia: insulin is released in response to glucose but in amounts consistently lower than in non-diabetic subjects. This is explained by failure of the b-cell's glucose-sensing apparatus, which depends on the integrated operation of GLUT-2, glucokinase, and the downstream enzymes that generate ATP from glycolysis of glucose. In contrast to common type 2 diabetes, insulin sensitivity is normal.

Various molecular lesions have now been identified. The first were mutations in the glucokinase gene (on chromosome 7p), which interfere with the enzyme's ability to phosphorylate glucose—the first and rate-limiting step in glycolysis. Glucokinase-dependent MODY (now termed MODY 2) only accounts for about 10 per cent of cases. It is characterized by very early onset hyperglycaemia which is mild and worsens slowly, taking decades to reach truly diabetic levels; it follows that microvascular complications are late to develop.

Other forms of maturity onset diabetes of the young are MODY 1, due to mutations in hepatic nuclear factor 4a (on chromosome 20q) and accounting for only 5 per cent of cases, and the most frequent (65 per cent of cases), termed MODY 3 and caused by hepatic nuclear factor-1a mutations (chromosome 12q). The hepatic nuclear factors are a family of transcription factors that regulate the expression of various genes, but their pathological relevance here is not clear.

Management of MODY is as for type 2 diabetes and using the same treatment targets, because it is now clear that patients with MODY are not protected against chronic complications. Diet and oral hypoglycaemic agents are often effective, especially in the milder MODY 2, but insulin may ultimately be needed.

Other types of diabetes (see Table 1)

Diabetes in pancreatic disease

Chronic pancreatitis, most commonly due to alcohol abuse, causes diabetes that needs insulin in about one-third of cases. Widespread flecks of fine to medium calcification are often scattered through the pancreas, outlining it on a plain abdominal radiograph. Concomitant destruction of the islet a cells means that glucagon secretion is lost as well as insulin; diabetic ketoacidosis is therefore rare, while hypoglycaemia can be profound and prolonged—a particular hazard in those who continue to drink alcohol. Acute pancreatitis causes acute hyperglycaemia in 50 per cent of cases but few develop permanent diabetes.

Carcinoma of the pancreas is associated with newly presenting type 2 diabetes, and should be suspected in older patients with weight loss (especially when accompanied by abdominal or back pain and jaundice). The mechanism is unknown but appears to be due to tumour products that cause insulin resistance rather than to b-cell loss.

Genetic diseases that cause diabetes through pancreatic damage include haemochromatosis and cystic fibrosis. In one-half of cases of haemochromatosis, heavy deposition of haemosiderin in the islets causes diabetes, usually requiring insulin; associated features are slate-grey skin pigmentation due to deposition of iron in the dermis ('bronze diabetes'), cirrhosis, secondary gonadal failure, and pyrophosphate arthropathy. Magnetic resonance imaging shows abnormal signals in liver and pancreas, while serum ferritin concentrations are greatly elevated; diagnosis is usually possible by means of molecular analysis of the *HFE* gene but Perl's stain for iron deposition in a liver biopsy may be necessary (see Chapter 11.7.1). Cystic fibrosis causes pancreatic exocrine failure, with an increasing risk of diabetes (often requiring insulin) that approaches 25 per cent in subjects who survive beyond 20 years of age.

Gestational diabetes

This includes all degrees of hyperglycaemia (impaired glucose tolerance as well as overt diabetes) diagnosed during pregnancy in previously normoglycaemic women. It is covered in Chapter 13.10.

Malnutrition-related diabetes

This controversial diagnostic category was omitted from the most recent World Health Organization classification. It included 'fibrocalculous pancreatic diabetes' and 'protein-deficient diabetes mellitus'. Fibrocalculous pancreatic diabetes was identified by dense pancreatic fibrosis, the formation of discrete and often spectacularly large stones in the dilated pancreatic ducts, and recurrent abdominal pain; protein-deficient diabetes mellitus was a vaguer entity that lacked the pancreatic stones. Patients conforming to these 'syndromes' were rare even in the tropical zones where they were described (less than 5 per cent of all diabetes), and the current consensus is that they represent type 2 diabetes or chronic pancreatitis superimposed on malnutrition.

Management of diabetes

The treatment of diabetes has traditionally concentrated on correcting hyperglycaemia, the most obvious and easily monitored biochemical abnormality and the cause of troublesome symptoms as well as specific chronic diabetic complications. This approach has not been entirely successful, partly because it is difficult to normalize blood glucose but also because macrovascular disease—the principal cause of morbidity and premature death—is heavily dependent on other factors, notably hypertension and dyslipidaemia. The current treatment targets for both type 1 and type 2 diabetes (Table 3) are therefore more holistic, tackling cardiovascular risk factors and obesity in addition to hyperglycaemia.

This section describes the roles of lifestyle modification and antidiabetic drugs, followed by specific treatment strategies for type 1 and type 2 diabetes.

Diet and lifestyle modification and management of obesity

About 80 per cent of patients with type 2 diabetes are obese, as are at least 30 per cent of those with type 1 disease. Obesity is arguably one of the greatest obstacles to successful management of diabetes: it worsens insulin resistance, dyslipidaemia, and hypertension and is now recognized in its own right as a risk factor for coronary-heart disease. Proven benefits of 10 per cent weight loss in type 2 patients with a body mass index of 30 to 40 kg/m ^{2} include falls in fasting glucose of 2 to 4 mmol/l and a 1 per cent decrease in HbA_{1c}—comparable with sulphonylureas or metformin—and reduced dosages of antidiabetic drugs, including insulin. There may also be variable improvements in blood pressure and dyslipidaemia (decreased triglycerides and low-density lipoprotein cholesterol, increased high-density lipoprotein). The traditional focus on obesity has been in type 2 diabetes, but there is no reason to assume that the cardiovascular hazards of obesity do not also apply to type 1 diabetes.

Weight reduction is regarded as the 'cornerstone' for treating obese type 2 diabetics but is often undermined by a lack of determination. Accordingly, doctors have little confidence in its efficacy and tend to assume that most obese patients will be 'dietary failures'. However, with clear advice, better understanding of the causes of obesity, and the use of realistic targets, the currently poor track record of diet and lifestyle therapy can be greatly improved. All members of the diabetes team must understand the principles (but not the detail) of lifestyle management so that a strong and unified message can be given to the patient.

The notion of the 'diabetic diet' must now finally be laid to rest. Traditionally, carbohydrate intake was restricted because of the simplistic assumptions that sugar alone raised blood glucose and might even be diabetogenic; this strategy favoured a high fat intake that undoubtedly helped to sustain obesity and probably predisposed to atheroma. Current advice is close to the 'healthy eating' recommendations for the whole population and can therefore be suggested for all the patient's family, which will greatly increase the chances of compliance.

The following diet and activity recommendations apply to both type 1 and type 2 diabetes. The aims are to:

1. Correct obesity, which worsens insulin resistance, reduces the efficacy of glucose-lowering, antihypertensive, and lipid-modifying drugs, and is an independent risk factor for macrovascular disease. Management of obesity is discussed in detail in Chapter 10.5.
2. Reduce cardiovascular risk, by limiting fat, cholesterol, sodium, and alcohol intakes.
3. Avoid hypoglycaemia in patients receiving insulin or sulphonylureas by optimizing the timing and content of meals.

The steps in designing dietary advice for the individual patient are shown in Fig. 6.

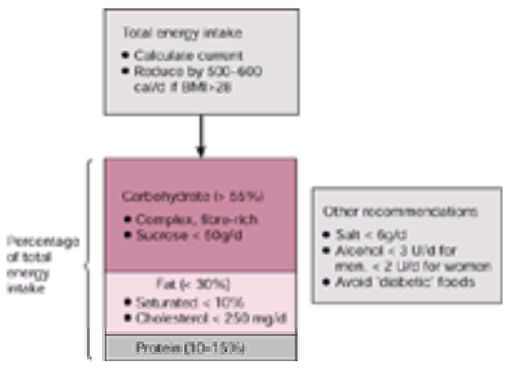

Fig. 6 Dietary recommendations for diabetic people. These guidelines now reflect 'healthy eating' for the general population, rather than a 'diabetic diet'.

Reducing total energy intake

This should be reduced by 500 to 600 cal/day (2100 to 2520 J/day) in patients who are overweight (body mass index over 28 kg/m ^{2}). This energy deficit mobilizes fat preferentially, whereas protein, glycogen, and water are also lost with more aggressive energy restriction; initially, the rate of weight loss will be 0.5 to 1.0 kg/week (adipose tissue contains around 7000 cal/kg (29 400 J/kg).

The desired energy intake should be calculated from standard formulae that employ the subject's age, sex, weight, and level of physical activity to estimate energy expenditure, which must equal energy intake under steady-state conditions. The standard dietary history is a waste of time for trying to assess energy intake, because overweight subjects consistently under-report how much they eat. Specific advice about how to cut energy intake is best left to the dietician, but hinges on reducing fat intake—a simple message that can be reinforced by the entire diabetes care team. Fat-rich foods not only have the highest energy density (9 cal/g (38 J/g) compared with 4 cal/g (17 J/g) for carbohydrate and protein), but also have poor satiating effects and so tend to encourage overeating.

The initial target should be 10 per cent loss of starting weight, not the 'ideal' body weight or body mass index, which is only rarely attained by obese diabetic patients. When energy intake is cut acutely, type 2 patients often show an immediate fall in blood glucose, due to a drop in hepatic glucose output, even before weight loss begins.

Weight loss during an energy deficit of 500 to 600 cal/day (2100 to 2520 J/day) is a slow process: for a 100 kg patient, 10 per cent weight loss may take several months. Frequent contact and encouragement are the best predictors of success, and the patient should be reassured that weight loss by a small but tolerable change in lifestyle is much more likely to be maintained than weight lost by a crash diet. As weight falls, resting energy expenditure also declines: it is proportional to lean body mass, which also decreases, although at a slower rate than fat. This means that greater reductions in energy intake (more than 600 cal/day (2520 J/day) will be needed to maintain the same rate of weight loss. If the 10 per cent target is met, further loss towards an 'ideal' body mass index of around 23 kg/m ^{2} may be feasible.

Weight loss is harder to achieve in diabetic patients than in their non-diabetic counterparts; possible reasons include fears about sugar rather than fat, and the adipogenic effects of insulin, sulphonylureas, and thiazolidinediones. In practice, weight loss of even 10 per cent is not commonly achieved by diet and lifestyle modification alone; only 15 to 30 per cent of newly diagnosed type 2 diabetic patients can normalize glycaemia initially by this means, and fewer than 10 per cent can sustain this for 5 years or more. The progressive b-cell dysfunction in type 2 diabetes (see above) makes it inevitable that the proportion of 'dietary failures' will increase steadily.

Improving dietary composition

Intakes of fat, salt, and refined sugar are generally too high in westernized populations. Current recommendations for healthy eating are based on evidence of beneficial effects on body weight, glycaemic control, lipids, and blood pressure (Fig. 6).

Fat should provide less than 30 per cent of total energy intake (in most industrialized countries, it accounts for 40 per cent). Polyunsaturated or monounsaturated fats (for example sunflower or olive oils respectively) are preferred to saturated animal fats, which should comprise less than 10 per cent of total energy intake. Patients may need to be reminded that 'good' unsaturated fats still contain 9 cal/g (38 J/g) and therefore sustain obesity just as effectively as the others. Cholesterol should be limited to less than 250 mg/day (less if dyslipidaemia is present).

Carbohydrates should account for more than 55 per cent of total energy intake, preferably in the form of foods rich in soluble fibre (such as pulses, root and leaf vegetables, and fruit); the current World Health Organization recommendation for the general population is for the consumption of at least four portions of fruit or

vegetables per day. Sugary drinks (especially fizzy glucose solutions that are supposed to give energy) should be avoided, except to treat hypoglycaemia. The present recommendation, which seems reasonable but is not based on evidence, is to limit added sucrose to less than 25 g/day and total sucrose intake to less than 50 g/day.

Protein should contribute 10 to 15 per cent of total energy—close to current levels in the general population. (For patients with renal impairment, see Chapter 20.10.1.)

Sodium intake should be less than 6 g/day, and less in patients with hypertension.

Alcohol contains 7 cal/g (29 J/g), and beers and wines in particular can be fattening. Intake should not exceed three units (30 g) per day in men and two units (20 g) per day in women, and should be further limited or avoided in those with hypertension or obesity. Alcohol can delay recovery from hypoglycaemia (see below); 'diabetic' beers (low sugar, but strong in alcohol) and spirits with sugar-free mixers are especially likely to provoke hypoglycaemia.

Moderate amounts of sucrose are acceptable (see above), while non-caloric sweeteners (such as aspartame) have no adverse metabolic effects. So-called 'diabetic' sweets and foods contain sorbitol or fructose instead of glucose, and are an expensive way to get diarrhoea; they should be avoided by patients, and withdrawn by the manufacturers.

Optimizing meal patterns

Judging the size and content of meals so as to limit glycaemic excursions remains an art rather than a science, and a skill which some patients develop with experience. Dosages of glucose-lowering drugs that act acutely to cover meals (short-acting insulin and sulphonylureas) can be tailored reasonably accurately to meals of similar composition but may not be matched to other meals, even when the total weights of carbohydrate, fat, and protein are similar.

There has been much interest in the ability of various foods to raise blood glucose, usually measured as the 'glycaemic index', i.e. the area under the curve of the rise in plasma glucose after eating a standardized load (50 g) of the food, expressed as a percentage of the area under the glucose curve after ingesting 50 g of glucose. Foods with a low glycaemic index include pulses and cereals, probably because of their high fibre and complex carbohydrate contents, while bread has a surprisingly high index. The glycaemic index of many foods such as potatoes and pasta varies widely according to the method of cooking (and even the shape of the pasta), and mixing different foods in a real-life meal has unpredictable effects on the overall postprandial glucose rise. It may be sensible to base meals around components with a low glycaemic index but it is clearly not feasible to use the index to adjust dosages of antidiabetic medication.

Increasing physical activity

Short-term exercise and improved physical fitness both increase insulin sensitivity, partly through increased translocation of GLUT-4 units to the surface of skeletal muscle cells; this effect is independent of insulin, and can enhance glucose uptake (under clamp conditions) better than metformin or the thiazolidinediones. Several studies, notably that conducted in Malmö, Sweden, have demonstrated that regular physical exercise reduces by 50 per cent the risk of impaired glucose tolerance progressing to type 2 diabetes, and also significantly decreases cardiovascular events. Exercise must therefore be encouraged in all diabetic patients, but the advice must be realistic, achievable, and safe. Brisk walking for 30 to 40 min every day is better physiologically than a hectic workout in the gym once or twice a week and is within almost everyone's reach.

Potential hazards of exercise are hypoglycaemia, which may be delayed by several hours (see below), and cardiac disease. Patients at risk should have an ECG, with consideration for an exercise tolerance test and echocardiography, and appropriate treatment for ischaemic heart disease or heart failure. Exercise remains beneficial and important in these cases but should be built up gradually.

Antiobesity drugs and bariatric surgery in diabetes

Antiobesity drugs may be indicated in selected obese diabetic patients with a body mass index over 28 kg/m ^{2} and who have demonstrated by losing weight beforehand through diet and exercise alone that they are prepared to make long-term changes in their lifestyle. Without this commitment, clinically useful weight loss is unlikely to be achieved or maintained beyond the period of drug prescription (currently 2 years for orlistat and 1 year for sibutramine); the medical and pharmacoeconomic benefits of modest weight loss for a couple of years in the obese patient's middle age are not known but are probably not dramatic.

Drugs currently available in many countries are orlistat, a gastrointestinal lipase inhibitor, and sibutramine, a combined serotonin/noradrenaline reuptake inhibitor. With each of these, up to 30 per cent of obese type 2 patients lose 10 per cent or more of body weight within 6 to 12 months, HbA_{1c} can fall by 1 per cent or more, and dosages of glucose-lowering drugs, including insulin, may be decreased.

Surgical treatment with gastric banding or gastric bypass operations is indicated in selected patients with a body mass index over 40 kg/m ^{2} (Chapter 10.5). This approach can achieve dramatic weight loss (up to 70 per cent of excess fat, maintained for several years), often with an impressive reversal of glucose intolerance: about 90 per cent of cases with type 2 diabetes or impaired glucose tolerance are returned to normoglycaemia.

Smoking

Smoking is at least as common among diabetic patients as in the general population. Smoking greatly amplifies macrovascular risk in diabetic subjects: 10-year mortality (mainly from myocardial infarction) is about 50 per cent higher than in diabetic non-smokers and twice as high as in non-diabetic non-smokers. Smoking may also accelerate the progression of nephropathy and possibly retinopathy.

Many diabetic people, especially young women, continue to smoke as a means of keeping thin, and because they fear gaining weight if they stop. Nicotine reduces fondness for sweet energy-dense foods and may also be mildly thermogenic. Weight gain after stopping smoking averages 3 kg but about 20 per cent of cases gain more than 6 kg; much of this weight is often lost within the following 1 to 2 years, and it can be limited or prevented by careful dietetic support beforehand and in the months after cessation. Moreover, the risks of continuing to smoke are much greater than this degree of weight gain, especially in diabetic people. Nicotine chewing gum may help patients to give up the habit.

Glucose-lowering drugs

Insulin

Insulin is the rational treatment for type 1 diabetes and the only drug that can normalize blood glucose in many type 2 diabetic patients. Unfortunately, subcutaneously injected insulin cannot match the physiological profile of normal insulin secretion (Fig. 7) and is a poor substitute for the finely tuned b cell with its nearly instantaneous capacity for 'in-flight' adjustment. Moreover, insulin given subcutaneously is absorbed into the systemic circulation rather than secreted into the portal system where an immediate effect on the liver, and first-pass clearance by that organ, are important in regulating the metabolic actions of insulin.

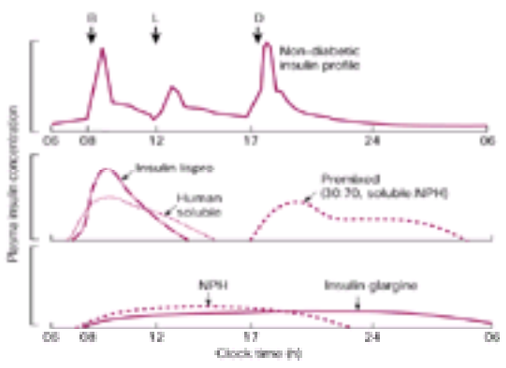

Fig. 7 Time course of insulin preparations, compared with the normal diurnal profile of plasma insulin concentrations in non-diabetic subjects (top). Breakfast (B), lunch (L), and dinner (D) were given as shown. Fast-acting analogues (such as lispro) act more rapidly than conventional soluble ones but are still sluggish compared with normal prandial insulin release. Premixed insulins injected in the early evening cover the evening meal adequately, but the long-acting component can cause hyperinsulinaemia and troublesome hypoglycaemia in the small hours. None of the conventional 'long-acting' insulins reliably lasts 24 h; new long-acting analogues such as insulin glargine may provide adequate background insulin levels with once-daily injections.

Insulin manufacture

Insulin was traditionally extracted from pork and beef pancreases in acid ethanol and purified by precipitation and recrystallization. Soluble (or 'crystalline') insulin prepared in this way was contaminated with other islet proteins, including glucagon and pancreatic polypeptide, which had an adjuvant-like effect and enhanced the immunogenicity of the injected insulin; immune reactions were relatively common with the 'dirty' animal insulins in use until the 1970s (see below). More sophisticated purification techniques including gel filtration yield 'highly purified' or 'monocomponent' insulins which only rarely provoke immune reactions.

Biosynthetic human-sequence insulin, produced by recombinant DNA technology, entered clinical practice in the early 1980s and was the first genetically engineered protein to be used therapeutically. The current approach is to introduce a synthetic gene for recombinant proinsulin or a novel insulin precursor into yeast; the secreted product is then cleaved enzymatically to yield insulin and C peptide.

There are some clinically relevant differences between the three species used therapeutically, although the shortcomings of insulin therapy relate mainly to the general pharmacokinetic misbehaviour of injected insulin. Human insulin is more lipophilic than porcine and bovine insulins and is slightly more rapidly absorbed: human soluble especially may lower glucose faster and patients being transferred from other species should be warned of this and prandial doses reduced initially by one-third. Human ultralente has a shorter and steeper action profile than its animal counterparts, particularly the bovine preparation; in real life, human ultralente behaves similarly to lente or isophane insulins and does not provide adequate basal levels for a full 24 h. Human insulin has been suggested to interfere with awareness of hypoglycaemia but the balance of evidence does not support this view (see below). Early beef insulins were especially prone to cause immune reactions (see below), although highly purified preparations do not appear to be particularly immunogenic.

Most insulin manufacturers are now turning to biosynthetic production of human-sequence insulin. Some patients prefer to continue using animal insulins—for reasons that may or may not appear scientifically sound—and these wishes should be respected by both clinicians and the pharmaceutical industry.

Insulin absorption

Absorption of insulin injected subcutaneously is slow and unpredictable. Individual day-to-day variability in the amount absorbed within a few hours can exceed 50 per cent. This means that small changes (less than 10 per cent) in insulin dosage are unlikely to influence glycaemic control, and that insulin treatment should generally not be adjusted on a daily basis.

Insulin absorption is influenced by the physical state of the insulin (soluble or delayed action), its speed of dissociation into monomers, the lipophilicity of the insulin species, and by blood flow and other characteristics of the injection site. Absorption is accelerated, and may lead to noticeably faster falls in blood glucose, by stimulating general or local blood flow through exercise, hot climate, saunas, and/or massaging the injection site. Conversely, absorption is slowed when subcutaneous blood flow is reduced, for example in cold conditions or hypovolaemic states. Lipohypertrophy, which may develop at frequently used injection sites, can significantly delay absorption—another reason for avoiding such areas.

The anatomical site of injection also influences the rate of subcutaneous absorption. It is fastest in the abdomen (also a good site to limit any effects of exercise) and arm, and slower in the leg. These differences are often eclipsed by the overall variability in absorption. Absorption from muscle is faster, presumably because of its higher blood flow, and this route is preferred for the emergency treatment of hyperglycaemia or ketoacidosis if the best option, controlled intravenous infusion, is not practicable.

Insulin preparations

Soluble (regular, or short-acting) insulin injected subcutaneously begins to lower glucose within 30 min, has a peak effect between 1 and 2 h and lasts 3 to 5 h (Fig. 7). This action profile is suitable for covering meals or hyperglycaemic emergencies and for use in insulin pumps or infusions. However, it would have to be injected several times per day to control hyperglycaemia around the clock, at the cost of frequent hypoglycaemia. Long-acting preparations are therefore used to cover basal insulin requirements.

Various approaches have been used to slow and prolong insulin absorption, especially the chemical combination of insulin into complexes that release it slowly. More recently, synthetic analogues have been designed whose structure promotes precipitation when injected subcutaneously (see Fig. 7).

Isophane insulins are also known as 'NPH' ('neutral protamine Hagedorn', from the director of the Danish laboratory where they were developed). They consist of a microcrystalline complex of insulin and the highly basic protein protamine (intriguingly isolated from fish sperm), together with trace amounts of Zn^{2+}. Isophanes were derived from protamine-zinc insulin which has a longer but highly unpredictable action profile. Isophanes produce peak plasma insulin levels at variable intervals between 4 and 8 h after injection, and their glucose-lowering action wears off rapidly after 10 to 12 h.

Insulin-zinc suspensions (lente insulins) employ higher Zn^{2+} concentrations which encourage insulin to form crystalline lattices. Varying the reaction pH can produce either larger crystals which are particularly slow to dissolve ('ultralente') or the amorphous 'semilente' which releases insulin faster; the familiar 'lente' is a 70:30 mixture of ultralente and semilente. Ultralente made with bovine insulin has a long, relatively flat action profile that can last 24 h or more, while human ultralente and the lente insulins of all three species have glucose-lowering profiles similar to that of isophane. These long-acting insulins have a cloudy appearance and need to be shaken before use to bring the insulin into suspension; visibly large particles or discoloration indicates that the insulin has become denatured and will have lost activity. Both lente and isophane insulins can be injected alone or mixed with soluble insulin.

Premixed insulins contain a short-acting soluble component together with a longer-acting lente or isophane. The aim is to provide prandial cover and then basal levels for several hours thereafter. Many preparations are available, with the proportion of short-acting insulin varying from 10 to 50 per cent. 30:70 mixtures are popular.

All these insulin types have been produced with porcine-, bovine- and human-sequence insulins, and are available in vials for pen injection devices.

Insulin analogues

The pharmacokinetic properties of native insulins of any species are poorly suited to subcutaneous injection: soluble insulins (despite their high-speed trade names) are too slow and prolonged in duration, while long-acting insulins do not provide reliable enough 24-h basal levels to be given once daily. Various synthetic insulin analogues, designed by molecular modelling, have improved physicochemical characteristics.

Fast-acting analogues are modified at the C-terminal end of the B chain, an area crucial in the self-association of insulin molecules, so as to resist dimerization and hexamerization. Insulin hexamers formed in the subcutaneous injection site, dissociate slowly into absorbable monomers, and this is a rate-limiting step in insulin absorption. Faster-acting analogues include insulin lispro (interchanging the B28 lysine and B29 proline residues of the normal human sequence) and insulin aspart, which carries aspartic acid at position B28 instead of the usual proline. They have an appreciably faster and shorter action profile (Fig. 7), and day-to-day variability in absorption and glycaemic responses may also be decreased. They can therefore reduce both prandial hyperglycaemia and the risk of postprandial hypoglycaemia. Overall, HbA_{1c} falls, with a reduced frequency of hypoglycaemia, when a fast-acting analogue is substituted for soluble insulin.

Long-acting insulin analogues are clear but precipitate when injected subcutaneously. Dissociation into monomers is at least as slow as with conventional long-acting

insulins and can provide basal levels for 24 h with a single daily injection, perhaps with less variability. An example currently entering clinical practice is insulin glargine (A21glycine, with two extra arginine residues extending the C terminus of the B chain).

Side-effects of insulin

Hypoglycaemia is the most common complication of insulin treatment and can be unpleasant, debilitating, and occasionally life-threatening.

Mild hypoglycaemia is common—many insulin-treated patients have at least one episode most weeks—but serious attacks causing unconsciousness or requiring the assistance of others are rare, about once every three patient years. Predictably, the frequency of both mild and severe attacks rises progressively when mean blood glucose levels are lowered by intensive insulin therapy; hypoglycaemia was three times more frequent in the tightly controlled group of the Diabetic Control and Complications Trial than in conventionally treated patients (see below).

The manifestations and treatment of hypoglycaemia are covered in detail later. As discussed there, there is no convincing evidence that the use of human as opposed to animal insulins specifically interferes with awareness of hypoglycaemic symptoms.

Weight gain is due to the anabolic effects of insulin, compounded by energy saved from glycosuria and sometimes by overeating after hypoglycaemia. Fear of weight gain discourages some patients, especially young women, from taking their full insulin dosages; deliberate omission or underdosing of insulin may be used surprisingly often to stay thin.

Lipohypertrophy is local thickening of subcutaneous tissue at frequently used injection sites, and is probably due to the lipogenic effects of high local insulin concentrations. Lipohypertrophy can be unsightly and can significantly delay insulin absorption. It can be prevented by rotating injections around several sites, and large lesions can be removed by liposuction.

Insulin allergy, now very rare with highly purified (especially human) insulins, can include local IgE-mediated erythematous reactions or even anaphylaxis. Lipoatrophy (localized pitting of the skin due to loss of subcutaneous fat) is apparently related to a chronic immune response generated around insulin crystals. 'Immune insulin resistance' was seen with impure animal and especially bovine insulins; high titres of insulin-binding antibodies mop up free insulin from the circulation, resulting in very high insulin requirements (occasionally more than 10 000 U/day), sometimes with unpredictable hypoglycaemia following release of antibody-bound insulin.

Insulin oedema is rare, and is usually seen in patients recovering from ketoacidosis who have been deprived of insulin for long periods. Fluid retention is probably due to the sodium-conserving effects of insulin on the renal tubule, and may cause ankle or generalized oedema. It usually resolves within a few days, although treatment with diuretics or ephedrine may be required.

Insulin regimens

Different individuals may need quite different insulin regimens, depending on their residual insulin reserve and severity of insulin resistance, as well as the desired tightness of control and the inconvenience that the patient will accept. Specific insulin schedules used in type 1 and type 2 diabetes are described later.

Insulin dosage

The healthy pancreas secretes about 40 to 60 U of insulin daily. Therapeutic insulin requirements range from less than this in thin type 1 patients (notably during the 'honeymoon period') to more than 200 U/day in very obese, insulin-resistant type 2 patients. High insulin requirements are often due to insulin resistance (see above), whereas low or falling dosages may be caused by weight loss (including anorexia nervosa), coeliac disease, or loss of counter-regulatory hormones in Addison's disease or hypothyroidism—all these conditions being associated with type 1 diabetes. Changing dosages, especially in previously stable subjects, should prompt investigation of these possibilities. Some patients with 'brittle' diabetes or psychological maladaptation to life with diabetes may pretend to take very high or very low dosages (see later).

Types of insulin

Formularies contain a bewildering assortment of insulins, many distinguished by imaginative claims about their action profile. Practically, prescribers should become familiar with regimens based on one or two preparations from the following broad classes:

1. Fast-acting insulin: either a soluble (regular) insulin such as Humulin S or Actrapid, injected 30 to 40 min before eating, or a faster-acting analogue (for example lispro or aspart) which can be given immediately before or even shortly after eating.
2. Long-acting insulin: either a lente insulin (for example Humulin Zn or Insulatard) or an isophane (for example Humulin I or Monotard). With either, circulating insulin falls to below useful levels after 10 to 14 h; they therefore need to be given twice daily in C-peptide negative patients, although those with residual insulin secretion (or who are given three premeal injections of soluble insulin) may be able to maintain good glycaemic control with a single bedtime injection. Bovine (but not human) ultralente can last a full 24 h, but its absorption is erratic. The long-acting analogues currently being introduced (such as insulin glargine) have flat, steady action profiles that may provide basal insulin levels with a single daily injection.
3. The timing of long-acting insulin injections does not have to be yoked to mealtimes as tightly as for soluble insulin but it is convenient to inject the morning dose at the same time as the prebreakfast soluble, either separately or mixed in the same syringe (glargine cannot be mixed with other insulins). When a second long-acting injection is needed, this is best given at bedtime, rather than together with the presupper soluble dose. This is because the action profile of long-acting insulin clashes with the physiological changes in insulin sensitivity that occur overnight. Growth hormone is normally secreted in large spikes on entering deep sleep, typically between 24.00 and 02.00 hours; this induces delayed insulin resistance which raises blood glucose during the hours leading up to breakfast. This 'dawn phenomenon' is accentuated if insulin levels are falling simultaneously—as happens if long-acting insulin is injected in the early evening. Another hazard with this timing is potentially dangerous nocturnal hypoglycaemia when insulin levels peak during the early morning (typically 02.00 to 04.00). Both problems can be reduced by delaying the long-acting injection to bedtime (22.00 to 23.00), when the risk of nocturnal hypoglycaemia is lower, and insulin levels generally persist long enough to counteract the insulin resistance of the dawn phenomenon.
4. Premixed insulins (for example 30 per cent short-acting with 70 per cent long-acting) are obviously more convenient than giving short- and long-acting insulins separately, but they lack flexibility. Premixed insulin injected 30 to 40 min before breakfast can achieve good glycaemic control through the morning and afternoon, but timing the evening dose is problematic: giving it before supper will tend to cause both early-morning hypoglycaemia and fasting hyperglycaemia because of the time course of the long-acting component, and simply increasing the evening dosage often makes nocturnal hypoglycaemia worse while failing to lower the prebreakfast glucose.

Insulin injections

Most insulin formulations are now available for both conventional syringes or pen injection devices. Pen injectors are compact, convenient, and easy to use: the required dose is 'dialled up' and injected by pressing the plunger; the ratchet mechanism of most pens gives an audible click that can help blind patients to count dosages.

Syringes and pens carry very fine (28 to 31 gauge) needles that allow insulin to be injected almost painlessly. The needle should be pushed in vertically and the insulin injected over a few seconds. 'Backtracking' of insulin to the skin surface, which can occasionally cause loss of several units of insulin, may be reduced by leaving the needle in place for a short while. A spot of bleeding may occur; very rarely, sudden hypoglycaemia may be due to direct injection of insulin into a subcutaneous vein.

Injections can be given into any site that is accessible and well upholstered with adipose tissue, especially the abdomen, thighs, buttocks, and upper arms. The abdomen has the advantage (theoretically at least) of relatively faster absorption that is less influenced by exercise, as compared with the limbs. Rotating injection sites, for example between the abdomen and leg, or around the quadrants of the abdomen, helps to avoid local reactions, especially lipohypertrophy which can make insulin absorption slow and erratic.

Jet injectors fire a metered dose of insulin as a high-pressure aerosol that penetrates the skin. These have is obvious appeal to patients with needle phobia, although there may be bruising and delayed discomfort at the injection site. Jet injectors are bulky and expensive and do not offer any pharmacokinetic advantages over

conventional injections.

Insulin pumps

Portable insulin pumps that administer continuous subcutaneous insulin infusion were developed by Pickup and colleagues in the late 1970s. Modern pumps are compact and light and worn in a belt or holster. Soluble insulin in a special cartridge is delivered through a fine-bore cannula and a butterfly-type cannula, which is inserted subcutaneously in the anterior abdominal wall and generally left in place for 1 to 2 days; the pump can be safely removed for 30 to 40 min for bathing or other activities. Different basal rates can be preprogrammed, and mealtime boluses are selected and given by pressing a button. Typical basal rates are 1 to 2 U/h during the day and 0.5 to 1 U/h overnight, with mealtime boluses (given 30 min before the main meals) amounting to about 50 per cent of the total daily dose. Insulin lispro has been used in pumps and may slightly improve control compared with conventional soluble insulin.

Continuous subcutaneous insulin infusion can achieve relatively steady insulin levels under laboratory conditions but cannot overcome the fundamental variability of subcutaneous insulin absorption. When used carefully by highly motivated patients who are supported by an experienced diabetes care team, continuous subcutaneous insulin infusion can achieve glycaemic control which is at least as good as that achieved with multiple injections; the two were used side by side in the Diabetic Control and Complications Trial. Insulin pumps are expensive (£1000 to £1500 (US$1500 to 2300)) as are consumables (another £1000 per year); medical backup can also be costly to provide. Continuous subcutaneous insulin infusion is only indicated for well-informed patients who are prepared to monitor their blood glucose frequently and take some responsibility for adjusting the pump. It is widely used in the United States and some European countries but less in the United Kingdom.

Infections at the infusion site with pyogenic skin commensals or unusual organisms (for example atypical mycobacteria) are uncommon but can be troublesome and cause rapid deterioration in glycaemic control. An increased rate of diabetic ketoacidosis was reported with earlier and less reliable pumps. With continuous subcutaneous insulin infusion, the subcutaneous insulin depot is only a few units, and any interruption of insulin delivery (such as with pump failure or cannula blockage) can lead to rapid rises in blood glucose and especially ketone levels. However, modern pumps carry no excess risk of diabetic ketoacidosis as compared with intensified injection therapy. Similarly, the risk of hypoglycaemia due to the pump over-running is now very low.

Continuous intraperitoneal infusion

The peritoneum is a good route for insulin administration: absorption is very rapid across its large surface area and insulin enters the portal circulation. Continuous intraperitoneal insulin infusion has been used in some cases, mostly employing a pump and reservoir implanted subcutaneously in the abdomen and delivering insulin through a flexible cannula sewn into the peritoneal cavity. The reservoir is filled with soluble insulin through an injection port lying just beneath the skin and is emptied by a liquid gas compression system at a rate that can be varied by an external electromagnetic control. Continuous intraperitoneal insulin infusion can provide basal insulin; meals need to be covered by additional insulin, usually injected subcutaneously.

Intraperitoneal pumps are expensive and convincing indications for their use are rare. They have been successful in some patients with apparently very high subcutaneous insulin dosages but surprisingly normal intravenous requirements. It is now clear that this situation is not due to a mysterious syndrome of 'subcutaneous insulin resistance', and that most of not all of these patients are interfering with their own treatment (see below). In this setting, continuous intraperitoneal insulin infusion is probably effective because these pumps are difficult to sabotage.

Oral hypoglycaemic agents

Sulphonylureas and repaglinide

The sulphonylureas were the first orally active glucose-lowering drugs to be used and were discovered in the 1930s when early sulphonamide antibiotics were found to cause hypoglycaemia. The 'first generation' (chlorpropamide, tolbutamide) have since been superseded by the 'second generation' (for example gliclazide and glibenclamide) and by newer agents such as glimepiride. Repaglinide acts in a similar way to the sulphonylureas.

Mode of action

Sulphonylureas are insulin secretagogues but insulin synthesis is not stimulated. Insulin levels peak within 1 to 2 h and decline within 4 to 6 h for the short-acting drugs (such as gliclazide) but may remain elevated for much longer with chlorpropamide and glibenclamide, which therefore carry a greater risk of hypoglycaemia. An 'extrapancreatic' action has also been attributed to sulphonylureas, i.e. improving insulin sensitivity. This effect is small and is probably explained by the non-specific decrease in insulin resistance ('glucotoxicity') when hyperglycaemia is corrected by any means.

Repaglinide acts in a similar way to the sulphonylureas but is structurally different. It is derived from the non-sulphonylurea part of the glibenclamide molecule (called meglitinide), which was found fortuitously to have glucose-lowering activity of its own.

Efficacy and potency

The ability of these agents to lower glycaemia depends on how much insulin is available for release from the b cells (which are already stimulated by hyperglycaemia) and by the severity of insulin resistance. In practice, all sulphonylureas lower basal and postprandial glucose levels by no more than 2 to 4 mmol/l and HbA_{1c} by 1 to 2 per cent; mild hyperglycaemia may therefore be corrected but patients with fasting glucose in excess of 13 mmol/l are very unlikely to achieve normoglycaemia (so-called 'primary failure'). Moreover, as b-cell function declines progressively in type 2 diabetes, many patients who initially respond well to sulphonylureas will subsequently need additional glucose-lowering drugs; this 'secondary failure' overtakes 5 to 10 per cent of patients per year, in a cumulative fashion. These limitations apply to all sulphonylureas and repaglinide: the more potent drugs have lower therapeutic dosages than the earlier agents but cannot lower glycaemia any further.

Pharmacokinetics

Most are taken twice daily with meals; glimepiride is taken once daily and repaglinide with each meal. Chlorpropamide has a very long action profile, while glibenclamide shows variable and sometimes prolonged hypoglycaemic activity. Sulphonylureas and repaglinide bind to circulating proteins and may be displaced by other strongly protein-bound drugs, causing hypoglycaemia (see below). All these drugs are cleared through the kidneys and can accumulate in renal failure, causing frequent hypoglycaemia and other side-effects. Gliquidone is metabolized mainly in the liver and may be slightly less hazardous in patients with renal impairment, although insulin is usually indicated in these cases.

Side-effects

Weight gain is due to the anabolic effects of hyperinsulinaemia, compounded by reduced losses of energy through glycosuria. Weight gain is typically 2 to 3 kg greater than with diet alone or metformin.

Hypoglycaemia is rarer than with insulin, but the risk is greater with longer-acting sulphonylureas (glibenclamide, chlopropamide), in renal failure, and in the elderly.

Sulphonylureas can cause allergic reactions including skin rashes (notably Stevens–Johnson syndrome) and marrow dyscrasias, and can precipitate acute intermittent porphyria. Side-effects exclusive to chlorpropamide include the syndrome of inappropriate secretion of antidiuretic hormone (see Chapter 20.2.1) and acetaldehyde-mediated facial flushing on drinking alcohol.

The cardiovascular safety of sulphonylureas has remained under a cloud since tolbutamide was associated with an excess of cardiovascular deaths during an essentially uninterpretable study (the UGDP) conducted in the 1970s; the presence of the SUR-2 receptor on cardiomyocytes has recently reinforced suspicions that these drugs may trigger ischaemia and arrhythmias (by preventing preconditioning). However, the recent United Kingdom Prospective Diabetes Study found no evidence that patients treated with sulphonylureas suffered cardiovascular events more often than those treated with insulin. Glimepiride is highly selective for SUR-1.

Indications and contraindications

These drugs are first-line therapy for type 2 patients in whom lifestyle and dietetic measures have failed to control hyperglycaemia. Because of their tendency to increase weight, they are best suited to non-obese patients. They can be usefully combined with metformin, which may partly offset weight gain, or insulin.

Insulin secretagogues are inappropriate for severely insulin deficient patients or during intercurrent illness, when insulin is needed, and are unlikely to be effective if fasting glucose exceeds 13 mmol/l. Sulphonylureas are contraindicated in renal failure: all should be stopped and insulin started if serum creatinine exceeds 250 µmol/l. Pregnancy has been viewed as a contraindication, because sulphonylureas cross the placenta and could cause fetal hyperinsulinaemia and perhaps teratogenesis; however, a recent study did not substantiate these concerns (see Chapter 13.10).

Many drugs interact with sulphonylureas, the most common interaction being hypoglycaemia due to displacement and/or decreased clearance of protein-bound sulphonylureas (for example by sulphonamides, fibrates, salicylates, and probenecid). Potential interactions must always be checked for any drug being contemplated in patients receiving sulphonylureas.

Choice of drug

There is little to choose between the newer agents; chlorpropamide is now obsolete. Glibenclamide should be avoided in the elderly because of its unpredictable tendency to cause hypoglycaemia.

Metformin

Metformin and phenformin are biguanides, the class of compounds responsible for the mild hypoglycaemic action of goat's rue (an otherwise undistinguished weed). Phenformin is no longer available in many countries because it carries a 10-fold greater risk of lactic acidosis, while metformin only recently entered clinical use in the United States.

Mode of action

Metformin acts primarily by inhibiting gluconeogenesis in the liver, thus reducing the raised hepatic glucose output which underpins basal and overnight hyperglycaemia; this effectively enhances the action of insulin on the liver. Peripheral glucose uptake may also be increased, while gastrointestinal side-effects may help to reduce fondness for food. Metformin does not stimulate insulin secretion.

Overall, metformin lowers blood glucose (especially postprandial) by 2 to 4 mmol/l and HbA_{1c} by 1 to 2 per cent, which is comparable to the effect of sulphonylureas. On its own, metformin does not cause hypoglycaemia, although this can obviously occur when it is combined with either a sulphonylurea or insulin. Weight does not usually increase with metformin, and may fall.

Metformin may have beneficial cardiovascular effects, as the United Kingdom Prospective Diabetes Study found a reduction in vascular events in the metformin-treated group only (see below). It is not clear whether this is related to specific metabolic effects of metformin (improved insulin sensitivity), to its antiobesity properties, or to other actions such as reported reductions in blood pressure and coagulability.

Pharmacokinetics

Metformin is given twice or thrice daily with meals. It is cleared mainly through the kidneys, and the increase in plasma levels in renal failure is a major risk factor for lactic acidosis.

Side-effects

Gastrointestinal symptoms (30 per cent of cases) include altered taste, loss of appetite, heartburn, abdominal discomfort and bloating, and diarrhoea (metformin is the commonest cause of this in the diabetic clinic). These problems are mostly mild, but may discourage the patient from taking the drug; they can be reduced by starting with a low dosage and increasing it slowly.

Lactic acidosis is very rare with metformin (about 3 cases per 100 000 patient-years) if it is carefully prescribed. This stems from the mode of action of metformin, namely the inhibition of hepatic gluconeogenesis—a process that constantly consumes the lactate produced by glycolysis. Blood lactate levels are modestly raised in patients receiving biguanides, and can escalate rapidly and cause life-threatening acidosis if lactate is overproduced (for example in respiratory or cardiac failure), or is not cleared by the liver (hepatic failure), or if metformin accumulates in renal failure. Lactic acidosis is described in detail later.

Megaloblastic anaemia can occur due to impaired absorption of vitamin B_{12}.

Indications and contraindications

Metformin is a first-line alternative to sulphonylureas in type 2 patients whose hyperglycaemia does not respond adequately to modification of diet and lifestyle; as it does not tend to cause weight gain, and may even reduce weight, it is often used in obese patients. Its addition can also be helpful in obese patients who are poorly controlled by sulphonylureas or insulin. Metformin is being evaluated in insulin-resistant conditions such as polycystic ovary syndrome and in impaired glucose tolerance.

Contraindications include all the major organ failures— renal, hepatic, cardiac, and respiratory. It should not be used when serum creatinine concentration exceeds 125 µmol/l.

Thiazolidinediones

Thiazolidinediones are a novel class of glucose-lowering drugs which improve insulin sensitivity. There are distinct differences between individual thiazolidinediones which influence their therapeutic spectrum and safety. Rosiglitazone and pioglitazone are currently available in many countries; troglitazone has been withdrawn because it caused rare but life-threatening hepatic damage.

Mode of action and pharmacokinetics

Thiazolidinediones bind to specific receptors in the nucleus which have the cumbersome title 'peroxisome proliferator activating receptor-g' (PPAR-g). PPAR-g and the related peroxisome proliferator activating receptor-a (the target for the fibrate class of lipid-lowering drugs) are ligand-activated transcription factors whose natural ligands appear to be fatty acid derivatives. PPAR-g that has bound a thiazolidinedione forms a heterodimeric complex with another nuclear receptor, RXR, bound to its own endogenous ligand, retinoic acid. The heterodimer then binds to specific recognition motifs found in the promoter sequences upstream of many genes, notably those involved in adipocyte and lipid metabolism.

The affinity of individual thiazolidinediones at PPAR-g parallels their glucose-lowering ability in animal models of type 2 diabetes, but their precise mode of action remains uncertain. Thiazolidinediones exert concerted effects that encourage the storage of triglyceride in mature adipocytes, including the differentiation of preadipocytes into adipocytes and enhanced expression of lipogenic enzymes; overall, circulating levels of free fatty acids fall and this may reduce hepatic glucose production and increase glucose uptake into muscle as described earlier. The net effect is to enhance the action of insulin—hence their description as 'insulin sensitizers'. Thiazolidinediones have negligible glucose-lowering action unless insulin resistance and hyperglycaemia are present. As with metformin, they do not cause hypoglycaemia when used alone, but can exaggerate the hypoglycaemic effects of insulin or sulphonylureas.

Efficacy and potency

Alone, all thiazolidinediones lower glucose by 2 to 3 mmol/l and HbA_{1c} by 1 per cent, somewhat less than the sulphonylureas. For unknown reasons, blood glucose declines slowly during thiazolidinedione treatment, and a maximal effect may not be reached for several weeks. Rosiglitazone is the most potent thiazolidinedione to date but, as with the more potent sulphonylureas, cannot lower blood glucose further than the other thiazolidinediones.

Pharmacokinetics

All are metabolized in the liver and cleared chiefly through the kidney. They are highly protein bound.

Side-effects

Weight gain, averaging 1 to 4 kg, is due mainly to fat deposition. This appears to spare the visceral depot associated with insulin resistance and does not negate the glucose-lowering action.

Fluid retention of unknown aetiology may cause a mild dilutional anaemia (haemoglobin typically falls by 1 to 2 g/dl) and ankle oedema (in 5 to 10 per cent of cases); rarely, heart failure may be precipitated in patients with pre-existing myocardial dysfunction, especially if they are also treated with insulin.

Hepatic damage, ranging from subclinical elevations of hepatic enzymes to fulminant and fatal hepatic necrosis (about one case per 1000 patient-years), has been reported with troglitazone but does not appear to be a risk with rosiglitazone or pioglitazone.

Indications and contraindications

Thiazolidinediones are currently re-garded as second-line drugs for treating type 2 diabetes when sulphonylureas or metformin are ineffective or insuitable. They can be combined with either a sulphonylurea or metformin, when HbA_{1c} may fall by more than 1 per cent; if HbA_{1c} has not fallen by more than 1 per cent within 6 months of adding a thiazolidinedione, it should be discontinued. When pioglitazone is used with insulin, insulin dosage can be reduced but weight gain may be problematic; rarely, heart failure may be precipitated (the combination of rosiglitazone with insulin is currently contraindicated). Subjects with impaired glucose tolerance treated with a thiazolidinedione have a lower risk of progressing to overt type 2 diabetes, and the drugs can improve hirsutism and menstrual dysfunction (sometimes inducing ovulation) in women with polycystic ovary syndrome.

Contraindications include hepatic dysfunction and congestive heart failure. Although these is no evidence of hepatotoxicity with thiazolidinediones other than troglitazone, it seems prudent to monitor liver enzymes periodically and to stop the drug if transaminases rise to more than 1.5 times the upper limit of normal, or if any other signs of hepatic dysfunction appear.

a-Glucosidase inhibitors

Acarbose (and the related miglitol and voglibose) are inhibitors of a-glucosidase, an enzyme of the brush border of the small intestine essential for the breakdown of dietary starch to disaccharides, which are then hydrolysed to the absorbable monosaccharides. Their rationale is to block digestion of complex carbohydrates and so damp post-prandial glycaemic rises. The therapeutic effect is small: post-prandial glucose may fall by 1 to 2 mmol/l, with predictably little impact on overnight glucose, and HbA_{1c} by 0.5 per cent or less. Side-effects due to carbohydrate malabsorption (flatus, abdominal bloating, gassy diarrhoea) are common and probably damage compliance. Despite its poor efficacy and low tolerability, acarbose is still widely prescribed and in some countries is regarded as a first-line drug.

Practical management of hyperglycaemia

Most newly diagnosed diabetic patients are easily allocated to either type 1 or 2 on clinical criteria (Table 2) and treatment is started accordingly. However, initial impressions may be misleading: a thin young patient may not need insulin because he has MODY, whereas a classical maturity-onset subject may lose weight rapidly and develop ketoacidosis because he has type 1 diabetes. Continuing monitoring and vigilance are therefore essential.

Type 1 diabetes

These patients must be given insulin immediately and for life. The insulin regimen will depend particularly on any remaining endogenous insulin, the patient's body weight, lifestyle, and motivation. Patients with residual insulin secretion, especially newly presenting and particularly during the 'honeymoon period'(see below), can often fill in gaps in insulin replacement and enjoy good glycaemic control with few injections and low insulin dosages. However, C-peptide negative patients will require exogenous insulin to cover both basal and prandial needs (Fig. 7) to achieve good control. Regimens include:

1. Twice daily long-acting insulin with preprandial short-acting insulin. Lente or isophane is injected before breakfast (and can be mixed with prebreakfast short-acting insulin) and at bedtime (see above). Soluble insulin is injected 30 min before breakfast and the evening meal, or a fast-acting analogue (such as lispro or aspart) given with food. Mid-day meals, unless large, are usually covered satisfactorily by the morning's long-acting dose and do not need separate short-acting insulin.
2. Once daily long-acting insulin with preprandial short-acting insulin is currently unsatisfactory because both lente and isophane run out too quickly, but longer-lasting analogues such as glargine may be effective when injected once daily at bedtime or breakfast. Short-acting insulin is given separately to cover meals, as above.
3. Premixed insulins injected before breakfast and before the evening meal suit some patients and many doctors, but often fail to control overnight and/or fasting glucose levels (see above).

Insulin dosages should be titrated according to blood glucose and HbA_{1c} monitoring (Table 3). Highly motivated patients may be suitable for continuous subcutaneous insulin infusion treatment as discussed above.

Starting insulin therapy

Patients at risk of ketoacidosis need hospital admission, while those who are clinically well can start insulin at home, supervised by a specialist diabetes nurse. Good control can often be achieved with long-acting insulin injected at breakfast and bedtime, starting with low dosages (for example 8–12 U in the morning and 4–6 U at night) to avoid potentially demoralizing hypoglycaemia. Short-acting insulin can then be added to cover excessive prandial hyperglycaemia. Wherever practicable, patients should be encouraged to give their own injections as soon as possible.

Newly diagnosed patients starting insulin need to be warned about a possible 'honeymoon period' of good glycaemic control, when the fall in glucose levels allows partial recovery of the remaining b cells. Blood glucose can often be easily controlled with low insulin dosages (and exceptionally, without exogenous insulin) but the honeymoon ultimately ends within a few months: blood sugar levels and insulin requirements then escalate, because of the progressive loss of remaining b cells.

Poor diabetic control and 'brittle' diabetes

In real life, relatively few type 1 patients approach the high-quality glycaemic control aspired to in Table 3. This largely reflects the pharmacokinetic shortcomings of current insulin preparations and the unpredictable nature of subcutaneous absorption. The patient's compliance is a crucial determinant of overall diabetic control; teenagers are notoriously resistant to advice abut diabetes, as with other matters, and many have markedly elevated HbA_{1c} concentrations. This clearly increases the risk of future diabetic complications.

A few patients have such poor metabolic control that they cannot live a normal life. Most have chronically high blood glucose and suffer recurrent hospital admissions with ketoacidosis; some suffer frequent hypoglycaemia, while others have an unstable or 'brittle' blood glucose profile that can swing rapidly between hyper- and

hypoglycaemia. Occasionally, endocrine or intercurrent illnesses are found to be responsible (Table 4), but most cases remain 'idiopathic' after even intensive investigation. It is now clear that poor compliance, often with deliberate interference with treatment, is responsible in many of these patients. Most are young women who tend to be obese and are generally hyperglycaemic despite apparently high insulin dosages; when tested under controlled conditions, however, their intravenous and subcutaneous insulin requirements are unremarkable. Many are probably omitting insulin or taking only small doses: common motives include escape from difficulties at school or home, or wanting to stay thin (disturbances of body image are common in this group). Initially, such patients may appear to lead charmed lives despite frequent hospital admissions but many die prematurely (especially from ketoacidosis or hypoglycaemia); significant diabetic complications frequently develop during their twenties or thirties.

Management can be extremely difficult. Patients with sustained poor control should be admitted selectively for intensive education, observation, and exclusion of other possible causes (Table 4). In some cases, it may be necessary to confirm that insulin is effective at conventional doses (for more information see the paper by Schade and Duckworth in Further reading). Even close supervision in hospital does not exclude ingenious interference with insulin treatment or glucose monitoring. Intensified insulin schedules or continuous subcutaneous insulin infusion may help in some cases but the key is more likely to be sympathetic counselling (perhaps with psychotherapy) of the patient and his or her family.

Experimental and future treatments for type 1 diabetes

Pancreatic transplantation, usually performed in conjunction with renal transplantation for patients with diabetic nephropathy, can achieve good results including long-term withdrawal of exogenous insulin in 10 per cent of cases. The whole gland or a segment is transplanted into the pelvis and anastomosed to the iliac vessels; to avoid damage from pancreatic exocrine secretions, the duct is either occluded or drained into the bladder (when urinary amylase excretion can indicate the health of the graft). Problems are the need for lifelong immunosuppression (required anyway for renal transplantation) and the global shortage of donor organs.

Pancreatic islet transplantation is gaining ground, especially transcutaneous injection into the portal vein of islets isolated from a donor pancreas; these colonize and function well in the liver, the first stop for insulin secreted physiologically. A novel immunosuppressive regimen without glucocorticoids can improve the outcome (most cases become insulin independent), but two or three donor pancreases are currently needed for each recipient.

Prevention of type 1 diabetes by aborting insulitis during the long prediabetic phase has been achieved by immunosuppression in some high-risk subjects, especially the siblings of type 1 patients who have diabetogenic HLA class II antigens and high titres of GAD and islet cell antibodies. Better immunosuppressive regimens may improve the results.

Antidiabetic drugs under development include aerosolized insulin that exploits the lung's large absorptive area and enters the bloodstream rapidly, and various low molecular weight insulin mimetics that either bind to the insulin receptor or enhance postreceptor signalling.

Management of type 2 diabetes

Dietary and lifestyle measures form an essential foundation for management of type 2 diabetes and must be maintained throughout, even though fewer than 10 per cent of patients can be controlled satisfactorily for more than a year by these means alone.

Patients who fail to meet the glycaemic targets in Table 3 should generally follow the steps outlined below, although compromises may be more appropriate in the elderly or those at risk of hypoglycaemia. Progress should be reviewed every 3 months or so if blood glucose is unacceptably high; the inexorable deterioration of b-cell function in type 2 diabetes means that there is no point in delaying decisions to increase drug doses or add insulin.

First-line oral hypoglycaemic agents for so-called 'dietary failure' are a sulphonylurea (or repaglinide) or, particularly for obese patients (those with a body mass index in excess of 30 kg/m^2), metformin. Dosages can be increased to a maximum over a few weeks. Should one class fail, the other can be tried but a dramatic improvement is unlikely.

Combination oral therapy: two of sulphonylurea (or repaglinide), metformin, or a thiazolidinedione can be used together. Some diabetologists would try adding acarbose at this stage. Triple therapy is generally not worth trying.

Long-acting insulin with a first-line oral agent: although seemingly illogical, a bedtime injection of isophane can control blood glucose overnight and before breakfast, and this apparently helps oral hypoglycaemic agents to act more effectively during the day. The combination of metformin (thrice daily with meals) with bedtime isophane often achieves good glycaemic control, while limiting the weight gain that commonly follows the introduction of insulin in type 2 patients. Isophane with a sulphonylurea or pioglitazone may increase weight; rosiglitazone is contraindicated in combination with insulin.

Insulin therapy can range from once- or twice-daily long-acting insulin in subjects with residual insulin, to the more intensified basal and prandial regimens used in type 1 diabetes. Large dosages (100 to 150 U/day) may be needed to achieve good glycaemic control in obese, highly insulin-resistant subjects. As in type 1 diabetes, rapidly acting and very long-acting analogues may be able to improve on the currently available native insulins.

Obesity (and therefore insulin resistance) may worsen when insulin treatment is started; possible reasons include reduced losses of energy through glycosuria, a tendency to relax dietary restriction when a more effective means of lowering glycaemia is introduced, and sometimes overeating during hypoglycaemic episodes. Increasing insulin resistance may lead to escalating insulin dosages. The possible hazards of insulin-induced obesity are not clear but could theoretically include vascular disease, which may be hinted at by the lower frequency of cardiovascular events among patients treated with metformin in the United Kingdom Prospective Diabetes Study trial. At present, however, the consensus is probably to aim for the glycaemic targets in Table 3 (which will reduce the risks of microvascular complications) and to accept an increase in weight, while actively treating other cardiovascular risk factors.

Experimental and future treatments for type 2 diabetes

GLP-1 is an incretin hormone that stimulates insulin secretion and may also induce satiety, particularly by delaying gastric emptying. Blood glucose can be lowered comparably to sulphonylureas with GLP-1 infused intravenously. Buccal and orally active preparations are under development, as are inhibitors of dipeptidyl peptidase IV, the enzyme which degrades GLP-1.

Combined peroxisome proliferator activating receptor a/g agonists have insulin-sensitizing and lipid-lowering actions in animals. Various novel insulin secretagogues and non-thiazolidinedione insulin sensitizers are in development; one agent (S15261) combines both these properties.

Antiobesity drugs could have an important impact in many type 2 patients. Agents currently in preclinical testing include neuropeptide Y receptor (Y5) antagonists, melanocortin-4 receptor agonists, and low molecular weight leptin mimetics (see Chapter 10.5).

Monitoring diabetic control

Treatment targets for blood glucose and type 1 and type 2 diabetes (Table 6) have been selected to reduce the risk of chronic diabetic complications. Avoiding acute episodes of hyper- and hypoglycaemia is also important.

Blood glucose monitoring

Blood glucose concentration can be easily and quickly measured in small drops of blood (a few microlitres or less), using various test strips; the ability to perform such measurements is an essential skill for all professionals delivering diabetes care and for most diabetic patients. Test strips contain glucose oxidase (which catalyses the oxidation of glucose to gluconic acid) together with a detection system to measure specific reaction products, either electrochemically or colorimetrically (using dyes sensitive to hydrogen peroxide). The signal is read by a reflectance meter or electrically, and converted into the glucose concentration in the sample. Colour-based test strips can also be read by eye against a printed standard scale, although this may be difficult for partially sighted or colour-blind patients.

A drop of blood is obtained by pricking the sides of the fingertip, avoiding the sensitive pads; various lancets and automatic finger-pricking devices are available.

Blood must cover the reaction area completely and be left in contact for exactly the period stipulated; some meters read out automatically at this point, whereas other strips must be wiped dry and left for the colour to develop. Failure to follow the manufacturer's instructions is the main cause of inaccurate readings, which are disturbingly frequent. With attention to detail, readings correspond closely to laboratory measurements of glucose (which also employ the glucose oxidase reaction) but are not reliable enough to be used for diagnosing diabetes.

Monitoring schedules

Type 2 diabetes treated with diet and oral agents can be monitored using fasting glucose and values in the midafternoon, both of which correlate with overall glucose level, measured once or twice per week.

Insulin-treated patients may need more frequent monitoring to adjust insulin dosages. Fasting glucose is determined by the previous evening's long-acting insulin, while values before the evening meal reflect mainly the morning's long-acting dose. Prandial short-acting insulin dosages can be titrated from the glucose rise 90 to 120 min after eating. Readings can be scattered across these time points on different days; most patients can be persuaded to check their glucose levels once or twice per day.

Written records help to bring out general patterns in glucose control. Patients must also be encouraged to check their glucose if they feel unwell and, crucially, frequently during intercurrent illness. Occasional tests during the night (especially between 02.00 and 04.00) are useful in patients at risk of nocturnal hypoglycaemia, including those injecting long-acting or premixed insulins in the early evening.

Checking the self-monitoring technique and the patient's action plan when glucose levels fall outside the target range is a core part of the patient's diabetic education.

HbA_{1c} and fructosamine

These tests measure the non-enzymatic reaction of glucose with circulating proteins (see below), and therefore reflect longer-term blood glucose levels. Glycated (glycosylated) haemoglobin (HbA_1) results from the combination of glucose with the N-terminal valine residue of the B chain of adult Hb (HbA), and can be separated from unaltered HbA by electrophoretic and other methods. HbA_1 includes the stable HbA_{1c} fraction, which is most closely related to average blood glucose levels over the preceding 6 to 8 weeks.

The various assay methods for HbA_{1c} are now being standardized to match the methodology used in the Diabetic Control and Complications Trial (DCCT), which defined the long-term risks of diabetic microvascular complications (see below). For assays conforming to DCCT standards, non-diabetic HbA_{1c} ranges from 3.5 to 5.5 per cent of total HbA, with 'good' control defined as less than 7 per cent and 'poor' control as more than 8 per cent; some poorly compliant patients have HbA_{1c} concentrations of 14 to 16 per cent. HbA_{1c} measurements are a useful index of medium-term glycaemic control, but may be invalidated by abnormal red cell turnover (values are spuriously low in haemolysis, bleeding, and pregnancy), in renal failure (carbamylated HbA coelutes with HbA_{1c}, falsely raising levels), and with abnormal haemoglobins (HbF also comigrates with HbA_1).

Serum albumin also undergoes glycation, which is measured by the fructosamine reaction. As albumin turns over faster than haemoglobin, the fructosamine concentration reflects mean blood glucose over the previous 1 to 2 weeks. Assays are cheap but not standardized between laboratories, and are generally less reliable and reproducible than measurements of HbA_{1c}.

Measurements of urinary glucose and ketones

Urinary glucose concentrations can be measured easily using glucose oxidase test strips, but are of limited use: urinary glucose concentration depends on the renal threshold (which can lie between 7 and 13 mmol/l), urine output, and the time since the bladder was last emptied. Crucially, hypoglycaemia cannot be detected. Urinary glucose measurements are acceptable in type 2 diabetic patients with a normal renal threshold who are not receiving hypoglycaemic medication (insulin or sulphonylureas) and in patients who decline to prick their fingers.

Urinary ketone measurements can be useful for predicting impending ketoacidosis, particularly during intercurrent illness when blood glucose is high. Moderate ketonuria can be caused by fasting or undereating, including during infections.

Structures for diabetes care

Diabetes is best managed by the combined efforts of a team of specialists with complementary and overlapping skills: physician, specialist diabetes nurse, dietician, and chiropodist. The specialist diabetes nurse has a crucial role in educating patients about diabetes and its practical management, and in starting and adjusting therapy. Many patients are more receptive and responsive to information given by specialist nurses than by doctors. There must be frequent contact with and easy access to other specialists (ophthalmologist, vascular surgeon, renal physican, obstetrician, and clinical psychologist), ideally in the setting of combined clinics. Each member of the team has a particular niche but all must agree common strategies (such as dietary advice for obesity) to avoid giving the patients conflicting or inconsistent information.

Diabetes care can be delivered effectively by hospital-based clinics, community 'miniclinics' run by well-informed general practitioners or practice nurses, or by 'shared care' schemes that involve both primary and secondary sectors. Because of the unpredictable course and potential complications of diabetes, all patients must be thoroughly reviewed each year and be rapidly referred for specialist help if the need arises.

A check list for the annual review is suggested in Table 5.

Diabetes education

Living and coping with diabetes is a considerable burden that is poorly appreciated by many doctors and nurses. Careful education about diabetes, its complications, and its practical management can provide great reassurance to patients and also reduce emergency hospital admissions and complications such as foot ulceration and amputation.

Diabetes education is most effectively provided by the specialist diabetes nurse, but all members of the diabetes care team should understand the key messages, and check and reinforce these whenever possible. These include:

- Causes of hyperglycaemia and diabetic symptoms.
- Own treatment: diet and lifestyle; drawing up and injecting insulin; oral agents; recognizing and treating hypoglycaemia.
- Self-monitoring technique; targets and danger levels; how to respond to poor control.
- 'Sick-day' rules: monitoring during intercurrent illness; how to adjust own treatment; when and how to call for help (see Table 6).

Employment, driving, and insurance

Because of the risk of hypoglycaemia, patients treated with insulin (type 1 or 2) are barred from active service in the police, fire service, or armed forces and from driving heavy-goods or public service vehicles. Specific diabetic complications, notably sight-threatening retinopathy, may preclude particular jobs or pastimes.

Patients must inform the driving licence authorities and their driving insurer that they are diabetic, and those receiving insulin or with clinically significant retinopathy may require periodic medical confirmation of fitness to drive. Frequent hypoglycaemia, especially with decreased awareness of symptoms, is a bar to driving.

Special life insurance policies are available from companies endorsed by patient-centred organizations such as Diabetes UK and the American Diabetes Association.

Many patients find it valuable to join these organizations.

Intercurrent events in diabetes and their management

Infections

Diabetic patients probably have increased susceptibility to pyogenic bacterial infections, especially when diabetes is poorly controlled. Hyperglycaemia can impair the killing of micro-organisms by neutrophils and macrophages and may also interfere with the function of T lymphocytes. Some infections particularly associated with diabetes include:

- Tuberculosis, often widespread and cavitating.
- Necrotizing fasciitis, rapidly spreading necrosis of subcutaneous tissues down to muscle, usually due to b-haemolytic streptocci with staphylococci and often anaerobes.
- Gas-forming infections with anaerobes and clostridia, including 'emphysematous' pyelonephritis, cholecystitis, cystitis, and foot infections. Plain radiography shows gas in the affected tissues.
- Diabetic foot ulcers (see below) are often infected, with the risk of osteomyelitis and deep soft-tissue spread.
- Urinary tract infections may be complicated by ascending infections with pyelonephritis and renal or perinephric abscess (sometimes with gas), and occasionally acute papillary necrosis. Severe loin pain and systemic symptoms, with deteriorating renal function, should suggest these possibilities and the need for urgent imaging.
- 'Malignant' or necrotizing otitis externa, due to pseudomonas infection, can invade the skull and facial nerve.
- Periodontal infections, sometimes causing tooth loss, are common.
- Rhinocerebral mucormycosis is a highly invasive fungal infection that originates in the sinuses but often spreads into the orbit and cranial cavity. Mortality is about 50 per cent, even with debridement and high-dose intravenous amphotericin B.

The bacterial infections often require aggressive intravenous antibiotic treatment with cover against anaerobes. Fastidious and rare organisms should be considered when standard antibiotic regimens are ineffective.

Diabetic control during infections

Minor viral infections rarely disturb diabetic control, but increased secretion of counter-regulatory stress hormones during severe infections, especially with fever, can rapidly worsen insulin resistance in both type 1 and 2 diabetes.

Type 1 patients may need twice as much insulin as usual, even if they are unable to eat. Failure to increase the insulin dosage will therefore allow glucose to rise, sometimes dramatically fast, and risk precipitating ketoacidosis. It is therefore essential to continue taking insulin, to monitor blood glucose frequently, and to increase insulin if sustained hyperglycaemia develops. A rise of 30 to 50 per cent in long-acting insulin is often enough, but requirements will be determined by blood glucose levels and should be decided in consultation with the diabetes care team. Avoidable deaths still occur every year because poorly educated patients (sometimes advised by ignorant doctors) reduce or even stop taking insulin because they feel ill, are not eating, and are worried about becoming hypoglycaemic. Clear 'sick-day' rules (Table 6) are a crucial part of diabetes education, which must be regularly checked and reinforced.

During severe infections, insulin needs may fluctuate rapidly and the safest way to give insulin is by continuous intravenous infusion, backed up by frequent (hourly) blood glucose measurements (see below).

Type 2 patients may similarly lose glycaemic control, and are often best transferred temporarily to subcutaneous or intravenous insulin.

Although not firmly evidence-based, it would seem best to maintain blood glucose between 5 and 10 mmol/l during intercurrent infections.

Myocardial infarction

This is discussed in detail later.

Surgery

Surgery can be hazardous to diabetic patients: the counter-regulatory stress response to surgical trauma can rapidly lead to hyperglycaemia and ketoacidosis, especially in insulin-deficient patients, while poorly controlled diabetes accelerates catabolism and delays wound healing. Moreover, insulin and the sulphonylureas can cause severe hypoglycaemia in fasted or anorexic patients, which can be particularly dangerous during general anaesthesia.

Glycaemic control must therefore be meticulous throughout the preoperative period. A routine management policy should be agreed between the diabetes care team, surgeons, anaesthetists, and ward staff, and this will greatly reduce the risks of operating on diabetic people. Fitness for surgery should be carefully assessed, in view of cardiovascular or other complications. Patients may need to be admitted some days before operation to optimize their treatment.

For type 2 patients who are well controlled by diet or oral agents and undergoing minor surgery only, long-acting sulphonylureas (glibenclamide) should be changed to short-acting ones (for example gliclazide) some days before surgery to reduce the risk of hypoglycaemia. Oral agents and breakfast should be omitted on the morning of operation and blood glucose should be monitored closely. Persistent hyperglycaemia should be treated with the intravenous glucose–potassium–insulin regimen described below.

For all other diabetic patients, subcutaneous insulin should be stopped on the morning of surgery, and a continuous intravenous infusion of balanced amounts of glucose, potassium, and insulin should be given (Table 7). If the patient is in steady state, the glucose–potassium–insulin (GKI) infusion will both maintain satisfactory glycaemic control (5–10 mmol/l) and prevent hypokalaemia. This regimen should be started on the morning of surgery and continued until the patient is able to eat and drink normally, when the usual treatment can be resumed. GKI bags must be changed if glucose levels are unsatisfactory. Alternatively, insulin may be given as a variable-rate intravenous infusion, which provides greater flexibility.

Acute metabolic complications of diabetes and their treatment

Diabetic ketoacidosis

This is uncontrolled hyperglycaemia with hyperketonaemia severe enough to cause metabolic acidosis. It remains a major cause of death in patients with type 1 diabetes under 20 years of age, and episodes still carry an overall mortality of 5 to 10 per cent (50 per cent in elderly patients with diabetic ketoacidosis precipitated by infection or myocardial infarction). Prompt diagnosis and careful management can prevent many deaths.

Causes

Diabetic ketoacidosis only develops when severe insulin deficiency, compounded by an excess of glucagon, stimulates lipolysis and a massive increase in ketogenesis (see above). It therefore almost always occurs in untreated or poorly treated type 1 diabetes and is generally regarded as the hallmark of that disease. However, diabetic ketoacidosis can occur in subjects with type 2 diabetes who are relatively insulin deficient, especially when the secretion of counter-regulatory hormones (especially glucagon) is increased by severe intercurrent illness. Precipitating factors include:

- Newly presenting type 1 diabetes.
- Omission or underdosing of insulin by established type 1 diabetic patients, which may be deliberate in patients with disturbances of body image.
- Intercurrent illness, such as infections, myocardial infarction, stroke, trauma, surgery, and burns. Many patients (and their doctors) fail to increase insulin

dosages or monitor blood glucose during such events.

About 30 to 40 per cent of episodes are unexplained; omitted or inadequate insulin treatment should always be suspected if no obvious infective or other cause is found.

Pathophysiology

Diabetic ketoacidosis is due to the accumulation of ketones, i.e. acetoacetate and its derivatives, 3-hydroxybutyrate (or b-hydroxybutyrate) and acetone (Fig. 8). They are generated by b oxidation of free fatty acids within the mitochondria of the liver. Free fatty acids enter the cytoplasm of hepatocytes and combine with coenzyme A (**CoA**) to form their fatty acyl-CoA derivatives. These are then transported into the mitochondria by the 'carnitine shuttle', a complex of two linked enzymes, carnitine palmitoyl transferase I (CPT-I) on the outer mitochondrial membrane and carnitine palmitoyl transferase II (CPT-II) on the inner. CPT-I, and the overall activity of the shuttle, is powerfully inhibited by insulin and stimulated by glucagon. Once inside the mitochondria, free fatty acids undergo b oxidation to yield ATP (oxidative phosphorylation) and acetyl-CoA. The latter is converted to acetoacetate, which may be oxidized to 3-hydroxybutyrate or undergo condensation to produce acetone.

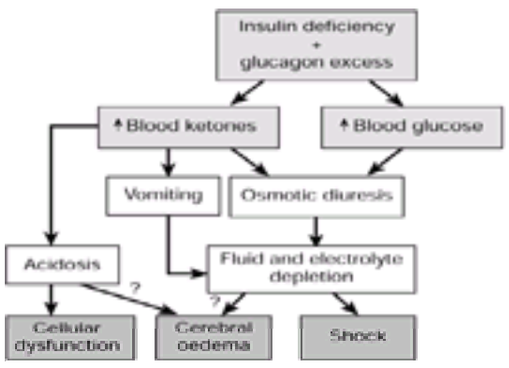

Fig. 8 Pathophysiological changes in diabetic ketoacidosis. Cellular dysfunction induced by intracellular acidosis, cerebral oedema, and shock are potentially life-threatening.

Ketones are transported out of the liver and are used as metabolic fuels by various tissues including the brain; they supply a few per cent of total energy needs after an overnight fast, but the proportion rises to over one-third during prolonged fasting. When produced in excess, they can accumulate rapidly, especially if plasma levels exceed 10 mmol/l (about 50 times normal), when tissue uptake mechanisms become saturated. Ketogenesis is greatly enhanced in uncontrolled type 1 diabetes because of the combination of low insulin with increased glucagon concentrations: lipolysis is unrestrained, and the uptake into liver mitochondria of the increased amounts of fatty acyl-CoA is stimulated by the synergistic effects on CPT-I of high glucagon and low insulin. The main consequences of raised circulating ketone levels are shown in Fig. 8 and listed below:

- Acidosis. Acetoacetate and 3-hydroxybutyrate are both moderately strong organic acids and lower the extracellular pH when the buffering capacity of plasma proteins is exceeded. Ion exchange across cell membranes leads to intracellular acidosis which compromises cellular metabolism because many crucial enzymes operate within a narrow pH range. Clinical measurements of acid–base status are confined to extracellular fluid and may underestimate the severity of intracellular acidosis.
- Diuresis. Ketones are filtered in the urine and are osmotically active. They therefore exacerbate the osmotic diuresis caused by glycosuria and the resulting polyuria, electrolyte losses, dehydration, and hypovolaemia.
- Nausea, through direct stimulation of the chemoreceptor trigger zone in the medulla.

Clinical features

Diabetic ketoacidosis usually presents with classical hyperglycaemic symptoms (Table 2), together with features of acidosis and hyperketonaemia:

- Acidotic (Kussmaul) breathing is deep, sighing hyperventilation which has been mistaken for panic attacks, pulmonary embolism, and left ventricular failure.
- Nausea and vomiting are ominous signs, because dehydration develops quickly in polyuric patients unable to drink.
- Drowsiness and coma occur late and may indicate early cerebral oedema.

The patient generally looks ill and may show postural hypotension and other signs of dehydration and hypovolaemia. Acetone (nail varnish remover) is volatile and may be smelled on the breath. Some patients are hypothermic due to heat loss from peripheral vasodilation, and this may mask the pyrexia of infection. Children with diabetic ketoacidosis often complain of abdominal pain, sometimes mimicking acute appendicitis or other surgical emergencies. A full examination is essential to identify any intercurrent illness.

Investigations and diagnosis

Once suspected, the diagnosis can be confirmed on the spot with a finger-prick blood glucose measurement and urinalysis for ketones. Treatment with intravenous saline and insulin should begin immediately, and baseline investigations carried out. Venous blood is taken for biochemical screening and arterial blood for pH and acid–base status. Additional tests to identify the cause of the episode should include a full blood count, urine and blood culture, chest radiograph, and, especially in older patients, ECG and cardiac enzymes or troponin levels.

Typical values and some diagnostic pitfalls in diabetic ketoacidosis are shown in Fig. 9. Plasma ketone levels are measured by some laboratories but are not usually needed for safe management. High ketone concentrations cause a large anion gap: i.e. plasma $[Na^+ + K^+]$ exceeds $[HCO_3^- + Cl^-]$ by more than 17 mmol/l.

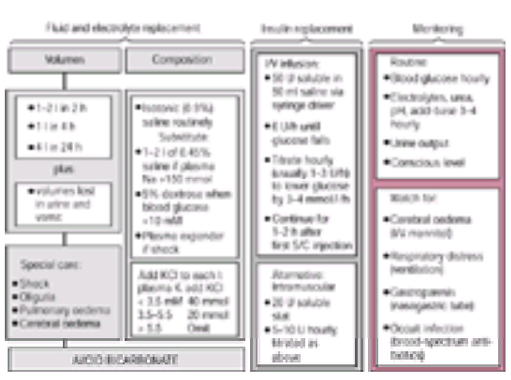

Fig. 9 Guidelines for the management of diabetic ketoacidosis.

Management

Diabetic ketoacidosis is a potentially life-threatening medical emergency that requires urgent treatment with scrupulous clinical and biochemical monitoring: many

avoidable disasters still happen because the patient is abandoned once treatment has been started. Severe diabetic ketoacidosis is best managed initially on a high-dependency or intensive care unit.

The highest priority is to correct hypovolaemia and dehydration, which will often improve acidosis and hyperglycaemia. Insulin replacement must also be started urgently. However, it now appears likely that the high mortality of diabetic ketoacidosis has been partly due to overenergetic replacement of intravenous fluids (especially bicarbonate) and perhaps insulin, which may predispose to the development of cerebral oedema. The treatment guidelines below (Fig. 9) are based on large studies that have reported very low mortality and morbidity.

Fluid replacement

Good intravenous access is crucial: a large peripheral vein may be used but a central venous cannula is safest for severely hypovolaemic patients and for the elderly or those at risk of heart failure, in whom monitoring of central venous pressure is essential.

Most patients recover rapidly with slower fluid replacement than was previously recommended. For those who are not shocked give:

- 1 to 2 litres in 2 h, then
- 1 litre over the next 4 h, then
- 4 litres over the next 24 h.

Fluid losses in urine or vomit should be added to these volumes. Shocked or oliguric patients may require faster fluid repletion, possibly with plasma expanders rather than saline, while slower replacement is safer in those with signs of fluid overload, heart failure, or any suspicion of cerebral oedema. Urine output must be monitored closely, as must blood pressure, central venous filling, and signs of pulmonary or peripheral oedema.

Saline containing potassium is the logical fluid to replace the losses of Na^+, K^+, and Cl^- induced by the osmotic diuresis of diabetic ketoacidosis. The use of intravenous bicarbonate to try to correct acidosis is contentious, both biochemically and in terms of clinical outcome (see below).

Isotonic (0.9 per cent) saline is used initially. Half-isotonic (0.45 per cent) saline has been suggested to replace 1 or 2 litres of isotonic saline, if severe hyperosmolarity (> 350 mosmol/kg) and/or hypernatraemia (> 150 mmol/l) are present. However, the rationale may be flawed: 0.9 per cent ('normal') saline is already hypotonic with respect to the patient's hypertonic plasma, and the use of even more hypotonic solutions would seem likely to exacerbate the intracellular movement of water which may lead to cerebral oedema. Five per cent dextrose is generally substituted when plasma glucose has fallen to 10 to 14 mmol/l to prevent hypoglycaemia (insulin is still required to prevent ketogenesis and promote glucose utilization in the tissues).

Intravenous sodium bicarbonate was previously recommended for severe acidosis. However, the hope that adding alkali will correct acidosis may be oversimplistic. HCO_3^- and H^+ ions (from 3-hydroxybutyric and acetoacetic acids) combine extracellularly to produce H_2CO_3, which dissociates to produce water and CO_2; this may reduce extracellular acidosis, but as cell membranes are impermeable to HCO_3^- ions, the all-important intracellular acidosis is not improved. Indeed, CO_2 can enter cells where it can combine with water to produce H_2CO_3, itself a weak organic acid that can dissociate into H^+ and HCO_3^- ions. Paradoxically, therefore, intravenous bicarbonate administration could worsen intracellular acidosis and there is evidence from animal models of acidosis that this occurs. Worryingly, a recent study identified bicarbonate administration as the most important independent predictor of cerebral oedema in children with moderately severe diabetic ketoacidosis. Another problem with high-strength (8.4 per cent) sodium bicarbonate solution is the intense thrombophlebitis it causes when given intravenously, which can obliterate even large central veins.

The current consensus is that bicarbonate is unlikely to do good but runs the risk of doing harm, and that it should not be used in the treatment of diabetic ketoacidosis

Potassium replacement

Diabetic ketoacidosis always depletes total body K^+ stores to a variable degree because of electrolyte losses through osmotic diuresis, but H^+/K^+ exchange across the plasma membrane encourages K^+ to leak out of cells in acidosis. Plasma K^+ levels can therefore be low, normal, or high, and dangerous hyperkalaemia can be present, especially if severe hypovolaemia causes prerenal failure. During insulin replacement, K^+ is carried intracellularly with glucose, and plasma K^+ levels can fall rapidly. Frequent monitoring of K^+ (every 3 to 4 h initially) is therefore essential in the safe management of diabetic ketoacidosis, and patients with marked K^+ disturbances should have continuous ECG monitoring.

Potassium replacement should be determined by current plasma K^+ levels:

- Add 20 mmol of KCl to each litre of intravenous fluid if K^+ is normal (3.5–5.0 mmol/l).
- Add 40 mmol/l of KCl to each litre if plasma K^+ is less than 3.5 mmol/l.
- Omit KCl if plasma K^+ is more than 5.0 mmol/l, because of the risk of precipitating arrhythmias.

Insulin replacement

Continuous intravenous infusion is the best way to give insulin in diabetic ketoacidosis; subcutaneous and intramuscular absorption are too erratic to be safe and the rate of fall of glucose (one of the factors implicated in cerebral oedema) cannot be easily controlled.

- 50 U soluble insulin (for example Actrapid or Humulin S) should be added to 50 ml isotonic saline (i.e. 1 U/ml) and delivered by a syringe driver pump, either into a separate vein or piggy-backed into the intravenous fluids line.

Because the half-life of insulin in the circulation is only a few minutes, blood glucose and ketone levels will rise rapidly if insulin delivery is interrupted; hourly monitoring of blood glucose is therefore mandatory during intravenous insulin. Failure of glucose to fall usually means that the pump has been turned off or that the infusion cannula is blocked. Initially, 6 U/h (i.e. 6 ml/h) should be given and once blood glucose has started to fall, the rate can then be titrated so that glucose falls by 3 to 4 mmol/l every hour. Faster rates of fall are unnecessary, commonly cause hypoglycaemia, and are thought to predispose to cerebral oedema. Most patients need 1 to 3 U of insulin per hour, and the requirement will become clear after 3 to 4 h of blood glucose onitoring.

A typical intravenous sliding scale (based on hourly glucose measurements) is:

- blood glucose less than 5 mmol/l: give 0.5U/h
- blood glucose 5 to 10 mmol/l: give 2 ml/h
- blood glucose more than 10 mmol: give 4 ml/h.

An alternative to the syringe driver is to dilute insulin into a larger volume (50 U soluble insulin into 500 ml of saline; 0.1 U/ml) and to regulate delivery (for example 20 ml/h (2 U/h)) using an electronic drip counter or a paediatric giving-set with a burette.

The GKI infustion used for perioperative management of diabetic patients is not appropriate because it assumes that the patient is in steady state (which is not the case) and because K^+ disturbances may be exacerbated; moreover, making up and changing GKI infusion bags is time-consuming and very rarely done as often as is needed to control the fall in glucose.

If it is impossible to give a controlled intravenous infusion, then intramuscular soluble insulin can be injected every 4 h or so, starting with 20 U and attempting to titrate subsequent dosages (for example 5–10 U hourly).

Other complications

Intercurrent illness must be treated energetically. Broad-spectrum antibiotics are often given prospectively. Myocardial infarction (see below) has a poor prognosis if it causes diabetic ketoacidosis.

Shock may lead to prerenal failure and sometimes acute tubular necrosis. Plasma expanders and inotropes may occasionally be required for severe hypotension, although rehydration as above is usually adequate.

Cerebral oedema still accounts for 50 per cent of fatalities in diabetic ketoacidosis, especially in children, although modern management protocols with slower fluid replacement and low-dose intravenous insulin infusion can markedly reduce its incidence. The cause is thought to be shifts of ions and water into the brain, particularly the movement of water into dehydrated, hypertonic cells when relatively hypotonic fluids reach the extracellular space. Such shifts would be predicted with isotonic and particularly with hypotonic fluids. Risk factors for cerebral oedema include over-rapid falls in blood glucose, excessive fluid replacement, and high insulin dosages. Insulin can affect various ion transport mechanisms in the brain, but its role remains mysterious and may simply reflect changes in extracellular osmolarity. Interestingly, CT scanning before fluid and insulin replacement has demonstrated subclinical cerebral oedema in children with diabetic ketoacidosis.

Swelling of the brain within the cranium causes coning, leading to cardiorespiratory arrest. It presents as a decline in consciousness, usually rapid and often when the patient's metabolic state has been stabilized. Papilloedema may be present, and CT or MR scanning will show characteristic swelling, with loss of cortical features and squashing of the ventricular system (Fig. 10). It is usually fatal (in more than 90 per cent of established cases), but intravenous mannitol (0.2 g/kg over 30 min, repeated hourly if there is no improvement) may help by raising the osmolality of extracellular fluid and drawing free water out of the brain; there is no firm evidence to support the use of dexamethasone.

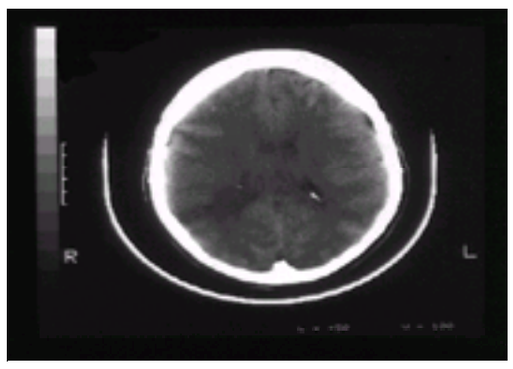

Fig. 10 Cerebral oedema in a patient recovering from diabetic ketoacidosis. The CT scan shows generalized swelling and loss of cortical detail with squashing of the cerebral ventricles.

Adult respiratory distress syndrome is due to accumulation of fluid in the alveoli, perhaps due to ionic and water shifts or to excessive leakiness of the pulmonary capillaries. Hypoxia is severe, and chest radiography shows an appearance like left ventricular failure but with a normal heart size. Risk factors include rapid fluid replacement. It carries a poor prognosis, but ventilation with high-concentration oxygen may be useful supportive treatment.

Acute gastric dilatation (gastroparesis) presents with vomiting and may show a succussion splash and a ground-glass appearance on abdominal radiograph. Nasogastric drainage may be needed to prevent aspiration, especially in the unconscious patient.

Hypothermia indicates a poor outcome. It may respond to rewarming with a space blanket.

Subsequent management

When the patient can eat and drink, intravenous fluids and insulin can be discontinued. There is no need for a GKI regimen; instead, the patient can be restarted on their usual insulin regimen (or on twice daily long-lasting insulin, if newly diagnosed). The intravenous insulin infusion should be maintained until the first injection has had time to act (3–4 h for long-acting insulin alone).

The causes of the episode must be determined if possible, and efforts made to prevent it from happening again. The patient's understanding of diabetes, including the 'sick-day' rules (Table 6), must be checked and reinforced if necessary. Recurrent diabetic ketoacidosis is a feature of brittle diabetes, and these patients need careful monitoring and counselling.

Hyperosmolar non-ketotic state (HONK)

Hyperosmolar non-ketotic state is distinguished from diabetic ketoacidosis by the absence of gross hyperketonaemia and metabolic acidosis. Hyperglycaemia can be greater than in diabetic ketoacidosis and, together with a rise in urea due to dehydration and prerenal failure, may elevate the plasma osmolality to well over 350 mosmol/kg.

Ketosis does not develop because circulating insulin levels are high enough to suppress lipolysis and ketogenesis; these patients are therefore C-peptide positive, with type 2 diabetes which is often previously undiagnosed. It is more common in people of Afro-Caribbean origin. Precipitating factors include myocardial infarction, stroke, infection, and diabetogenic drugs such as glucocorticoids and thiazide diuretics; fizzy glucose drinks may also contribute.

Presentation is typically with classical hyperglycaemic symptoms (polyuria, intense thirst, weight loss, blurred vision), without the features of ketoacidosis. Confusion, drowsiness, and coma are commoner than in diabetic ketoacidosis.

Complications include thrombotic events such as stroke and peripheral arterial occlusion, and deep venous thrombosis and pulmonary embolism, these being due to increased blood viscosity. Mortality exceeds 30 per cent because these patients are old and often have a serious precipitating illness.

Biochemical features of hyperosmolar non-ketotic state are:

- Hyperglycaemia: often over 50 mmol/l, sometimes over 90 mmol/l.
- Hypernatraemia: often over 155 mmol/l (may be artefactually depressed by high glucose levels).
- Uraemia due to dehydration, with or without renal failure.
- Hypersmolality: over 350 mosmol/kg.
- Blood and ketone levels are normal or only slightly raised (usually through anorexia).
- Arterial pH, venous bicarbonate, and anion gap show no features of severe acidosis.

Management is largely as for diabetic ketoacidosis:

- Saline replacement must be particularly cautious in older patients, in whom cardiac disease is common. Half-isotonic (0.45 per cent) solution is often given if plasma sodium exceeds 150 mmol/l or osmolality exceeds 350 mosmol/kg; the rationale for preferring this to isotonic saline is not proven, but the risks of cerebral oedema appear to be lower than in diabetic ketoacidosis.
- Potassium levels must be carefully monitored and replaced as above.

- Intravenous insulin infusion at low doses rapidly controls hyperglycaemia in most cases.
- Low-dose heparin (5000 U subcutaneously 8-hourly) should be given prophylactically, but full anticoagulation should be reserved for proven thromboembolism as the risks of fatal gastrointestinal bleeding are high. Intercurrent illness must be sought and treated appropriately.

After recovery, many of these patients can be successfully weaned off insulin. Drugs and other precipitating factors must be identified and avoided if possible.

Lactic acidosis

Lactate is generated by glycolysis and its levels rise rapidly during tissue anoxia (for example during shock, cardiac failure, or pneumonia) or when the liver is prevented from utilizing it as a gluconeogenic substrate (for example in hepatic impairment). Lactic acidosis is best known in diabetic patients as a rare but often fatal complication of the biguanides, phenformin and metformin, which act mainly by inhibiting hepatic gluconeogenesis. The risk is about 10 times higher with phenformin than with metformin, and it is very rare during metformin treatment as long as other predisposing factors (the major organ failures) are avoided.

Lactic acidosis presents as coma with metabolic acidosis (reduced arterial pH and venous bicarbonate) and a wide amino gap due to hyperlactataemia. Blood glucose levels are usually raised.

Treatment is still unsatisfactory. Intravenous sodium bicarbonate may paradoxically aggravate intracellular acidosis, although forced ventilation to blow off carbon dioxide may help (see above). Haemodialysis may both clear lactate and hydrogen ions, and correct any sodium overload following bicarbonate administration. Sodium dichloroacetate, which stimulates pyruvate dehydrogenase to metabolize lactate, is undergoing evaluation.

Mortality remains high (over 30 per cent), partly because of the organ failures that commonly coexist.

Hypoglycaemia

Hypoglycaemia is an inevitable side-effect of antidiabetic drugs that raise circulating insulin levels, namely insulin itself and sulphonylureas; it does not occur with metformin or thiazolidinediones alone, or with dietary restriction. Common contributory factors are:

- Accelerated insulin absorption, for example due to exercise or hot surroundings.
- Unfavourable timing of insulin injection: injecting too soon before eating can cause late postprandial hypoglycaemia, while long-acting insulins injected in the early evening often cause nocturnal hypoglycaemia.
- Too much insulin injected: dosage errors are quite common, particularly in the elderly.
- Inadequate food intake: missed, delayed, or small meals; vomiting, including gastroparesis.
- Exercise hastens insulin absorption while enhancing insulin action; delayed hypoglycaemia may occur many hours later because muscle continues to take up glucose to replenish glycogen.
- Alcohol inhibits hepatic gluconeogenesis, preventing the increase in hepatic glucose output that is crucial for restoring euglycaemia.
- Impaired awareness of early warning symptoms (see below).

Progressively more frequent or severe attacks may be caused by various conditions, which should always be sought:

- Weight loss, including anorexia nervosa and appetite disorders (relatively common in young women with type 1 diabetes).
- Loss of counter-regulatory hormones: Addison's disease, hypothyroidism, hypopituitarism, blunted glucagon secretion in long-standing type 1 diabetes.
- Intestinal malabsorption, notably coeliac disease (commoner in type 1 diabetes).
- Renal failure, which impairs the clearance of insulin.
- Deliberate inappropriate injection of insulin, often in the context of 'brittle' diabetes.

Manifestations

Clinical features of hypoglycaemia are due to an autonomic discharge, predominantly sympathetic, together with the cerebral effects of neuroglycopenia. Falling glucose levels are sensed by glucose-sensitive neurones, which are found in the periphery (vagal sensory endings in the portal vein) and medulla as well as the hypothalamus. This triggers a powerful sympathetic discharge that releases adrenaline from the adrenal medulla and noradrenaline from sympathetic nerve endings, causing the familiar 'flight or fight' response. Features include pallor (cutaneous vasoconstriction), sweating, tremor (a b_2-adrenergic effect on skeletal muscle) and tachycardia; systolic blood pressure rises due to increased cardiac output while pulse pressure widens—giving the typical bounding pulse—because b_2-mediated vasodilatation in skeletal muscle causes peripheral resistance to fall.

Hypoglycaemia also triggers the secretion of counter-regulatory hormones, namely glucagon and adrenaline (both crucial to restoring euglycaemia), growth hormone, and cortisol. Collectively, these inhibit insulin secretion and raise blood glucose by enhancing hepatic glycogenolysis and gluconeogenesis, causing glucose to pour out of the liver. Defects in glucagon or adrenaline release (which occur for example in long-standing type 1 diabetes), or in the ability of the liver to produce glucose (for example the presence of ethanol which inhibits gluconeogenesis, or a recent glucagon injection which depletes liver glycogen) will delay recovery of blood glucose.

The physiological and neurological features of hypoglycaemia usually develop in a fixed sequence when blood glucose is lowered in a controlled fashion in the laboratory. However, this hierarchy may not be apparent in real life, and some patients specifically lose their awareness of the early warning symptoms (see below). Key events as glucose falls are:

- ~3.8 mmol/l: increased glucagon and adrenaline secretion
- ~3.0 mmol/l: onset of hypoglycaemic symptoms
- ~2.8 mmol/l: neuroglycopenia and cognitive impairment
- at less than 1.0 mmol/l: coma.

Symptoms of hypoglycaemia

The symptom complex can be extremely variable, and hypoglycaemia should be suspected as the cause of any 'funny turn' in patients treated with insulin or sulphonylureas. Autonomic manifestations include sweating, tremor, tachycardia, and hunger, while neuroglycopenia can cause drowsiness, confusion, inco-ordination, dysarthria, and automatic or disinhibited behaviour; distinct neurological deficits include aphasia, diplopia, and hemiparesis. Non-specific malaise and headache afterwards are also common. Nocturnal episodes may pass completely unnoticed by the patient, or may cause sweating and restlessness (often obvious to the patient's partner), vivid nightmares, or a hung-over feeling the following morning.

Awareness of hypoglycaemic symptoms

Diabetic patients rely on the early autonomic symptoms (sweating, shaking, and hunger) to warn them of an impending hypoglycaemic attack, when corrective action can be taken. In some patients the early warning symptoms are attenuated or not noticed at all; this clumsily named 'hypoglycaemia unawareness' is potentially dangerous because severe neuroglycopenia (confusion, fitting, irrational behaviour, coma) may suddenly incapacitate the patient. Reduced awareness of hypoglycaemia occurs particularly in two settings, which may coexist:

- Long-standing type 1 diabetes. Some 30 to 50 per cent of patients with diabetes of more than 20 years' duration have decreased awareness of symptoms, and many also show a flat glucagon response to hypoglycaemia. Blunted recognition of hypoglycaemia by the central nervous system may be responsible.
- Excessively tight glycaemic control impairs awareness of hypoglycaemia; for unknown reasons, even a single episode can blunt perception of symptoms and counter-regulatory hormone responses for some days. Conversely, relaxing control and avoiding hypoglycaemia completely for several weeks can partially restore awareness of warning symptoms.

The use of human insulin has been suggested to impair awareness of hypoglycaemic symptoms. Human insulin is relatively lipophilic—hence its faster subcutaneous absorption—which could theoretically promote its entry into the brain. Insulin may act directly on the brain to affect various autonomic processes, but detailed comparisons of human and animal insulins, both in the laboratory and in real life, have not shown any species differences in counter-regulatory responses or the intensity of hypoglycaemic symptoms.

Sequelae of hypoglycaemia

Even the most dramatic neurological manifestations of acute hypoglycaemia—including aphasia, hemiparesis, fitting, and unconsciousness—usually resolve rapidly when blood glucose is normalized. Recovery from profound coma may take many hours or even days, and this is probably due to cerebral oedema. Patients who survive severe and prolonged hypoglycaemic coma may show permanent neurological damage, including memory loss, aphasia, and a vegetative state. There are concerns that repeated mild attacks, especially in children and perhaps particularly at night, can cause cumulative intellectual impairment, but this is not yet proven.

Severe hypoglycaemia has been implicated in precipitating myocardial infarction or stroke, particularly in the elderly; rises in blood pressure and increased coagulability of the blood following sympathetic stimulation may contribute. Like any convulsions, hypoglycaemic fits may cause injury, including limb and vertebral crush fractures.

Prolonged severe hypoglycaemia can be fatal and is one of the most common causes of death in young type 1 patients. Post-mortem studies show neuronal damage and necrosis in the hippocampus and cerebral cortex. Hypoglycaemia has been suspected as a cause of death in patients found unexpectedly dead in bed; arrhythmias may be responsible.

Diagnosis and detection of hypoglycaemia

Hypoglycaemia is easy to diagnose but is also easily missed; differential diagnoses include transient ischaemic attacks, psychosis, drunkeness, epilepsy, and migraine. Symptoms may be instantly recognizable to some patients, but may present atypically. If suspected, the blood glucose levels should be checked, taking care to avoid under-reading artefacts with reagent test strips. Urinalysis is obviously of no use—hence all patients receiving insulin or sulphonylureas must be able to check their blood glucose. The patient's close associates should also know how to diagnose and treat hypoglycaemia.

Various experimental hypoglycaemia detectors are undergoing development, including measurements of subcutaneous glucose by implanted sensors or transcutaneous near-infrared spectroscopy, but none is yet suitable for routine clinical use.

Prevention and treatment of hypoglycaemia

Insulin-treated patients fear hypoglycaemia as much as blindness or renal failure, and this may prevent them from tightening their diabetic control as much as their doctors would prefer. Many doctors underestimate the impact of hypoglycaemia; asking about it and trying actively to prevent it are an essential part of diabetes care.

Attention to the factors listed above should help to reduce the frequency and severity of attacks. Advice about exercise, moderating alcohol intake, and timing of insulin injections and meals are particularly important. Nocturnal hypoglycaemia can be reduced by checking the blood glucose at bedtime, and by taking long-acting carbohydrate (for example bread or cereal) if the level is less than 6 mmol/l.

Blood glucose levels of less than 3 mmol/l should be treated immediately (Table 8). Oral glucose or sucrose or other carbohydrate should be given if the patient can swallow safely. Give 20 to 30 g (e.g. six Dextrosol tablets or 150 ml Lucozade) initially; if possible, check blood glucose 15 min later and repeat if the glucose has not risen. Taking too much carbohydrate—which is understandable, given the unpleasantness of hypoglycaemia—can cause marked rebound hyperglycaemia.

If the patient is unconscious, give either:

- Glucagon 1 mg (0.5 mg in children), subcutaneously or intramuscularly; with either route glucose should rise within 10 to 15 min. Side-effects of glucagon include malaise, nausea, and abdominal discomfort and, because it acts primarily by breaking down hepatic glycogen (a limited resource), a second injection may be ineffective.
- Intravenous glucose: 15 to 20 g intravenously, as 50 per cent or 10 per cent solution (the former may cause painful thrombophlebitis, even if given into a large vein).

Glucose gels or jam can be smeared inside the mouth and cheeks in the unconscious patient, but these alone are unlikely to correct serious hypoglycaemia.

On recovery, blood glucose should be checked and oral glucose given as above. Slow recovery from coma may be due to cerebral oedema, which has a high mortality (around 10 per cent) but may respond to intravenous mannitol and forced ventilation with high inspired oxygen concentration.

Once the episode is treated, its cause must be identified if possible and corrective action taken to prevent it from happening again.

Chronic complications of diabetes

Long-term tissue damage is now the major burden of the disease, the greatest source of fear for diabetic people, and the most expensive item in the diabetes health-care budget. The list of complications is depressingly long but fortunately at least 40 per cent of diabetic patients escape clinically significant complications, and improved diabetes care should reduce the risks even further.

Microvascular complications—retinopathy, nephropathy, and neuropathy—are specific to diabetes and reflect damage inflicted on the microcirculation throughout the body. Retinopathy and nephropathy are obviously 'microvascular' disorders; the microcirculation of nerves (vasa nervorum) is also damaged in diabetic neuropathy, although other functional and structural abnormalities in the nerves themselves probably contribute. Macrovascular disease is simply atherosclerosis. This causes typical coronary heart disease, stroke, and peripheral arterial disease, but often behaves more aggressively than in non-diabetic people.

Other complications are due to irreversible biochemical and structural changes in tissues chronically exposed to hyperglycaemia. These include cataract, whose formation during normal ageing is accelerated by diabetes, and specific soft tissue disorders such as limited joint mobility (diabetic cheiroarthropathy).

Causes of chronic diabetic complications

Role of hyperglycaemia

Tissue lesions are identical in all types of diabetes, indicating that hyperglycaemia (or a closely related metabolic abnormality) is likely to be responsible. Microvascular disease in the retina, kidneys, and nerves is generally determined by the severity and duration of hyperglycaemia, although individual susceptibility varies considerably. By contrast, macrovascular disease does not display a clear dose–response relationship with hyperglycaemia: instead, the risk is increased above glucose values that lie below the 'diabetic' range (see above).

Recent intervention studies have confirmed that improving glycaemic control is rewarded by partial protection against microvascular complications but not atheroma. This principle is valid for both type 1 and type 2 diabetes, and is now embodied in their treatment targets (Table 3). Two 'landmark' studies are generally cited, although several smaller ones have also reached the same conclusion.

Type 1 diabetes

The Diabetic Control and Complications Trial (DCCT) was a 12-year North American study of over 1400 patients that compared 'intensive' insulin treatment (aiming

for an HbA_{1c} of 6 per cent) with 'conventional' (i.e. bad) regimens of once or twice daily injections (HbA_{1c} about 9 per cent). Intensive treatment consisted of at least three daily injections or the insulin pump (continuous subcutaneous insulin infusion), and achieved a mean HbA_{1c} of 7 per cent.

The DCCT concluded that improved glycaemic control reduced the risks of microvascular complications . In subjects who were initially free of complications, intensified treatment for 9 years decreased the prevalence of a defined degree of background retinopathy by 70 per cent (i.e. from 55 per cent with conventional treatment to 15 per cent), while the risks of developing microalbuminuria or clinical neuropathy fell by 33 per cent and 70 per cent respectively (Fig. 11). In subjects who already had background retinopathy at baseline, intensified treatment reduced the overall progression of retinopathy by 50 per cent; more importantly the risks of suffering sight-threatening retinopathy or requiring laser treatment were reduced by a similar degree. The development of clinical nephropathy (overt albuminuria) and neuropathy were each decreased by about 60 per cent. By contrast, intensified insulin treatment did not reduce the prevalence of macrovascular disease.

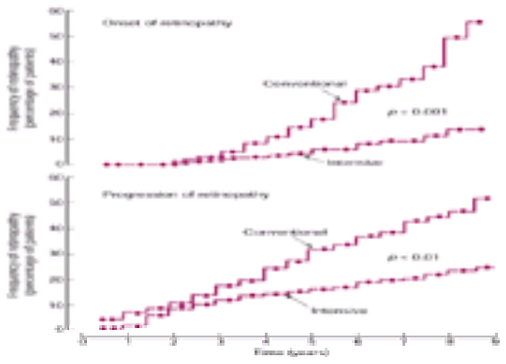

Fig. 11 Intensive insulin therapy and improved diabetic control reduces the risks of type 1 diabetic patients developing retinopathy (upper panel) and of established retinopathy progressing (lower panel). Data from the Diabetic Control and Complications Trial (DCCT).

Type 2 diabetes

The United Kingdom Prospective Diabetes Study (UKPDS) was guided through its 20-year course by the late Robert Turner, who died shortly after it was completed. This huge trial followed the outcome of over 5000 patients treated with diet and lifestyle alone (termed 'conventional' treatment), or together with sulphonylureas, metformin or insulin; confusingly, sulphonylureas and insulin treatments were both described as 'intensive' treatment. The trial confirmed the real-life difficulty of achieving good glycaemic control, especially against the progressive deterioration of type 2 diabetes: very few patients achieved and maintained the 'intensive' target fasting plasma glucose of 6 mmol/l. The trial has been criticised for its convoluted design (which diluted its statistical power) and both the lumping and splitting of data for outcome analysis. Nevertheless, it yielded useful messages about the importance of treating both hyperglycaemia and hypertension and about the natural history of the disease itself. Its conclusions were broadly similar to those of the DCCT: improved glycaemic control decreased the risk of microvascular complications. Lowering HbA_{1c} from 7.9 per cent (conventional) to 7.0 per cent (intensive) decreased the lumped rate of microvascular events by 25 per cent (Fig. 12), including sight-threatening retinopathy (20 per cent) and development of microalbuminuria (33 per cent). Across a reasonably wide range of HbA_{1c}, lowering HbA_{1c} by 1 per cent reduced the risk of microvascular disease by about one-third. Improved glycaemic control had no overall effect on macrovascular disease, although metformin treatment only significantly decreased cardiovascular events (see above).

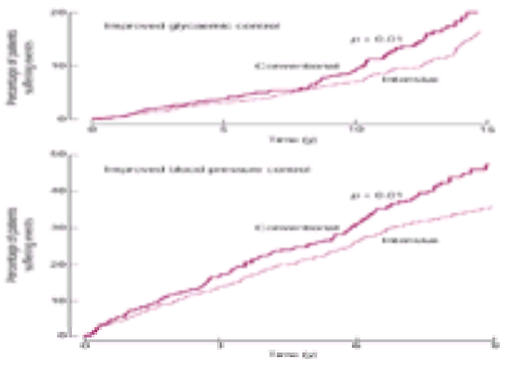

Fig. 12 Benefits of improving glycaemic and blood-pressure control in type 2 diabetic patients. Upper panel *:* 'intensive' treatment with glucose-lowering drugs reduces the risks of suffering any microvascular complication by about 25 per cent. Lower panel: tighter control of blood pressure reduces the risks of suffering any diabetes-related complication (including micro- and macrovascular disease) by about 24 per cent. Note the scale differences in both axes. Data from the United Kingdom Prospective Diabetes Study (UKPDS).

Possible mechanisms of hyperglycaemic tissue damage

High glucose levels can damage the function and structure of many tissues. The mechanisms currently thought most relevant to human diabetic complications probably operate to different degrees in different tissues.

Glycation of proteins and macromolecules

Glycation begins with the non-enzymatic combination of glucose and other reactive sugars with amino groups of proteins, and with acceptor groups of other long-lived macromolecules such as nucleic acids. Glycation is initially reversible, yielding a Schiff base which undergoes molecular rearrangement to form an Amadori product. Amadori products then undergo further reactions, including covalent crosslinking with the sugar groups in other glycated proteins. These irreversibly modified molecules, collectively termed 'advanced glycation endproducts', resist normal degradation mechanisms and thus accumulate.

Advanced glycation endproducts (AGE) can interfere with tissue structure and function in several ways. Stiffening of connective tissue in the limited joint mobility syndrome (see below) is related to crosslinking of collagen by AGE, while the same process in the proteins of the lens fibre (crystallins) causes cataract. AGE also damage blood vessels, and formation of AGE in the basement membrane increases vascular permeability. AGE in the arterial wall may bind low-density lipoprotein and promote atherogenesis. Curiously, endothelial cells carry specific receptors for AGE (so-called 'RAGE)', the binding of which generates oxygen free radicals that may induce oxidative damage and favour coagulation.

Overactivity of the polyol pathway

Polyols are sugar alcohols formed from their respective sugars (for example sorbitol from glucose) under the action of aldose reductase, the rate-limiting enzyme of the polyol pathway. This enzyme is expressed in various tissues susceptible to diabetic complications, notably the retina, glomerulus, lens epithelium, and Schwann cells of the nerves.

Glucose is preferentially shunted through the polyol pathway under hyperglycaemic conditions, generating sorbitol which is poorly diffusible and therefore accumulates intracellularly. This, together with reciprocal intracellular depletion of myoinositol (another polyol, involved in phosphatidylinositol metabolism) may lead to activation of protein kinase C (see below) and the production of highly reactive sugars that can glycate proteins. Increased glucose flux through the polyol pathway

also generates oxygen free radicals and can deplete antioxidants which normally mop up free radicals.

At present, the importance of the polyol pathway in humans remains uncertain, and aldose reductase inhibitors (for example sorbinil and ponaltrestat) have failed to show any convincing benefits in human microvascular complications.

Protein kinase C activation

This enzyme is stimulated by diacylglycerol, which is generated intracellularly in hyperglycaemia. Protein kinase C may mediate adverse effects such as increased vascular permeability and enhanced basement membrane synthesis, although the mechanisms remain obscure.

Abnormal microvascular blood flow

Diabetes interferes with blood flow through the microcirculation, potentially impairing the supply of nutrients and oxygen to the tissues. Resting blood flow is increased in the retina, glomerulus, and other tissues, apparently in response to hyperglycaemia; this may damage the endothelium, favouring thrombogenesis (diabetes also enhances the coagulability of the blood) and perhaps the release of vasoconstrictors such as the endothelins, which may cause microvascular occlusion.

Other factors

Individual susceptibility to microvascular and macrovascular complications varies widely, to a degree that is not entirely explicable by differences in hyperglycaemia. Other risk factors include hypertension, which predisposes to atheroma and is also crucial in determining the rate of deterioration of diabetic nephropathy (see Chapter 20.10.1) and perhaps retinopathy. Smoking is implicated in retinopathy and nephropathy as well as macrovascular disease. Familial clustering of markers for nephropathy has been reported (Chapter 20.10.1), but no convincing candidate genes have yet emerged.

Diabetic eye disease

Eye complications are greatly feared by diabetic patients, with good reason: in the United Kingdom and most westernized countries, diabetes (especially diabetic retinopathy) is the most common cause of blindness in people of working age. Annual screening is advisable with prompt referral for laser treatment if appropriate.

Diabetic retinopathy

This is an easily demonstrated example of the microvascular damage that diabetes inflicts throughout the body. The retina is particularly vulnerable because of its high metabolic and oxygen demands and its dependence on an intact blood–retinal barrier; moreover, small lesions that would pass unnoticed in other vascular beds can have a devastating impact on the patient and his or her quality of life. The Plate section for Section 25 shows the stages and lesions of retinopathy.

Epidemiology

Minor 'background' changes, especially the characteristic microaneurysms, are very common in type 1 patients. Microaneurysms begin to appear after 5 years, affecting about 50 per cent of cases at 10 years and virtually all after 20 years. By contrast, the formation of new vessels that defines proliferative retinopathy emerges after 10 years, reaching a plateau at about 40 per cent of all cases after 20 years. The incidence of maculopathy follows a similar curve, ultimately affecting 10 to 20 per cent of cases (more in older subjects). These different patterns suggest that distinct processes are responsible, and that susceptibility to neovascularization and maculopathy may be determined by factors additional to hyperglycaemia.

In type 2 patients, background changes and sometimes maculopathy and proliferative retinopathy may be present at diagnosis, consistent with the generally long duration of subclinical hyperglycaemia.

All grades of retinopathy can complicate any type of diabetes of sufficiently long duration, with some provisos. Retinopathy may be slow to appear in the mildly hyperglycaemic variants of MODY, while some racial groups (for example Native Americans and Afro-Caribbeans) appear more susceptible. The sexes are equally affected.

Aetiology and pathogenesis

Progression of retinopathy is generally related to the severity and duration of hyperglycaemia, while lowering blood glucose can slow or even prevent the process (see above). Hyperglycaemia damages the retinal vessels in various ways; glycation of key proteins and overactivity of protein kinase C appear to be more important than abnormalities of the polyol pathway.

When differences in glycaemic control are allowed for, there remains considerable individual variability in susceptibility. Genetic factors appear less important than in nephropathy (see above), while hypertension and possibly cigarette smoking may accelerate progression.

Increased vascular permeability, which leads to macular oedema and hard exudates, is an early abnormality, demonstrable by fluorescein angiography. Likely causes include glycation and other changes in the basement membrane of the microvessels, abolishing the negative charge which normally repels plasma proteins such as albumin, and endothelial cell damage, which opens up the tight intercellular junctions that constitute the blood–retinal barrier. Local production of vascular endothelial growth factor, which enhances permeability, may also contribute. Fallout of pericytes, the specialized contractile cells that enclose the capillaries, may weaken the capillary wall, increasing retinal blood flow and leading to the formation of microaneurysms. Increased retinal blood flow, perhaps following pericyte loss and hyperglycaemia *per se*, may cause endothelial damage and thrombogenesis and also enhance protein extravasation. Capillary occlusion is probably due to the formation of microthrombi following endothelial damage and diabetes-related changes in coagulability. Closure produces areas of capillary non-perfusion, which can be surprisingly widespread when shown by fluorescein angiography, and ultimately foci of ischaemia where the retina may infarct (causing cotton-wool spots) and angiogenesis may be stimulated.

New vessel formation is thought to be stimulated by growth factors released by ischaemic tissues, which cause endothelial cells to proliferate. A currently favoured angiogenic factor is vascular endothelial growth factor, a 46 kDa dimeric protein which is expressed, together with its receptors, by retinal endothelial cells; its expression is enhanced by hypoxia and its effects include both increased vascular permeability and endothelial cell proliferation. New vessels sprout initially as solid buds of endothelial cells that later canalize. They can grow within the retina, forward into the vitreous, or across the iris, and are indirectly responsible for the main vision-threatening complications of diabetic retinopathy. They are fragile and rupture easily, causing retinal, preretinal (subhyaloid), vitreous, or anterior chamber haemorrhages, while the fibrous tissue that proliferates around them can cause retinal traction and detachment and lead to glaucoma.

Lesions, clinical stages, and natural history

The stages of diabetic retinopathy are summarized in Fig. 13, and the lesions are illustrated in the Plates for Section 25.

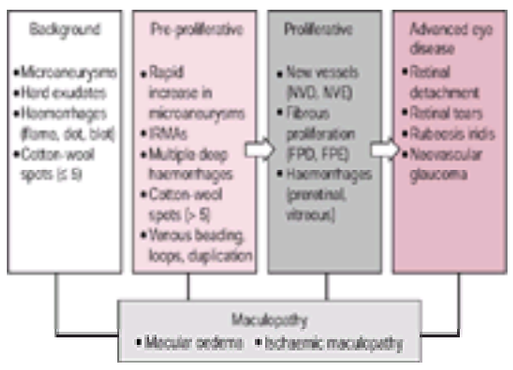

Fig. 13 Stages of diabetic retinopathy. Maculopathy may develop at any stage. IRMAs, intraretinal microvascular abnormalities; NVD/NVE, new vessels on the disc/elsewhere; FPD/FPE, fibrous proliferation on the disc/elsewhere.

Background retinopathy

Individual lesions may appear and regress but their total density tends to increase with lengthening duration of diabetes. Vision is not damaged unless maculopathy coexists; over 50 per cent of patients do not progress beyond this stage.

Microaneurysms are outpouchings of capillaries, perhaps representing ballooning of the weakened capillary wall or endothelial buds attempting to revascularize ischaemic retina. They appear as tiny red dots. Microaneurysms are not fixed features: about 50 per cent disappear within 3 years. The sudden appearance of numerous microaneurysms often indicates worsening retinal ischaemia and can herald preproliferative and proliferative changes.

Hard exudates are due to the precipitation in the retina of lipoproteins and other circulating proteins that escape from abnormally leaky retinal vessels. They are yellow-white spots or streaks with a waxy or shiny appearance, and often form clusters or arcs (a circinate pattern) around the macula and foci of capillary leakage. Like microaneurysms, their distribution and extent can vary markedly with time.

Haemorrhages are due to the rupture of weakened capillaries, their size and shape depending on their situation. Small 'dot' and larger 'blot' haemorrhages are spheroidal because they are contained within the densely packed deeper layers of the retina, whereas 'flame' haemorrhages track along nerve fibre bundles in the more superficial layers. Haemorrhages outside the retina (preretinal or vitreous) generally originate from new vessels and therefore indicate proliferative change.

Maculopathy

Disease of the macula, serious enough to affect central vision, can accompany any stage of diabetic retinopathy including background, and may be present in newly diagnosed type 2 patients.

Macular oedema is due to extravasation of plasma proteins across abnormally leaky capillaries. It may cause only retinal thickening which may be undetectable by routine fundoscopy, even when advanced enough to reduce visual acuity. Exudates, often circinate, and spotty 'cystoid' changes may occur.

Ischaemic maculopathy is the result of extensive capillary closure and can cause severe central visual loss. As with macular oedema, fundoscopy may appear deceptively normal; the macula may simply look featureless.

Maculopathy presents as progressive and painless loss of central vision. Testing of visual acuity is important in routine screening for maculopathy: poor acuity with no obvious explanation (for example cataract, vitreous haemorrhage) must always prompt further investigations for macular oedema or ischaemia. Retinal thickening can be identified easily by slit-lamp examination, while fluorescein angiography will demonstrate both ischaemic areas (hypofluorescent) and sites of vascular leakage (hyperfluorescent).

Preproliferative retinopathy

This stage indicates worsening retinal ischaemia which, if left untreated, often leads to the formation of new vessels. It is defined by one or more of the following, of which intraretinal microvascular abnormalities and venous beading are the most ominous:

- Multiple deep round haemorrhages, especially when appearing over a short period.
- Multiple (more than five) cotton-wool spots, which are due to the accumulation of axoplasm at the edges of retinal infarcts. They appear as dead-white patches with vague borders.
- Intraretinal microvascular abnormalities (IRMA) are flat clusters of abnormal capillaries which, unlike new vessels, are confined to the retina and do not leak fluorescein.
- Venous abnormalities include dilatation (due to general retinal hyperaemia and the shunting of blood around infarcted or non-perfused areas), beading, looping, and reduplication. Beading probably represents the terminations of occluded capillaries, while looping and reduplication may be due to local diversion of blood flow.
- Arterial abnormalities include occlusion, when the vessel is reduced to a thin white line.

Proliferative retinopathy

New vessels appear as fine fronds or arcades of abnormal structure, commonly arising on the optic nerve head ('new vessels disc' or 'NVD') or 'elsewhere' ('NVE'), especially at the bifurcation of veins. Greyish fibrous tissues and haemorrhages may be found in association.

Proliferative retinopathy threatens vision through the complications of the abnormal new vessels, namely haemorrhage, retinal detachment, and glaucoma. Overall, only 10 per cent of untreated patients retain useful vision after 10 years. New vessels on the disc (NVD) carry the worst prognosis: if left untreated, the chances of becoming blind within 5 years are over 50 per cent (compared with 30 per cent for new vessels elsewhere (NVE)). Vitreous haemorrhages tend to recur, and 30 per cent of eyes are blind within 1 year of the first bleed. Fortunately, laser photocoagulation has revolutionized the outlook for proliferative retinopathy.

Advanced diabetic eye disease

This represents endstage damage that commonly leads to blindness; vitreoretinal surgery has improved the prognosis somewhat:

- Vitreous and preretinal haemorrhages develop when new vessels grow forward from the retina, cross the potential preretinal (subhyaloid) space, and enter the vitreous. These vessels rupture easily: associated fibrous tissue contracts and tears them, as does the normal shrinkage of the vitreous with age. Vitreous haemorrhages appear as reddish or dark opacities that may completely fill the eye and block the view of the retina. Preretinal (subhyaloid) haemorrhages have a flat top (if the subject has been upright), because the red cells sediment within the haemorrhage cavity.
- Retinal detachment occurs: the retina is pulled off the underlying choroid by contracting strands of fibrous tissue associated with the formation of new vessels or previous vitreous haemorrhages. The retina may appear wrinkled (traction lines) or thrown into folds or bumps, sometimes with a visible tear.
- New vessels grow on to the iris (rubeosis iridis), usually in the context of widespread proliferative retinopathy. Vessels and diffuse reddening of the iris may be seen with the ophthalmoscope. The main complication is glaucoma, caused by proliferating fibrovascular tissue obstructing the filtration angle in the anterior chamber. Signs include circumcorneal injection, a fixed irregular pupil and corneal haze; the eye is often intensely painful.

Symptoms of diabetic retinopathy

There may be no visual symptoms, even with extensive proliferative changes, until sight-threatening complications occur:

- Vitreous haemorrhage and retinal detachment cause sudden loss of vision that is painless but often terrifying. Retinal detachment occurring behind a vitreous haemorrhage may be reported by the patient as a further deterioration in already poor vision.
- Maculopathy presents as a gradual painless decline in central vision, which may not be noticed by the patient but is picked up on routine eye screening.
- Rubeosis and particularly neovascular glaucoma cause worsening vision with pain and redness in the eye.

Other causes of visual loss need to be considered in diabetic patients, including cataract, stroke, retinal artery or vein occlusion, and hypoglycaemia and glaucoma.

Examination of the eyes in diabetic patients

This should be performed routinely on diagnosis, annually thereafter (or every 6 months if marked background or other changes are present), and immediately if the patient reports any change in vision. There should be close liaison with the ophthalmologist, and a low threshold for referral: indications for seeking expert advice are shown in Table 9.

Visual acuity must be checked with a Snellen chart, with the pupils undilated, and both uncorrected and corrected for refraction errors (with the patient's spectacles or a pinhole). Poor visual acuity (worse than 6/12) that is not correctable and has no other obvious cause (cataract, vitreous haemorrhage) is usually due to maculopathy, and this must be actively excluded (see below).

The iris and pupil are examined for evidence of rubeosis or glaucoma. Pupillary reflexes should be checked: an afferent pupillary defect (see Section 25) indicates severe retinal or optic nerve disease, such as retinal detachment.

Fundoscopy must be used to check both eyes through fully dilated pupils: peripheral new vessels may otherwise be invisible. Relative contraindications to mydriatics are intraocular lens implants; referral to the ophthalmologist is then advisable. The disc, entire retina, and macula must be carefully scanned. Binocular ophthalmoscopy provides good all-round and three-dimensional views, especially of vitreous haemorrhage and retinal detachment.

Additional specialist investigations include:

- Retinal photography: including 'non-mydriatic' cameras that allow photography of most of the retina, through partly dilated pupils (in a darkened room). These are widely used in community screening for retinopathy.
- Slit-lamp microscope: useful for examining the anterior chamber (for rubeosis and glaucoma) and assessing retinal thickness (for detecting macular oedema).
- Fluorescein angiography: fluorescein injected intravenously binds to albumin and so only escapes outside abnormally permeable vessels; sites of leakage are highlighted by persistent fluorescence when the retina is photographed under ultraviolet light. This is useful for showing the foci of leakage (for example for targeting laser photocoagulation) and for the diagnosis of macular oedema.
- B-scan ultrasound provides a cross-sectional image of the eye and can show retinal detachments that are invisible on fundoscopy because of a dense vitreous haemorrhage or cataract.

Management of diabetic retinopathy

Specific treatments for sight-threatening retinopathy have improved greatly, but general preventative measures are still crucial. These include:

- Tight glycaemic control, as highlighted by the DCCT and the UKPDS. Paradoxically, a rapid reduction in hyperglycaemia can provoke a transient deterioration in retinopathy, with worsening of the background condition or the development of preproliferative changes. This is probably due to an acute fall in retinal blood flow (which is elevated by hyperglycaemia), thus worsening ischaemia in already underperfused areas. Typically, the acute lesions resolve and the overall long-term outcome is improved if good glycaemic control can be maintained.
- Control of hypertension is likely to be important; the EUCLID study of enalapril showed beneficial effects which may reflect the inhibition of angiotensin-converting enzyme as well as lowering of blood pressure.
- Stopping smoking: smoking is thought to hasten the progression of retinopathy.
- Regular eye screening is essential, because even severe diabetic retinopathy may cause few or no symptoms.

Specific treatments

Laser photocoagulation can preserve useful vision in many cases of proliferative retinopathy and maculopathy. The blue-green light of the argon laser is maximally absorbed by vascular structures. It has a spot size of 50 to 500 µm and can be used to target discrete lesions such as clusters of leaking vessels identified by fluorescein angiography, but is usually employed to destroy larger areas of generally diseased retina. Panretinal photocoagulation ablates the peripheral retina with 1500 to 2000 burns that spare only a keyhole-shaped central area that includes the disc, the macula, and the maculopapillary nerve bundle running between them. Panretinal photocoagulation effectively concentrates the remaining retinal blood flow on to this crucial region which serves central, high-resolution colour vision, at the expense of the periphery. It is indicated for formation of new vessels (on the disc or elsewhere and rubeosis), and can be very effective: the chance of blindness within 5 years is reduced from 50 per cent to 25 per cent in patients at risk. It is increasingly used in the preproliferative phase to prevent the formation of new vessels. Photocoagulation is also used to treat macular oedema, in a 'grid' pattern around the central macula to destroy leaky capillaries; this reduces the 3-year risk of becoming blind from 30 per cent to 15 per cent.

Vitreoretinal surgery can now restore useful vision to some blind or severely impaired eyes. Techniques include vitrectomy (aspiration of vitreous haemorrhage and fibrovascular debris) and reattachment of detached or torn retina (using high-powered lasers to 'stitch' down the retina). Easy and rapid access to ophthalmologists and surgeons is often critical: for example, a detached retina must be repaired within a few weeks if it is to remain viable.

Practical aids for visual handicap range from pen injection devices and 'talking' blood glucose meters, to social support networks and national organizations for the visually impaired.

Cataract in diabetes

The normal lens transmits light because the fibre cells of the lens and the stacks of crystallin proteins which they contain are aligned in parallel. Normal ageing causes irreversible chemical modification ('browning') of the crystallins, with crosslinking and distortion that interrupt transmission of light and thus cause clouding of the lens. Diabetes accelerates the formation of these senile cataracts, probably through non-enzymatic glycation and crosslinking of AGE-modified crystallins.

Cataract is the most common cause of severe visual loss in diabetic patients over the age of 30, and is usually a typical 'senile' nuclear cataract with a characteristic radial spoke pattern. Much rarer is the 'snowflake' cataract with opacities scattered through the lens, which tends to occur in children presenting with severe hyperglycaemia. Here, the 'opacities' are reversible and are presumably due to local pockets of osmotic imbalance which distort the alignment of the lens crystallins.

Treatment of cataracts is conventional, usually removal and replacement by an intracapsular plastic lens. Long-term outcome is often not as good as in non-diabetic patients, because of coexisting maculopathy or proliferative retinopathy.

Gaucoma is more common in diabetics.

Other ocular problems

Cranial nerve palsies, especially of the third and sixth nerves, cause typical limitations of eye movement, often with acute onset of pain (see below and Chapter 23.13.15).

Eye infections include the rare but extremely destructive mucormycosis, which often spreads from the sinus to involve the orbit (see Chapter 7.12.1).

Diabetic neuropathies

Clinical syndromes

Diabetes damages nerves, both somatosensory and autonomic, in various ways that cause clinically distinct syndromes (Fig. 14). Subclinical nerve damage is common among diabetic patients, but significant neuropathic symptoms are fortunately unusual.

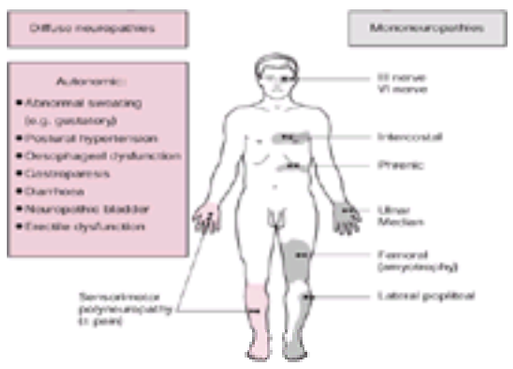

Fig. 14 Clinical manifestations of diabetic nerve damage.

Diffuse symmetrical polyneuropathy

This is classically a distal 'glove and stocking' peripheral polyneuropathy that affects all sizes of sensory and motor fibres; a variant selectively picks off small C fibres (see below). Both forms may be accompanied by neuropathy involving the sympathetic and parasympathetic divisions of the autonomic nervous system.

Aetiology

The diffuse nature of the nerve damage and its predilection for longer nerves is typical of toxic and metabolic neuropathies, and suggests cumulative damage that must reach a critical level before the function of a nerve is impaired. Both metabolic and vascular factors may contribute. The duration and severity of hyperglycaemia are generally related to the prevalence of neuropathy, while the DCCT confirmed that good glycaemic control decreased by the risks of developing neuropathy by about 70 per cent. Hyperglycaemia could damage nerves by glycation of key proteins. In the nerves of diabetic animals, polyol pathway overactivity has also been implicated (Schwann cells express aldose reductase), while myoinositol depletion may impair nerve conduction by inhibiting Na^{+},K^{+}-ATPase activity; in human diabetic neuropathy, however, the roles of polyols are less convincing and a role for aldose reductase inhibitors has not been demonstrated. There is some evidence of blockage of the vasa nervorum by microthrombi, which could follow the formation of AGE and the other mechanisms described earlier. Microvascular occlusion could contribute to intraneural hypoxia, demonstrated in the nerves of both animal and human diabetics.

Pathological changes affect both axons and Schwann cells. Axons fall out by dying back distally, sometimes accompanied by sprouting of regenerating nerve endings. Schwann cell damage leads to segmental demyelination. Nerve conduction velocity is slowed, in proportion to structural nerve damage.

Epidemiology and natural history

About 30 per cent of unselected diabetic patients have evidence of neuropathy on formal testing, but only 10 per cent suffer significant symptoms. Signs of neuropathy may be present in up to 10 per cent of newly diagnosed type 2 diabetic patients.

Nerve function generally worsens progressively over months or years, and areas of numbness may advance up the legs and occasionally involve the hands. Symptoms, including pain, may be variable; pain in particular may develop acutely, especially after weight loss or periods of poor diabetic control. Acute flareups tend to resolve after weeks or months, especially if glycaemic control is improved.

Symptoms and signs

Sensory symptoms are the commonest manifestation; muscle weakness occasionally predominates. Sensory symptoms may include loss of sensation, which can be profound, as well as 'positive' symptoms of pain, paraesthesiae, and allodynia (i.e. pain provoked by a normally innocuous stimulus, such as light touch or contact with bedclothes). Loss of the sense of touch and joint position may give the sensation of walking in thick socks, and Romberg's sign may be positive. Reduced pain sensation, which paradoxically may coexist with neurogenic pain, is potentially dangerous and an important cause of damage to neuropathic feet (see below). Horrifying accounts involving neuropathic diabetic feet include full-thickness burns to the soles after crossing a hot beach, pressure ulceration from a day's walking in tight new shoes, and transfixing the foot inside the shoe by stepping on a nail.

The mechanism of neuropathic pain is unknown; spontaneous firing of unstable regenerating nerves may be responsible. Pain is typically neurogenic, usually described as burning, shooting, or electric shock-like sensations, often with unpleasant pins and needles and allodynia. The feet and legs are usually affected, and the hands only rarely; neuropathic symptoms in the hands are usually due to damage to the ulnar and/or median nerves, which can be bilateral (Fig. 15 and Plate 1). Pain is characteristically worse at night, and can severely disturb sleep and cause depression (and suicide).

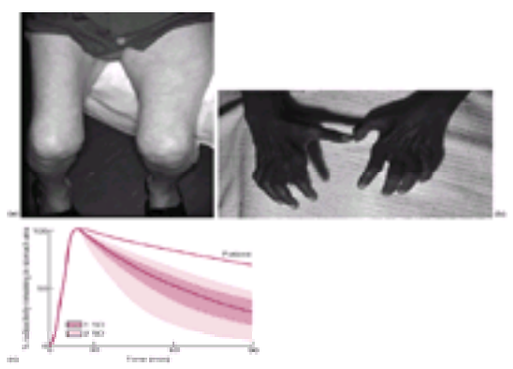

Fig. 15 (a) Diabetic amyotrophy: quadriceps right wasting due to femoral neuropathy (with thanks to Dr Geoff Gill, University Hospital Aintree, Liverpool). (b) Wasting of small muscles of the hands due to both ulnar and median nerve lesions. (See also Plate 1.) (c) Gastroparesis: grossly delayed gastric emptying. The normal range for clearance of the radiolabelled test meal from the stomach area is shown in in the darker shade (50 per cent confidence interval) and lighter shade (95 per cent confidence interval).

Examination may reveal symmetrical 'stocking' sensory loss affecting all modalities. Sensory deficits are frequently patchy and may be much less impressive than the symptoms suggest; clinical findings may even be normal in acute painful neuropathy. Tendon reflexes in the legs are often reduced or absent, and there may occasionally be marked muscle wasting. Neuropathic foot problems due to somatosensory and autonomic nerve damage may also be obvious, including ulceration, increased skin blood flow, and Charcot's arthropathy. The hands are less commonly involved.

Diffuse small-fibre neuropathy

This rare variant affects especially young women with type 1 diabetes, and may be autoimmune in origin. There is loss of temperature and pain sensation in a stocking distribution, other modalities remaining intact. Autonomic neuropathy is frequent, usually with postural hypertension, gustatory sweating, and diarrhoea. Ulceration and Charcot's arthropathy affecting the feet are common.

Autonomic neuropathy

Autonomic disturbances commonly accompany somatosensory neuropathy, and the autonomic nerves are presumably damaged by the same mechanisms. Up to 40 per cent of unselected diabetic people have abnormal tests of autonomic neuropathy, but only a few of these suffer major symptoms; however, these can be very debilitating and these patients have a significantly reduced life expectancy. The sympathetic and parasympathetic divisions are both affected.

Clinically apparent features are commonest in patients with long-standing diabetes and include:

- Abnormal sweating, mediated by cholinergic sympathetic nerves; this is one of the commonest autonomic symptoms. Profuse 'gustatory' sweating of the face and trunk (the area supplied by the superior cervical ganglion) may be provoked by eating, while sweating in the feet is often reduced.
- Postural hypotension, with a systolic fall exceeding 20 mmHg on standing, is due to failure of the normal sympathetically mediated increases in cardiac output and vasoconstrictor tone. This causes dizziness and blackouts, which may be mistaken for arrhythmias or myocardial ischaemia. Symptoms and the degree of postural drop may vary considerably with time. Postural hypotension may be exacerbated by the vasodilator effects of antihypertensives, nitrates, tricyclic antidepressants (used to treat neuropathic pain), and insulin.
- Disturbed gastrointestinal motility. Dysphagia may be due to oesophageal dysmotility. Gastric stasis, due to failure of the pylorus to relax when the antrum contracts, causes particular difficulties with emptying liquids and presents with recurrent vomiting. There may be obvious fullness in the epigastrium, sometimes with a succussion splash. Disturbances of motility in the colon most commonly lead to diarrhoea (characteristically but not always worse at night), which may be exacerbated by bacterial overgrowth of the relatively immotile small bowel. As with all these gastrointestinal symptoms, diarrhoea is often episodic and may alternate with constipation. Anorectal dysfunction is luckily rare, but can cause severe faecal incontinence.
- Neuropathic bladder, due to damage to the sacral nerves, prevents normal emptying and can lead to a permanently distended, sometimes palpable, bladder, with overflow incontinence. Hydroureter and hydronephrosis are other complications, and ascending urinary tract infections are common.
- Sexual difficulties include failure of erection (a parasympathetic response mediated by the sacral nerves) and sometimes failure of ejaculation (a sympathetic reflex transmitted by the lumbosacral outflow). Erectile failure is relatively common in diabetic men, affecting about 50 per cent of those over 55 years; as in the non-diabetic population, depression and anxiety (including fears about poor sexual performance) are common contributory factors. Arterial inflow to the corpora cavernosa may be compromised by atheromatous disease of the pudendal arteries or common iliac arteries, the latter causing the Leriche syndrome of impotence with claudication of the buttocks.
- Abnormal blood flow. Sympathetic denervation allows vasodilatation and relaxation of precapillary sphincters in the skin, hence the warm skin and distended veins characteristic of the neuropathic foot. Increased blood flow in bone may be an early abnormality in Charcot's arthropathy.
- Sudden unexplained death is more common in patients with severe autonomic symptoms. Possible causes include cardiorespiratory arrest and arrhythmias triggered by hypoglycaemia, awareness of which is blunted in many patients with long-standing diabetes.

Acute mononeuropathies

These syndromes are due to acute damage to isolated peripheral nerves, presumably due to a vascular event rather than metabolic damage. Limited histological studies show focal demyelination, probably consistent with this. Occasionally, two or more nerves can be affected more or less simultaneously (mononeuritis multiplex).

Diabetic amyotrophy

This is due to damage of one of the major nerve trunks or roots (radiculopathy) supplying the leg. The femoral nerve is most commonly involved, causing symptoms in the quadriceps muscle; other muscle groups are less often affected. Femoral neuropathy causes neurogenic pain of acute onset (burning or lancinating, usually severe), with weakness and often surprisingly rapid wasting in the quadriceps, and loss of the knee tendon reflex (Fig. 15). For unknown reasons, some patients have extensor plantar reflexes, in which case a spinal or cauda equina lesion must be excluded.

Amyotrophy most commonly presents in patients over 50 years of age, often following a period of poor diabetic control. Pain usually resolves spontaneously over several months, especially if diabetic control is improved, but muscle strength and tendon reflexes may take much longer to return.

Cranial and other nerve palsies

These are common, affecting the third and sixth nerves in particular. Third nerve palsy is often accompanied by pain behind the eye, and may need to be differentiated from an aneurysm of the posterior communicating artery; however, unlike in classical third nerve palsy, ptosis and pupillary dilatation are usually absent. Acute neuropathic damage may also affect the phrenic nerve (causing an elevated hemidiaphragm), and intercostal or truncal nerves, causing shingles-like pain and sometimes localized bulging of the abdominal wall. All these acute palsies tend to resolve spontaneously.

Pressure palsies

These include the median, ulnar, and occasionally lateral popliteal nerves, and are thought to be due to pressure damage superimposed on hypoxic or otherwise compromised nerves. These present in the classical way, but often recover slowly and incompletely, and respond poorly to surgical decompression (see Fig. 15).

'Insulin neuritis'

This is a transient deterioration in nerve function, often with pain and dysthaesiae affecting the legs symmetrically, which follows an acute improvement in glycaemic control, usually after starting insulin therapy. It may be due to an acute fall in nerve perfusion analogous to the decrease in retinal blood flow thought to explain a temporary deterioration in retinopathy under these circumstances (see above). Symptoms usually resolve within weeks or months.

Diagnosis of diabetic neuropathies

Peripheral sensorimotor neuropathies

A carefully taken history is usually diagnostic. The key qualities of neuropathic pain should distinguish it from claudication and night cramps.

Sensory deficits should be mapped on the legs and hands, for both large-fibre (vibration with a 128-Hz tuning fork, joint position sense, light touch, temperature, e.g. with a cold tuning fork) and small-fibre modalities (pin prick, light touch); objective losses may not match the patient's symptoms. A useful test uses the Semmes–Weinstein nylon monofilament, which is pressed against the skin until it buckles; the patient's inability to feel the 10-g filament indicates neuropathy severe enough to predict foot ulceration. Various bedside instruments can be used to assess specific sensory modalities, such as the biothesiometer (for vibration sense) and thermal threshold testers; age-related normal ranges are available for these methods but they are quite variable and add little to routine management. Muscle wasting and weakness should be sought, and the tendon reflexes checked.

Peripheral diabetic neuropathy must be differentiated from other metabolic neuropathies, including vitamin B_{12} deficiency, uraemia, and alcohol, all of which may affect diabetic patients.

Autonomic neuropathy

The most convenient tests are of cardiovascular autonomic function, which detect loss of the normal reflexes that modulate heart rate during respiration (mainly vagal) and that increase heart rate and blood pressure on standing (sympathetic). The simplest test is to measure heart rate (RR interval) from an ECG tracing during controlled deep breathing (5 s inspiration, then 5 s expiration, repeated for 1 min); the physiological bradycardia on expiration is lost, with a difference of less than 10 beats/min between inspiration and expiration. Reflex bradycardia during the Valsalva manoeuvre is similarly abolished. More sophisticated measures employing spectral analysis of variability of heart rate during normal breathing are more sensitive.

Postural hypotension is defined as a drop of more than 20 mmHg drop in systolic blood pressure, measured 30 s after standing. Postural drops often vary considerably through the day and from week to week.

Abnormalities of cardiovascular autonomic tests are common in patients with long-standing diabetes, especially type 1, and do not necessarily indicate that symptoms such as vomiting, diarrhoea, or erectile dysfunction are due to autonomic neuropathy. Other specific tests include:

- Gastroparesis: a plain abdominal radiograph may show a 'ground glass' appearance in the epigastrium, while endoscopy (always indicated to exclude pyloric obstruction) shows a dilated, poorly contracting stomach with a closed pylorus. Gastric emptying studies using radiolabelled test meals show delayed disappearance of radioactivity, particularly of a liquid test meal; however, abnormalities may not be consistent with the severity of symptoms (see Fig. 15).
- Neuropathic bladder and associated hydroureter and hydronephrosis can be confirmed by ultrasound or intravenous urography.
- Erectile failure is often multifactorial (see above). If it is due to autonomic neuropathy, other signs of autonomic dysfunction, especially neuropathic bladder, are usually prominent.

Treatment of diabetic neuropathies

General measures

Poor glycaemic control should be corrected. As well as helping to prevent the development of neuropathy, this may curtail pain in the acute syndromes; insulin neuritis is rare and usually self-limiting. Once established, chronic sensory motor neuropathy tends to progress, irrespective of glycaemic control. Specific treatments which aim to prevent or reverse diabetic nerve damage—aldose reductase inhibitors and aminoguanidine (which prevents the formation of AGE)—have so far been disappointing. Numb feet are at greatly increased risk of ulceration and require sensible shoes and good foot care (see below).

Pain may be difficult to treat; pain management programmes in specialized pain relief clinics may be helpful. The following should be tried in sequence:

- Simple analgesics (aspirin, paracetamol) are mostly unhelpful. Opiates are generally regarded as ineffective in neurogenic pain and are yet to be tested adequately in diabetic neuropathy.
- Tricyclic drugs suppress neurogenic pain, in addition to their antidepressant effects. Amitryptiline or imipramine can be started at 25 mg at bedtime (10 mg in the elderly), increasing weekly to a maximum of 75 to 150 mg. Side-effects, including postural hypotension, may limit the dosage. A phenothiazine such as fluphenazine (2.5–5 mg) is said to enhance the analgesic effect of tricyclics but its use is not evidence-based and it often exacerbates postural hypotension.
- Anticonvulsants, which stabilize the neurone membrane and may prevent spontaneous firing of C fibres, may be substituted for trycyclics or used in combination with them. Carbamazepine (initially 100 mg once or twice daily, up to 800 mg/day in divided doses) is often effective. Sodium valproate or phenytoin are alternatives. Gabapentin appears promising, but has yet to be compared adequately with tricyclics. Gabapentin has been given at doses of 900 to 3600 mg/day in divided doses—rather more than the standard antiepileptic regimen but apparently well tolerated.

Pain in the feet may respond to topical application of capsaicin ointment; capsaicin causes the burning sensaton of hot chillies, and depletes the pain-transmitting C fibres of the neurotransmitter substance P. Pain may be transiently worsened after application but relief can last for many hours. Contact hypersensitivity (allodynia) can be helped simply with a bed cradle to prevent contact with bed clothes, or by applying Opsite® adhesive plastic film to the skin.

Other drugs that have proved successful in some but not all trials include oral mexiletine (a class 1b antiarrhythmic agent that stabilizes nerve cell membranes; up to 450 mg/day in divided doses) and clonazepam (0.5–3 mg) in patients whose sleep is disturbed by 'restless legs'. Some patients unresponsive to drug therapy may benefit from implantation of a dorsal column stimulator, designed to exploit the 'gate' control of pain transmission.

Autonomic neuropathic symptoms may be treated as follows:

- Excessive sweating may be controlled by oral clonidine or topical 1 per cent glycopyrrholate ointment; systemic anticholinergics such as poldine have also been effective but have many side-effects, including urinary retention.
- Postural hypotension may be helped simply by raising the head of the bed at night. Fludrocortisone can be useful, but aggravates coexistent supine hypertension; very high doses (up to 1 mg/day) may be needed. The a_1-adrenergic agonist midodrine (2.5–10 mg daily) may also be helpful, but can also worsen hypertension.
- Vomiting due to gastroparesis often responds to metoclopramide or domperidone, and the prokinetic drug erythromycin (cisapride has been withdrawn because of arrhythmias). Some patients unresponsive to drug therapy may require intrajejunal feeding, most conveniently by percutaneous endoscopic gastrostomy; some patients benefit from surgical drainage procedures such as a roux-en-Y gastrojejunostomy.
- Diarrhoea is often improved or cured by erythromycin or tetracycline when bacterial overgrowth is a contributory factor.
- Neuropathic bladder may respond to regular bladder training, but intermittent self-catheterization may be needed.
- Erectile dysfunction can be treated with oral sildenafil 4 mg, which should be taken about 1 h before intercourse. It is effective in about 50 per cent of diabetic patients but is absolutely contraindicated in those taking nitrates in any form, because of the risk of profound hypotension and circulatory collapse. Alternatives, if sildenafil is contraindicated or ineffective, include the injection of vasodilators such as papaverine or prostaglandin E_1 into the corpus cavernosum, intraurethral alprostadil, or the use of vacuum tumescence devices. Coexistent contributory factors such as depression, alcohol, or drugs (including b-blockers and thiazides) should be sought and treated. Counselling of the couple is obviously important.

Diabetic nephropathy

This is covered in detail in Chapter 20.10.1.

Macrovascular disease

Diabetes of all types increases the background risk of atheroma, amplifying the hazards of additional cardiovascular risk factors such as hypercholesterolaemia, hypertension, and smoking. Atheroma appears earlier, spreads faster and more extensively, and carries greater morbidity and mortality than in non-diabetic people. Overall risks for myocardial infarction, stroke, and limb ischaemia are two to four times higher than in the general population, and diabetic women lose the premenopausal protection which their euglycaemic counterparts normally enjoy. This increased level of risk is comparable with that in non-diabetic subjects who have already suffered a myocardial infarct. Accordingly, it has been argued that primary cardiovascular prevention for diabetic patients should be as active as secondary prevention in the non-diabetic population. Macrovascular disease, especially coronary heart disease, is the main cause of premature death in type 2 diabetes.

As discussed earlier, cardiovascular risk is increased above glucose levels that lie below the 'diabetic' range: IGT also predisposes to coronary-heart disease, but not to retinopathy. This relationship probably explains why 'tight' glucose control has not yet been shown to prevent macrovascular disease, because none of the trials (for example the DCCT or the UKPDS) has managed to achieve even near normoglycaemia. There is a very strong relationship between microalbuminuria and premature death from cardiovascular disease (see Chapter 20.10.1). This presumably reflects widespread damage to the endothelium, which both predisposes to atheroma formation and enhances albumin leakage in the glomerulus.

Cardiovascular risk factors tend to cluster together with type 2 diabetes in the so-called 'metabolic syndrome X' (see above). These risk factors are also common in the type 1 diabetic and the non-diabetic populations. Because their impact is worsened by diabetes, they require active management. Treatment of obesity and smoking is discussed in Chapter 10.5 and Chapter 3.5.

Dyslipidaemia in diabetes

Type 1 and type 2 diabetes are both commonly accompanied by lipid disorders that are strongly atherogenic but may appear deceptively trivial on routine screening (Fig. 16).

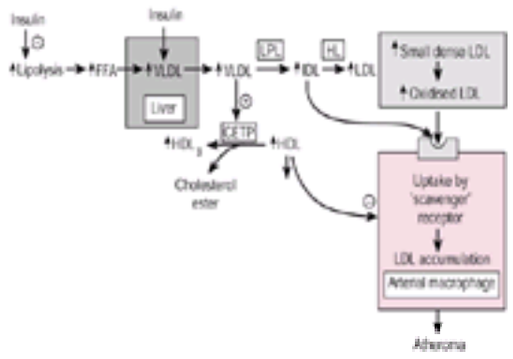

Fig. 16 Mechanisms of lipid abnormalities in diabetes. Insulin resistance or loss of insulin leads to increased lipolysis and hepatic secretion of very low-density lipoprotein (VLDL). High levels of VLDL stimulate cholesterol ester transfer protein which converts the antiatherogenic high-density lipoprotein (HDL) into HDL_3, which lacks this protective effect. VDLPs are stripped of triglyceride by lipoprotein lipase to yield atherogenic intermediate-density lipoprotein (IDL), and then by hepatic lipase to produce low-density lipoprotein (LDL), including the highly atherogenic small dense oxidized fractions. These, with IDL, are taken up by arterial wall macrophages, forming the 'foam cells' that initiate the atheromatous plaque.

In poorly controlled type 1 diabetes, the most obvious abnormality is hypertriglyceridaemia. This is due mainly to increased production of very low-density lipoprotein by the liver, driven by high levels of free fatty acids resulting from enhanced lipolysis in fat; triglyceride levels can be lowered by improved insulin therapy. Total cholesterol concentrations are often 'normal', while HDL may be increased, although this is predominantly the HDL_3 subclass which does not confer protection against atheroma (see Chapter 11.6). As stressed below, a 'normal' cholesterol is not necessarily reassuring because modified LDL particles in diabetes are particularly atherogenic and because cardiovascular risk in diabetic people is increased at all levels of cholesterol.

Dyslipidaemia in type 2 diabetes is also subtle, and similar to that of obesity and syndrome X. High-density lipoprotein cholesterol is reduced, increasing the ratio of LDL to HDL, while triglycerides are often modestly raised. The abnormalities are also due to excessive production of VLDL by the liver, due to insulin resistance rather than insulin deficiency: free fatty acids levels are raised by lipolysis (adipocytes are resistant to the normal antilipolytic action of insulin), while the inhibition by insulin of hepatic production of VLDL is lost. High levels of VLDL favour the production of two highly atherogenic cholesterol particles, namely IDL and small dense LDL, which is easily oxidized; both IDL and oxidized LDL are taken up, via specific receptors, by macrophages in the artery wall and are then transformed into foam cells (see Chapter 11.6). High triglyceride levels also accelerate the removal of cholesterol ester (via cholesterol ester transfer protein) from HDL, ultimately reducing levels of HDL and producing the non-protective HDL_3 fraction.

Risks of dyslipidaemia

Cardiovascular events including fatal myocardial infarction are three to four times commoner among diabetic patients than in the general population, across a wide range of cholesterol levels including 'normal' values. The risks of the slightly raised triglyceride concentrations are less obvious, and are currently the subject of large-scale trials with fibrates.

Management

This remains controversial, although the consensus is that diabetic people benefit at least as much from statin therapy as the non-diabetic population. The high background risk of diabetes is reflected in the lower treatment thresholds for hypercholesterolaemia in the various risk-factor tables (see Chapter 11.6), and lipid-lowering drugs are now used at ever lower cholesterol levels. Indeed, the American Diabetes Association recommends statin therapy for any diabetic patient with a total cholesterol of more than 5 mmol/l, aiming to maintain cholesterol below this level. It seems reasonable at present to consider adding a fibrate if triglycerides then remain in excess of 2.3 mmol/l.

Pharmacoeconomic arguments may intrude, and it is debatable whether dyslipidaemia should be treated exhaustively in patients who make no effort to stop smoking. Other factors that aggravate dyslipidaemia—obesity, poor glycaemic control, and drugs such as thiazides and b-blockers—should be tackled if possible.

Hypertension

Hypertension commonly accompanies diabetes: about 40 per cent of type 2 patients are hypertensive at diagnosis, and probably two-thirds of the diabetic population are inadequately treated with respect to current management guidelines (Table 3).

Causes

Essential hypertension is an integral feature of the metabolic syndrome X, associated with obesity and insulin resistance. Possible mechanisms include enhanced central sympathetic tone (possibly mediated in part by raised insulin levels), and increased total body sodium and extracellular fluid volume, to which the Na^+-retaining effects of hyperinsulinaemia could contribute; loss of insulin-induced vasodilatation due to insulin resistance could also play a role. Secondary hypertension may also develop because of specific diabetic complications, notably nephropathy (loss of the normal nocturnal dip in blood pressure can be an early feature: see Chapter 20.10.1), stenosis of the renal artery due to atheroma, and stiffening of the larger conduit arteries causing isolated systolic hypertension. Supine hypertension can coexist with postural hypotension—a particularly difficult combination to treat effectively.

Treatment targets

The blood pressure thresholds for active management have fallen progressively, with wider appreciation of the damage inflicted by even modest hypertension in diabetic patients and of the benefits of control of blood pressure. The American Diabetes Association now recommends 130/80 mmHg (recorded in the clinic) as the treatment target for blood pressure, and that consistently higher values require active treatment; levels exceeding 140/90 mmHg are increasingly regarded as unacceptably poor. Ambulatory blood pressure readings are lower than those recorded in the clinic, and mean daytime levels of less than 130/75 mmHg are the current target. Target blood pressure (clinic readings) for patients with microalbuminuria is 125/75 mmHg.

Impact of hypertension in diabetes

Like all cardiovascular risk factors, the atherogenic hazards of hypertension are amplified in the diabetic population. Hypertension also plays a crucial role in accelerating the progression of diabetic nephropathy and also of retinopathy. Several studies have shown that treating hypertension reduces the risks of myocardial infarction and stroke by 30 to 70 per cent; in the UKPDS, 'tight' blood pressure control (averaging 144/82 mmHg compared with 154/87 mmHg in less tightly controlled subjects) reduced stroke by 40 per cent and the need for photocoagulation by 30 per cent, although strangely, no effect on myocardial infarction was observed (Fig. 12).

Management

This should begin with lifestyle modification, including restricting energy intake and increasing exercise in the obese, and reducing alcohol and sodium intakes. If actually carried out, these general measures can lower blood pressure at least as effectively as many antihypertensive drugs. Most patients, however, will require drugs and many need combination therapy. Antihypertensive drugs can be used in the conventional stepped approach (Chapter 15.16.1.3) to achieve the target blood pressure, ideally 130/80 mmHg; less stringent targets may be appropriate for elderly patients or those who cannot tolerate tight blood pressure control because of other problems.

The choice of hypotensive drugs is less important than the level of blood pressure achieved, although some agents have properties that are better suited to diabetes.

All these drugs can worsen or precipitate postural hypotension in autonomic neuropathy.

Diuretics

High-dose thiazides (e.g. 5 mg bendrofluazide) can worsen hyperglycaemia in type 2 diabetes, apparently by impairing insulin secretion (a consequence of K^+ depletion) and possibly increasing insulin resistance. Low dosages (for example, 2.5 mg bendrofluazide) do not appear to aggravate glucose intolerance. Diuretics can precipitate hyperosmolar non-ketotic coma, while thiazides may also worsen dyslipidaemia.

b-Blockers

b-Blockers may also raise blood glucose in type 2 patients by increasing insulin resistance (possibly related to weight gain) and by interfering with insulin release (which is stimulated by b_2 adrenoceptors). b-blockers can also aggravate dyslipidaemia and impotence, while non-cardioselective agents can mask the sympathetically driven symptoms of hypoglycaemia. Low dosages of cardioselective b-blockers (for example, atenolol or metopropol) are safe, and are also indicated for treating angina and in the secondary prevention of myocardial infarction.

Angiotensin converting enzyme (ACE) inhibitors

These can effectively control blood pressure when combined with low-dose diuretics and are useful in the many diabetic patients who also have heart failure or left ventricular dysfunction, especially following a myocardial infarct. They reduce proteinuria, by relaxing the efferent arterioles in the glomerulus, and slow the development of both nephropathy and retinopathy; some evidence points to specific beneficial effects in nephropathy, in addition to the lowering of blood pressure (see Chapter 20.10.1). ACE inhibitors do not worsen blood glucose or lipids, and may even improve insulin sensitivity. They are contraindicated in renal artery stenosis, which is relatively common in arteriopathic diabetic patients, and can cause dangerous hyperkalaemia in those with hyporeninaemic hypoaldosteronism (type 4 renal tubular acidosis) which can be associated with diabetic nephropathy.

Calcium channel antagonists

These have no adverse metabolic effects and are useful in patients with angina or tachyarrhythmia.

Other drugs

Other drugs include a_1-adrenoreceptor antagonists (for example doxazosin), which may slightly improve insulin sensitivity; angiotensin II receptor antagonists (for example losartan, candesartan), which are useful alternatives when angiotensin converting enzyme inhibitors are poorly tolerated because of cough; and moxonidine, a centrally acting sympathetic drug acting on imidazoline I_1 receptors.

Coronary heart disease

Compared with their non-diabetic counterparts, clinically significant coronary heart disease is over twice as common in diabetic men and postmenopausal women and four times commoner in premenopausal women.

Angina

It is said that myocardial ischaemia can be painless in patients with long-standing diabetes and autonomic neuropathy, presumably because of sensory denervation of the heart; however, the overall prevalence of 'silent' myocardial ischaemia appears to be similar to that in the general population.

Angina should be treated first with conventional drugs, remembering the diabetogenic and other hazards of b-blockers and the potential of nitrates and calcium-channel antagonists to aggravate postural hypertension. Recent studies have confirmed that coronary artery stenting and bypass grafting markedly reduce fatal myocardial infarction in diabetic patients; it follows that exercise testing and coronary angiography should be performed sooner rather than later in those with worsening angina.

Myocardial infarction

The risk of fatal myocardial infarction is as high in diabetic people as in non-diabetics who have already suffered an infarct. Mortality from myocardial infarction is over twice as high as in matched non-diabetic controls, whether or not thrombolytic agents are used. About 75 per cent of diabetic patients are dead within 5 years of their first infarct, the main causes of death being heart failure and acute cardiogenic shock.

Primary prevention

Independent risk factors—hypertension, dyslipidaemia, smoking, and obesity—must be treated energetically in all diabetic patients, and poor glycaemic control should be tightened even though this alone is unlikely to protect against coronary heart disease. Specific prophylactic therapy, comparable to secondary prevention measures (i.e. measures given after an initial infarct) in the non-diabetic population, is increasingly recommended for diabetic people with any evidence of ischaemic heart disease, because their risk of infarction is so high. This includes a cardioselective b-blocker (for example, atenolol or metoprolol) and/or an angiotensin converting enzyme inhibitor if echocardiography shows left ventricular dysfunction with an ejection fraction of less than 40 per cent. b-Blockers improve survival at least as much as in the general population; the case for angiotensin converting enzyme inhibitors is not yet proven in diabetes. Some authorities recommend aspirin in all diabetic patients over 40 years of age, although the dosage (75–300 mg/day) remains undecided.

Acute myocardial infarction should be managed as follows (Table 10):

- Thrombolytic drugs should be given; survival is improved at least as much as in the non-diabetic population. Proliferative retinopathy is not a contraindication, and the risk of intraocular haemorrhage is very low.
- Glycaemic control should be optimized during the acute episode. There is evidence that long-term survival is improved if intensive insulin treatment is started on admission of a diabetic patient and continued for some months afterwards. The Diabetes Mellitus Insulin Glucose Infusion in Acute Myocardial Infarction (DIGAMI) Study showed that late (> 1 year) cardiovascular deaths were significantly reduced by one-quarter (from 44 per cent to 33 per cent after 3 years) in hyperglycaemic patients who received an insulin–glucose infusion in the coronary care unit, followed by multiple daily subcutaneous insulin injections for 3 months. Follow-up studies in progress should identify which elements conferred protection; theoretical mechanisms include lowering of free fatty acid levels, which may worsen ischaemic myocardial damage. In the meantime, it is reasonable to control hyperglycaemia (aiming for 5–10 mmol/l) during the first 48 h in all known diabetic patients, and in those diagnosed diabetic at admission (blood glucose over 11 mmol/l, with HBA_{1c} in the diabetic range). This can be done most easily with a simple sliding scale continuous intravenous insulin infusion as used to treat diabetic ketoacidosis (see above). Delivering insulin as a 1 U/ml solution with a syringe driver avoids unnecessary intravenous fluids—this is an important consideration, as heart failure is a common (and often fatal) complication of myocardial infarction in diabetic people. Alternatively, the (cumbersome) DIGAMI protocol can be used (see Malmberg K *et al*. in Further reading).
- Secondary prevention must include aspirin with a b-blocker and/or angiotensin converting enzyme inhibitors, as discussed above. Total cholesterol should be reduced to less than 4.8 mmol/l with a statin, with the option of adding a fibrate to control residual hypertriglyceridaemia. Early echocardiography and exercise testing or equivalent stress testing are needed, followed when appropriate by coronary angiography and ultimately referral for coronary angioplasty and stenting or bypass grafting.

Stress-induced hyperglycaemia and myocardial infarction

The intense sympathetic discharge triggered by an infarct can push blood glucose acutely into the diabetic range in previously normoglycaemic individuals. Stress-induced hyperglycaemia can be distinguished from previously undiagnosed diabetes because the HBA_{1c} will be normal. The acute management of these

individuals is uncertain; they were classified as 'diabetic' in the DIGAMI Study and also enjoyed improved survival with intensive insulin therapy. Pending further information, a pragmatic strategy would be to control glycaemia tightly during the admission with intravenous insulin for 48 h as described above, and then to monitor blood glucose closely and treat any persistent hyperglycaemia with insulin.

Heart failure

This is common in diabetic people with ischaemic heart disease and is a major cause of death in those who suffer an infarct. In addition to ischaemia from coronary artery disease, a specific diabetic cardiomyopathy may contribute to failure, as left ventricular function may be impaired in the absence of obvious atheroma on coronary angiography. Various defects in contractility and calcium flux within cardiomyocytes have been identified in diabetic animal models, but their relevance to humans is not clear. Echocardiography may show specific abnormalities early in diastole as well as areas of dyskinesia and a reduced ejection fraction. Moderate or severe left ventricular dysfunction, with an ejection fraction of less than 40 per cent, should be treated with an ACE inhibitor.

Stroke

Cerebrovascular accidents, mostly embolic, are two to five times commoner in diabetics than in the general population. They are managed conventionally. As with myocardial infarction, a stroke can acutely raise blood glucose in both diabetic and non-diabetic people. Trials are currently under way to determine whether tight glycaemic control can also improve the outcome of a stroke in hyperglycaemic individuals; for the moment it seems reasonable to keep blood glucose within the range 7 to 10 mmol/l, with the early use of insulin (probably subcutaneously) if this proves difficult.

Peripheral vascular disease

This is very common in the legs, often with diffuse disease distally as well as in the iliac and femoral arteries. Consequences include intermittent claudication, pain at rest, and gangrene which is usually dry and may lead to the loss of one or more toes. Severe atheroma in the iliac arteries can cause the Leriche syndrome, with buttock claudication and erectile failure; the latter may also be due to involvement of the pudenal arteries.

Investigation and management are conventional. Intermittent claudication may improve with the simple advice to stop smoking and keep walking, but a shortening claudication distance or pain at rest require urgent investigation. Angiography often shows widespread atheroma, and this may preclude reconstructive surgery. Otherwise, standard operations such as femoral–popliteal bypass and the use of the saphenous vein *in situ* for more distal disease can achieve good results and must not be withheld from people simply because they have diabetes. Nonetheless, diabetes still accounts for about one-half of all non-traumatic leg amputations.

Patients with diabetic renal failure or autonomic neuropathy may show calcification of the artery walls, often easily visible in the digital arteries on plain radiography of the feet (Fig. 17 and Plate 2). This medial sclerosis (Mönckeberg's) is not directly related to atheroma, although the two often coexist.

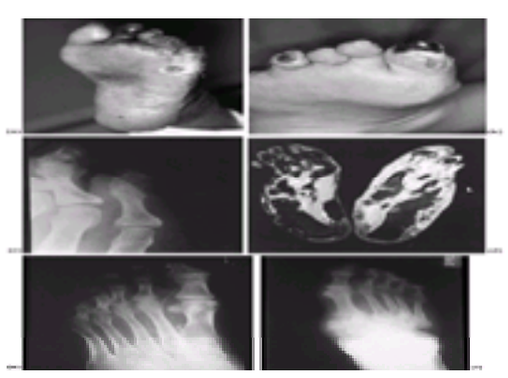

Fig. 17 The diabetic foot. (a) Typical punched-out neuropathic ulcer on the lateral aspect of the sole in an ischaemic foot with gangrene of the second, fourth, and fifth toes. (b) Ulceration and digital gangrene, caused by wearing tight shoes on a severely ischaemic foot. (c) Osteomyelitis in the diabetic foot. Early changes can be subtle: in this case, an erosion at the lateral edge of the distal end of the proximal phalanx of the fifth toe. ^{111}In-labelled white cell scanning showed an intense 'hot spot' at this site (with thanks to Dr Hans Laasch, Manchester Royal Infirmary). (d) Osteomyelitis affecting the proximal phalanx of the left big toe and the adjacent metatarsophalangeal joint, visible as an abnormally high signal on MR imaging. Associated oedema shows as a high signal in the surrounding soft tissues (with thanks to Dr King Sun Leong, Whiston Hospital). (e) Mönckeberg's medial sclerosis, outlining the digital arteries on this plain radiograph. (f) Charcot's arthropathy, showing massive destruction of the distal ankle joint. (See also Plate 2.)

Other manifestations of peripheral vascular disease include angina-like abdominal pain after eating, which is due to narrowing of the mesenteric artery, and renal artery stenosis which can contribute to hypertension and precipitate acute renal impairment soon after starting an angiotensin converting enzyme inhibitor.

Diabetic foot disease

The feet are at the mercy of various diabetic complications and problems such as ulceration and resistant deep infections often cause long and expensive hospital admissions. Ulceration and severe ischaemia leading to gangrene of the toes or forefoot are the commonest problems.

Diabetic foot disorders are best managed in a dedicated combined clinic. Prevention is extremely important. Many problems can be avoided by teaching the patients basic foot care, by regularly checking their feet and shoes, and by providing prophylactic chiropody and special footwear as appropriate. Charcot's arthropathy most commonly affects joints in the ankle or foot.

Neuropathy damages the foot through motor, sensory and autonomic involvement. Distal motor neuropathy alters the posture of the foot by weakening its small intrinsic muscles and allowing the unopposed action of the long extensors to claw the foot, concentrating pressure on the heel and the metatarsal heads. Shear forces generated by walking and shoes cause the skin over pressure points to thicken into callus; eventually, pressure damage leads to foci of liquefactive necrosis deep within the callus, and these break through to the surface to form an ulcer (Fig. 17).

Autonomic denervation opens up arteriovenous anastomoses, shunting blood to the skin—hence the warm skin and dilated veins of the neuropathic foot. Shunting may also deprive the tissue bed of oxygen and nutrients, thus worsening ischaemia from arterial disease. Increased blood flow may also be an initiating factor in Charcot's arthropathy (see below). Sensory denervation and loss of pain sensation can allow the foot to be damaged by agents such as over-tight new shoes, a drawing pin, or sharp stones in the shoe.

Ischaemia, due to peripheral vascular disease and possibly microvascular damage, can lead to ischaemic ulceration and to gangrene of the toes or forefoot (Fig. 17).

Foot ulceration

This is usually multifactorial, although one cause (for example, neuropathy) may initiate or dominate the process.

Trauma includes the normal wear and tear of walking in shoes and damage from foreign bodies, often undetected because of neuropathy. Inexpert do-it-yourself chiropody is another cause.

Infection commonly complicates diabetic foot ulcers, and often penetrates deep into the soft tissues and bone. Mixed organisms are usually responsible, including staphylococci, pseudomonas, and anaerobic organisms, sometimes gas-forming. Osteomyelitis is particularly ominous and requires urgent diagnosis and treatment

(Fig. 17).

Clinical features of diabetic foot ulcers

Primary neuropathy and ischaemic ulcers can generally be distinguished as below, but careful examination of the whole foot is essential so that all the possible contributory causes can be adequately treated.

- Primarily neuropathic ulcers occur at high-pressure sites (heel, metatarsal heads) and appear cleanly punched out of the surrounding callus (Fig. 17). The foot may be numb, with or without neuropathic pain, and the ulcer is often painless and may not have been noticed by the patient. Typical neuropathic features including clawed posture of the foot, warm skin, and sensory loss.
- Ischaemic ulcers tend to affect the edges of the foot and are often painful. There may be a history of intermittent claudication, absent foot pulses, and cold skin, sometimes with obviously ischaemic toes or previous amputation (Fig. 17).
- Traumatic ulceration may hint at its causes, for example symmetrical damage across the toes and margins of the feet from tight shoes (Fig. 17).
- Infection may cause local signs of inflammation, although the skin may appear deceptively normal even over extensive and serious deep infection, and pain may be absent. Anaerobes and pseudomonas characteristically produce a foul smell, while gas formation may occasionally cause crepitus in the subcutaneous tissues.

Investigation of diabetic foot ulcers

Effective treatment depends on identifying the cause(s) of ulceration. Neuropathy and ischaemia are assessed and managed as above. Swabs or curettings from deep in the ulcer should be cultured for both aerobic and anaerobic organisms. Plain radiography of the foot may show gas in the soft tissues or osteomyelitis, which can be difficult to distinguish from Charcot's arthropathy; MRI scans and ^{111}In-labelled white cell scans are highly specific for infection (Fig. 17).

Management of diabetic foot ulcers

Predominantly neuropathic ulcers are treated by the chiropodist to remove callus, and the foot protected with a lightweight plaster cast to unload pressure from the affected area, which accelerates healing while keeping the patient mobile; this may need to be worn for several weeks. Extra-depth or custom-built shoes, or pressure-absorbing socks, will reduce pressure loading and help to prevent recurrence. Ischaemia is treated as above, aiming to avoid or limit amputation.

Infection must be treated with appropriate antibiotics and repeated cultures may be needed to ensure that mixed infections, especially including fastidious organisms and anaerobes, are completely covered. Soft-tissue infections may respond to oral broad spectrum antibiotics such as amoxicillin and flucloxacillin, or coamoxiclav, combined with metronidazole if anaerobic infection is suspected; deep infections and osteomyelitis may require some weeks of intravenous treatment with drugs such as clindamycin, and surgical debridement. Amputation may be needed in refractory cases.

Charcot's arthropathy

This is fortunately rare, affecting fewer than 0.5 per cent of diabetic patients. It usually occurs in those with dense peripheral neuropathy and profound sensory loss, often with symptomatic autonomic damage. Reduced pain sensation is assumed to favour traumatic damage, and acute flareups are often preceded by injuries, which may be apparently trivial. Interestingly, blood flow to the affected area is increased early in the Charcot process, possibly because sympathetic denervation allows dilation of arterioles supplying the bone; this may stimulate osteoclast activity and bone resorption.

The ankle and joints in the mid- and forefoot are most commonly affected; non-weight-bearing joints are very rarely involved. The natural history is variable but can lead to massive destruction of the articular surfaces and resorption of adjacent bone, often with a large effusion that can become acutely inflamed and mimic septic or inflammatory arthritis. In advanced cases, the joint degenerates into a 'bag of bones'. The process is generally painless, but acute flareups can cause discomfort. The most important differential diagnosis is from septic arthritis and osteomyelitis. Radiographic appearances are characteristic in advanced cases (Fig. 17), but may be ambiguous early on; ^{99}Tc^{m} bone scans show increased uptake while the white cell scan is usually negative. Magnetic resonance imaging is probably best able to distinguish Charcot's arthropathy from osteomyelitis. An acutely inflamed joint may need to be aspirated to exclude infection, especially if systemic symptoms, neutrophilia, or raised erythrocyte sedimentation rate are present.

Treatment is often unsatisfactory. Non-steroidal anti-inflammatory drugs can provide symptomatic relief, while off-loading pressure with a plaster-cast boot may temporarily halt bone destruction, but neither appears to improve eventual outcome. Pamidronate may slow the disease process by inhibiting osteoclast activity. Surgery should be avoided if possible, because the Charcot process may then spread to neighbouring joints. Occasionally, amputation is the only option for a dangerously unstable or painful foot.

Other tissue complications of diabetes

Limited joint mobility, also known as the diabetic hand syndrome or cheiroarthropathy, is probably due to glycation of collagen and other connective tissue proteins. It is particularly common in type 1 diabetes, and may develop during childhood. It causes worsening flexion deformities of the fingers so that their palmar surfaces cannot be opposed when the hands are pushed together (the 'prayer sign'), often with Dupuytren's contracture. Median and ulnar nerve lesions, presumably compressive, are often associated. Rarely, thickening of skin over the metacarpophalangeal and interphalangeal joints causes Garrod's knuckle pads (Fig. 18 and Plate 3).

Fig. 18 The hands in long-standing diabetes. (a) Limited joint mobility (cheiroarthropathy), showing the 'prayer sign'. (b) Thickening of the skin over the knuckles and proximal interphalangeal joints (Garrod's pads). (See also Plate 3.)

Necrobiosis (lipoidica diabeticorum) is strongly associated with diabetes, although 25 per cent of affected patients are normoglycaemic. Necrobiosis is the hyaline degeneration of collagen. The lesions present as trophic, non-scaling yellowish areas, often with telangiectasias (Fig. 19 and Plate 4). They are commonest on the shins but may appear elsewhere, slowly enlarge, and may perforate. Their progression is unrelated to glycaemic control. Topical or locally injected steroids may be helpful. (The histologically similar granuloma annulare is not convincingly associated with diabetes.)

Fig. 19 Necrobiosis lipoidica diabeticorum (with thanks to Dr Geoff Gill, University Hospital, Aintree, Liverpool). (See also Plate 4.)

Diabetic dermopathy ('shin spots') is the commonest skin disorder in diabetic patients and is also seen in non-diabetic patients. These atrophic brownish or erythematous lesions, usually in the pretibial area, generally cause no problems and often resolve within a year or so.

Diabetic bullae (bullosis diabeticorum) are due to subepithelial splitting and present as tense and painful blisters which appear and heal within a few weeks. Differential diagnoses include pemphigoid.

Diabetic osteopenia: poorly controlled type 1 diabetes causes general loss of bone mineral, although this does not appear to increase fracture rate significantly. Plain radiographs of the feet may show low-density phalanges that taper and may be smoothly eroded— an appearance imaginatively described as resembling partly sucked candy.

12.11.2 The genetics of diabetes

J. A. Todd

Type 1 diabetes

Type 1 is the most severe form of diabetes, with acute onset, often in children. Within white European populations, incidence varies from three cases/100 000 individuals in the population per year in Romania to over 45/100 000 per year in Finland. Its main cause is a massive and irreversible destruction of the islet b cells by the body's own immune system, in an immune-mediated autoimmune response. Life-threatening insulin deficiency results. The median age at diagnosis is about 12 years. However, as many as 25 per cent of cases are now diagnosed under age 5 years and the disease can still be diagnosed over age 60 years

The immune attack of the islets probably begins, in most cases, before age 2 years, even though diagnosis may not occur until many years later. Most autopsy pancreas samples from children who died during acute onset of the disease show immune infiltration, especially cytotoxic T lymphocytes. Newly diagnosed patients and subjects in families with the disease are positive for autoantibodies against several proteins expressed in b cells. The first of these autoantibodies to appear are those against the insulin molecule itself, and current knowledge indicates that it is a primary, aetiological antigen in b-cell destruction. The immune-mediated nature of the disease is also supported by the observations that the immunosuppressant, cyclosporin, can alter the disease course and that it very strongly associated genetically with the T lymphocyte activation genes, the HLA class II genes. The disease is clustered in families, along with other immune-mediated diseases such as thyroid disease and rheumatoid arthritis. Spontaneous rodent models of type 1 diabetes also indicate that immune-mediated destruction of b cells underlies type 1 diabetes. Most importantly, the disease can be transferred from diabetic mice to healthy recipients using T lymphocytes only. It is unlikely that the b cells themselves are passive targets of a dysregulated immune system and resistance to type 1 diabetes may well involve genes expressed in b cells.

The factors that determine the initiation and duration of the, often long, prodromal phase before diagnosis are unknown. In many countries, the incidence of type 1 diabetes is increasing dramatically, two to three-fold over the last 20 to 30 years, particularly in children under age 5 years. This cannot be due a change in the gene pool and must reflect an increasingly permissive environment. Diet and infection have both been implicated, by analogy with conditions such as coeliac disease, in which gluten is the major triggering factor, but as yet no major factor has been identified. The role of the environment cannot be underestimated. Nevertheless, there can be very few cases with a purely environmental aetiology as at least 95 per cent of cases possess the known disease-associated alleles at the major locus, the HLA class II genes. The HLA genotype is a necessary factor but not a sufficient one to explain disease occurrence. Environmental factors (not best described as 'triggers') are probably not necessary and are definitely not sufficient, but because we live lifestyles with numerous diet and infection exposures they undoubtedly play a role in most cases, either in disease initiation or precipitation in individuals genetically predisposed to the disease. It is likely that no single type 1 diabetes non-HLA gene is necessary; it remains to be determined whether combinations of non-HLA alleles is necessary. Even if the genotype of individuals is identical (monozygotic twins or inbred strains of mice) and the environment shared, for example inbred diabetic mice in a animal facility with highly regulated and uniform, infection-free environment, there is a large discordance in disease occurrence owing to unknown stochastic or random developmental factors. Despite a fully disease-permissive environment and genotype, disease might still not develop.

Disease inheritance

Type 1 diabetes is classified as a multifactorial or complex disease and not a single-gene or simple mendelian disease because possession of the disease genotype does not guarantee development of the disease—the penetrance of the genotype is less than 100 per cent. Most evidently, only 25 to 70 per cent of genetically-identical twins both develop type 1 diabetes. The disease is strongly inherited but this inheritance is complex.

By analysis of the occurrence of disease in families, the mode of inheritance was modelled most parsimoniously by a single major locus in combination with many other loci but with lesser individual effect than the major locus. This is referred to as a 'polygenic background'. It has its roots in the classical theory of the genetics of continuous traits or phenotypes for which numerous alleles, each with small effect, contribute to the overall (disease) phenotype. The transmission of disease in families, measured as the risk of disease, follows a distinctive pattern: a rapid non-linear decline in risk from first-degree relatives (6 per cent) to third-degree relatives, at which point the risk is not much different from the risk in the general population (0.4 per cent). A simple, single-gene disease exhibits a linear decline in risk. The rapid decline in risk in type 1 diabetes families is explained by the need for susceptibility alleles at several loci to be present simultaneously. Hence, marriage of a susceptible family member to a carrier of a non-susceptibility allele at one of the disease-associated loci can substantially reduce risk. An analogy is the removal of one can in a pyramid of cans resulting in collapse of the entire pile. Multigenerational families with type 1 diabetes are very rare due to this polygenic inheritance.

Molecular genetics

The major locus, at the HLA region on chromosome 6p21, is not due to allelic variation in one gene, but in several genes that can be epistatic with each other. Such complexity can only be verified by finding the actual disease loci and identifying the relevant functions of their products. A necessary step in this process is to estimate how major is the major locus. These estimates, unfortunately, depend on which genetic model is assumed and include estimates of the contribution of HLA to the clustering of type 1 diabetes in families ranging from 40 to 70 per cent. In addition, HLA-identical siblings develop type 1 diabetes less frequently than identical twins, indicating the modifying effect on HLA disease genes by non-HLA genes across the genome.

Advances in technology, and painstaking collection of data from families with two or more affected siblings, the only type of multiplex families actually available, have allowed direct evaluation of the relative contributions of different regions of the genome to familial clustering. This is referred to as linkage analysis, in which the siblings share diabetes and they also share the chromosome regions that cause the diabetes more often than expected by chance (assuming random transmission of alleles under Mendel's laws). The first genome-wide searches for linkage showed conclusively that type 1 diabetes is a major locus disease because no convincing loci other than HLA were found, despite good statistical power. This is not the case for other, closely related autoimmune diseases such as rheumatoid arthritis, autoimmune thyroid disease, or multiple sclerosis in which, although the HLA region is linked to disease, its effect is not as dominating as in type 1 diabetes. In these three diseases, it appears that no single locus has a major effect. Yet, because adopted unrelated children brought up in families with multiple sclerosis have the same risk as a randomly selected member of the general population, it is certain that familial clustering is due to shared alleles. There are, however, many disease loci (with susceptibility or resistance alleles) scattered across the genome. This situation presents a practical problem in that genes of small effect require hundreds, if not thousands, of sib-pairs to achieve convincing statistical support for deviation from random allele sharing. Except in the context of international consortia combining data sets, or perhaps in certain populations such as Iceland where remarkable family records are available, this is not feasible.

Association studies

Genes for both rare, mendelian diseases and common, complex diseases can be detected and precisely mapped by analysing the sharing of alleles by unrelated cases compared to unaffected controls. This is referred to as association or linkage disequilibrium mapping. It assumes that a proportion of living cases have inherited the same mutation from the original person in whom the disease-predisposing mutation or polymorphism arose. Cases (and controls) that carry the allele of the mutation share not only this allele but also the flanking DNA. If the mutation arose very recently in the population then the amount of flanking DNA associated with the mutation will be much larger than if, for example, the mutation predated the colonization of Europe. This is because homologous recombination of chromosomes will not have had enough time to break up the physical linkage between the mutation allele and alleles of the flanking loci that were present at the time when the mutation occurred. When recombination events between nearby loci have recombined their alleles completely, such that combinations of alleles at neighbouring loci (haplotypes) occur at frequencies no different from that expected by chance (that is the product of the allele frequencies observed in the population), then the alleles

are said to be in linkage equilibrium. When alleles occur together non-randomly, they are said to be in linkage disequilibrium.

Whereas 2000 evenly spaced, biallelic or single nucleotide polymorphisms are sufficient to search the genome for chromosome regions that show linkage to disease, over 100 000 are required to probe the genome for chromosome regions or markers that are so close to a disease causal variant that the marker alleles and the disease locus alleles are in association or linkage disequilibrium. The density of polymorphic markers will depend on the demographic history of the population and the particular region of the genome. Single nucleotide polymorphisms occur as frequently as 1 per 1000 base pairs of DNA, so that as many as 3 million polymorphisms occur in the genome. Technologies are being developed that are capable of carrying out hundreds of thousands of assays to identify alleles at polymorphic loci across the genome, especially those that occur in the regions of genes that either encode proteins or determine their expression. By resequencing the human genome from tens of individuals, hundreds of thousands of polymorphisms are being identified and mapped onto the first draft of the sequence.

Until the ability to generate and type dense maps of polymorphic markers from large chromosome regions is a reality, both technically and economically, geneticists are restricted to focusing efforts on candidate genes—genes for which the expression or presumed function might be of relevance to the development of the disease. This more limited approach has historically been moderately successful. The candidate gene-association approach was used to identify the only two known genes for type 1 diabetes, the HLA class II genes and the repetitive DNA polymorphism in the 5' regulatory region of the insulin gene, on chromosomes 6p21 and 11p15, respectively (designated *IDDM1* and *IDDM2*). As marker typing technology improves, candidate genes will be analysed in much larger numbers.

Linkage studies in type 1 diabetes are continuing and meta-analyses of over 1000 affected sib-pair families are underway. This number of families provides the statistical power to detect disease loci with intermediate effects. Chromosome regions that show significant evidence of linkage to disease will be subjected to a more systematic association analysis in which very dense maps of polymorphisms will be developed, in the order of several single nucleotide polymorphisms per 10 kb of DNA, and typed in cases, controls, and families to find disease-associated regions that explain the linkage of the broader chromosome region to the disease. This is still a daunting task given current technology. Disease-linked chromosome regions usually encompass 15 cM to 15 Mb of DNA, indicating that at least 1500 evenly spaced polymorphic markers might have to be typed before the disease locus is located. This assumes that the linked region contains one disease locus, which seems unlikely given data from the mouse model of type 1 diabetes, and the fact that thousands of genes function in the immune system, for which a high polymorphism is beneficial in the defence against infection. Before embarking on such studies, it will be necessary to be confident that the evidence for linkage of the chromosome region to disease is convincing (P, probability, value less than 2×10^{-5}) and that the association study has sufficient statistical power to detect the association at P values in the range of 10^{-5} to 10^{-8}. These low P values take into account the very large number of tests carried out in studies of this kind. If a linked region contains several disease genes and each has several alleles, some or all which might be rare (1–5 per cent allele frequency in the population), then the prospects for sufficiently powerful studies are not favourable. If association studies are undertaken without prior evidence of linkage then, in the absence of convincing data implicating the function of the gene in disease, P values in the order of 10^{-8} are required to achieve results significant at the 5 per cent level (P = 0.05), taking into account the hundreds of thousands of tests that would be conducted across the whole genome. This assumes that hundreds of thousands of polymorphic markers, or at least all markers required to detect all haplotypes and constitute a continuous linkage disequilibrium map across the entire genome, have been typed in the study or are anticipated to be typed in future studies worldwide. Until technology is available that can tackle a 'whole genome assocation analysis' studies will be restricted to candidate genes or chromosome regions linked to disease.

Type 1 diabetes genes

We know the identity of two of the genes (termed insulin-dependent diabetes mellitus, IDDM, genes): *IDDM1* is comprised of a number of genes of related function, the human leucocyte antigen (HLA) class II genes, encoded in tandem in the major histocompatibility complex on chromosome 6p21. The *HLA-DQB1*, *-DQA1*, and *-DRB1* loci act as a 'superlocus' in disease with many alleles at the three different, but adjacent and homologous, loci interacting in epistatic ways. Their products allow T lymphocytes to recognize foreign and self-proteins in the form of peptide bound to the surface-expressed HLA class II molecules. They ensure that the body's immune system can recognize self-proteins and remain tolerant to them. Certain alleles, the most potent of which are referred to collectively as DR3 and DR4, are permissive for the anti-b-cell immune response, whereas other alleles, such as DR2, are dominantly protective against type 1 diabetes. The precise mechanisms underlying HLA class II mediated susceptibility and resistance are still uncertain. Moreover, this information, concerning a necessary and key step in disease pathogenesis, has not been translated into a way of modulating disease susceptibility. Although the translation of genetic–physiological research results such as these into therapy is the main goal, early attempts to block or modify HLA class II function directly in autoimmune disease have not been successful.

The second locus is referred to as *IDDM2*, now identified as a polymorphic DNA sequence composed of repeats of short oligonucleotides embedded in the 5' regulatory region of the insulin gene on chromosome 11p15. The two main variants of this polymorphism differ in size (that is number of repeats), sequence, and in their regulation of expression of the insulin gene. This differential regulation of insulin at the transcriptional level varies according to the tissue; very low levels of insulin are expressed in the thymus, the organ in which HLA class II molecules mediate the establishment and maintenance of immune tolerance. The type 1 diabetes protective allele of the insulin gene 5' repeat polymorphism is associated with increased expression of insulin (and its precursor preproinsulin) in the thymus. Since insulin is a key autoantigen in type 1 diabetes, a plausible model for the physiological action of this polymorphism in disease protection is increased tolerance to insulin and its precursors owing to their increased expression, and consequently HLA class II molecule-mediated immune tolerance. Peptides from insulin (and/or its precursors) bind to the HLA class II molecules in the generation of a healthy, b-cell tolerant T lymphocyte repertoire. This model fits much of the available data, particularly from rodent models of the disease. There are, however, missing links; for example the precise peptides involved, the affinity with which they bind to different HLA class II allotypes, and the consequences of these events for the immune system downstream of the HLA class II peptide T lymphocyte antigen receptor are uncertain. Again, it is not clear how this presumed pathway can be modulated to restore immune function to a level at which an individual is resistant to disease. This challenge is particularly acute since the very first events in disease and in immune tolerance may occur before age 2 years.

The risk of carrying disease-susceptible HLA class II and insulin gene alleles does not exceed 30 per cent. Informing a family member or an individual of this risk is not useful, and maybe harmful, in the absence of a safe way to modulate this risk and restore normal function. In a research context, the longitudinal follow-up of children from birth who carry the HLA susceptibility alleles or have type 1 diabetic parents could provide insights into the environmental factors that determine the development of the disease. The typing of protective alleles, such as HLA DR2, or more precisely the DQB1*0602 allele, already has some diagnostic benefit in clinical trials to prevent the disease. Positivity for the protective allele provides a criterion for exclusion from a trial, since DR2/DQB1*0602 positive subjects are at least 50 times less likely to develop type 1 diabetes than a randomly selected member of the population.

Current research

The search is proceeding for other type 1 diabetes genes using the genetic approaches of linkage and association. In concert with these efforts new tools are being applied, including the mass, parallel analysis of gene transcription using microarrays, the analysis of protein expression and modification using mass spectroscopy, the analysis of events *in vivo* using imaging techniques, and the investigation of cell metabolism using nuclear magnetic resonance spectroscopy. These approaches, in combination, will provide further details of immune system and islet cell physiology in the search for pathways and pathway–environmental factor interactions that could be manipulated to prevent the disease or rejection of transplanted islets or b cells.

12.11.3 Hypoglycaemia

V. Marks

Introduction

Hypoglycaemia means low blood glucose concentration (<3.0 mmol/l). It is not a disease entity but a biochemical abnormality whose importance lies in its effects upon brain function. These are responsible, directly or indirectly, for the signs and symptoms produced by hypoglycaemia and often provide the first clue to the presence of curable or preventable disease.

The brain obtains glucose from the blood by means of facilitated transport and mainly utilizes the glucose-transporting protein GLUT 1. The activity of this protein is increased by hypoglycaemia and reduced by hyperglycaemia. It is not insulin-dependent. Although blood glucose concentration is the single most important factor determining glucose availability to the brain, it is not the only one. Indeed there is a poor correlation between blood glucose concentration and the severity and nature of cerebral symptoms—especially in diabetic patients. It is therefore important to distinguish hypoglycaemia, a description of blood glucose, from neuroglycopenia, which is responsible for the signs and symptoms to which hypoglycaemia gives rise.

Four distinct, but not mutually exclusive, neuroglycopenic syndromes are recognized:

1. Acute neuroglycopenia, the most common, is normally associated with iatrogenic and experimental hypoglycaemia and is characterized by profuse sweating, anxiety/nervousness, tremor, tachycardia, hunger, and paraesthesia—all of which can be attenuated by adrenergic and cholinergic blockade—and by speech and visual disturbances, unsteady gait, confusion, and a sense of fatigue, which are independent of the autonomic nervous system.
2. Subacute neuroglycopenia occurs in most varieties of spontaneous hypoglycaemia and, when it occurs in insulin-treated diabetic subjects, is called hypoglycaemia unawareness. It is characterized by a reduction in spontaneous movements and speech, somnolence, inefficient cerebration and work performance, personality change, and amnesia of varying severity. Other signs and symptoms common to acute and subacute neuroglycopenia include transient hemiplegia, hypo- or hyperthermia, convulsions, diploplia, and strabismus. The symptoms of both acute and subacute neuroglycopenia are ephemeral but, unless aborted by restoration of normoglycaemia, can progress to stupor, coma, or, in exceptional cases, death from cerebral oedema.
3. Chronic neuroglycopenia is rare and virtually confined to patients with hypoglycaemia due to insulinoma or diabetic patients over-zealously treated with insulin. It is characterized by insidious changes in personality, defective memory, psychosis—often with paranoid features—or mental deterioration resembling dementia.
4. Hyperinsulin neuronopathy, the clinical features of which may be mistaken for motor neurone disease, is a form of chronic neuroglycopenia. Temporary elevation of the blood glucose level has no discernible effect on cerebral or neuronal function but removal of the causative agent often does over the course of a year or two.

Experimental and iatrogenic hypoglycaemia

There is a hierarchy in the activation of brain centres as hypoglycaemia develops which is, however, not often observed in spontaneous hypoglycaemia. The tissue most sensitive to a falling blood glucose level is the normal pancreatic b-cell which virtually ceases secreting insulin as blood glucose concentrations fall to about 4.0 to 4.2 mmol/l. The sympathetic nervous system is activated and glucagon is secreted as the blood glucose concentration reaches about 3.7 mmol/l. Stimulation of growth hormone secretion occurs at glucose levels of about 3.5 mmol/l and that of ACTH and cortisol at about 3.3 mmol/l. The threshold for vasopressin release has not been determined. Most subjects experience symptoms only after their blood glucose concentration has fallen below 3 mmol/l but objective evidence of minor cognitive impairment, of which the subject is usually completely unaware, occurs at concentrations nearer 4 mmol/l.

Patients, whether diabetic or not, with recent experience of hypoglycaemia often tolerate lower blood glucose levels before symptoms develop and counter-regulatory hormones are secreted. They remain, however, just as sensitive to the deleterious effect of hypoglycaemia on cognitive function.

Some of the cerebral symptoms of neuroglycopenia and effects upon neuronal viability are due to liberation of the excitatory amino acids, glutamate and aspartate, rather than solely to decreased intracellular energy production.

Definition

Hypoglycaemia is defined arbitrarily by the blood glucose concentration; it is not determined by whether symptoms are present or not. For most purposes, an arterial (or capillary) blood glucose concentration below 3.0 mmol/l can be considered diagnostic of hypoglycaemia and one of 2.5 mmol/l or less pathological and demanding

of investigation as to cause. The possibility that a patient's symptoms are of neuroglycopenic origin should not be dismissed solely on the basis of blood glucose concentration. Normoglycaemic neuroglycopenia must be considered.

Classification

Iatrogenic hypoglycaemia as a consequence of insulin or sulphonylurea treatment for diabetes is common and accounts for most hypoglycaemia encountered in practice. It seldom presents diagnostic difficulties. There are, on the other hand some 100 or so causes of spontaneous hypoglycaemia, all of which are rare. Collectively, they are responsible for 0.1 per cent of all patients arriving in accident and emergency or medical investigation departments.

Table 1 lists the main causes of hypoglycaemia, which vary in frequency from country to country. Although all may occur in infants and children, the main causes of hypoglycaemia in this age group are not usually encountered in adults.

Presentation

Patients classically present either to accident and emergency in a stuporose or comatose state with concurrent hypoglycaemia or to outpatient departments with a normal blood glucose level but a history suggestive of recurrent neuroglycopenic episodes or progressive neurological/psychological dysfunction.

Management of the stuporose/comatose hypoglycaemic patient

Hypoglycaemia should be suspected in any case of altered consciousness, coma, hemiplegia, apparent alcoholic intoxication, or epilepsy, and eliminated or supported (though not established) by a point-of-care blood glucose determination. The diagnosis is confirmed by formal laboratory glucose analysis. Hypoglycaemia may also be caused by, and contribute to the symptomatology of, congestive cardiac failure, liver or kidney disease, malaria, and other severe infections. Management falls quite clearly into two separate phases.

Emergency treatment

Glucose 25 g (50 ml of 50 per cent w/vol) should be given intravenously to alleviate hypoglycaemia after sufficient venous blood (20 to 30 ml) has been withdrawn for subsequent laboratory analysis to determine its cause. Glucagon 1 mg may be given intramuscularly if venous access is not available, especially in cases of iatrogenic hypoglycaemia (in which it is usually effective).

Recovery of consciousness ordinarily occurs within 10 min. A further injection of 25 g glucose plus 100 mg hydrocortisone is indicated if recovery is delayed beyond 20 min. Specific measures to reduce brain swelling must be introduced if recovery does not occur within a further 20 min.

Prolonged, formerly called irreversible, hypoglycaemic coma is due to cerebral oedema and a consequence of profound hypoglycaemia generally lasting 5 h or more. Its treatment includes the use of intravenous mannitol and dexamethasone. Blood glucose must be monitored constantly and sufficient glucose infused to keep it within the range 5 to 10 mmol/l until consciousness is restored or permanent brain damage established. In cases of suicidal insulin or sulphonylurea overdose, glucose in doses up to 80 g/h given as a 25 to 50 per cent solution through a central line may be required.

Investigation

The second stage and third stages are similar to those employed in investigating patients suspected of suffering from a hypoglycaemic disorder but currently asymptomatic (Fig. 1).

Fig. 1 Investigation of a patient suspected of suffering from hypoglycaemia who is hypoglycaemic (but not unwell from some other cause, e.g. congestive cardiac failure, septicaemia, liver or renal failure) at the time of examination. It is customary to measure plasma total insulin immunoreactivity (IRI), C-peptide, proinsulin, b-hydroxybutyrate, growth hormone, IGF-1 and IGF-2, alcohol, and sulphonyureas simultaneously or sequentially on the initial hypoglycaemic blood sample. + to ++++: insulin >30 to 300 000 pmol/l; C-peptide >150 to 10 000 pmol/l; proinsulin >20 pmol/l; GH ³ 5 mU/l; BHB >600 µmol/l; alcohol ³2 to 100 mmol/l. –ve: insulin <25 pmol/l; C-peptide <100 pmol/l; GH <1 mU/l; B-OH <600 µmol/l; IGF-1 < 10nmol/l; IGF-2 <45 nmol/l. Abbreviations: IEM = inborn errors of metabolism, NICTH = non-islet cell hypoglycaemia, GH = growth hormone, B-OH = b-hydroxybutyrate, IR-AA = insulin receptor autoantibodies, AIS = autoimmune insulin syndrome.

Management of the asymptomatic patient suspected of having a hypoglycaemic disorder

Diagnosis takes place in three sequential stages:

1. suspicion of hypoglycaemia and its confirmation by measurement of the blood glucose concentration during a 'spontaneous' neuroglycopenic episode;
2. determination of its aetiology on the basis of specific investigative procedures;
3. localization of the lesion responsible if the hypoglycaemia has an anatomicopathological rather than a purely metabolic aetiology.

Confirmation of hypoglycaemia

Most patients, excepting those presenting in stupor or coma, are normoglycaemic and asymptomatic when first seen. Suspicion of hypoglycaemia is aroused by a history of subacute neuroglycopenia, that is episodes of altered behaviour or disturbed consciousness or, in a minority of cases, symptoms suggestive only of acute neuroglycopenia. Because of the nature of their illness, patients are often unable to supply a reliable history of their condition.

Exclusion or confirmation that a patient's symptoms are hypoglycaemic in origin can often be achieved by teaching them, or their relatives, to collect capillary blood during spontaneous symptomatic episodes occurring in the course of everyday life. Blood collected into specially prepared tubes or filter paper should be sent to the laboratory for glucose analysis since point-of-care monitoring systems are insufficiently reliable in the hypoglycaemic range to warrant initiation of detailed investigation and may cause confusion. A blood glucose concentration during a symptomatic episode greater than 3.5 mmol/l effectively eliminates hypoglycaemia as its cause. Glucose concentrations lower than this are unusual and require further investigation.

Hyperinsulinism

This is a misnomer for the syndrome to which insulinoma gives rise. It would better be called dysinsulinism since its hallmark is inappropriate rather than excessive secretion of insulin or proinsulin.

Insulinoma

Insulin-secreting tumours (insulinomas) are the most common type of neoplasm affecting the endocrine tissues of the pancreas. They have an incidence of one case or more per million of the population. Eighty per cent of insulinomas are benign and solitary, 7 to 10 per cent are multiple—often as part of the MEN 1 syndrome—and 8 to 10 per cent malignant. They occur at any age but are rare before the age of 10 and infrequently diagnosed after the age of 70. The lack of cases after age 70 may be due to their mode of presentation, which is often that of progressive dementia, rather than to their rarity. There is a 6:4 ratio in favour of women for benign but not for malignant tumours.

Insulinomas are composed mainly, or exclusively, of b-cells. Most are between 10 and 20 mm in diameter at diagnosis, though tumours as small as 5 mm in diameter have been associated with severe symptoms. Regardless of size, they occur at all sites in the pancreas with equal frequency.

Histological classifications, whilst valuable for the light they throw on insulin secretory mechanisms, contribute little to clinical management. Malignant insulin-secreting tumours are impossible to distinguish, clinically or histologically, from benign ones unless metastases are present. Some have the histological appearance of carcinoid tumours and both may contain and secrete other peptide hormones of which glucagon, somatostatin, ACTH, and GhRH are amongst the commonest. Only rarely, however, do these biochemical endocrinopathies manifest themselves clinically. There is no evidence that malignant tumours ever begin as benign tumours or that benign tumours ever become malignant.

The average time between the onset of symptoms and diagnosis of insulinoma is currently about a year but symptoms persisting over 30 years or more without evidence of permanent brain damage are not unknown. Diagnostic delays are usually due to reluctance by patients to seek help or failure by clinicians to suspect hypoglycaemia, rather than any difficulties in confirming the presence of an insulinoma once the possibility has been considered. Only very rarely is an insulinoma found at autopsy as the cause of unexplained death.

In a minority, probably not exceeding 1 to 2 per cent, functionally defective b-cells are distributed throughout the pancreas rather than in discrete tumours. Clinically and biochemically, such patients are indistinguishable from patients with insulinomas. Biologically, such patients resemble infants with persistent hyperinsulinaemic hypoglycaemia of infants (formerly nesidioblastosis).

Chemical pathology

Endogenous hyperinsulinism is characterized by failure of the abnormal b cells to stop secreting insulin in response to hypoglycaemia. This is ordinarily the most sensitive physiological response to a falling blood glucose concentration and becomes apparent at a level (4.2–4.0 mmol/l) well above the threshold for neuroglycopenic symptoms. A consequence of insulin secretion persisting during fasting is inhibition of hepatic glucose release and a gradual fall in blood glucose to below the level capable of sustaining normal brain function.

Paradoxically, the functionally abnormal b cells are often insensitive to hyperglycaemia *per se* and so produce glucose intolerance as well as fasting hypoglycaemia. They do, however, respond, often excessively, to other insulin secretagogues including glucagon, sulphonylureas, L-leucine, and the intestinal incretins GIP and GLP-1, and may therefore present with reactive rather than fasting hypoglycaemia.

Typically, plasma cortisol and growth hormone levels in patients with insulinomas are normal even in the presence of hypoglycaemia. This would ordinarily be considered evidence of hypothalamicopituitary insufficiency but responsiveness returns after restoration of permanent normoglycaemia. Plasma free fatty acid and b-hydroxybutyrate concentrations are typically suppressed (<600 µmol/l) but rise, though not to expected levels, during prolonged fasting.

Diagnosis

Diagnosis is made by demonstrating that the symptoms are caused by hypoglycaemia, provoked by fasting and/or rigorous exercise, relieved by intravenous glucose, and are caused by inappropriate insulin and/or proinsulin secretion. Plasma concentrations of total immunoreactive insulin, C-peptide, proinsulin, and proinsulin-like fragments are all high with regard to the prevailing blood glucose concentration but are not necessarily high in absolute (quantitative) terms.

Thus in the presence of concurrent hypoglycaemia (blood glucose less than 3 mmol/l), plasma total immunoreactive insulin concentrations of more than 30 pmol/l and C-peptide concentrations more than 100 pmol/l are inappropriately high. When both peptide levels are inappropriately high, a diagnosis of endogenous hyperinsulinism is virtually certain, providing sulphonylurea ingestion and various rare autoimmune diseases and infections, such as malaria, can be excluded. If hypoglycaemia is absent at the time of sampling plasma insulin, C-peptide and proinsulin assays become uninterpretable.

Fasting under close observation for up to 72 h produces symptomatic hypoglycaemia with inappropriate hyperinsulinaemia (proinsulinaemia and C-peptidaemia) in over 98 per cent of insulinoma patients but not in healthy men and women who, if they do become hypoglycaemic, invariably have appropriately suppressed plasma insulin levels. As an alternative to prolonged fasting, the overnight fasted patient can be exercised to exhaustion on a treadmill. In insulinoma patients, this fails to produce the normal suppression of plasma insulin and C-peptide secretion. It is, however, rarely necessary to subject a patients to these tests, especially if investigations are restricted to those who have blood glucose levels below 3 mmol/l during spontaneous episodes occurring in every-day life. Dynamic function tests including oral glucose, tolbutamide, glucagon, L-leucine, and insulin–hypoglycaemia/C-peptide suppression tests are unnecessary for the diagnosis of hyperinsulinism.

Some 5 to 10 per cent of insulinomas secrete only, or mainly, proinsulin and thus the diagnosis may be missed if an insulin-specific assay, rather than one capable of detecting total immunoreactive insulin, is used. Moreover, unusually efficient extraction of insulin by the liver can lead to low plasma total immunoreactive insulin concentrations in peripheral blood in the presence of genuinely inappropriate insulin secretion. This can occur in infants with nesidioblastosis as well as in adults with endogenous hyperinsulinism in whom inappropriately high plasma C-peptide levels will confirm the diagnosis. Hyperproinsulinaemia, that is a plasma proinsulin concentration of greater than 20 pmol/l, is found in some 95 per cent of patients with endogenous hyperinsulinism; its absence should raise doubts about the accuracy of the diagnosis.

Pre- and intraoperative localization

A diagnosis of endogenous hyperinsulinism, established on the basis of inappropriate hyperinsulinaemia, is almost synonymous with one of insulinoma. The treatment of choice is surgical ablation. Localization by an experienced surgeon at laparotomy is remarkably (96 per cent) successful but can be further improved by use of intraoperative ultrasound.

Though virtually every imaging technique has been advocated for preoperative localization of insulinoma, none is sufficiently reliable to justify dismissing a diagnosis made on sound clinical and biochemical grounds. Endoscopic ultrasound, with a 90 per cent prediction rate, and pancreatic intra-arterial calcium injection with hepatic venous sampling are currently the only imaging techniques that are useful for localization prior to operation. Venous sampling is especially indicated when surgery has failed to reveal a tumour and/or diffuse islet hyperplasia is suspected. It is the only way of establishing a diagnosis of non-insulinoma pancreatogenic hypoglycaemia.

Treatment

Surgical ablation ensures an excellent prognosis with no reduction in life expectancy except when the tumour is malignant. Even then, since these tumours grow slowly and rarely spread beyond the liver, removal of the primary tumour, and as many hepatic secondaries as possible, may add years of useful life. Operative mortality for adenomas is under 2 per cent, except in the elderly. Benign tumours recur in up to 5 per cent of patients.

In patients over 70 years of age, and others in whom surgery is impracticable, treatment with diazoxide (200–600 mg/day) combined with chlorothiazide (1 g/day) to increase its effectiveness, is well tolerated. It is the treatment of choice in hyperinsulinism due to diffuse islet hyperplasia, non-insulinoma pancreatogenic hypoglycaemia, and after surgical debulking in cases of metastatic insulinoma. Only when diazoxide/chlorothiazide treatment fails to relieve hypoglycaemia are other drugs, such as octreotide, b-blockers, or calcium channel blockers worth trying. In patients with malignant insulinomas, embolization or surgical debulking of hepatic

metastases may produce remissions lasting several years—as may treatment with cytotoxic agents such as streptozotocin and 5-fluorouracil.

Non-islet cell tumour hypoglycaemia (NICTH)

The symptoms of hypoglycaemia produced by non-islet cell tumours (NICTH) may be indistinguishable from that of insulinoma. The symptoms are almost invariably those of subacute neuroglycopenia and the features of autonomic nervous activation are absent. Biochemically, NICTH is characterized by fasting hypoglycaemia, hypoketonaemia, and low plasma total immunoreactive insulin, C-peptide, and proinsulin levels. Growth hormone, ACTH, and glucagon secretion are depressed during both hypo- and normoglycaemia and plasma IGF-1 levels are always low—unlike in insulinoma when they are normal or high.

NICTH can occur with almost every histological type of malignant tumour but is rare. Although sarcomas are disproportionately well represented, less than 1 per cent of them develop hypoglycaemia. It is, however, common in patients with haemangiopericytomas, which are themselves rare. Amongst the carcinomas, no histological type is exempt from NICTH but only in primary hepatomas is it at all common.

Chemical pathology

Regardless of histological type, hypoglycaemia due to non-islet cell tumours (NICTH) results from overproduction of an abnormally large form of IGF-2. This has many of the biological and immunological properties of IGF-2 itself but binds less avidly to plasma IGF binding proteins (IGF-BP) of which there are at least six normally present in plasma.

Big IGF-2 is generated by the removal of a 24 amino acid leader sequence from the N-terminus of prepro IGF-2. Normally, it then undergoes cleavage at its carboxy terminus to produce regular IGF-2. Failure to do so leaves the E-domain intact and the secretion of big IGF-2—the cause of NICTH.

There is characteristically a marked reduction in the most plentiful of the plasma binding proteins, IGF-BP3, and a partial compensatory increase in IGF-BP2 the net effect of which is, however, to reduce IGF protein binding capacity. Consequently plasma 'free (big) IGF-2' is increased without any corresponding increase in total immunoreactive IGF-2.

The exact mechanism by which big IGF-2 produces hypoglycaemia is unknown and may involve several steps, the most important of which is activation of insulin and IGF receptors on peripheral tissues and their increased uptake of glucose. The next most important is suppression of glucagon and growth hormone secretion.

Ectopic insulin secretion

Ectopic insulinomas are confined to the duodenum and are rare (<1 per cent). Ectopic insulin production by a non-islet cell tumour is extremely rare and has been established in only one case and suggested in five others. The coincidence of an insulinoma and another type of tumour has been described rather more often.

Diagnosis

The diagnosis of NICTH is seldom in doubt once thorough investigations into the cause of hypoglycaemia have been initiated:

1. Hypoglycaemia, once it has developed, seldom remits for more than very brief periods after meals.
2. The tumours are usually, though not invariably, sufficiently large to reveal themselves either on physical examination or as a result of comparatively straightforward imaging.

In the laboratory, findings of low plasma insulin, C-peptide, and proinsulin concentrations (<30, <100, and <20 pmol/l respectively) in the presence of hypoglycaemia and hypoketonaemia are highly suggestive of NICTH. Clinical laboratory assays typically measure both big and regular forms of IGF-2 and generally reported as normal (50–100 nmol/l) but IGF-I levels are invariably low (<10 nmol/l). Consequently, plasma IGF-2:IGF-1 ratios, expressed on a molar basis, are abnormally high (>10) and not seen in any other condition except gross undernutrition. Assays for the E-domain of proIGF-2 have been developed. Although useful for establishing recurrence, they provide less accurate initial diagnostic information than the IGF-2:IGF-1 ratio.

Treatment

Treatment of choice is surgical. In rare cases of benign tumour NICTH, the cure is permanent. In malignant cases, ablation or debulking of secondaries may produce prolonged remissions. Symptomatic relief may be obtained by the use of a combination of diazoxide and chlorothiazide but less predictably than with insulinoma. Prednisolone, in doses up to 60 mg/day, produces improvement in the biochemical profile and remissions from hypoglycaemia in many cases but has no effect upon tumour growth itself. Growth hormone and long-acting glucagon preparations also produce symptomatic relief given alone or with prednisolone.

The postprandial syndrome

The appearance of symptoms suggestive of acute neuroglycopenia in relation to the ingestion of food has been called the postprandial syndrome. It has many causes, one of the less common is hypoglycaemia.

Reactive hypoglycaemia

Following an initial rise, venous blood glucose concentrations may decrease in normal healthy volunteers as far as 2 mmol/l below fasting levels after ingestion of a liquid glucose load of 75 g or more on an empty stomach. A smaller fall in arterial blood glucose also occurs and may, in up to 50 per cent of normal healthy subjects, be accompanied by mild symptoms. This phenomenon, referred to as reactive hypoglycaemia, rarely occurs in every day life when normal mixed meals are eaten. When it does, diagnostic difficulties may arise since symptoms are usually vague, unspecific, and indistinguishable from those due to other illnesses, especially neurosis.

In the period 1950 to 80, the diagnosis of reactive hypoglycaemia, referred to by lay writers simply as 'hypoglycaemia', reached epidemic proportions in the United States. In most cases, the diagnosis was based on misattribution of the normal response to oral glucose. Whilst some patients with postprandial syndrome may have a lower threshold to neuroglycopenia, experiencing symptoms at (arterial) blood glucose levels of 3.5 to 4.0 mmol/l rather than the more customary level of 2.8 to 3.3 mmol/l, most do not. Nor do they manifest any abnormalities of glucose homeostasis.

Criteria for the recognition and diagnosis of reactive hypoglycaemia were laid down at the Third International Symposium on Hypoglycaemia, adherence to which has greatly reduced the number of persons misdiagnosed. The criteria include a history of food-stimulated autonomic symptoms appropriate to acute neuroglycopenia—a capillary blood glucose concentration measured during a spontaneous symptomatic episode below 3 mmol/l and rapid relief by oral glucose. Sometimes, when suspicion is high and blood collection during every day life proves difficult, it may be necessary to give the patient a standard meal and observe the glycaemic, symptomatic, and electroencephalographic responses over the ensuing 5 h. The oral glucose load test is not appropriate.

The term reactive hypoglycaemia is not a definitive diagnosis in its own right; it is only the first step towards determining causation. Almost every condition in which hypoglycaemia is induced by fasting, may present as reactive hypoglycaemia. Organic causes, including acquired and inherited metabolic derangements, must, therefore, be eliminated before making a diagnosis of idiopathic reactive hypoglycaemia—which is rare. Conditions in which patients experience only reactive, but not fasting, hypoglycaemia include partial gastrectomy and jejuno–oesophageal anastamosis (also referred to as alimentary hypoglycaemia), autoimmune insulin syndrome, and, recently identified, non-insulinoma pancreatogenous hypoglycaemia. Reactive hypoglycaemia, unaccompanied by fasting hypoglycaemia, occurs in up to 2 per cent of patients harbouring insulinomas.

Clinical features

Typically, patients present with a history of transient episodes of dizziness, anxiety, palpitations, sweating, hot flushes, and even convulsions or brief periods of altered consciousness extending over a period of 1 to 30 years. Between episodes they are well and asymptomatic. Patients rarely notice any relationship of

symptoms to food but may do so when prompted. Physical, including radiological, investigation is generally normal except in alimentary hypoglycaemia. In them, but few others, food-induced reactive hypoglycaemia may be of sufficient severity as to cause loss of consciousness.

Acute-neuroglycopenia-like symptoms experienced by some patients with the postprandial syndrome are rarely associated with any abnormality of glucose homeostasis or insulin secretion though exaggerated enteroglucagon, GIP, and *t*GLP-I response to food may occur. What role, if any, these hormones play in the aetiology of the syndrome is unknown. Some patients with these symptoms are sensitive to modest reductions in blood glucose concentration to which most healthy subjects would be oblivious and in them the possibility of non-hypoglycaemic neuroglycopenia may be entertained.

Alcohol-induced reactive hypoglycaemia

Symptomatic reactive hypoglycaemia may occur in healthy young subjects after ingesting a mixture of alcohol, sucrose, and quinine given as gin and tonic and, less commonly, with other mixtures of alcohol and carbohydrate on an empty stomach. Simultaneous ingestion of carbohydrate-rich snacks increases the severity of the hypoglycaemia; snacks rich in fat reduce it.

Diagnosis

Diagnosis of reactive hypoglycaemia is suggested by the clinical history and confirmed or refuted by glucose measurements made on capillary blood collected during spontaneous symptomatic episodes. Other laboratory tests, including measurement of plasma insulin, C-peptide, proinsulin, and b-hydroxybutyrate are used to exclude conditions such as non-insulinoma pancreatogenous hypoglycaemia, autoimmune insulin syndrome, and other conditions that do not produce hypoglycaemia during fasting but do require specific treatment.

Capillary blood glucose concentrations of less than 3.5 mmol/l, measured in an accredited laboratory on two or more occasions, establishes hypoglycaemia as a factor in the symptomatology. The oral glucose load test, formerly the lynch-pin for diagnosis, may be frankly misleading especially when conducted on individuals who have taken a self-prescribed low carbohydrate diet (<100 g/day) and should rarely be employed. A standard glucidic breakfast providing 100 g of readily assimilated starchy food has been advocated in its stead but is seldom indicated.

Treatment

Prevention of fluctuations in blood glucose is key to the management of reactive hypoglycaemia and is achieved by minimizing intake of rapidly absorbed carbohydrates such as sucrose, bread, and potato starch. Frequent small meals, rich in dietary fibre—and taken without alcohol—offer the best chance of symptomatic relief. Incorporation of soluble dietary fibre supplements, such as guar and glucomannan, in meals and taking a-glucosidase inhibitors, such as acabose and miglitol, with them reduce blood glucose excursions but their side-effects are often worse than discomfort from minimal hypoglycaemia.

Prognosis

Idiopathic postprandial syndrome is a self-limiting disorder but may be resistant to all physical treatments. Some patients respond well to psychotherapy and/or avoidance of alcohol.

Autoimmune hypoglycaemia

Autoimmune diseases are important causes of spontaneous hypoglycaemia. Three main types are recognized.

Autoimmune insulin syndrome

The autoimmune insulin syndrome occurs throughout the world but is rare outside Japan. It is due to polyclonal autoantibodies to insulin resembling those produced in response to exogenous insulin but more likely to bind proinsulin and its cleavage products including C-peptide.

Hypoglycaemia typically occurs as a late response to the ingestion of food. Insulin secreted early in response to a meal is sequestered by antibodies present in the plasma and rendered temporarily inactive. Dissociation of the insulin–antibody complex, after absorption is complete, produces an inappropriately high free plasma insulin level resulting in hypoglycaemia. This, though often profound, is of limited duration, rarely leading to coma and never to death.

There is often a history of autoimmune disease affecting other organs, especially the thyroid, and many patients have received treatment with methimazole, carbimazole, or other thiol-containing drugs.

Free plasma insulin concentrations are always inappropriately high and C-peptide usually depressed during hypoglycaemia. C-peptide concentrations may, however, be normal or high depending on the binding characteristics of the autoantibody.

Treatment is dietary and aimed at avoiding excessive insulin secretion in response to meals until spontaneous remission occurs, usually within a few years of onset. Surgery, in the mistaken belief that the patient has islet hyperplasia or insulinoma, must be avoided.

Insulin-receptor autoantibodies

Hypoglycaemia due to insulin-receptor autoantibodies is rare but may be the first indication of the causative disease. More often it develops in a patient already known to be suffering from an autoimmune disease or a neoplasm—especially lymphoma. Typically, hypoglycaemia is intractable but occasionally occurs only in response to food. Its immediate cause is binding of stimulatory autoantibodies to insulin receptors on hepatic and peripheral cell membranes, simulating the effects of insulin itself.

Clinically, the symptoms are indistinguishable from that of insulinoma though usually of shorter duration and greater severity. Plasma C-peptide and proinsulin concentrations are low (<20 pmol/l). Plasma insulin, though also often low, may be very high (>1000 pmol/l) due to its delayed clearance from the blood. Diagnosis can usually be inferred from the clinical associations and evidence suggestive of hyperinsulinism, that is coincident low blood glucose and b-hydroxybutyrate, but depressed plasma C-peptide, proinsulin (and usually insulin), concentrations rule it out. Definite diagnosis depends upon demonstrating antireceptor antibodies in the patient's plasma using *in vitro* bioassay techniques.

Treatment is that of the primary disease. Glucocorticoids and other immunosuppressants have been used with benefit in some cases but although remissions may occur, the prognosis is generally poor.

Islet-cell-stimulating antibodies

Antibodies capable of stimulating insulin release from isolated pancreatic b-cells *in vitro* have been held responsible for a form of hyperinsulinaemic hypoglycaemia analogous to Grave's disease of the thyroid. The evidence is, however, inconclusive.

Drug and toxin-induced hypoglycaemia

Medicines and toxins, such as alcohol, paracetamol, quinine, *Amanita* (toadstools), and *Blighia* (ackee) are collectively amongst the most frequent causes of non-iatrogenic hypoglycaemia. They produce their effects in various ways, mostly by interfering with hepatic glucose production, counter-regulatory hormone action, or by stimulating insulin secretion.

Alcohol hypoglycaemia

Alcohol-induced hypoglycaemia is the most common cause of non-iatrogenic hypoglycaemia. The patient is usually stuporose or comatose. Sometimes they are aggressively unco-operative and their symptoms attributed to alcoholic intoxication rather than to hypoglycaemia. Characteristically, hypoglycaemia develops within 6 to 36 h of the ingestion of moderate to large amount of alcohol (>30 g) by fasting or malnourished subjects who may be, but often are not, habituated to alcohol. Hypothermia is more common than with other causes of hypoglycaemia and may provide the first clue to diagnosis. Children, in whom there is a 25 per cent mortality, are particularly susceptible to this type of hypoglycaemia.

Blood glucose is less than 2.5 mmol/l and alcohol almost always present, generally at a concentration below 20 mmol/l (100 mg/100 ml). Plasma and urinary ketones are high but often overlooked because traditional tests for ketones detect only acetone and acetoacetate rather than b-hydroxybutyrate—the redox pair member normally present in alcoholic ketoacidosis.

Once considered, the diagnosis is seldom in doubt and is due to inhibition by alcohol of hepatic gluconeogenesis from lactate and glycerol. It can be confirmed by demonstrating hypoglycaemia, raised plasma b-hydroxybutyrate, and low plasma insulin, C-peptide, and proinsulin levels together, in most cases, with measurable amounts of alcohol.

Consciousness can be restored with intravenous glucose but not glucagon—which is ineffective. Long-term treatment is avoidance of the predisposing factors.

Accidental, factitious, and felonious hypoglycaemia

In these states, although hypoglycaemia is due to exogenous hypoglycaemic agents, this fact is not revealed by the history. The correct diagnosis emerges only from critical examination of laboratory test results and other non-clinical or forensic evidence. Typically the patient is hypoglycaemic and stuporose or comatose when first seen and—unless the possibility of drug-induced hypoglycaemia is suspected from the outset, and appropriate samples of blood and urine collected for insulin, C-peptide, proinsulin, and sulphonylurea assay—the correct diagnosis may never be made.

Sulphonylureas

Dispensing or prescription errors are an important cause of hypoglycaemia—a sulphonylurea being substituted for another drug with a similar name (e.g. diabinese™ for diamox™). In hospital, victims of accidental hypoglycaemia often have received medication intended for someone else. Because patients are often elderly and slip slowly into hypoglycaemic coma without warning, the diagnosis may be delayed or missed completely.

Deliberate sulphonylurea overdose with suicidal or felonious intent is uncommon. It may be difficult to distinguish from accidental overdose in a diabetic patient unless the plasma sulphonylurea level is abnormally high or a suicide note is found. Treatment with diazoxide and intravenous glucose may be required for many days to prevent recurrent hypoglycaemia.

Insulin

Factitious insulin-induced hypoglycaemia is as common in previously healthy subjects as in insulin-dependent diabetics and is due to deliberate, but concealed, injection of insulin. The history suggest insulinoma but is eliminated by the laboratory results which reveal high plasma insulin and low C-peptide (and proinsulin) concentrations during hypoglycaemia. In long-standing factitious hypoglycaemia, and in insulin-treated diabetics, insulin antibodies may be present in the plasma. Although once considered a strong pointer to factitious hypoglycaemia, the presence of insulin antibodies should nowadays suggest autoimmune insulin syndrome.

Suicidal overdosing with insulin is not confined to diabetic patients and is usually unsuccessful. Most patients are found within 12 h of injecting themselves and are restored to consciousness by appropriate treatment. Plasma C-peptide is unrecordably low and (free) insulin concentrations generally greater than 2000 pmol/l. In factitious hypoglycaemia, a form of Munchausen syndrome, plasma insulin concentrations are generally lower than this.

Murder or attempted murder with insulin is exceedingly rare and virtually confined to infants, critically ill patients, and the elderly. The victims are often dead when first seen; if suspected, the diagnosis can be made retrospectively by demonstrating inordinately high concentrations of insulin in blood drawn from a peripheral blood vessel or in tissue removed from the putative injection site. Blood, cerebrospinal fluid, and vitreous glucose measurements are uninterpretable after death.

Organ failure

Hypoglycaemia can occur, sometimes as a dominant feature, in almost any serious and life threatening illness. Most notably are: congestive cardiac failure; acute liver failure; chronic renal failure; bacterial, viral, and parasitic infections (especially malarial); and terminal malnutrition. The cause of the hypoglycaemia is seldom in doubt but its recognition and restoration of normoglycaemia sometimes dramatically alters the course of the illness.

Endocrine hypoglycaemia

Hypoglycaemia is a rare but important presenting sign of several endocrine disorders of which Addison's disease, pan-hypopituitarism, and isolated ACTH deficiency are the most common. The typical clinical features of endocrinopathy are inconspicuous and the diagnosis may be missed unless specifically sought through appropriate laboratory testing. Paradoxically, reactive hypoglycaemia is a rare manifestation of pheochromocytoma with which its symptomatology may be confused. Primary glucagon deficiency has only once been documented as a cause of hypoglycaemia.

Inborn errors of metabolism

Many inborn errors of carbohydrate metabolism—which usually present as hypoglycaemia in childhood—can first manifest themselves in adult life. Mild variants may be responsible for obscure cases of hypoglycaemia which occur only under very stressful conditions, such as prolonged fasting or exceptionally violent exercise, and for which no endocrine or organic cause can be found.

12.12 Hormonal manifestations of non-endocrine disease

H. E. Turner and J. A. H. Wass

Introduction

Several endocrine syndromes may develop in association with diseases that are not primarily disorders of an endocrine gland. In most the cause is a tumour, usually but not invariably malignant, that develops in tissue not normally looked upon as the site of the particular hormone synthesized. Other 'non-endocrine conditions' may also be associated with either hormonal excess or deficiency, for example sarcoidosis and AIDS. Certain drugs may also modify hormonal biochemistry and cause hormonal imbalance syndromes.

Syndromes of ectopic hormone secretion

In 1941, Albright suggested that the hypercalcaemia sometimes associated with malignant disease without osteolytic metastases might be due to the secretion by the tumour of a parathyroid hormone-like peptide; we now know that this is true (parathyroid hormone related protein, PTHrP). Later it was shown that hypersecretion of adrenocorticotrophin (ACTH), not from the pituitary but from an ectopic site, was the cause in about one-fifth of patients with Cushing's syndrome.

Although 'ectopic' hormone secretion has classically been recognized in the context of neoplasia, and defined as the release of a hormone from a site different from the gland that normally produces the hormone, it is increasingly being recognized that many hormones are synthesized by 'non-endocrine' tissue. Thus the syndromes of neoplastic ectopic hormone secretion are actually due to the pathological over-secretion and/or inappropriate production of hormones. Increasing recognition of the importance of paracrine secretion of hormones such as insulin-like growth factors (IGF-1), their modulation by growth factors and binding proteins, for example IGFBPs1, 2, and 3, and their role in progression of neoplasia adds greatly to these complexities.

Many different hormones are ectopically secreted by neoplasms arising in diverse organs, notably the bronchus, breast, pancreas, kidney, and ovary as well as in mesenchymal tissue. Although a particular endocrinopathy may be associated with a specific type of tumour in a particular organ, the relationship is not invariable. An example is the lung, where squamous cell carcinomas are often associated with hypercalcaemia due to parathyroid hormone related peptide, while small cell lung cancer and bronchial carcinoid tumours are both associated with ectopic ACTH secretion, but with very different clinical manifestations. Indeed, many neoplasms elaborate more than one hormonal substance at the same or at different times and thus may produce a mixed endocrine picture (for example pancreatic endocrine tumours producing ACTH and insulin). Furthermore, the amount of ectopic hormone(s) produced may fluctuate from time to time (for example cyclical Cushing's syndrome in ectopic ACTH secretion). In some instances, the changes induced by the ectopic hormone may mimic very closely, and be clinically indistinguishable, from those found in the true endocrinopathy. In others, the picture is less characteristic and dominated more by abnormalities of biochemistry or hormone levels. Thus, in many cases of ectopic ACTH production by small cell lung cancer, the downhill course of the illness may be too rapid for the classical features of florid Cushing's syndrome to develop, and hypokalaemic alkalosis with diabetes predominates.

Criteria for diagnosis

The diagnosis of ectopic hormone production depends on a number of criteria, although it is seldom practicable or possible to confirm them all:

1. There is an association of the tumour with an endocrine syndrome.
2. Even though the endocrine syndrome may not be clinically florid, there is an elevated or inappropriately raised plasma level of the putative hormone.
3. Removal or suppression of the tumour induces a regression of the endocrinopathy and a fall in the hormone level.
4. The clinical picture and hormone levels are uninfluenced by removal of the gland that normally secretes the hormone.
5. The hormone level is higher in venous blood draining the tumour than in the arterial blood supplying it.
6. Extraction or immunohistochemical staining shows a higher concentration of the hormone in the tumour than in adjacent, non-involved tissue.
7. Demonstration can be made of tumour cell synthesis of identifiable hormones *in vitro* or of mRNA coding for the hormone.

Chemical structure

Most syndromes of ectopic hormone secretion are due to peptide hormones. It is rare for tumours to secrete steroid hormones because of the complexity of the enzyme cascade required for steroid biosynthesis. Tumours may, however, be associated with altered steroid metabolism—for example increased aromatase activity in hepatocellular carcinoma leads to feminization and gynaecomastia due to androgen conversion to oestrogens.

The precise amino acid sequences of hormones of ectopic origin are being increasingly defined. In general, they appear to resemble closely those of their normally occurring counterparts (except parathyroid hormone (PTH) and PTHrP). There is a tendency for a greater proportion of higher molecular weight precursors, prohormones, or subunits and fragments to be associated with an ectopic origin than with 'true' endocrinopathies but it is not always clear whether this is due to differences in biosynthesis or in intracellular or extracellular processing. Minor differences in molecular structure are sometimes reflected in disparities between

bioassay and immunoassay.

Prevalence

Clinically evident syndromes are less common than biochemical or hormonal abnormalities. The prevalence of ectopic production of ACTH, corticotrophin-releasing hormone (CRH), parathyroid hormone related protein (PTHrP), calcitonin, chorionic gonadotrophin (hCG), prolactin, or growth hormone, without clinical manifestations, is high when extensive biochemical and hormonal assays are applied to patients with cancer. These assays bring closer the prospect of finding a diagnostic 'marker' for tumours in general and, in particular, as is already the case with the monitoring of hCG or its subunits, to determine the response of tumours to treatment.

Hypercalcaemia in the absence of detectable bony metastases is the most common abnormality. It occurs in about 15 per cent of patients with squamous cell carcinoma, usually of the bronchus, carcinoma of the kidney, ovary, or breast. Next most common in neoplastic diseases is the syndrome of inappropriate antidiuresis (SIAD), usually associated with a small cell lung cancer and reported in 40 per cent of such cases. Cushing's syndrome due to ectopic ACTH or CRH secretion occurs in about 5 per cent of patients with small cell lung cancer, and in association with other neoplasms. Biochemical accompaniments of Cushing's syndrome in the absence of the clinical features are much more common, occurring in 50 per cent of patients with small cell lung cancer.

Pathogenesis

As techniques for molecular analyses have evolved, it has become clear that every somatic cell is capable of synthesizing every polypeptide hormone. However, only under pathological circumstances is that capability ever likely to be expressed. A variety of hypotheses for ectopic hormone synthesis and secretion have been made. None explains all of the observed facts. Fundamentally, all cells inherit an identical complement of DNA. They are therefore totipotential and have all the coded information required for the synthesis of all proteins and peptides, including protein hormones. The normal inability of non-endocrine tissue to synthesize hormones is ascribed to 'repressors' that mask specific segments of the DNA molecule. It seems possible that when a cell becomes malignant this normal repression becomes ineffective, allowing the unmasked DNA to synthesize proteins or peptides 'foreign' to the cell concerned. Such a 'de-repression' hypothesis does not explain why certain tumours are more prone to secrete certain ectopic hormones. Neuroendocrine cells, characterized by the presence of peptide hormone granules, are likely to be the origin of some tumours associated with hormone secretion, such as small cell lung cancer and bronchial carcinoids. Another hypothesis suggests that there are a small number of special proliferative cells in normal mature tissues that have fetal characteristics with the ability to produce peptide hormones—a process of 'dysdifferentiation' rather than 'de-repression'. There is currently no unifying mechanism with supportive experimental evidence to explain ectopic hormone production. Further information on the control of gene expression and hormone production, the role of oncogenes, and paracrine growth factors may provide further insight.

Treatment

Treatment of the clinical or biochemical abnormalities associated with endocrinopathies of non-endocrine origin is best directed at the primary disorder. In neoplastic disease, this may involve surgical excision, radiotherapy, or chemotherapy. Sometimes the tumour secreting the ectopic hormone is extremely difficult to locate even with the use of sophisticated imaging techniques such as magnetic resonance imaging (MRI), radiolabelled isotope scanning (e.g. ^{111}Indium-penetreotide imaging), or using selective venous catheterization.

More specific therapy may be necessary to contain the metabolic abnormality until such time as the fundamental disorder can be controlled. For example immediate measures may be required to reduce hypercalcaemia with fluids and bisphosphonates, or steps taken (administration of metyrapone) to diminish corticosteroid secretion from adrenal glands stimulated by ectopic ACTH secretion.

Ectopic secretion of calciotropic hormones

Malignancy is the most common cause of hypercalcaemia in the hospital inpatients and may be due to direct tumour spread to the bones or related to secreted calcium-releasing factors. Often several different mechanisms are involved in the same patient.

After its discovery in 1987, it was shown that PTHrP is responsible for hypercalcaemia in up to 70 per cent of patients with this tumour-associated phenomenon. PTHrP shares amino acid homology with PTH between positions 2 and 13 of the 84 residues of PTH and acts via the PTH receptor. The PTHrP gene is located on the short arm of chromosome 12; that of PTH is on chromosome 11. The PTHrP gene may be activated by transactivation, hypomethylation (renal carcinomas), or the effect of growth factors and cytokines, including IGF-1 and epidermal growth factor, while glucocorticoids and vitamin D_3 suppress PTHrP levels. Unlike PTH-mediated hypercalcaemia, dihydroxycholecalciferol is suppressed in PTHrP-mediated hypercalcaemia. PTHrP is made by squamous carcinomas as well as renal, bladder, ovary, skin, pancreas, and breast carcinomas, and lymphomas.

Other factors can be involved in hypercalcaemia unassociated with osseous metastases. 1,25-Dihydroxy vitamin D_3 is not uncommonly made by lymphoproliferative tumours, which are either high grade or widely disseminated. Transforming growth factor-a (TGFa) which stimulates osteoclastic bone resorption, is also made by squamous carcinoma, and renal and breast carcinomas. Some tumours cosecrete both TGFa and PTHrP. Interleukin-1, which is a very powerful stimulator of osteoclastic bone resorption, is also made by squamous carcinomas as well as some haematological malignancies. Tumour necrosis factor (TNF) and lymphotoxin also stimulate osteoclastic bone resorption. These related cytokines cause hypercalcaemia *in vivo*; lymphotoxin is produced by cultured myeloma cells *in vitro* and accounts for the hypercalcaemia seen in this condition. Prostaglandins of the E series may also cause hypercalcaemia.

It is important to remember that primary hyperparathyroidism itself is common, particularly in the elderly; two diseases may coexist. For this reason, primary hyperparathyroidism should always be considered when hypercalcaemia occurs, even if it is in a patient within the setting of malignant disease. It is now possible to differentiate between these two conditions by using the PTH two-site radioimmunoassay.

Paraneoplastic hypercalcaemia may be either asymptomatic or dominate the clinical picture and be life-threatening as a consequence of dehydration and renal failure. The features of hypercalcaemia and its general management are discussed elsewhere (see Chapter 12.6).

Oncogenic osteomalacia is a rare syndrome usually associated with benign mesenchymal tumours (e.g. haemangiopericytomas) where phosphaturia, hypophosphataemia, and normocalcaemia are associated with suppressed 1,25 dihydroxy vitamin D. It may be due to an unknown phosphaturic factor which also inhibits 1-a-hydroxylase.

Syndrome of inappropriate antidiuresis (SIAD)

This syndrome is usually, but not invariably, associated with high levels of circulating arginine vasopressin. Other, as yet unidentified, antidiuretic substances are sometimes involved. There is hyponatraemia and impaired water excretion in the absence of hypovolaemia, hypotension, or deficiency of cardiac, renal, thyroid, or adrenal function. Associated with hyponatraemia, there is a reduction in plasma osmolality and inappropriately normal/low urine concentration.

Bronchogenic carcinoma is the commonest malignancy associated with SIADH. Although SIADH in association with malignancy may be due to the tumour itself, it may also result from treatment (e.g. chemotherapy such as cyclophosphamide), an intercurrent illness such as pneumonia, or a complication such as hydrocephalus or cerebrovascular accident (Table 1).

Ectopic ACTH secretion

Pro-opiomelanocortin (POMC) is a 31 kDa precursor for both ACTH and b-lipotrophin as well as for other polypeptides derived from it, including g-lipotrophin and b-endorphin. A variety of non-pituitary tumours are capable of secreting POMC-derived peptides, accounting for about 20 per cent of patients with Cushing's syndrome. Approximately 50 per cent of these ectopic ACTH-producing tumours are in the lung and the rest are present in a variety of other tissues (Table 2). Some tumours, particularly pancreatic islet cell tumours which are seldom (< 5 per cent) associated with Cushing's syndrome, can, in addition to ACTH, also secrete a number of other hormones, including insulin, gastrin, and glucagon (see Chapter 12.10). This accounts for the usefulness, when screening for ectopic ACTH, of measuring other hormones (e.g. calcitonin, hCG) which may be cosecreted, the presence of which raises the suspicion of an ectopic hormone-secreting tumour. Very

rarely, corticotrophin releasing hormone (CRH) is secreted ectopically in association with ACTH.

While small cell lung cancer is the most common source, carcinoids anywhere, but particularly bronchial carcinoids, phaeochromocytoma, and medullary carcinoma of the thyroid may also secrete ACTH ectopically (Table 2).

The exact mechanism of synthesis of ectopic POMC-derived peptides is still debated. POMC mRNA can be found in the majority of tumours, but ACTH secretion is much less common, probably due to the lack of the signal sequence required for translocation. Changes in promoter usage and also in POMC processing may lead to ectopic secretion of ACTH. In addition, many tumours associated with ectopic ACTH secretion are of neuroendocrine morphology and may arise from progenitor cells associated with ACTH secretion.

Presentation

The clinical picture is variable. In patients with small cell lung cancer who have a rapidly progressive tumour, the physical features of Cushing's syndrome may not have time to develop. The major features are weight loss, proximal muscular weakness, polyuria, thirst, oedema, carbohydrate intolerance with glycosuria, and sometimes pigmentation due to ACTH. Hypokalaemic alkalosis is a characteristic finding; the plasma potassium is less than 3.2 mmol/l and the bicarbonate greater than 30 mmol/l, the urine potassium loss being the direct cause of most of the symptoms. This hypokalaemia is in part due to the very high cortisol levels, which have a mineralocorticoid action, and corticosterone and 11-deoxycorticosterone which may also be produced in excess. The 11b-hydroxysteroid dehydrogenase enzyme may also function abnormally, causing decreased inactivation of cortisol and corticosterone. The serum cortisol level is usually greatly elevated (>1000 nmol/l) and the plasma ACTH level is also raised (>200 µg/l). These high levels do not usually occur in pituitary-dependent Cushing's disease.

When the ectopic sources are other than a small cell lung cancer, the clinical manifestations may be quite indistinguishable from Cushing's disease and cushingoid features may antedate by months or years any evidence of a tumour causing ectopic ACTH secretion. The degree of elevation of ACTH is less marked than with small cell lung cancer and is proportional to tumour size. Some carcinoid tumours may be small and difficult to locate. The real problem is to differentiate ectopic ACTH secretion from pituitary-dependent disease (Table 3). The presence of a hypokalaemic alkalosis(< 3.2 mmol/l) is very useful test in the differential diagnosis. Lack of suppression on high-dose dexamethasone testing is found in 90 per cent patients with ectopic disease, but also up to 20 per cent with pituitary disease. However, the CRH test is very useful in differentiation as patients with ectopic ACTH secretion show an absent rise in cortisol whereas pituitary dependent disease is associated with an exaggerated response in 95 per cent patients. Because most of the tumours secreting POMC are in either the chest or abdomen, MRI or computed tomography (CT) will often reveal the source of ectopic hormone secretion. In patients in whom the lesion is not readily visible by imaging techniques, selective venous catheterization and sampling may help determine a source of ACTH by comparing levels at various sites within the venous system. Such sampling should include inferior petrosal sinuses in case of pituitary-dependent disease.

Treatment

Removal of the primary growth or its control with radiotherapy or chemotherapy will relieve the endocrine manifestations. A relapse may occur if metastases develop because these, too, usually secrete ACTH. When it proves impossible to control a primary tumour, adrenocortical hypersecretion may be reduced by 'medical adrenalectomy', giving the 11b-hydroxylase inhibitor of the conversion of 11-deoxycortisol to cortisol, metyrapone (500–4000 mg/day). Aminoglutethimide (1000–1500 mg/day) may also be used but frequently causes a skin rash. Ketoconazole (400–800 mg/day), which can cause fatal liver damage, and the adrenolytic drug mitotane are also useful. RU-486, a glucocorticoid antagonist at the receptor level, has been used as palliative therapy for some patients (10–30 mg/kg per day). Lastly, the long-acting somatostatin analogue, octreotide (0.3 mg/day, subcutaneously), has also been used in the treatment of ectopic ACTH syndrome.

Bilateral adrenalectomy is an alternative approach, but frequently it is not practical for patients with rapidly progressive metastatic disease. It may be possible to embolize the arterial supply of the adrenal gland if patients are not suitable surgical candidates for adrenalectomy. Medical treatment needs to be monitored carefully so that adrenal insufficiency is avoided.

Ectopic secretion of insulin-like growth factors

The insulin-like growth factors, IGF-I and II, share some sequence homology and actions of insulin. IGF-II is important in fetal growth, whereas IGF-I, synthesized in the liver, mediates most of the actions of growth hormone. IGFs circulate bound to one of six binding proteins (IGFBPs). Of these, the most important is IGFBP3, which itself is growth hormone-dependent and binds 75 per cent of IGF-I and IGF-II.

IGF-II secretion from tumours may be associated with hypoglycaemia. Usually the tumour is large and of mesenchymal origin, arising in the abdomen or thorax. Symptoms are those of neuroglycopenia—sweating, tachycardia, disorientation, drowsiness, fits, and coma. Histology shows a mesothelioma, a fibrosarcoma, or other sarcoma such as a leiomyosarcoma. Other neoplasms associated with hypoglycaemia are haemangiopericytoma, hepatoma, adrenal carcinoma, lung carcinoma, Wilms' tumour, and colonic carcinoma.

IGF-II secretion leads to suppression of growth hormone and insulin, and reduced production of IGFBP3, IGF-I, and acid labile subunit (ALS), leading to reduced formation of the IGF–IGFBP3–ALS complex which protects the IGFs from degradation. IGF-II circulates as a smaller complex which has enhanced tissue and receptor bioavailability, allowing access to the insulin receptor. There is also an increase in the large molecular weight molecules and the increased amounts of 'big' IGF-II not detected on radioimmunoassay. Growth hormone deficiency, decreased gluconeogenesis, and increased glucose metabolism by the tumour, which is usually large, may also contribute to hypoglycaemia. Treatment of these tumours is difficult. The hypoglycaemia is often not responsive to diazoxide, glucagon, octreotide, or corticosteroids. However, administration of growth hormone may be effective—increasing IGFBP3 and IGF-I and antagonizing the effect of excess IGF-II. The underlying tumour may be resistant to radiotherapy; surgery, although effective if possible, is not always feasible.

IGF-I and IGF-11 may also play an important role in tumour progression. Studies of breast cancer cells have suggested that IGF-I may have local mitogenic effects, and a role for IGF-II has recently been proposed in hepatocellular, colorectal, and adrenocortical tumours.

Ectopic human chorionic gonadotrophin secretion

Human chorionic gonadotrophin is a glycoprotein consisting of an a- and a b-subunit. The a-subunit is species specific and is the same for all glycoprotein hormones (luteinizing hormone (LH), follicle stimulating hormone (FSH), and thyroid stimulating hormone (TSH)). The b-subunit determines receptor interaction and specific hormone activity. The b-subunit of hCG is very similar to that of LH and this can cause problems with cross-reaction in assays. Clinically silent, ectopic secretion of hCG, with or without its free a- and b-subunits, occurs in many patients (Table 4).

In the first decade of life, ectopic hCG production may cause isosexual precocious puberty in boys with hepatoblastoma. hCG, through its LH-like action, causes Leydig cell stimulation in the testes. In turn, testosterone levels reach those of a normal adult, and secondary sexual characteristics develop together with premature skeletal maturity. The testes remain small because there is no seminiferous tubule growth as this is dependent on FSH. Precocious puberty is rare in girls.

Intracranial teratoma, choriocarcinoma, and pinealoma are associated with ectopic hCG secretion. In men this may be associated with gynaecomastia. In some this is due to cosecretion of oestrogen which may, in women, be associated with dysfunctional uterine bleeding. Other tumours associated with hCG secretion are testicular tumours, ovarian adenocarcinoma, and stomach, pancreatic, and liver tumours.

hCG is a useful tumour marker in gestational trophoblastic disease (choriocarcinoma) and in some men with testicular tumours, and provides an early warning of recurrent disease. However, it is important to measure other tumour markers, for example a-fetoprotein, which may also be secreted by non-seminomatous germ cell tumours. Discordance of marker levels and tumour progress may be seen. In central nervous system disease, cerebrospinal fluid/plasma ratios may help in the correct localization of tumours, as hCG does not cross the blood–brain barrier and levels in cerebrospinal fluid remain undetectable in pregnancy. Thus, cerebrospinal fluid concentrations higher than plasma suggest primary central nervous system disease.

In some patients, most commonly with choriocarcinoma and massive elevation of hCG, the latter, through its weak TSH activity, due to its biochemical similarity to TSH, may cause goitre and hyperthyroidism. This most frequently occurs in women, is not associated with eye signs, and is usually associated with modest biochemical abnormalities. Treatment of the tumour results in a resumption of a euthyroid state but, if this is not possible, carbimazole or propylthiouracil may be

required.

Ectopic human placental lactogen

Human placental lactogen (hPL), also called human chorionic somatomammotropin (hCS), is a trophoblastic hormone which may be secreted ectopically in association with lung tumours, testicular tumours, and trophoblastic disease. It is usually associated with gynaecomastia in men, and these tumours may also be associated with increased levels of oestradiol and hCG.

Ectopic growth hormone releasing hormone and growth hormone secretion

Most patients with acromegaly (98 per cent) have benign growth-hormone-producing pituitary adenomas. Less than 2 per cent of patients with acromegaly have ectopic growth hormone releasing hormone (GHRH) production. A patient with a carcinoid tumour of the pancreas producing GHRH enabled the final elucidation of the structure of this important hypothalamic peptide which stimulates anterior pituitary growth hormone secretion. Besides the pancreas, lung carcinoid tumours, small cell lung cancer, and phaeochromocytoma may produce GHRH ectopically and cause acromegaly by stimulation of the pituitary somatotrophs. Histologically, the two can be differentiated by the presence of somatotroph hyperplasia in ectopic GHRH secretion. These tumours are usually clinically apparent and GHRH levels in the circulation are elevated. GHRH can also be secreted by hypothalamic hamartomas, which also result in anterior pituitary somatotroph hyperplasia.

Ectopic growth hormone secretion has been reported in patients with bronchial, pancreatic, and gastrointestinal carcinoma, and cells cultured from an undifferentiated lung cancer have been shown to synthesize growth hormone *in vitro*. Breast carcinoma and ovarian tumours may also occasionally secrete growth hormone but no clinical syndrome has been clearly identified as caused by ectopic growth hormone.

Ectopic prolactin secretion

Prolactin may be secreted by bronchial carcinoma and renal cell carcinoma; the usual endocrine manifestation is galactorrhoea and there may be marked hyperprolactinaemia. These abnormalities are reversed if the tumour is controlled or removed. Difficulties in differential diagnosis may arise unless the underlying abnormality is clinically obvious or suspected, because in most instances the hyperprolactinaemia will be attributed to a prolactin-secreting adenoma. Suspicion of an ectopic source may only arise when the prolactin level is not lowered by bromocriptine treatment. An autocrine role for prolactin in breast and prostate cancer has recently been postulated.

Ectopic calcitonin secretion

Increased serum calcitonin levels are encountered in a variety of cancers apart from medullary carcinoma of the thyroid. The most common of these are small cell lung cancer, leukaemia, and neoplasms of the breast and pancreas. It is often produced as part of a multihormonal profile in conjunction with, for example, gastrin, ACTH, and somatostatin. Ectopic calcitonin may differ from the normal hormone in having more high molecular weight components; it does not cause any apparent symptoms and does not produce hypocalcaemia.

Ectopic renin secretion

Although hypertension associated with hyper-reninism and increased aldosterone production is usually due to a renal lesion, ectopic secretion of renin has also been described in association with cancer of the lung, pancreas, and ovary. The clinical picture is usually dominated by the underlying neoplasm but the patient has hypertension and the cause of this may be suspected from the associated hypokalaemia and its accompanying muscle weakness. Effective treatment of the primary lesion will reduce the increased renin and aldosterone levels and hence the raised blood pressure. When the underlying cause cannot be eradicated, the use of an angiotensin enzyme inhibitor will control the hypertension.

Ectopic aldosterone secretion

Hypertension and hypokalaemia related to ectopic secretion of aldosterone from a non-adrenal neoplasm have been described in patients with ovarian tumours. Its pathogenesis is different from the others described in this section. The aberrant production of a steroid, aldosterone, rather than a peptide, is presumably due to biochemical change in the ovarian steroidogenic cells. Attention is likely to be focused on a suspected lesion of the adrenal zona glomerulosa because the hyperaldosteronism is associated with low plasma renin activity. The ovarian lesion may initially be clinically silent and only revealed by pelvic imaging.

Endocrine manifestations of non-endocrine diseases

Systemic disease of non-endocrine glands may influence endocrine function due to a specific effect of the disease itself, due to a general response to either acute or chromic illness, or due to drug therapy used to treat the illness itself (Table 5). Often hormonal perturbations may be a complex mixture of all of these mechanisms, as may be seen for example in AIDS or critically ill patients on intensive therapy units. This section includes examples of systemic disease causing endocrine disorders.

A commonly encountered hormonal disturbance encountered in many hospital inpatients is the 'sick euthyroid syndrome'. Peripheral conversion of T_4 to T_3 is reduced, and typical thyroid function tests in this syndrome are a normal or reduced TSH in association with reduced T_3 and T_4 (and increased rT_3 if measured). Severe illness may also interfere with hypothalamopituitary function and lead to hypogonadotrophic hypogonadism. Possible mechanisms include increased cortisol levels, stress, cytokines, or opioids given as analgesia.

Disorders influencing hypothalamopituitary function

Anorexia nervosa is associated with complex changes in hypothalamopituitary function, with reduction in GnRH and gonadotrophin secretion leading to hypogonadotrophic hypogonadism but increased growth hormone secretion is associated with increased peripheral resistance to growth hormone.

Iron overload due to haematological conditions such as b thalassaemia major and to haemochromatosis may cause iron deposition in the anterior pituitary gland, and in particular in the gonadotrophs. This leads to hypogonadotrophic hypogonadism, which may be ameliorated to a degree by venesection and iron chelation therapy. Haemochromatosis may also lead to other hormonal changes due to pancreatic involvement causing diabetes mellitus, and cirrhosis associated with secondary hyperaldosteronism and hypogonadism.

Thyroid

Hyperemesis gravidarum in the first trimester of pregnancy may be associated with clinical and biochemical features of thyrotoxicosis, as the molecules hCG and TSH share very similar b subunits, allowing cross reactivity when high levels of hCG occur.

Opportunistic infections of the thyroid gland may occur, in conditions associated with immunosuppression such as AIDS. Infection with cytomegalovirus, *Cryptococcus*, and *Pneumocystis carinii* have been described. In addition, some patients with HIV infection have increased T_4 and T_3 due to increased thyroid binding globulin. As the disease progresses, T_4 and T_3 levels fall as patients develop biochemical features of sick euthyroidism.

Adrenal

Opportunistic infections (CMV, atypical mycobacteria, *Cryptococci*, *Toxoplasma*, and *Pneumocystis*), lymphoma and Kaposi's sarcoma may involve the adrenal glands in HIV and AIDS. The adrenal gland is the most commonly involved endocrine gland at autopsy. However, frank adrenal insufficiency is rare because this requires destruction of over 90 per cent of the adrenal cortex.

Gonads

Chemotherapy and irradiation may be associated with gonadal failure due to hypothalamopituitary gonadotrophin deficiency following, for example, cranial irradiation or due to testicular/ovarian damage following cytotoxic drug therapy such as cyclophosphamide, cisplatin, and busulfan.

Coeliac disease is associated with reversible male infertility due to androgen resistance, and improves on a gluten free diet. Alteration of gonadal steroid metabolism may occur in, for example, chromic liver disease, particularly if alcohol related. Elevated sex hormone binding globulin (SHBG) and oestradiol levels are associated with a reduction in bioavailable testosterone leading to testicular atrophy, gynaecomastia, and erectile impotence.

Gynaecomastia

Palpable breast glandular tissue is prevalent in population studies of men and boys. Subareolar glandular tissue more than 2 cm diameter is found in 35 to 60 per cent of men. Gynaecomastia may occur as a result of different conditions (Table 6) as well as drug therapy, and results from an alterations in the ratio of oestrogen to androgen. Gynaecomastia has been found in association with testicular and adrenal neoplasms, Klinefelter's syndrome, thyrotoxicosis, cirrhosis, primary hypogonadism, malnutrition, and ageing (Table 6). An increase in free oestrogen, a decrease in free endogenous androgens, androgen-receptor defects, and partially enhanced secretions of breast tissue may underlie these changes. Increased aromatization of oestrogen precursors occurs in patients with obesity, liver disease, and hyperthyroidism, and as a result of ageing.

Calcium

Hypercalcaemia in sarcoidosis is due to increased circulating 1,25 dihydroxy vitamin D. This is produced by alveolar macrophages in a dose-dependent fashion stimulated by g interferon, which is one factor responsible for the maintenance of the inflammatory process in sarcoidosis. Other granulomatous disorders (tuberculosis, histoplasmosis, coccidiomycosis, ruptured silicone breast implants) may rarely be associated with hypercalcaemia due to the same mechanism. Treatment with glucocorticoids or hydroxychloroquine are effective in lowering 1,25 dihydroxycholecalciferol and calcium.

HTLV-1 infection may be associated with hypercalcaemia, due to transactivation of the PTHrP gene on chromosome 12.

Drug-induced endocrine manifestations

Several pharmaceutical drugs may induce manifestations of endocrine disease. More commonly they may influence the results of hormonal assays and lead to mistaken diagnosis. It may not be a major problem when it is known that the patient is taking a particular compound and, from its molecular structure, it is appreciated that such a substance could influence the endocrine system or the results of hormonal assays. The problem is greater, however, when the drug in question has no clear relationship to a hormone and the mechanism by which it induces an endocrine manifestation, or interferes with an assay procedure, is not readily apparent.

Thyroid

Abnormalities of thyroid function test measurements

Drugs can interfere with thyroid function tests. Some act by inhibiting the conversion of thyroxine (T_4) to triiodothyronine (T_3), others by increasing thyroid-binding globulin. b-Blockers with membrane stabilizing properties, such as propranolol, inhibit peripheral conversion of T_4 to T_3. Oral cholecystographic agents and amiodarone, a heavily iodinated antiarrhythmic agent, are also potent inhibitors of T_4 to T_3 conversion and produce decreased serum T_3 concentrations and an increase in reverse T_3. Oestrogen increases thyroid-binding globulin, due to an increase in the sialic acid content of thyroxine-binding globulin, which prolongs its half-life in the circulation. Thus women on oestrogens, for example the contraceptive pill, have high total T_4 concentrations but are euthyroid. Such results may also be seen on tamoxifen. Heroin and methadone addicts also have raised levels of thyroxine-binding globulin, as do patients on the lipid-lowering agent, clofibrate.

A decreased serum T_4 does not necessarily indicate the presence of hypothyroidism. Many pharmacological agents lower the total T_4 concentration by interfering with the binding of T_4 to one or more of the thyroid-binding proteins. Therapeutic levels of phenytoin lower the level of serum T_4 and high concentrations are capable of inhibiting the binding of T_4 and T_3 to thyroid-binding globulin. High doses of salicylates have the same effect. Diclofenac, a non-steroidal anti-inflammatory drug structurally similar to thyroxine, also interferes with thyroid hormone binding. Phenylbutazone, anabolic steroids, and glucocorticoids may also be associated with a low total T_4 and normal thyroid function. Measurement of free thyroxine (fT_4) will obviate the problems of misleading results from the measurement of total T_4.

Drug-induced hyperthyroidism

Amiodarone may cause hyperthyroidism due to its high iodine content, or due to a destructive thyroiditis. Biochemically, there may be a marked elevation of total thyroxine, a relatively normal level of T_3, and a suppressed TSH. Often thyrotoxicosis is masked by the b-blocking effect of the drug. Because of the large iodine load, it may be very difficult to treat with antithyroid drugs, and steroids may also be necessary to suppress thyroid hormone levels into the normal range. Even if amiodarone is stopped, its effects continue for many weeks because it is predominantly stored in adipose tissue. Contrast media and iodine-containing cough medicines may similarly induce hyperthyroidism (Jod–Basedow phenomenon).

Drug-induced hypothyroidism

Increased iodide intake may also lead to decreased iodide trapping and a decrease in synthesis of thyroid hormones, hypothyroidism, and goitre. Iodine is contained in a number of 'tonics' and cough medicines. Amiodarone, besides producing thyrotoxicosis, may cause iodine-induced hypothyroidism in patients replete with iodine. Lithium blocks iodine uptake and the release of thyroid hormones. It also interferes with cAMP formation and thus inhibits the effects of TSH stimulation and may lead to goitre, although only 2 per cent of patients on lithium actually develop clinical features of hypothyroidism.

Adrenal cortex

Abnormalities of adrenal hormone measurements

Drugs may interfere with tests of adrenal function. Thus, for example, phenytoin accelerates metabolism of dexamethasone, and patients on phenytoin may not suppress cortisol normally during dexamethasone suppression tests. Furthermore, during the assessment of adrenal reserve, chronic topical application of steroids, as well as inhalation of steroids for asthma, may suppress adrenal function. Oestrogens, by enhancing hepatic production of cortisol-binding globulin, which binds between 90 and 97 per cent of circulating cortisol, increases cortisol-binding globulin two- to threefold. Thus, assessment of glucocorticoid replacement in patients on oestrogens is influenced by this effect and oestrogens should be stopped 6 weeks prior to the test.

Drug-induced Cushing's syndrome

Chronic, excessive intake of alcohol causes alcoholic pseudo-Cushing's syndrome. These patients behave biochemically as if they have Cushing's syndrome with absent dexamethasone suppression. This occurs through a centrally mediated mechanism with hypersecretion of pituitary ACTH and secondary secretion of cortisol by the adrenals.

Drug-induced primary aldosteronism

Primary aldosteronism can be mimicked by the mineralocorticoid effect of glycyrrhizic acid contained in both carbenoxolone and liquorice. Cortisol is normally inactivated by conversion to the inactive metabolite, cortisone, by the enzyme 11b-hydroxysteroid dehydrogenase but these compounds inhibit the enzyme, which is important in the kidney because it protects renal mineralocorticoid receptors from cortisol.

Drug-induced adrenal insufficiency

The antifungal agent, ketoconazole, and the short-acting anaesthetic, etomidate, are imidazole derivatives with significant inhibitory effects on 11b-hydroxylase. While they do not usually produce clinical insufficiency, they may do so in subjects with limited pituitary or adrenal reserve. Rifampicin and phenytoin, which both accelerate the metabolism of cortisol by inducing hepatic mixed-function oxygenase enzymes, can also provoke adrenal insufficiency in similar patients with limited pituitary or adrenal reserve. In such patients, increased doses of replacement therapy are necessary.

Gonads

Several drugs can affect testicular function, leading to hypogonadism and infertility. Mechanisms include the direct inhibition of testosterone synthesis or competitive inhibition of androgen action at receptor level. Spironolactone acts as a partial androgen receptor antagonist. Alcohol reduces testosterone levels acutely and chronically, by both a central and a gonadal effect on testosterone synthesis, secretion, and metabolism. Cimetidine has antiandrogen effects due to direct interaction with the androgen receptor and it may also exert antiandrogen effects at the pituitary and hypothalamus leading to gynaecomastia and impotence in males. Anticonvulsants, for example phenytoin, increase sex hormone-binding globulin and therefore decrease free testosterone levels. They also enhance testosterone to oestradiol conversion. Sulfasalazine causes reversible male infertility associated with oligospermia.

Infertility may occur as a result of cytotoxic therapy, caused in particular by the alkylating agents such as cyclophosphamide. These produce depletion of the germinal epithelium and lead to a raised FSH level, and oligo- or azoospermia, but normal LH and testosterone levels in males, and may lead to premature ovarian failure in women.

In women, hirsutism can be caused by a number of drugs, including danazol, phenytoin, diazoxide, and minoxidil.

Pharmacological doses of glucocorticoids may lead to hypogonadism because of inhibited gonadotrophin release. Drugs such as tricyclics, benzodiazepines, antihypertensives, and antipsychotics may also lead to hypogonadotrophic hypogonadism in both sexes.

Prolactin

Prolactin is controlled predominantly by a hypothalamic inhibitory mechanism through dopamine secretion. A number of drugs can cause hyperprolactinaemia and galactorrhoea usually acting through a dopaminergic mechanism. They may elevate prolactin to a sufficient extent to cause a clinical suspicion of prolactinoma, and in such patients a careful drug history is particularly important. Metoclopramide, pimozide, and sulpiride all act as dopamine antagonists and may considerably elevate prolactin, with all the attendant effects thereof. Fluoxetine may also lead to elevated serum prolactin, although tricyclic antidepressants are not usually associated with hyperprolactinaemia.

Phenothiazines, chlorpromazine, perphenazine, and trifluoperazine also act as dopamine antagonists, as do haloperidol and butyrophenone. Reserpine and methyldopa both decrease catecholamine stores and may cause hyperprolactinaemia. Oestrogens, in high doses, may slightly elevate prolactin but normal contraceptive pills do not. Verapamil, by decreasing dopaminergic tone, may also increase prolactin levels.

Gynaecomastia

Gynaecomastia may occur due to treatment with various drugs (Table 6). Drugs such as spironolactone and ketoconazole, which can displace steroids from sex-hormone binding globulin, displace oestrogens more easily than androgens. Activation of the oestrogen receptors in breast tissue may take place with drugs that have structural homology with oestrogen, such as digoxin; griseofulvin and cannabis may have the same effect. A decrease in androgen occurs in older men and with drugs such as spironolactone and ketoconazole that inhibit the biosynthesis of testosterone. The mechanism for the induction of gynaecomastia by captopril and calcium-channel blockers (nifedipine) is unclear. With cimetidine and omeprazole, this effect may be due to a direct antiandrogen effect or the inhibition of liver cytochrome P450.

Posterior pituitary

The syndrome of inappropriate antidiuresis is characterized by normovolaemic hyponatraemia with persistent secretion of vasopressin, despite a reduced plasma osmolality. A number of drugs can cause this syndrome, including thiazide diuretics, vincristine, vinblastine, cyclophosphamide, chlorpropamide, phenothiazines, carbamazepine, clofibrate, and tricyclic antidepressants (Table 1).

Nephrogenic diabetes insipidus can be induced by lithium in the therapeutic range, and up to 20 per cent of patients receiving long-term therapy may develop this complication. Demethylchlortetracycline produces dose-dependent nephrogenic diabetes insipidus, and both the concentrating defect and the unresponsiveness to vasopressin are reversible on cessation of the drug.

Parathyroid

Lithium therapy can cause an increase in parathyroid gland size, either with hyperplasia or adenoma. This hyperparathyroidism leads to mild hypercalcaemia and sometimes osteoporosis. Thiazide diuretics, by causing haemoconcentration and hypocalciuria, may also result in mild hypercalcaemia but this is usually transient (4–6 weeks); after this time, other causes of hypercalcaemia should be sought.

Vinblastine and colchicine inhibit parathyroid hormone secretion which may result in hypocalcaemia.

12.13 The pineal gland and melatonin

T. M. Cox

The pineal gland is prominent in birds, reptiles, and other vertebrates in which it responds to sunlight by the secretion of hormones that affect reproduction and thermoregulatory behaviour. In humans the gland has been known since antiquity. Although an endocrine function was considered for many years, this was only given credibility in 1958 by the pioneering work of Lerner, who isolated a small molecule from bovine pineal glands that he named melatonin because it caused blanching of melanophores in vertebrate skin. Many questions remain unanswered about the function of the human pineal gland, but its secretion of the chronobiotic molecule, melatonin, has prompted enormous interest in the fields of travel medicine, neurophysiology, and endocrine research.

Structure

The pineal is less than 1 cm in its longest diameter and weighs less than 0.2 g; it lies above the posterior aspect of the third cerebral ventricle. Normal pineal tissue contains nests of large epithelial-like cells; it also contains neuroglial components, principally of astrocytic type, which occasionally become malignant. Human pineal tissue calcifies with age but this does not necessarily diminish its secretory activity. The pineal gland is considered to reside outside the functional blood–brain barrier.

Pathology

Pineal tumours are rare and are of three types: pinealomas, which represent a neoplastic expansion of the large epithelial cells that cluster within a fibrous stroma in the adult pineal; glial tumours, that resemble astrocytomas occurring elsewhere to cause gliomas in the central nervous system; and teratomas, which arise in the midline within residual pluripotential embryonic cells. It has been known for many years that pineal tumours may disturb sexual maturation and it had been long considered that the pineal secreted a substance that inhibits gonadal function, thus explaining the precocious puberty associated with pineal disease. Treatment of pineal tumours by surgical excision or radiation appears to suppress melatonin secretion leading to sleeping difficulties; melatonin replacement therapy has been reported to benefit such patients with defective melatonin release.

Melatonin

Melatonin, like serotonin, is an endogenous indoleamine derived from tryptophan. The first step in indoleamine synthesis is the 5-hydroxylation of tryptophan by tryptophan hydroxylase—an enzyme with requirements for dioxygen, iron, and tetrahydrobiopterin. The enzyme arylalkylamine, *N*-acetyl transferase, regulated by the sympathetic transmitter noradrenaline, appears to be the rate-limiting step in melatonin synthesis. The enzyme is localized principally in the pineal gland but also within specific cells in the upper gastrointestinal tract. Melatonin binds to specific receptors including the seven-transmembrane G-protein coupled receptors (Mel 1A and 1B) as well as nuclear receptors (including the transcription factor RXR/OR-a) that are associated with melatonin signalling. Membrane G-protein receptors for melatonin are principally expressed in the nervous system whereas the nuclear transcription factor is expressed in the periphery. Melatonin (formal chemical name, *N*-acetyl-5-methoxytryptamine) has been found within membrane-bound bodies in pinealocytes. In experimental animals these show light-dependent morphological changes associated with melatonin secretion under altered environmental light conditions. Melatonin appears to exert its main effects through MT-1 receptors in discrete regions of the hypothalamus that modulate the secretion of growth hormone-releasing hormone (GnRH). This occurs through a complex interneurone circuit which includes neurones containing serotonin, dopamine, and glutamate transmitters.

The role of melatonin and the pineal gland in photoperiodism

Exposure to light influences the secretion of melatonin, and melatonin release is suppressed particularly under illuminance with short-wavelength light. There is evidence that a photoreceptive system, which does not involve retinal rods or cones, mediates this effect. Rhythmic melatonin secretion leads to concentrations in the plasma or cerebrospinal fluid that are up to 10 times higher at night than in the daytime; maximum concentrations are observed in childhood and melatonin levels thereafter decline with age. It appears that melatonin serves as a chronobiotic molecule which acts to delay the sleep–wake cycle of the intrinsic body clock in the suprachiasmatic nucleus. There is evidence that the endogenous clock has a cycle of longer than 24 h, but becomes entrained to synchronize with daily environmental rhythms. Several syndromes associated with long-term insomnia in humans appear to result from slower or faster sleep–wake cycling. Melatonin may play a critical role in such entrainment, since synthesis of melatonin in the pineal induced at night is regulated by sympathetic outflow from the suprachiasmatic nucleus. Exposure to light at high illuminancy may improve disorders of the circadian rhythm that affect sleep. Experiments conducted in blind people have led to the use of synthetic melatonin, before the normal endogenous nocturnal peak, to re-entrain the biological clock. Melatonin-replacement therapy has thus been suggested as a means to improve sleep in night-shift workers, in elderly individuals with insomnia, in patients with pineal tumours, and in those suffering from the effects of jet lag, who have desynchronized rhythms. Careful balance studies have shown that jet lag is associated with asynchronous sleep–wake urine sodium secretion, disturbed fluid balance, and other biochemical abnormalities.

Pharmaceutical use of melatonin

Many studies have been carried out to investigate the efficacy of melatonin as a chronobiotic agent for the alleviation of symptoms associated with rapid eastward travel (jet lag). This application is based on the photoperiodism of humans and other primates and the demonstrated efficacy of melatonin in the regulation of circadian rhythm disturbances in experimental animals. The results of a recent comprehensive study by Herxheimer and Petrie to assess the effectiveness of oral melatonin, taken in different dosing regimens for alleviating jet lag after travel across several time zones, show that the agent is effective in preventing or reducing jet lag. Its short-term use appears to be safe on an occasional basis.

The review showed that in 9 out of 10 trials, melatonin taken close to the target bedtime at destination decreased jet lag in flights crossing five or more time zones. Daily doses of melatonin between 0.5 and 5.0 mg orally appeared to be similarly effective, although sleep was induced faster and better after 5 mg rather than 0.5 mg. Use of a slow-release preparation of 2 mg of melatonin was relatively ineffective in this study suggesting that a short-lived, higher peak was more effective. The drug appears to be relatively safe and side-effect reporting has been low—except in patients with epilepsy or those who are taking warfarin in whom convulsant effects or increased bleeding, respectively, have been reported. It appears possible that melatonin potentiates the action of warfarin. Given that melatonin acts physiologically to regulate the onset of puberty, excess use of melatonin may theoretically influence reproductive development in children and reduce sexual activity, if overused, in adults. No evidence of these effects has yet been reported.

In summary, the evidence is that oral ingestion of melatonin may be indicated for occasional use after transmeridian flights that would induce daytime fatigue and sleep disturbance associated with the gastrointestinal complaints, weakness, malaise, and loss of mental efficiency and other symptoms that typify with jet lag. Clearly, since the drug is not as yet licensed in all countries, routine pharmaceutical control quality must be established. Its use and safety in pregnancy has not yet been completely validated. At a time when prion-related diseases may result from the ingestion or injection of material derived from brain or other animal tissue, only pure biosynthetic melatonin should be considered for human use. Melatonin derived from bovine pineal or other biological sources should be avoided.

Melatonin is widely taken in certain communities, particularly in the United States, where it is claimed to provide indiscriminant protection against ageing, degenerative diseases, cancer, immune dysfunction, and reproductive and psychiatric illnesses. None the less it should be acknowledged that melatonin does have diverse physiological actions in humans, as in other vertebrates, which are incompletely understood. At present the principal indication for exogenous melatonin is for the control of sleep disorders and treatment of symptoms associated with jet lag, rather than the many conditions for which our scientific understanding of its proposed

benefits is as yet inchoate.

13.1 Physiological changes of normal pregnancy

D. J. Williams

Since modern *Homo sapiens* emerged 100 000 years ago, it is estimated that the human population has increased from 50 000 to around 6000 million. Such reproductive success has defied gross reproductive inefficiency. Only 20 to 35 per cent of fertilized ova result in a successful pregnancy (10–25 per cent of *in vitro* fertilizations), most failing around the time of implantation with chromosomal abnormalities. The usual outcome of a successful pregnancy is a single offspring, produced after 9 months. Indeed, if the fetal brain was not programmed to outgrow the maternal pelvic outlet, anthropological comparisons with the great apes indicate that human pregnancy would last 16 months. The price of a relatively short pregnancy is neonatal immaturity and a prolonged period of nurture.

Preparing for pregnancy

The female body prepares for pregnancy during every menstrual cycle. It is not only the endometrium that anticipates implantation of a fertilized ovum, but the whole cardiovascular system. During the postovulatory or luteal phase of each menstrual cycle there is a decrease in systemic vascular resistance by approximately 20 per cent, leading to a 10 per cent fall in mean arterial pressure compared with the follicular phase. Cardiac output increases by almost 20 per cent, and renal vasodilatation increases both renal blood flow and glomerular filtration by approximately 10 per cent. All of these changes resolve with involution of the corpus luteum and onset of menses.

Haemodynamic changes in pregnancy

If fertilization is successful, there is progression of the haemodynamic changes established in the menstrual cycle. A progressive fall in systemic vascular resistance by up to 40 per cent creates a maximal decrease in mean arterial pressure by the end of the first trimester. Diastolic blood pressure falls between 5 and 15 mmHg, before rising to non-pregnancy levels at term, whilst systolic blood pressure remains unchanged throughout pregnancy. A gestational increase in heart rate from approximately 72 to 85 beats/min and of stroke volume by up to 30 per cent combine with the reduction in systemic vascular resistance to increase cardiac output. By 24 weeks, cardiac output reaches a maximum of 50 per cent above non-pregnant levels, which is sustained until term, except in the supine position during the third trimester when cardiac output falls as the gravid uterus compresses the inferior vena cava. Left ventricular wall thickness and left ventricular mass increase progressively throughout pregnancy, by up to 30 per cent and 50 per cent respectively. Cardiac output returns almost to prepregnancy levels within 2 weeks of delivery.

Distribution of increased cardiac output

Although it is technically difficult to measure blood flow to particular maternal viscera during pregnancy, it is clear that the timing and extent of changes to blood flow varies between organs. This is summarized in Fig. 1. Mammary artery blood flow increases early in pregnancy, breast tenderness and swelling being amongst the first symptoms.

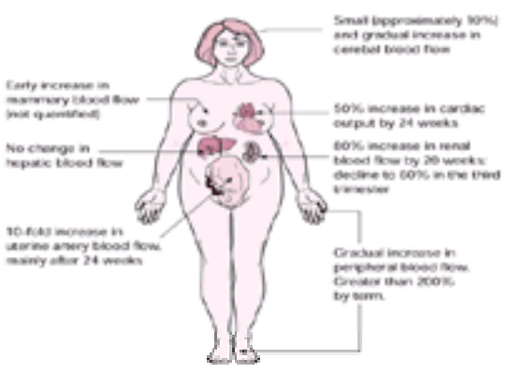

Fig. 1 Changes in maternal organ blood flow during healthy pregnancy.

Mechanism of haemodynamic change

The onset of physiological change during the menstrual cycle suggests that maternal rather than fetoplacental factors initiate gestational adaptation. Oestrogen, mainly in the form of 17B-oestradiol, is a potent vasodilator. It is produced by the corpus luteum during the luteal phase of each menstrual cycle and for the first 10 weeks of pregnancy. After 10 weeks, the placenta elaborates its own 17B-oestradiol, so that by term maternal oestradiol levels are approximately 250-fold higher than those found during the menstrual cycle. 17B-oestradiol relaxes vascular smooth muscle through both endothelium-dependent and independent mechanisms. All of the endothelium-derived vasodilators, nitric oxide, prostacyclin, and endothelial-derived hyperpolarizing factor have been implicated in the gestational fall of systemic vascular resistance. Much less is known about the vascular effects of progesterone. Circulating progesterone levels increase by a similar amount to 17B-oestradiol and may play a role in reducing pressor responsiveness to angiotensin II. Although the precise mechanism of maternal vasodilatation is likely to be different in different vascular beds, a healthy endothelium is essential for normal cardiovascular adaptation to pregnancy.

Fluid balance during pregnancy

Arterial dilatation creates a relatively 'under-filled' state, which stimulates the renin–angiotensin–aldosterone system. As a result, sodium and water retention throughout pregnancy leads to a 6 to 8 litre rise in total extracellular fluid volume. An increase in plasma volume is apparent by week 6 and continues until week 32 when it is 40 per cent (approximately 1.2 l) above non-pregnant levels. Furthermore, shortly after conception the osmotic threshold for thirst falls and plasma osmolality drops by 10 mosmol/kg. A concomitant fall in the threshold for secretion of antidiuretic hormone (AVP) prevents a water diuresis and sustains low plasma osmolality until term. During the second half of pregnancy, placental production of vasopressinase increases maternal antidiuretic hormone degradation, but plasma antidiuretic hormone levels remain stable as pituitary secretion of antidiuretic hormone increases four-fold. Plasma atrial natriuretic peptide levels are normal until the second trimester, when they rise by approximately 40 per cent.

Immunological changes during pregnancy

It is often presumed that pregnant women are immunosuppressed in order that the fetal 'semiallograft' can survive. This is not true. Certain aspects of maternal immunity are modulated, but it is the placenta that deserves most credit for eluding maternal immunity. Much harm is prevented by the physical separation of maternal and fetal blood. Fetal haemolytic disease is an example of the harm that can follow a breach in this barrier, a Rhesus-negative mother becoming isoimmunized against Rhesus-positive fetal blood.

In normal pregnancy, the placenta has to invade uterine tissue and become bathed in maternal blood. To avoid a hostile immune response, the surface layers of placenta express a unique non-polymorphic HLA G, rather than classical histocompatibility antigens. It is thought that HLA-G confers resistance to lysis by maternal T cells and natural killer cells. The placenta also expresses a plethora of complement control systems to protect itself from maternal complement (serum levels of complement factors C3 and C4 are elevated during pregnancy).

The number and activity of natural killer cells in maternal peripheral blood are diminished during pregnancy, and fetal survival is further enhanced by a shift away from maternal T-helper 1 responses that promote cell-mediated immunity, towards a stronger T-helper 2 response that promotes antibody production. In consequence, pregnant women are more prone to severe infections with intracellular pathogens such as malaria and leprosy and are more likely to suffer reactivation of viruses such as Epstein–Barr. Conversely, circulating levels of maternal immunoglobulin increase and once transferred to the fetus have a role in passive immunity. The mechanism by which these immune changes take place is unclear, but increased circulating levels of metabolically active cortisol may play a role.

Healthy pregnancy is also a proinflammatory state. Neutrophils increase in number and develop a proinflammatory phenotype. Mean total white cell count increases to 9.0×10^{9}/l and can rise as high as 40.0×10^{9}/l during labour, returning to normal within 6 days. Erythrocyte sedimentation rate (ESR) rises as a consequence of increased fibrinogen and globulin. An ESR over 30 mm/h is usual and up to 70 mm/h is within normal limits. Circulating levels of C reactive protein do not change during healthy pregnancy. Anatomical changes to the maternal immune system include involution of the thymus and enlargement of the spleen.

Ventilatory changes during pregnancy

The increased metabolic demands of pregnancy lead to a progressive increase in oxygen consumption, reaching almost 20 per cent by term. To compensate, pregnant women breathe more deeply, tidal volume increasing from approximately 500 to 700 ml, whilst respiratory rate remains unchanged. Effective alveolar ventilation actually surpasses the body's demand for oxygen, creating a respiratory alkalosis with PCO_2 falling from 5.0 to 4.0 kPa. Over-breathing is stimulated by direct effect of progesterone on the respiratory centre, particularly increasing sensitivity to CO_2.

Renal changes during pregnancy

An 80 per cent increase in renal blood flow and 55 per cent increase in glomerular filtration rate occur by 16 weeks gestation. The rise in renal blood flow causes the kidneys to swell so that they appear approximately 1 cm longer on ultrasonography. The renal pelvis and ureters dilate, sometimes appearing obstructed to those unaware of these changes.

Serum levels of creatinine and urea fall, so that levels considered normal outside pregnancy can suggest renal impairment during pregnancy. Proteinuria increases slightly during pregnancy, but levels over 260 mg/24 h should be considered abnormal. Gestational glycosuria reflects reduced tubular glucose reabsorption and does not necessarily indicate abnormal carbohydrate metabolism. Furthermore, reduced tubular absorption of bicarbonate creates a metabolic acidosis that compensates for the respiratory alkalosis, keeping maternal pH at 7.4.

The production of all three renal hormones, erythropoietin, active vitamin D, and renin, increases during healthy pregnancy, but their effects are masked by other physiological changes. In early pregnancy, peripheral vasodilatation exceeds the renin–aldosterone mediated plasma volume expansion, so blood pressure falls by 12 weeks. The 40 per cent expansion of plasma volume exceeds the effect of a two to four-fold increase in maternal serum erythropoietin levels, which stimulates only a 25 per cent rise in red cell mass. This creates a 'physiological anaemia', which should not normally cause haemoglobin concentration to fall to less than 9.5 g/dl (see Chapter 13.3). Similarly, active vitamin D circulates at twice non-gravid levels, but concomitant halving of parathyroid hormone levels, as well as hypercalciuria and increased fetal requirements, keeps plasma ionized calcium levels unchanged.

Liver metabolism during pregnancy

The size of the liver and its blood flow appear not to change during healthy pregnancy, hence liver blood flow accounts for proportionately less of the cardiac output as pregnancy progresses. There are, however, changes to hepatic synthetic function and metabolism. Circulating concentrations of fibrinogen, ceruloplasmin, transferrin, and binding-proteins, for example thyroid-binding globulin, increase, while serum albumin levels fall by approximately 25 per cent. Serum cholesterol increases by 50 per cent and triglycerides by up to 300 per cent. The normal ranges for aspartate transaminase, alanine transaminase, gamma glutamyl transferase, and bilirubin decrease by at least 20 per cent from the first trimester until term. After the fifth month, placental production of alkaline phosphatase increases maternal plasma levels by up to four-fold. Telangiectasia and palmar erythema are common signs of healthy pregnancy that resolve postpartum.

Gastrointestinal system

Nausea and vomiting affect about 60 per cent of women during the first trimester. The rise and fall of human chorionic gonadotrophin (hCG) levels correlate chronologically with the onset and improvement of these symptoms, but the role of hCG in gestational nausea is unproven and the cause remains unknown. Relaxation of intestinal smooth muscle by progesterone creates many of the other pregnancy-induced gastrointestinal changes. Gastric motility and small bowel transit are slowed, especially during labour. The gallbladder enlarges and empties slowly in response to meals. A decrease in lower oesophageal pressure makes gastro-oesophageal reflux more common.

Endocrine changes

Thyroid function

During pregnancy, the thyroid faces three challenges. Firstly, increased renal clearance of iodide and losses to the fetus create a state of relative iodine deficiency. In geographical areas where dietary iodine intake is low, pregnancy stimulates growth of thyroid goitres. Secondly, high oestrogen levels induce hepatic synthesis of thyroid binding globulin, but free thyroxine and tri-iodothyronine levels remain within the normal range throughout pregnancy. Thirdly, placental hCG shares structural similarities with thyroid-stimulating hormone and has weak thyroid-stimulating hormone-like activity. Although hCG rarely stimulates free T4 levels into the thyrotoxic range, trophoblastic disease and hyperemesis gravidarum are often associated with high hCG levels and can lead to hyperthyroxinaemia. In these circumstances, the mother remains clinically euthyroid.

Pituitary function

Once ovulation has occurred and the uterus is prepared for implantation, the maternal pituitary makes only a small contribution to a successful pregnancy. The only pituitary hormone to increase significantly during pregnancy (by approximately 10-fold) is prolactin, which is responsible for breast development and subsequent milk production.

Pituitary secretion of growth hormone is mildly suppressed during the second half of pregnancy by placental production of a growth hormone variant. The role of the latter is unclear, but may contribute to gestational insulin resistance.

Placental production of adrenocorticotrophic hormone leads to an increase in maternal adrenocorticotrophic hormone levels, but not beyond the normal range for non-pregnant subjects. Free cortisol levels double and in the second half of pregnancy may contribute to insulin resistance and striae gravidarum.

High oestrogen levels during pregnancy stimulate lactotroph hyperplasia, resulting in pituitary enlargement. These high levels, together with those of progesterone, suppress luteinizing hormone and follicular stimulating hormone. Plasma follicular stimulating hormone levels recover within 2 weeks of delivery, but pulsatile luteinizing hormone release is only resumed in women who do not breast feed. In suckling mothers, prolactin inhibits gonadotrophin-releasing hormone and hence luteinizing hormone.

Coagulation

In anticipation of haemorrhage at childbirth, normal pregnancy is characterized by low grade, chronic intravascular coagulation within both the maternal and uteroplacental circulation. There are increased levels of clotting factors (V, VIII, and X), decreased levels of the endogenous anticoagulant protein S and decreased fibrinolytic activity. These changes lead to an acquired protein C resistance in up to 38 per cent of pregnant women. However, postpartum contraction of the uterus by oxytocin is probably more effective at preventing haemorrhage than any changes to the coagulation system.

Carbohydrate metabolism

During the first trimester, women are more sensitive to insulin than when non-pregnant. From 20 weeks onwards, insulin resistance develops, hence women in the second half of pregnancy respond to a glucose load by producing more insulin, but with less effect. Obese women, who are already insulin resistant, are more likely to develop gestational diabetes. Hormones that might mediate this insulin resistance include cortisol, progesterone, oestrogen, and human placental lactogen. Placental production of human placental lactogen, a growth hormone-like protein, coincides temporally with insulin resistance.

Skin and hair during pregnancy

Hyperpigmentation affects up to 90 per cent of pregnant women. Areas that are normally hyperpigmented, such as the areolae and vulva, become darker. This may be mediated by oestrogen and progesterone, which are powerful melanogenic stimulants. Hair growth increases during pregnancy and hair loss is accelerated postpartum. The gestational rise in corticosteroids and ovarian androgens contributes to the number of hairs in the growing phase (anagen). Postpartum, the levels of these hormones fall and hairs move back into the resting phase (telogen).

13.2 Nutrition in pregnancy

D. J. Williams

Introduction

The ability to adapt to different environmental and nutritional conditions is a key requirement for reproductive success. In the developed world, where food is generally plentiful, dietary recommendations are based on the average food intake amongst healthy pregnant women. In nations where food is scarce, dietary recommendations are based on minimal requirements for health and fall far below the average intake of a woman who eats to satisfy her appetite. Pregnant women adapt several metabolic pathways to minimize extra nutritional requirements and optimize fetal growth. However, despite these metabolic adaptations, millions of pregnant women are unable to provide enough nutrition for their fetus to thrive. Poor prenatal nutrition not only affects perinatal outcome, but also appears to dictate susceptibility to some adult diseases and possibly the health of the next generation.

Weight gain in pregnancy

Well-nourished mothers with free access to food gain up to 30 per cent of their prepregnancy weight, of which only 25 per cent is fetal. By contrast, mothers with limited access to food gain as little as 10 per cent of their prepregnancy weight, of which up to 60 per cent is fetal. Liberal weight gain increases birth weight, but also increases the rate of caesarean section and maternal complications such as gestational diabetes and pre-eclamspia. Limiting weight gain increases the incidence of low birth weight (defined as less than 2500 g at term). In 1990 the Institute of Medicine in the United States published guidelines for weight gain in pregnancy that were adjusted according to prepregnancy maternal weight (Table 1). These recommendations, based on large observational studies, have stood the test of many subsequent analyses and minimize the overall risk of both low and high (more than 4500 g at term) birth weights.

Caucasian women who kept within the Institute of Medicine recommendations retained 1 kg postpartum, while black women retained 3 kg. Opponents of the recommendations therefore believe that they are too generous and encourage postpartum weight retention. However, only 23 per cent of obese women could keep within the guidelines, and those unable to do so doubled their risk of a poor pregnancy outcome and increased the likelihood of postpartum weight retention. Unless the mother is under- or overweight (BMI less than 19.8 or more than 29 kg/m^2), measurement of weight gain during pregnancy is a poor predictor of pregnancy outcome.

Pregnancy weight gain in the developing world

In developing nations more than 20 per cent of babies are of low birth weight, of which only 25 per cent are premature; in comparison, in developed nations only 6 per cent of babies are of low birth weight, of which most (55 per cent) are premature. Nutritional supplements for malnourished women during pregnancy need to be administered with care. Chronic malnutrition limits maternal stature, including pelvic size. Hence protein and energy supplements in pregnancy may disproportionately increase fetal growth and lead to obstructed labour, a major cause of maternal and perinatal death in the developing world. A pragmatic recommendation is to be particularly aware of this possibility when including primiparous women of less than 1.5 m in height in supplementary feeding programmes aimed at accelerating fetal growth. Furthermore, improved obstetric care must accompany nutritional advice.

Energy requirements during pregnancy

The rate of human fetal growth is slow and the daily incremental energy stress of human pregnancy is relatively low compared with that in other species. This allows a mother time to adapt her metabolism and energy expenditure to diverse nutritional conditions. In well-nourished societies the total energy costs of pregnancy can be as high as 520 MJ (124 000 kcal), compared with –30 MJ (–7100 kcal) in countries where food is scarce (Fig. 1).

Fig. 1 Estimated total energy costs of pregnancy in different nutritional environments. The women from The Gambia were supplemented with a balanced protein-energy diet. (From Prentice and Goldberg (2000).)

The three major components of energy expenditure in an average well-nourished mother are growth of the fetus and reproductive tissues (about 18 per cent), new maternal fat stores (about 38 per cent), and increased maternal metabolism (about 44 per cent). Poorly nourished women try to maintain fetal growth by depressing their basal metabolic rate until late pregnancy and by laying down less fat. Although such adaptations usually result in successful reproduction, they are inevitably a compromise with regards to perinatal health. However, attempts to quantify minimal energy requirements for good perinatal health will always be confounded by huge individual variability and practical difficulties of attributing a single nutritional component to morbidity—a multifaceted problem.

In well-nourished women, the basal metabolic rate changes little until about 16 weeks' gestation, then increases rapidly until term (Fig. 2). During the middle trimester large amounts of maternal fat are laid down as energy stores. If food intake becomes limited during late pregnancy, maternal fat can be mobilized to support the period of most rapid fetal growth. This strategy of fat storage before anticipated energy demands is also used by birds before migration and hibernating mammals. Even poorly nourished women with low gestational weight gains lay down some extra fat. Conversely, well-nourished women with free access to food rarely need to

utilize all their fat stores to support late fetal growth. Excess fat remains difficult to lose postpartum.

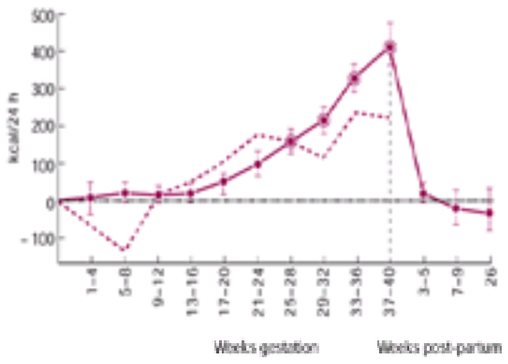

Fig. 2 The energy cost of gestational increase in basal metabolic rate in well nourished women in the United Kingdom (data derived from over 100 pregnancies). This amounts to 30 100 kcal (solid line) each pregnancy, when the total gestational energy requirement was 69 050 kcal. Total energy intake increased by only 22 000 kcal (dashed line). Maternal energy expenditure must reduce by 47 000 kcal to meet the extra demands of pregnancy. (Adapted from Durnin (1991), with permission.)

In the United Kingdom, the calculated total energy cost of pregnancy is about 70 000 kcal (Table 2). As a consequence, pregnant women have been recommended to increase energy intake by around 250 kcal/day during the last two trimesters. However, careful studies of well-nourished women have found that maternal energy intake actually increases by little more than 100 kcal/day after the first trimester (22 000 kcal in total) (Fig. 2). The shortfall of nearly 50 000 kcal is made up by an economy of energy expenditure, including reduced physical activity and diet-induced thermogenesis.

The mechanisms that control the diverse metabolic responses to pregnancy are not understood. Leptin, a protein produced by adipose tissue and the placenta, circulates in increasing amounts during pregnancy and controls peripheral energy status and body fat. Ob/ob mice (deficient in leptin) become insensitive to exogenous leptin when pregnant, consistent with the build-up of maternal fat stores until the last trimester. Furthermore, leptin is integrated with the hypothalamo–pituitary–gonadal axis and may explain why thin women with low leptin levels remain infertile until they have adequate fat stores. A precise role for leptin during pregnancy remains to be elucidated.

Carbohydrate metabolism

During the first half of pregnancy, women produce more insulin in response to a glucose load and are more sensitive to exogenous insulin than in the non-pregnant state. These changes affect carbohydrate and lipid metabolism to favour increased fat production and storage. During the second half of pregnancy a woman becomes increasingly resistant to insulin, so that at term the action of insulin is 50 to 70 per cent lower than in the non-gravid state. As a consequence the fat stores laid down in the first half of pregnancy are mobilized and postprandial blood glucose levels remain higher for longer. Circulating levels of fatty acids and glycerol increase and are used by the mother as an energy source in preference to glucose and amino acids, which are left for the fetus. As a consequence, fasting pregnant women oxidize fat and produce ketones far sooner than they do when they are not pregnant. Women with an exaggerated peripheral resistance to insulin develop gestational diabetes mellitus.

Protein metabolism

Pregnancy is an anabolic state. Protein and nitrogen metabolism adapt early and gradually throughout healthy pregnancy to provide for tissue growth. Well-nourished women are estimated to accumulate an extra 500 g to 1 kg of protein during pregnancy. Almost half of the protein accumulates as increased maternal lean body mass, while the rest lies within the fetus and reproductive tissues.

In the United Kingdom the daily increment of dietary protein has been calculated to increase gradually throughout pregnancy to 8.5 g at term, but this does not take into account reduced hepatic metabolism of branched chain amino acids and hence reduced urea synthesis. The rate of urea synthesis declines by 30 per cent during the first trimester and by 45 per cent during the third trimester, hence serum urea concentration falls, providing more nitrogen for protein synthesis.

Vitamins and micronutrients

In some parts of the developing world micronutrient deficiencies are endemic and have serious consequences for fetal, neonatal, and maternal well-being, for example hypothyroidism due to iodine deficiency and night blindness due to vitamin A deficiency. Such deficiencies are rare in developed countries.

Calculated increments in the recommended daily allowance of specific nutrients are derived from estimates of the cost of fetal growth and increased maternal metabolism. These calculations do not usually take account of maternal metabolic adaptations that make the need for extra nutrients unnecessary, for example increased intestinal absorption of calcium offsets the need for an increase in dietary calcium. Conversely, increased folic acid excretion leads to an underestimate of folic acid requirements. Furthermore, individual micronutrients interact with each other and changes to one may have a detrimental effect on the activity of another.

It is now widely accepted that supplemental folic acid (400 µg/day) during the first trimester reduces the risk of neural tube defects. With this exception, extra vitamins and micronutrients are not necessary for healthy pregnant women who eat a balanced diet. Indeed, excessive amounts of certain micronutrients can be harmful to the fetus.

Vitamin A

Vitamin A is a lipid-soluble vitamin essential for healthy embryogenesis and fetal growth. Preformed vitamin A is found in dairy products and liver: the recommended daily allowance during pregnancy is 2000 to 2700 iu/day (670–899 retinol equivalents; RE). Vitamin A deficiency is endemic in some parts of the world: some small studies have shown a minor increase in birth weight with maternal vitamin A supplements of 6000 to 8000 iu/day (2000–2670 RE/day). Breast milk is rich in vitamin A, and is important for neonatal immunity.

Excessive doses of vitamin A in the diet (more than 15 000 iu/day (5000 RE/day)), or supplements of vitamin A (more than 10 000 iu/day), are teratogenic. Pregnant women who take vitamin A supplements of more than 10 000 iu/day (3335 RE/day) have a 1 in 57 risk of a birth defect attributable to this. Drugs that are derived from vitamin A, such as the retinoids (for example isotretinoin), are associated with an estimated 25-fold increased risk of malformation. As a consequence, the American College of Obstetricians and Gynecologists has recommend that the daily dose of vitamin A should not exceed 5000 iu/day (1665 RE/day) during pregnancy. The carotenoids (b-carotene) that are precursors to vitamin A do not appear to be teratogenic and are now being substituted for preformed vitamin A in multivitamin preparations. In general, vitamin A supplements are unnecessary for well-nourished women and potentially harmful to the fetus.

Thiamine (vitamin B_1)

Thiamine deficiency is endemic in some developing countries, but is also a global problem in women with hyperemesis gravidarum. Severe and persistent vomiting during pregnancy leads to thiamine deficiency and can cause Wernicke's encephalopathy. Thiamine replacement is therefore an essential supplement for women with hyperemesis gravidarum.

Vitamins C and E

Serum vitamin C levels fall by about 50 per cent during pregnancy, hence it is recommended that this amount is supplemented, although benefits are unproven. The

antioxidant properties of vitamins C and E may reduce the risk of pre-eclampsia, but larger studies are needed to confirm this possibility.

Iodine

More than 800 million people live in iodine-deficient areas. Inadequate dietary iodine leads to maternal hypothyroidism and is detrimental to *in utero* growth and development. Supplemental iodine (usually added to salt) given to pregnant women can prevent these consequences.

Zinc

Zinc deficiency is associated with intrauterine growth restriction and teratogenesis. During pregnancy, maternal zinc levels remain stable through increased intestinal absorption. Excess iron supplements, smoking, alcohol abuse, or subsistence cereal diets high in phytate can all inhibit zinc absorption: under such conditions pregnant women may benefit from 25 mg zinc daily.

Iron

During pregnancy expansion in plasma volume exceeds the increase in red cell mass causing a fall in haemoglobin concentration. Healthy pregnant women not taking iron supplements drop their haemoglobin from 13.3 g/dl to 11.0 g/dl by 36 weeks' gestation. The minimum incidence of low birth weight (less than 2500 g at term) and preterm labour is associated with a haemoglobin of 9.5 to 10.5 g/dl. In the non-gravid state, a haemoglobin of 9.5 to 10.5 g/dl would indicate anaemia, but unless the mean corpuscular volume is less than 84 fl, supplemental iron is probably unnecessary. A meta-analysis of randomized controlled trials examining the benefit of supplemental iron found a significant reduction in women with a haemoglobin of less than 10 g/dl, but no effect, beneficial or harmful, on maternal or fetal outcome.

In the developing world, anaemia (of multiple causes) is endemic. The risk of maternal death is increased with severe anaemia (haemoglobin less than 7.0 g/dl), a condition where supplemental iron is unlikely to have much effect. Evidence that mild to moderate anaemia is associated with increased maternal and fetal risk is hard to find. Despite this, many developing countries advocate a policy of iron and folic acid supplementation for all pregnant women. More studies are necessary to monitor the effects of this policy on maternal and perinatal outcome.

Anaemia in pregnancy is discussed in more detail in Chapter 13.16.

Calcium

The growing fetus gains about 50 mg calcium per day by midpregnancy and about 300 mg/day at term. The breastfed infant receives about 250 mg of calcium in breast milk each day. The recommended daily allowance of calcium during pregnancy and lactation is 1.2 g/day, but women with much less dietary calcium undergo metabolic adaptations to meet the demands of pregnancy and lactation without any detriment to their health or that of the fetus.

During pregnancy, maternal calcium absorption increases twofold, stimulated by increased 1,25-dihydroxyvitamin D activity due to placental synthesis of 1,25-dihydroxyvitamin D and increased renal 1-a-hydroxylase activity. Although urinary calcium excretion doubles during pregnancy, fasting urinary calcium excretion, corrected for the increased creatinine clearance, is unchanged. The concentration of parathyroid hormone falls during pregnancy, suggesting that the pregnant woman receives enough calcium for her growing fetus. There are two caveats: one is the pregnant adolescent who needs to meet the demands of her own growth and that of the fetus; the other is the apparent benefit of supplemental calcium for women on a low-calcium diet, not a normal calcium diet, to prevent pre-eclampsia.

Following delivery, circulating 1,25-dihydroxyvitamin D concentrations return to non-pregnant levels. During the first 3 to 6 months of breastfeeding, mineralization of the maternal axial skeleton declines by approximately 3 to 5 per cent. After 6 months, bone demineralization recovers whether or not breastfeeding continues. Calcium supplements of 1 g/day given to lactating women do not prevent bone demineralization or improve the calcium concentration of breast milk, even if the woman is on a low-calcium diet. Furthermore, repeated long periods of breastfeeding in women with a low calcium intake do not contribute to osteoporosis in later life.

Fetal programming—the influence of fetal nutrition on adult disease

Epidemiological studies have found that low birth weight due to intrauterine growth restriction (rather than prematurity) is associated with an increased risk of cardiovascular disease in adulthood. It is hypothesized that a poorly growing fetus makes metabolic adaptations *in utero* to optimize growth and development. Despite these physiological adaptations birth weight remains low, and because of them the individual is indelibly programmed to insulin-resistant syndromes that are detrimental to long-term cardiovascular health. These issues are discussed in Chapter 15.4.1.1.

It has also been suggested that impaired insulin-mediated fetal growth and insulin resistance in later life is genetically determined. Fetal growth is partly genetically programmed, but the intrauterine environment appears to be more important: the relationship between birth weight and the body size of a surrogate mother who receives a donor egg is stronger than with the genetic mother.

Animal studies have shown that the composition of maternal diet can influence fetal growth and consequently blood pressure in her offspring. At present not enough is known about the mechanisms that control human fetal growth to give maternal nutritional advice that might eventually reduce the risk of cardiovascular disease in her children. Understanding these mechanisms may be fundamental to ameliorating the global epidemic of cardiovascular disease.

Foods to avoid during pregnancy

Food contaminated with *Listeria monocytogenes* can cause listeriosis. During pregnancy, this organism has a predilection to replicate at the uteroplacental site, leading to septic abortion in early pregnancy, or neonatal listeriosis in later pregnancy. To reduce the risk of infection with listeria, pregnant women should avoid eating soft ripened cheeses, all types of pâté, and undercooked meats. This is discussed in section 13.15.

Acute maternal infection with *Toxoplasma gondii* can cross the placenta to the fetus. Congenital infection is least likely during early pregnancy, but more severe when it occurs. The risk of congenital infection can be kept to a minimum by not eating undercooked meat, taking care while handling raw meat, and avoiding contact with cat faeces. This is discussed in Chapter 13.15.

Food cravings during pregnancy

Common food cravings during pregnancy are for dairy products and occasionally for non-organic material such as soil (pica). Common aversions are to alcohol, caffeine, and meats.

13.3 Medical management of normal pregnancy

D. J. Williams

Introduction

Until very recently *Homo sapiens* thrived with nothing but the most primitive antenatal care. The introduction of hospital-based childbirth in the United Kingdom was a disaster. In the mid 1800s it became clear to some that unhygienic medical practice was responsible for puerperal sepsis and a high maternal mortality rate. From the 1930s, maternal mortality in the United Kingdom fell from 1 in 100 deliveries in the worst maternity hospitals, to 1 in 10 000 deliveries today. Globally, however, there are still 585 000 pregnancy-related maternal deaths each year, meaning that one woman dies every minute of every day as a consequence of pregnancy and childbirth.

With the exception of a high death rate from AIDS in many developing nations, the causes of maternal mortality worldwide are similar to those found in developed countries before the implementation of modern obstetric practices (Fig. 1). In the developed world, the dramatic reduction in the number of maternal deaths from obstetric complications has not been matched by a similar fall in deaths associated with pre-existing maternal disease. This latter observation is partly due to the success of modern medicine in helping more women with congenital or chronic disease to survive until reproductive age, and partly due to the inability of physicians to manage otherwise familiar medical conditions during pregnancy.

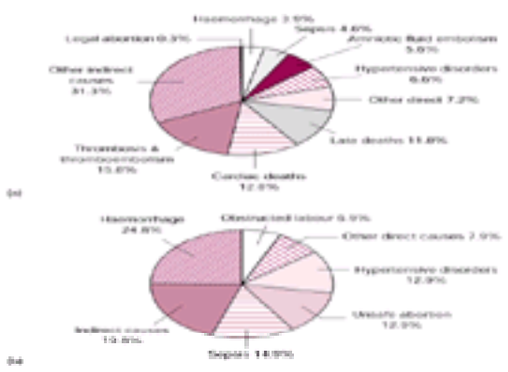

Fig. 1 (a) Causes of maternal mortality in the United Kingdom 1994–6 (adapted from Department of Health (1998)). (b) Causes of 585 000 maternal deaths worldwide in 1990. Direct deaths are a direct consequence of pregnancy; indirect deaths are due to the effects of pregnancy on pre-existing maternal disease. (Reproduced from Liljestrand (1999), with permission.)

Misplaced concern about fetal welfare often denies the mother life-saving investigations and treatment. Substandard care is therefore responsible for many maternal deaths in consequence. Clinical anxiety may be amplified when a doctor is presented with a healthy woman who has everything to lose by meddlesome intervention. The general physician should therefore be aware of the symptoms and signs of normal pregnancy and familiar with advice on how women should prepare for and maintain a healthy pregnancy.

Maternal factors that influence pregnancy outcome

Maternal age

More women are having babies later in life than ever before. In the United States, between 1969 and 1994, the median age at first birth increased from 21.3 to 24.4 years and the proportion of first time mothers aged 30 years or more increased from 4 per cent to 21 per cent. The prevalence of pregnancy-induced hypertension, gestational diabetes, and thrombosis is increased in women over 35 years.

Fetal aneuploidy, most notably trisomy 21 (Down's syndrome), also increases with maternal age. At 25 years of age, the risk of a pregnancy with trisomy 21 is 1:1250, at 35 years it is 1:385, and at 45 years it is 1:30. These risks can be refined during pregnancy (from 16 weeks) by information derived from measurement of maternal serum concentrations of a-fetoprotein, human chorionic gonadotrophin, and unconjugated oestriol (the triple test). Some centres derive a risk of chromosomal abnormality from an ultrasound measurement of skinfold thickness at the back of the fetal neck (nuchal translucency screening, around 12 weeks). Women found to be at high risk of a chromosomal abnormality can be offered diagnostic testing with amniocentesis (which carries a 0.5 to 1.0 per cent risk of miscarriage).

Maternal weight

Maternal health is threatened by a high prepregnancy weight. Pre-eclampsia and gestational diabetes mellitus are more common in overweight women (body mass index (**BMI**) more than 26), and the risk of late fetal death is also increased. However, maternal obesity protects against the delivery of an infant which is small for gestational age, whereas underweight women (BMI less than 19) are more prone to have babies with lower birth weights.

Weight gain during healthy pregnancy varies between 10 and 16 kg in Western societies, i.e. about 20 per cent of prepregnancy weight. Lean, nulliparous women who eat to appetite gain 0.65 to 1.1 kg during the first 10 weeks of pregnancy, about 0.45 kg per week during the second trimester, and about 0.36 kg per week during the last trimester. Maternal weight gain correlates poorly with fetal growth. Unless the mother is underweight before pregnancy (BMI less than 19), regular antenatal measurements of maternal weight are not helpful and fetal growth is most accurately assessed by serial ultrasound measurements.

Past medical history

Pregnancy is a medical stress test for the woman, which is particularly evident in those with chronic medical disorders. A diseased maternal organ may lose residual function attempting to accommodate the physiological demands of pregnancy. Furthermore, women with severe pre-existing disease are more likely to have an adverse fetal outcome.

Pregnancy can also uncover subclinical disease; for example inherited thrombophilias may lead to thrombosis only in combination with the hypercoagulable environment of healthy pregnancy. However, the physiological changes of pregnancy are not always damaging: some conditions improve, whilst others deteriorate (Table 1).

Family history

Gestational conditions tend to run in families. Pre-eclampsia, gestational diabetes mellitus, obstetric cholestasis, and probably hyperemesis gravidarum and postnatal depression have genetic components. Inherited thrombophilias may also have a direct impact on pregnancy outcome.

Infertility and multiple pregnancies

In 1978 the birth of the first baby by *in vitro* fertilization (**IVF**) gave hope to the 15 per cent of couples who are infertile. Since then over 200 000 children have been born throughout the world using IVF, and in the United Kingdom a healthy baby is born from 17.4 per cent of IVF cycles on average. The cause of infertility may itself lead to problems in pregnancy, for example women with polycystic ovary syndrome are at increased risk of pregnancy-induced hypertension and gestational diabetes.

In most cases of IVF, two embryos are returned to the woman. As a consequence, 28.9 per cent of deliveries from IVF conceptions lead to multiple births. Following natural conception, multiple births affect only 11 per 1000 pregnancies in the United States and Europe. Women with multiple pregnancies are more vulnerable to pre-eclampsia and premature delivery.

Ovarian hyperstimulation syndrome

To increase the yield of eggs, women receiving IVF undergo ovarian stimulation with gonadotrophins, following which up to 14 per cent develop an ovarian hyperstimulation syndrome, which is severe in 1 to 2 per cent of cases. In ovarian hyperstimulation syndrome, multiple follicles develop into corpus lutea that produce excessive amounts of progesterone, resulting in massive ovarian enlargement and increased vascular permeability. Protein-rich fluid shifts into serous cavities, causing ascites, and in more severe cases pleural and pericardial effusions. The fluid shift results in haemoconcentration and hypotension, increasing the risk of thrombosis and reducing renal perfusion. Most cases of ovarian hyperstimulation syndrome are mild, but death has followed acute respiratory distress, hepatorenal failure, thromboembolism, and rupture of grossly enlarged ovaries. Management is mainly supportive, including careful fluid balance, thromboprophylaxis, analgesia, and adjustment of luteal stimulation under the guidance of a specialist in assisted conception. In some cases, paracentesis relieves pressure symptoms.

Diagnosis of pregnancy

Pregnancy can be diagnosed within a day of missing a menstrual bleed by identifying a rise in concentration of urinary human chorionic gonadotrophin. At this time the embryo is 2 weeks old, but obstetric convention dictates that the gestation of pregnancy is calculated from the first day of the last menstrual period, i.e. 2 weeks earlier than embryonic age. Teratogenic drugs interfere with organ development in the 2 to 8 weeks postconception (embryonic period). After 9 weeks and until delivery, the conceptus is known as a fetus, but it is still vulnerable to the effects of drugs given to the mother.

Screening of maternal health during pregnancy

Pregnancy is an opportunity for women to be screened for occult disease. In the United Kingdom, healthy women are encouraged to register with an antenatal clinic at 12 to 14 weeks' gestation. However, by this gestation they will have missed the opportunity to take folic acid prophylaxis against neural tube defects, and may not recognize the need to adjust social behaviour (see below) or stop regular medications.

At the first antenatal visit, a medical and obstetric history is combined with cardiovascular examination, urinalysis, and laboratory tests. Identification of maternal infection with HIV, hepatitis B, or syphilis is crucial for appropriate management of the woman and her partner, and to minimize the risk of vertical transmission to the infant. Rhesus antibody screening allows prophylactic measures to prevent haemolytic disease of the fetus.

Further antenatal checks are usually performed at 20 weeks (combined with a detailed scan of the fetus), 26 to 28 weeks (combined with a glucose tolerance test and full blood count), 30, 32, 34 (full blood count), and 36 weeks, then weekly until delivery. At each visit, obstetric assessment is combined with a check of blood pressure and urinalysis.

Screening for asymptomatic bacteriuria during healthy pregnancy and subsequent treatment reduces the risk of maternal pyelonephritis and fetal morbidity. The cost-effectiveness of such screening depends on the prevalence of asymptomatic bacteriuria in the pregnant population. If the prevalence is less than 5 per cent, as in many developed nations, screening is probably not cost-effective. However, in the developing world asymptomatic bacteriuria is far more common and screening is worthwhile. As the recurrence rate of asymptomatic bacteriuria is about 30 per cent, women identified with an occult infection should be screened monthly throughout the remainder of their pregnancy. These issues are discussed in Chapter 13.5.

Symptoms and signs of healthy pregnancy

Fatigue

Fatigue is a common symptom that often begins early in healthy pregnancy. Towards term, changes in maternal size and shape as well as nocturia cause insomnia. If daily living is significantly compromised, anaemia or hypothyroidism should be excluded.

Cardiovascular system

The hyperdynamic circulation of pregnancy causes alterations to the cardiovascular system that can mimic heart disease (see Chapter 13.6). Furthermore, palpitations, dizziness, syncope, and dyspnoea are common symptoms of healthy pregnancy. Failure to distinguish between benign physiological change and significant pathology creates unnecessary anxiety and investigations.

Clinical examination

During healthy pregnancy, the peripheral pulses are full, bounding, and often collapsing, suggesting aortic regurgitation to the untutored. From mid-gestation onwards the jugular venous pressure becomes more obvious and may be raised due to increased intra-abdominal pressure. The apex beat is more forceful and because of the

increase in cardiac output may suggest cardiomegaly in normal patients. However, if the apex beat is more than 2 cm outside the midclavicular line, this should be considered abnormal. On auscultation, an ejection systolic flow murmur can be heard in up to 90 per cent of healthy pregnant women. During the last trimester, increased mammary blood flow can produce a bruit that varies with the pressure of the stethoscope.

In developed countries it is very rare for new heart lesions to be identified during pregnancy: most women with heart disease are diagnosed early in life. By contrast, women from developing nations are more likely to present with previously unrecognized cardiac abnormalities.

Palpitations

Transient sinus tachycardia, up to 130 beats/ min, and premature atrial and ventricular ectopic beats are common features of healthy pregnancy, especially in women who complain of palpitations. As pregnancy may expose previously asymptomatic abnormalities of cardiac conducting tissue, investigations should include a 12-lead ECG. During healthy pregnancy, the QRS axis moves to the left as the diaphragm becomes elevated and Q waves and inverted T waves are frequently seen in lead III and aVR. Pregnant women with syncope or presyncope coinciding with palpitations should have a 24-h Holter monitor. Thyrotoxicosis, anaemia, hypokalaemia, excess caffeine, or tobacco should be excluded.

Oedema

By the end of pregnancy, 80 per cent of healthy women will have some degree of oedema. This is due to a fall in plasma albumin concentration of 5 to 10 g/litre and reduced venous return. Unless peripheral oedema is very severe, or is associated with pulmonary oedema, diuretics should be avoided: they attenuate the plasma volume expansion of healthy pregnancy, which can lead to restriction of fetal growth. Severe and rapid onset of oedema, especially affecting hands and face, may herald pre-eclampsia and warrants further assessment.

Blood pressure

Peripheral vasodilatation leads to a slight fall in blood pressure by the end of the first trimester, which gradually returns to non-pregnant values during the third trimester. Systolic and diastolic readings are approximately 10 mmHg higher when measured sitting or standing as compared with the left lateral position, hence blood pressure should be measured with the mother in the same position at each antenatal visit. A blood pressure reading before 20 weeks' gestation is essential to allow later discrimination between pre-existing hypertension and pregnancy-induced hypertension.

Respiratory system

Dyspnoea

The physiological hyperventilation of pregnancy leads to a subjective feeling of breathlessness in about 70 per cent of women. The maximum incidence of breathlessness is between 28 and 31 weeks' gestation, but approximately 50 per cent of women will feel breathless before 20 weeks. The early onset of dyspnoea and improvement towards term suggests that the gravid uterus has little influence on this physiological symptom. Women with gestational dyspnoea are more sensitive to CO_2 and hypoxia than asymptomatic women and respond with excessive ventilation. However, physiological dyspnoea does not usually interfere with daily activities and further investigations are only necessary if symptoms or signs suggest cardiorespiratory disease, for example chest infection, pulmonary embolus, or heart failure.

Radiological imaging in pregnancy

In general, management of pregnant women should consider the health of the mother before that of the fetus. Nowhere is this consideration ignored more than with the use of X-rays. Although ionizing radiation is a known carcinogen, there is very little—if any—increased risk of childhood cancer following prenatal exposure to X-rays. Radiation from a chest radiograph is minimal (0.02 mSv), equivalent to 3 days of background radiation. During healthy pregnancy, chest radiographs show an increased cardiothoracic ratio and pulmonary vascular markings. Pregnant women suspected of a pulmonary embolus should not be denied a ventilation-perfusion scan (1.3 mSv).

Gastrointestinal system

Nausea and vomiting

During early pregnancy, approximately 75 per cent of all healthy women will feel nauseated and up to 50 per cent will vomit. Nausea usually begins around the fifth week; by the 14th week it will have resolved in 50 per cent of women, but 10 per cent of healthy pregnant women will still feel nauseated at 22 weeks. Contrary to popular belief, nausea is rarely confined to the mornings (less than 2 per cent), but affects 80 per cent of sufferers all day. Beneficial palliative measures include rest, eating carbohydrates, and drinking carbonated drinks.

Vomiting is severe and persistent in approximately 1.5 per cent of pregnant women. This progresses to hyperemesis gravidarum when there is dehydration, weight loss, and ketonuria (see section 13.09). Ptyalism is a frequent accompaniment, due to an inability to swallow saliva. Biochemical changes often include elevated liver transaminases, elevated free T_4, and depressed thyroid-stimulating hormone. Hyperthyroxinaemia associated with hyperemesis gravidarum coincides with the rise and fall of serum human chorionic gonadotrophin, which has thyroid-stimulating activity. Treatment of hyperemesis corrects the abnormal biochemistry.

Antiemetics have not been fully evaluated in early pregnancy. The clinician must therefore balance the potential risks of teratogenesis with the risks of leaving the mother malnourished, inadequately hydrated, and vulnerable to thrombosis. Most antiemetics, including antihistamines, phenothiazines, metoclopramide, pyridoxine (vitamin B_6), and ginger have been used to treat hyperemesis with some success and without fetal harm. More severe cases have responded to steroid treatment (prednisolone 30 mg daily) or serotonin antagonists. Intravenous rehydration and occasionally parenteral nutrition are necessary. Hyperemesis gravidarum can lead to Wernicke's encephalopathy, hence thiamine (vitamin B_1) supplementation is essential.

New onset of nausea and vomiting during the second half of pregnancy suggests pathology unrelated to hyperemesis and may herald pre-eclampsia. Gastro-oesophageal reflux is a common problem of late pregnancy that usually improves with antacids or a change in diet, but persistent symptoms during pregnancy have been safely treated with H_2 receptor antagonists or proton pump inhibitors. Increased circulating progesterone levels relax intestinal smooth muscle and commonly provoke constipation. Increased dietary fibre and avoidance of unnecessary iron supplements provide symptomatic relief.

Neurological system

Headaches are common in healthy pregnancy. Many pregnant women develop migrainous type headaches for the first time in early pregnancy: if these are recurrent or do not respond to occasional paracetamol, then regular aspirin 75 mg daily or propranolol 10 to 20 mg thrice daily are good prophylactic measures. Severe, persistent headache that presents for the first time in pregnancy, or is accompanied by focal neurological signs, requires investigation with magnetic resonance imaging (see section 13.12).

Introduction of an epidural catheter during labour can lead to accidental puncture of the dura and leak of cerebrospinal fluid, causing headache that improves when lying flat. If there is no improvement within 24 h, then an injection of 2 to 3 ml of autologous blood at the site of dural puncture (blood patch) usually resolves the headache.

Carpal tunnel syndrome affects approximately 20 per cent of healthy pregnancies. It begins during the second half of pregnancy and is associated with excessive weight gain and fluid retention. Pain and numbness of the first three fingers and wrist can be severe. Wrist splints alleviate symptoms, usually making surgical intervention inappropriate, as the majority of cases recover within a few weeks of delivery.

Musculoskeletal system

Low back and pelvic pain affect approximately 50 per cent of all pregnancies. A combination of mechanical stress on the spine and pelvis and the effects of relaxin, a hormone produced by the corpus luteum to relax ligaments in anticipation of childbirth, are believed to be responsible. Some women develop radicular symptoms as the uterus presses on nerve roots and the lumbar sacral plexus, but only 1 per cent develop true sciatica with a dermatomal distribution. Progressive neurological symptoms necessitate further investigations, often with magnetic resonance imaging. Most women will benefit from massage, exercises, or a maternity cushion. Others gain relief from transcutaneous electrical nerve stimulation or a trochanteric support belt. Non-steroidal anti-inflammatory drugs should be avoided in the third trimester, and used sparingly in early pregnancy because of fetal effects.

Skin

Pruritis is a common symptom of late pregnancy, thought to be related to increased cutaneous blood flow. If there is an associated rash, then gestational skin conditions need to be considered (see Chapter 13.13). If there is no rash, then liver function should be checked to exclude obstetric cholestasis.

Supplements for a healthy pregnancy

Folic acid and multivitamins

In the United Kingdom and United States spina bifida or anencephaly (neural tube defects) affect approximately 1 in 1000 pregnancies. The neural tube develops and then closes within 28 days of conception. Women who take 400 µg folic acid daily around the time of conception and for the first 2 months of pregnancy reduce their risk of a pregnancy complicated by neural tube defects by approximately 70 per cent. Foods fortified with folic acid provide only 100 µg folic acid and natural folate-rich foods even less: these lower doses of folic acid are of no proven benefit as prophylaxis against neural tube defects. Women who have had a baby affected by spina bifida, who are taking anticonvulsants, or who have coeliac disease, require higher doses of folic acid (5 mg daily).

Multivitamin preparations without folic acid do not reduce the risk of neural tube defects. Multivitamins taken periconceptually may reduce the risk of some congenital heart defects, but beyond the first trimester are of no proven benefit for healthy women on a balanced diet.

Iron

During healthy pregnancy the haemoglobin concentration falls as plasma volume expands. A gestational fall in haemoglobin of 3 g/dl to 9.5 to 10.5 g/dl is associated with the least incidence of small babies and premature delivery. Conversely, a haemoglobin of more than 12 g/dl at the end of the second trimester is associated with a three-fold increase in pre-eclampsia and intrauterine growth restriction (both are plasma contracted states). In the developed world, supplemental iron should be reserved for those who have a haemoglobin of less than 9.5 g/dl and a mean corpuscular volume of less than 84 fl in the third trimester. In the developing world, malnutrition and chronic infection diminish iron stores that are further exhausted during pregnancy. Under these conditions, routine supplemental iron and folate may have the potential to improve maternal and neonatal outcome (see section 13.02 for further discussion).

Prophylaxis against pre-eclampsia

Pre-eclampsia affects approximately 3 to 5 per cent of healthy nulliparous women. It is a heterogeneous, multisystem disorder to which predisposed women are vulnerable in different ways. Aetiology is uncertain, but likely to be multifactorial. It is no surprise, therefore, that none of the prophylactic measures given in an attempt to reduce the incidence of pre-eclampsia have proved to be beneficial in large randomized controlled trials. Such measures have included low-dose aspirin, dietary magnesium, zinc, and calcium, antihypertensive drugs, fish oil supplements, and antioxidant vitamins. A clearer understanding of the pathogenesis of pre-eclampsia is necessary before we can expect success from prophylactic measures, and when these are available they will probably need to be individualized.

Thyroxine and iodine

During the first trimester, neurodevelopment of the fetus depends on maternal thyroxine and subclinical hypothyroidism in the mother has been associated with impaired neurodevelopment of the infant. It has therefore been suggested that all women should be screened during early pregnancy, or before conception, for hypothyroidism. The difficulties of implementing this measure are probably outweighed by more easily applied public health measures to increase iodine intake. The benefit of thyroxine replacement in women with 'low normal' thyroxine levels has not been established.

Behavioural habits during pregnancy

Exercise

Pregnancy outcome is improved by regular exercise throughout a healthy pregnancy. The gestational increases in both cardiac output and respiratory work are enhanced further by exercise. In late pregnancy, non-weight-bearing exercises such as swimming are usually preferred. Exercise may be harmful to women with impaired cardiac or respiratory function who struggle to fulfil the physiological demands of pregnancy alone.

Alcohol

Heavy alcohol consumption during pregnancy leads to the 'fetal alcohol syndrome' in approximately one-third of offspring. The susceptibility of the fetus to alcohol depends on genetic vulnerability, nutritional status of the woman, and her abuse of other drugs. The developmental and neurological abnormalities that make up the fetal alcohol syndrome affect approximately 1 to 2 per 1000 live births. Drinking one to two units of alcohol each day has not been shown to be harmful to the fetus.

Tobacco

Women should stop smoking during pregnancy as it impairs fetal growth. Nicotine gum contains less nicotine than cigarettes and none of the other toxins, making them a preferable alternative during pregnancy. Nicotine patches provide a constant release of nicotine throughout the day that exceeds that of periodic nicotine gum. Smoking is a major source of oxidant stress, but paradoxically women who smoke before and during pregnancy suffer less pre-eclampsia than non-smokers.

Caffeine

Large quantities of caffeine (more than six cups of coffee a day) increase the risk of spontaneous abortion. Moderate caffeine consumption is unlikely to be harmful.

Travel

Aircraft are pressurized to an oxygen partial pressure equivalent to that found at 8000 ft (2440 m) above sea level. During a routine commercial flight, healthy pregnant women (32 to 38 weeks' gestation) increase their heart rate and blood pressure but drop their oxygen saturation. Despite these maternal responses, fetal heart rate remains unchanged. Airlines are reluctant to carry women after 36 weeks' gestation. Long flights also increase the risk of deep vein thrombosis.

Lactation

Breastfeeding is beneficial to the infant. However, the mother who breastfeeds for 6 months or longer transiently loses 4 to 5 per cent of bone density in her lumbar spine. Calcium supplementation does not prevent this transient loss of bone mineral density, which recovers spontaneously 6 months after delivery, whether or not the mother continues to breast feed.

Postnatal depression

Almost half of all women develop the 'maternity blues'. This is characterized by tearfulness, anxiety, and irritability, starting around the third to fifth postpartum days and usually resolving with nothing more than reassurance by the tenth day. Approximately 10 per cent of women develop non-psychotic postnatal depression 4 to 6 weeks postpartum, with a maximum incidence at 3 months postpartum. The depression is similar to that occurring at other times, but is often accompanied by thoughts of harming the baby. Although most women recover without treatment over 3 to 6 months, recovery can be hastened by counselling. Women who fail to respond to counselling or who have severe depression may benefit from antidepressant treatment. Small amounts of tricyclic antidepressants and selective serotonin reuptake inhibitors appear in breast milk, but not enough to recommend stopping breastfeeding. Nonetheless, the infant should be watched for possible unwanted effects. Women who have had postpartum depression are more likely to suffer depression in later life.

Future maternal health

'Gestational syndromes' must be monitored postpartum until they resolve or reveal occult disease. For example, proteinuria related to pre-eclampsia can take up to 12 months to disappear, but may expose the 2 to 5 per cent of women with pre-eclampsia who have occult renal impairment. Similarly, abnormal liver function that does not resolve postpartum suggests non-gestational liver disease.

Insulin resistance underlying gestational diabetes mellitus resolves immediately postpartum. However, women who have had gestational diabetes mellitus have a 20 to 60 per cent risk of developing type 2 diabetes mellitus within 5 to 16 years of pregnancy. Similarly, both pregnancy-induced hypertension and pre-eclampsia, but not eclampsia, increase the mother's risk of cardiovascular disease in later life (Fig. 2).

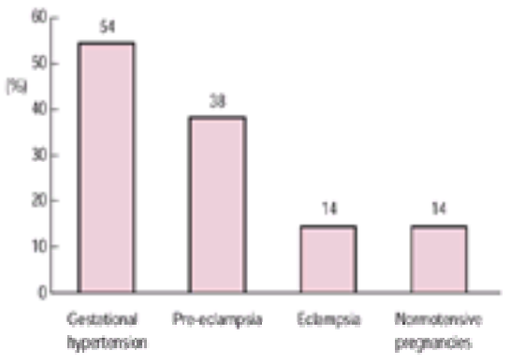

Fig. 2 Prevalence of hypertension 13.7 ± 5.1 years after pregnancy-induced hypertension (111 women), pre-eclampsia (80 women), eclampsia (14 women), and normotensive pregnancies (86 women). (Reproduced from Marin *et al*. (2000), with permission.)

Despite all of the above, most women complete an uncomplicated pregnancy. This bodes well for maternal health during subsequent pregnancies. Furthermore, those who were normotensive during pregnancy are less likely than the national average to have cardiovascular disease in later life.

13.4 Hypertension in pregnancy

C. W. G. Redman

Cardiovascular changes in pregnancy

Cardiac output increases during the first trimester to about 1.5 l/min above the levels of non-pregnant women. No further increase occurs in the second and third trimesters. Towards full term, it declines in the supine but not lateral recumbent position, owing to the pressure of the gravid uterus on the inferior vena cava, which reduces venous return to the heart. In the third trimester, about two-thirds of the additional cardiac output is distributed to the placental circulation and to augment renal plasma flow. The increased output is the result of both a greater stroke volume and a higher pulse rate. Plasma volume increases progressively during the second and third trimesters and is significantly correlated with the birthweight of the conceptus, being higher in multiple pregnancies. Arterial pressure falls in the second half of the first trimester at about the same time as the cardiac output is increasing, meaning that peripheral resistance decreases relatively more than the cardiac output increases. The uteroplacental circulation is too small at this time to cause these changes, which must therefore result from a generalized arteriolar dilatation.

In the later weeks of pregnancy, there is a tendency for the diastolic pressure to rise slowly towards what it was before pregnancy began, the systolic pressure remaining more or less unchanged. However, in the supine position, with vena caval compression and reduced venous return, the arterial pressure may be atypically low with a narrowed pulse pressure and reflex vasoconstriction. The fall in systolic pressure may exceed 30 per cent in 10 per cent of cases and cause 'the supine hypotension syndrome' —evident as restlessness, faintness, hyperpnoea, and pallor.

Hypertension in pregnancy: definition, causes, and terminology

Definition

The average blood pressure during the first half of the second trimester is about 120/70; 140/85 and 160/95 correspond to two and three standard deviations above the mean, respectively. Hypertension in obstetric practice is conventionally recognized at or above an arbitrary threshold of 140/90. This is appropriate for the first half of pregnancy, but in the second half about one-quarter of all women will be hypertensive by this criterion, meaning that these limits are too low to define an unusual group that merits extra clinical attention. About 2.5 per cent have a maximum arterial pressure of 160/105 or more and about 1 per cent of 170/110 or more; these are more relevant limits for identifying third trimester hypertension.

Causes of hypertension in pregnancy

Hypertension in pregnancy has three possible aetiologies. Most important, it may be caused by the pregnancy as part of the syndrome of pre-eclampsia, a specific disorder of pregnancy that is common, dangerous, and poorly understood. Second, it may represent chronic hypertension, a long-term attribute of the woman. In some women chronic hypertension may be revealed for the first time during pregnancy—typically towards the end; but the condition is of the woman not of her pregnancy. Third, and much more rarely, it may be a new medical condition coinciding with pregnancy by chance.

Pre-eclampsia is a common syndrome that becomes evident in the second half of pregnancy (although its origins may lie in the first half). It is defined in terms of the transient development of new hypertension and proteinuria, these may be severe, but regress after delivery.

Terminology

Eclampsia is characterized by grand-mal convulsions. Pre-eclampsia (previously called pre-eclamptic toxaemia (PET)) is so called because it may precede eclampsia, as well as a number of other possible crises. These other crises (described below) are just as dangerous as eclampsia and occur as commonly or even more so. Not all cases of eclampsia are preceded by a prodromal illness of pre-eclampsia, so the terminology is altogether too simplistic to describe the events that can occur. Toxaemia is an obsolete expression, previously used to describe any hypertension or proteinuria in pregnancy, whether pregnancy-induced or not.

Pregnancy-induced hypertension (PIH), transient hypertension of pregnancy, or gestational hypertension are terms used to describe new hypertension, which appears after mid-term (20 weeks) and resolves after delivery. They therefore describe one of the components of the pre-eclampsia syndrome. For reasons that are historical rather than logical, and which are to some extent arbitrary, PIH is deemed to be a mandatory part of pre-eclampsia. However, PIH on its own (a common clinical presentation) is not pre-eclampsia; at least one more sign is required to make the diagnosis. The clusters of clinical features that comprise any syndrome are chosen for convenience; they describe outward appearances and embody no special truth about the underlying disease or diseases. When a syndrome such as pre-eclampsia is 'defined', rules are set that bring consistency to what is being discussed. The rules may be sensible or not, but their validity cannot be tested because there is no standard to which to refer. All the definitions of pre-eclampsia suffer from these limitations and none can be said to be the best. The conventional components of the cluster are PIH combined with new proteinuria that regresses after delivery.

Almost all hypertension presenting before mid-term (gestational age of 20 weeks) indicates pre-existing or chronic hypertension, the rare exceptions being women with atypical very early onset pre-eclampsia. However, normotension in the first half of pregnancy does not necessarily mean long-term normotension: the fall in blood pressure induced in early pregnancy may be exaggerated in some women and many with relatively severe hypertension may have normal blood pressures (without treatment) by 12 weeks; indeed, in one study as many as 60 per cent of women with chronic hypertension defined before pregnancy were normotensive by the end of the first trimester. In other words, some women enjoy the benefits of pregnancy-induced normotension just as others suffer the disadvantages of pregnancy-induced hypertension. Pregnancy-induced normotension tends to be lost in the third trimester. If the prepregnancy blood pressures are unknown then this may be misinterpreted as pregnancy-induced hypertension rather than recognized for what it is, namely re-establishment of the normal, long-term blood pressure.

Pregnancy-induced hypertension thus represents at least two clinical situations; early pre-eclampsia or occult, chronic hypertension. In many cases, the signs of pre-eclampsia are not confirmed, but nevertheless the blood pressure reverts to normal after delivery. It is possible that these cases represent the very early stages of pre-eclampsia, an alternative being that an innate tendency to hypertension has been revealed in pregnancy but will become overt only many years later. The studies

have not been done to confirm or refute this suggestion.

Pre-eclampsia

Pre-eclampsia becomes evident in the second half of pregnancy, during labour or even, for the first time and without apparent preceding problems, in the immediate puerperium, but it always resolves more remotely after delivery. It is common, can be dangerous to both mother and baby, and of unknown cause.

A typical definition of pre-eclampsia is given in Table 1. This and other current definitions require that hypertension and proteinuria, both pregnancy-induced, should be present before the syndrome is recognized. It is now acknowledged that the disorder originates in the placenta, meaning that pre-eclampsia is probably the most common form of secondary hypertension in clinical practice. It is increasingly evident that there are related syndromes, characteristic of the end of pregnancy, which share the same placental causes but do not necessarily provoke hypertension. Hence, although hypertension is conventionally required as a defining feature of pre-eclampsia, it is better considered to be one of several useful signs, but not a central part of the pathology which is more extensive and can involve the maternal liver, clotting, and nervous systems.

The incidence of pre-eclampsia depends on how it is defined and how assiduously the signs are sought. It is possible only to estimate the size of the problem; in the United Kingdom the incidence is of the order of one in 20 to 30 maternities.

Some of the factors that affect susceptibility are listed in Table 2; these include fetal-specific as well as maternal-specific components. Primigravidae are several times more prone to the condition. In parous women, pre-eclampsia particularly affects those who have had the problem before. The predisposition to pre-eclampsia is in part familial, probably genetic, but the pattern of inheritance is not clear. Other factors must also be relevant because pre-eclampsia does not affect identical twin sisters concordantly.

Certain medical problems predispose to pre-eclampsia, including some (chronic hypertension, renal disease) that can mimic the disorder. Superimposed pre-eclampsia refers to the mixed syndrome comprising pre-eclampsia in an individual with pre-existing hypertension or renal disease. In the absence of a specific diagnostic test for pre-eclampsia it can be difficult or impossible to disentangle what elements of proteinuric hypertension are caused by a chronic medical problem or which arise from superimposed pre-eclampsia, and the conventional definitions of pre-eclampsia cease to apply. If a woman is permanently proteinuric there are, for example, no accepted criteria for diagnosing 'proteinuric pre-eclampsia'. Nevertheless, it seems that chronically hypertensive women are three to seven times more likely to develop higher blood pressures and proteinuria ('superimposed pre-eclampsia') than normotensive women. Women with hypertension associated with chronic renal disease are particularly susceptible.

Aetiology and pathogenesis of pre-eclampsia

The primary pathology of pre-eclampsia is not known for certain, but the presence of a placenta is both necessary and sufficient to cause the disorder. A fetus is not required as pre-eclampsia can occur with hydatidiform mole. A uterus is probably not required because pre-eclampsia may develop with abdominal pregnancy (that is an ectopic pregnancy in the peritoneal cavity). Central to management is delivery, which removes the causative organ, namely the placenta. The primary involvement of the placenta explains why pre-eclampsia is associated with two syndromes not one; the fetal syndrome of nutritional and respiratory deprivation can be as important a part of the illness as the maternal syndrome, or even more so.

The placental problem appears to be a relative ischaemia secondary to deficiencies in the uteroplacental circulation or to an excessively large placenta (with multiple pregnancies for example). The uteroplacental circulation may be compromised by two lesions involving the spiral arteries, which are the end-arteries supplying the intervillous space. The first, poor placentation, is a partial lack of the structural modifications of the spiral arteries that occur between weeks 8 and 18 (before there is clinical evidence of pre-eclampsia), when the arteries become dilated in preparation for the hugely expanded uteroplacental blood flow of the second half of the pregnancy. The second is 'acute atherosis', when aggregates of fibrin, platelets, and lipid-loaded macrophages (lipophages) partially or completely block the ends of the arteries. Neither change is specific to pre-eclampsia; they can also occur with intrauterine growth retardation without a maternal syndrome. Hence the spiral artery changes may be only an associated, but not primary, feature of pre-eclampsia. The relationship of pre-eclampsia with processes that depend on placentation could mean that it originates much earlier than when the maternal syndrome becomes overt. Once pre-eclampsia is established, uteroplacental blood flow is reduced. There is no direct evidence that placental ischaemia can cause pre-eclampsia but in various animal models impeding the placental blood supply can induce a pre-eclamptic-like illness.

The secondary pathology of pre-eclampsia includes all the features of the maternal syndrome, short of decompensation. The maternal syndrome is typically variable in the time of onset, speed of progression, and the extent to which it involves different systems including arterial, coagulation, renal, central nervous, and hepatic. Until recently it was impossible to explain how a single pathological process might cause not only hypertension but also convulsions, disseminated intravascular coagulation, jaundice, hepatic dysfunction, or normotensive proteinuria (among others). However, the concept that the maternal endothelium is the target organ for the pre-eclampsia process has resolved this difficulty. In short, the maternal syndrome is not primarily a hypertensive problem, but the sum of the consequences of diffuse endothelial dysfunction, causing widespread circulatory disturbances in different organ systems as well as generalized arterial and coagulation abnormalities. Latterly, it has been shown that the endothelial dysfunction is one aspect of a more generalized, systemic maternal inflammatory response that also affects circulating leukocytes and other components of the inflammatory system (for example the clotting system). Moreover, this increased inflammatory response is well established in the third trimester of normal pregnancy, when it is not intrinsically different from that in pre-eclampsia except that it is milder. It is thought that pre-eclampsia develops when the pregnancy-induced, systemic inflammatory response causes one or other maternal system to decompensate. In other words, the disorder is not a separate condition but simply the extreme end of a range or continuum of maternal, systemic inflammatory responses engendered by pregnancy itself. This concept has profound implications for clinical practice. If true, it is unlikely that there ever will be a single cause, single diagnostic test, or single preventive measure for pre-eclampsia.

Under certain circumstances the secondary disturbances of pre-eclampsia can become so severe that they cause decompensation, and the tertiary pathology is what makes the condition so dangerous for the mother and baby. It leads to a number of crises that are listed in Table 3.

Clinical characteristics of pre-eclampsia

Usually, hypertension precedes proteinuria, although the converse can happen. Pre-eclampsia is more variable than is generally appreciated—in the time of onset for example. Thus, although pre-eclampsia is defined as presenting after 20 weeks, it may occur earlier or, at the other extreme, become evident only after delivery. The speed with which it progresses and how it involves different maternal systems is also variable.

The hypertension of pre-eclampsia appears to be caused by an increased peripheral resistance secondary to generalized, maternal endothelial dysfunction. There is no single haemodynamic pattern, both increased and decreased cardiac output having been reported. Some of the differences between studies may reflect drug use, for example treatment with vasodilators stimulates cardiac output by reducing afterload. The blood pressure is typically unstable at rest, possibly owing to reduced baroceptor sensitivity. Circadian variation is altered with, first, a loss of the normal fall in blood pressure at night then, in the worst cases, a reversed pattern with the highest readings during sleep.

Pre-eclampsia may cause arterial pressures that are well above the level (i.e. a mean pressure of about 140 mmHg) at which arterial and arteriolar damage would be expected. It is not, therefore, surprising that an important cause of maternal death from pre-eclampsia and eclampsia is cerebral haemorrhage, the pathology of which is similar to that seen in other hypertensive states. As far as it is known, cerebral haemorrhage is the only consequence of pre-eclampsia likely to be affected by antihypertensive treatment.

The involvement of the kidneys in pre-eclampsia has long been recognized. Proteinuria usually develops after the onset of hypertension, although in 10 per cent of cases it is detected first. The proteinuria is moderately selective, increases until delivery, and not uncommonly exceeds 10 g/24 h, pre-eclampsia being the commonest cause of nephrotic syndrome in pregnancy. It is associated with impaired glomerular perfusion and filtration, both reflected in a reduced creatinine clearance and increased plasma creatinine and urea concentrations. The typical renal glomerular lesion of pre-eclampsia is glomerular endotheliosis, when the endothelial cells of the glomeruli swell and block the capillary lumina so that the glomeruli appear enlarged and blood-less. The lesion, which represents direct histological confirmation of endothelial damage in pre-eclampsia, has been defined in research investigations; renal biopsy is never indicated for clinical management. Hyperuricaemia, resulting from a reduced renal urate clearance, is often an early feature of pre-eclampsia, preceding proteinuria and is useful for diagnosis at that stage. However, it is not consistently present so that its absence does not exclude the condition. It tends to be associated with hypocalciuria, another

early change in renal function. As the plasma urate rises, the plasma concentrations of urea and creatinine at first remain steady, tending to increase slowly after proteinuria has become established. The tertiary pathology of renal involvement in pre-eclampsia is acute renal failure arising from either tubular or cortical necrosis.

Generalized oedema is an inconsistent feature. It may develop suddenly and is associated with accelerated weight gain. Ascites is not uncommon with severe disease. Laryngeal oedema can cause respiratory obstruction and difficulties with intubation when general anaesthesia is required. Pulmonary oedema is a dangerous complication. In association with modern methods of ventilatory support it may progress to the adult respiratory distress syndrome, which is increasingly a cause of maternal death in this condition.

The clotting system is often, but not invariably, disturbed in pre-eclampsia, with accelerated intravascular generation of thrombin and parallel reductions in the platelet count ascribed to increased consumption. The time course is variable, but a fall in the platelet count may be a relatively early sign—antedating proteinuria for example. However, even when eclampsia supervenes, the majority of women have normal platelet counts at the time of presentation. The coagulation disturbances may decompensate to give overt disseminated intravascular coagulation (DIC). A further complication is microangiopathic haemolysis that may cause a sudden drop in haemoglobin associated with haemoglobinuria, fragmented or distorted red cells (schistocytes) on the peripheral blood film, and reduced serum haptoglobin concentrations.

The severe clotting abnormalities of pre-eclampsia, particularly DIC, are often associated with liver pathology, long recognized as an important and dangerous component of the disorder. When there is also the associated complication of haemolysis, the acronym HELLP syndrome has been used to label the concurrence of haemolysis, elevated liver enzymes, and low platelet counts. This is often not associated with marked hypertension or other conventional indices of severe pre-eclampsia. Indeed, liver damage and low platelet counts have been observed in primigravidae without hypertension or proteinuria but with the typical hepatic histology of pre-eclampsia, including fibrin deposition in the sinusoids. Epigastric pain and vomiting are the typical symptoms of the HELLP syndrome, which may present so suddenly as to be misinterpreted as biliary colic or other surgical emergencies. Hepatic tenderness and raised serum liver enzymes are the signs. Serum bilirubin is usually normal, but jaundice is possible and may be a presenting feature. In certain severe cases, typically of multiparae rather than primiparae, there may be bleeding under the liver capsule which may rupture to cause massive haemoperitoneum, shock, and (usually) maternal death. These issues are discussed in Chapter 13.9.

Eclampsia is the most dramatic evidence of involvement of the nervous system. It resembles other forms of hypertensive encephalopathy, having similar symptoms and cerebral pathology. One of the complications of hypertensive encephalopathy is cortical blindness, a feature of severe pre-eclampsia and eclampsia as well. Average blood pressures in eclampsia are high (170–195/110–120), but cases with much lower blood pressures are not as rare as with non-obstetric forms of hypertensive encephalopathy. Eclampsia is not associated with gross papilloedema or retinopathy. Ten per cent of cases of eclampsia are totally unheralded, that is without a warning prodrome of hypertension and proteinuria. The name hypertensive encephalopathy is misleading in that it suggests that the syndrome is caused by hypertension. The hypertension is an associated feature; there is no good evidence that hypertension causes eclampsia or other forms of hypertensive encephalopathy, and none that adequate medical control of the blood pressure prevents eclampsia. It is now generally agreed that eclampsia results from acute cerebral circulatory disturbances secondary to endothelial dysfunction. Cerebral vasospasm with focal ischaemia and oedema are major features that have been demonstrated by magnetic resonance imaging or CT scanning.

Diagnosis of pre-eclampsia

Pre-eclampsia is usually symptomless, hence its detection depends on signs or investigations. Nonetheless, one symptom is crucially important because it is so often misinterpreted. The epigastric pain, which reflects hepatic involvement and is typical of the HELLP syndrome, may easily be confused with heartburn, a very common problem of pregnancy. However, it is not burning in quality, does not spread upwards towards the throat, is associated with hepatic tenderness, may radiate through to the back, and is not relieved by giving antacids. It is often very severe, described by sufferers as the worst pain that they have ever experienced. Affected women are not uncommonly referred to general surgeons as suffering from an acute abdomen, for example acute cholecystitis.

In general, none of the signs of pre-eclampsia is specific; even convulsions in pregnancy are more likely to have causes other than eclampsia in modern practice. Diagnosis, therefore, depends on finding a coincidence of several pre-eclamptic features, the final proof being their regression after delivery. There are two ways to make the diagnosis. For research purposes the rules have to be followed that require the presence of both pregnancy-induced hypertension (PIH) and pregnancy-induced proteinuria. However, this is too restrictive for clinical practice, where there are presentations with the broad attributes of pre-eclampsia that do not fit these strict definitions; clinicians need to take a broader view and accept a wider range of combinations of the possible features of the syndrome, some of which are listed in Table 4. As with all syndromes, the more of the features that are clustered together the more certain is the diagnosis, but the absence of any one feature does not exclude the diagnosis. For example eclampsia can occur without proteinuria, and even hypertension seems not to be an essential component. To diagnose pre-eclampsia superimposed on long-term hypertension or renal disease there are, as stated already, no clear rules. In these circumstances, the diagnosis has to be made intuitively by judging the exacerbation of the long-term hypertension or proteinuria, in association with the appearance of other associated signs.

In practical terms, hypertension, proteinuria, and excessive weight gain have to be the signs of interest for screening in routine antenatal clinics. Different definitions have been proposed as to what constitutes hypertension, but the details are less important than the principle of an increment from a recording taken in the first half of pregnancy, which establishes the existence of pregnancy-induced hypertension (PIH). Between weeks 20 and 30 the blood pressure is normally steady so that even a small, consistent rise is clinically important. Between week 30 and term the diastolic will rise by about 10 mmHg on average. A sustained rise of at least 25 mmHg to a threshold of 90 mmHg or more is typical of pre-eclampsia. However, these are only guidelines: there is no clinical situation where rigid interpretation of the blood pressure is helpful.

The same applies to other measurements such as changes in the plasma urate. As a rough guide, abnormal levels are in excess of 0.30, 0.35, 0.40, and 0.45 mmol/l at 28, 32, 36, and 40 weeks respectively; or, if a baseline taken before 20 weeks is available, then increases of 0.10, 0.15, 0.20, and 0.25 mmol/l at 28, 32, 36, and 40 weeks respectively.

Proteinuria and evidence of reduced glomerular filtration rate are later signs. The changes in the measurements of renal function are usually within the normal range for non-pregnant individuals. In general, abnormal concentrations of plasma creatinine and urea are above 100 µmol/l and 6.0 mmol respectively. The proteinuria of pre-eclampsia ranges from 0.5 to 15 g/24 h depending on the individual and the stage of evolution of the disorder. In terms of stick testing, 0.5 g/24 h corresponds to at least + in every specimen of urine tested, and when this point is reached the disease can be said to have entered its proteinuric phase.

Thrombocytopenia ($<100 \times 10^9$/l) and increased plasma fibrin/fibrinogen degradation products (or specific fragments thereof such as the D-dimer) tend to be late developments, if they occur at all. The same is true for raised liver enzymes. In regard to the latter, it should be noted that plasma alkaline phosphatase is always elevated in late pregnancy because of the contribution from the placental isoenzyme, hence its measurement is not a useful guide to hepatic function. Serum bilirubin is rarely abnormal. Gamma-glutamyl transferase is increased only late in the evolution of the HELLP syndrome. The best simple tests are plasma aspartate amino transferase or lactate dehydrogenase.

New hypertension and the *de novo* occurrence of one other sign allows the diagnosis to be made with reasonable certainty, but PIH on its own is not pre-eclampsia, although the term is commonly, but wrongly, used to mean mild or early pre-eclampsia. It is true that PIH maybe the first indication of the onset of pre-eclampsia, but until other signs appear this remains unconfirmed. Often spontaneous or induced delivery prevents further developments so that a final certain diagnosis cannot be made.

Complications of pre-eclampsia

Complications of pre-eclampsia are listed in Table 3. Eclampsia complicates 1 in 2000 maternities in the United Kingdom and carries a maternal mortality of 2 per cent. The HELLP syndrome is commoner, probably about 1 in 500 maternities, but may be as dangerous as eclampsia itself. These two major maternal crises can present unheralded by prodromal signs of pre-eclampsia. In other words, our terminology is not exact in the sense that eclampsia can precede pre-eclampsia. Antepartum eclampsia is likely to occur earlier in gestation and is more dangerous than that presenting in labour or after delivery, and preterm disease is generally more dangerous than that at term (Table 5). Most postpartum crises develop in the first 12 h after delivery, but later is possible and eclampsia has been documented as late as 22 days after delivery.

Cerebral haemorrhage is a lesion that can kill women with pre-eclampsia or eclampsia. In that cerebral haemorrhage is a known complication of severe hypertension in other contexts, it must be assumed that this is a major predisposing factor in this situation, although this has not been proved. Adult respiratory distress syndrome

appears to have become more common, it is not known whether this is a consequence of modern methods of respiratory support rather than of the disease itself.

Prevention of pre-eclampsia

All the evidence is that, once it becomes overt, pre-eclampsia cannot be reversed except by delivery. Reliable methods of primary prevention are therefore needed, but none that is completely effective is known. If the concepts of pathogenesis described previously are correct, it is unlikely that any single measure will be effective for all susceptible women, but specific measures of reducing the susceptibilities among subgroups of women may be identified. Measures that may be effective or are definitely not effective are summarized in Table 6.

There is no evidence that blood pressure control attenuates the progression of early pre-eclampsia, nor that it prevents superimposition of pre-eclampsia in chronically hypertensive women who otherwise are more susceptible to the disorder. The only clear advantage of antihypertensive treatment is where the hypertension is so severe that delivery is essential to preserve maternal safety. At early gestational ages antihypertensive treatment can allow prolongation of pregnancy in this context, the benefit not being from prevention but palliation. However, the extent of the presumed benefit has not been measured because severe hypertension is a reason for exclusion from randomized trials of treatment, hence in all contexts antihypertensive treatment helps to protect the mother from the consequences of her problem, but not from the problem itself.

Trials of antiplatelet agents, in particular low doses of aspirin, have given mixed results. Those which have shown antiplatelet therapy to be ineffective have tended to be the largest with the least selective recruitment. There may be a modest effect in preventing or delaying the maternal syndrome, if low-dose aspirin is started early enough, well before the onset of signs. The benefits appear to be greatest in preventing early-onset pre-eclampsia (which is relatively rare) and least in preventing the disorder presenting at term (which is common). Antiplatelet therapy does not benefit women if started after the signs of pre-eclampsia have appeared. As yet there has been no clear demonstration that perinatal survival is improved. Low dose aspirin in pregnancy seems to be safe, but there may be a slight increase in maternal bleeding problems around the time of delivery. No adverse effect on the fetus has yet been identified.

At the time of writing there is one small trial suggesting benefit from the prophylactic use of antioxident vitamins C and E started in midgestation in carefully selected groups of at-risk women. It is too soon to know if this is likely to be confirmed as a safe and effective preventive regimen.

Management of pre-eclamptic hypertension

Control of the blood pressure is only a part of patient management. The definitive treatment is always delivery, which removes the cause of the problem, that is the placenta. If the affected woman can be delivered before irreversible damage has occurred (for example cerebral haemorrhage) a complete and rapid recovery is assured. Hence the purpose of medical management is to protect the mother from the dangers of her illness during the relatively brief interval after the disease is diagnosed and before elective delivery. The main objective is to prevent extreme hypertension. The threshold at which antihypertensive treatment should be started is a matter of opinion, a conservative criterion being to begin treatment if maximum readings (systolic or diastolic) repeatedly reach or exceed 170 or 110 mmHg, respectively.

Hydralazine has been the preferred antihypertensive agent for the treatment of acute severe pre-eclampsia, given intravenously by either continuous infusion (5–10 mg/h) or intermittent boluses (of 5 mg), or by intramuscular or subcutaneous injections (of 5–10 mg). After intravenous administration there is a delay of about 20 to 30 min in the onset of action and its effect is relatively short-lived, lasting 2 to 3 h. Side effects are common and include reflex tachycardia, anxiety, restlessness, hyper-reflexia, and severe headaches. These symptoms and signs may affect 50 per cent of women and simulate the features of impending eclampsia, when the symptoms of the disease cannot be disentangled from those caused by the treatment. Labetalol, a combined a and b-adrenergic blocking agent that can be given intravenously, lowers the blood pressure smoothly but rapidly without the tachycardia characteristic of treatment with hydralazine. A typical regimen starts with 20 mg/h, which is doubled every 30 min until control has been gained, but there are no adequate trials of its parenteral use in pregnancy to show how it might affect perinatal outcome. Sodium nitroprusside and nitroglycerine are rapidly acting vasodilators that have been used to manage hypertensive emergencies in pregnancy, but both should be reserved for use by specialists, usually in the context of intensive cardiovascular monitoring. The danger is of overdose with problems associated with extreme and sudden hypotension.

The calcium channel blocking agent, nifedipine, is an effective vasodilator that acts rapidly when given by mouth. Nifedipine capsules, which act too abruptly (within 10–15 min), should not be used. The slow-release tablets have a slower onset of action (about 60 min) but a more prolonged effect; whereas a long-acting preparation, formulated for once a day administration, is less convenient for acute control of pre-eclamptic hypertension. Nifedipine is at least as safe as hydralazine to use in pregnancy and is less likely to cause troublesome tachycardia. In theory, nifedipine could interact with parenteral magnesium sulphate given to prevent or treat eclampsia because the magnesium ion inhibits calcium channels; in practice there has been a report of two cases of profound hypotension in this context. Nimodipine, another calcium channel blocker but with a selective effect on the cerebral circulation, may have particular advantages for treating cerebral ischaemia in eclamptic women.

P>Diuretics are avoided because they exacerbate the hypovolaemia of pre-eclampsia, which is often severe, but they are indicated if complications such as pulmonary or laryngeal oedema occur.

Good blood pressure control in pre-eclampsia does not ameliorate its other features; the disease persists and remains relentlessly progressive until delivery. Escape from control is common. Adequate treatment does not prevent other complications such as eclampsia, the HELLP syndrome, abruption, or progressive fetal respiratory impairment. A persisting inability to control maternal arterial pressure is one of several indications for immediate delivery.

Longer-term control of pre-eclamptic hypertension

The control of pre-eclamptic hypertension must always be extended for a few days at the least, and frequently for longer. Therefore, once the blood pressure has been controlled acutely, the effects of treatment need to be prolonged. The requirements are for a drug that is safe in pregnancy, has an onset of action in 6 to 12 h, allows some titration of effect, and can safely be combined with a second drug if needed. The choice lies between methyldopa and various b adrenergic blocking agents (b-blockers).

In adequate doses, methyldopa can control the blood pressure within 6 to 12 h: a loading dose of 500 to 1000 mg is followed by 250 to 750 mg four times a day. Sedation is the rule for the first 48 h and thereafter tiredness is common. Postural hypotension is rarely a problem in the antenatal patient. Although b-blockers cause fewer subjective side-effects, their safety in pregnancy has not been so exhaustively investigated. A preparation such as atenolol, with its slow onset of action and flat dose–response curve, is not ideal for the day to day titration of blood pressure control, but its short-term safety for the fetus and neonate has been adequately demonstrated. Oxprenolol and labetalol are faster-acting alternatives; which agent is preferred depends on the clinician's familiarity with their use.

Recent evidence suggests that long-term lowering of the blood pressure has a modest but statistically significant effect in reducing the baby's birthweight. Whether this has any long-term implications is not known. However, it is a good reason for using antihypertensive agents parsimoniously and only where there is clear evidence of a maternal risk.

Prevention of eclamptic convulsions

Eclampsia is probably caused by focal cerebral vasoconstriction and ischaemia secondary to endothelial damage and therefore is neither the result of hypertension, nor prevented by antihypertensive treatment. The best mode of prevention is well-timed delivery. It is debated whether any prophylactic anticonvulsant medication needs to be offered routinely in all cases of advanced pre-eclampsia and, if so, what it should be. Intravenous diazepam (5 mg by slow intravenous injection) is preferred to stop eclamptic convulsions, although most are self limiting. Thereafter, it is reasonable to use medication to prevent recurrent convulsions. Agents that improve cerebral perfusion are more effective than those that suppress neuronal excitability. In the former category is parenteral magnesium sulphate, widely used in the United States to prevent or treat eclampsia; in the latter is phenytoin. There is now clear evidence from a large, double-blind, controlled trial that magnesium sulphate administration is superior.

Chronic hypertension complicating pregnancy

Pregnant women with chronic hypertension tend to be older, fatter, slightly taller, and frequently with clear family histories of hypertension. Owing to the physiological

changes of pregnancy, their hypertension may be ameliorated or masked by the beginning of the second trimester so that the diagnosis is missed unless prepregnancy blood pressure readings are available. As explained above, the blood pressure tends to climb back to the levels that characterize the non-pregnant state towards the end of the third trimester. If these are high this normal change can be misinterpreted as pre-eclampsia, the distinction being that the blood pressure fails to settle after delivery.

Pre-eclampsia superimposed on chronic hypertension tends to be more severe, to occur at earlier stages of pregnancy, to cause more fetal growth retardation, and to be recurrent in later pregnancies. Pre-eclampsia occurring in normotensive women tends not to recur. If a blood pressure of 140/90 in the first half pregnancy is taken as evidence of chronic hypertension, then affected individuals have an approximately five-fold increased risk of later pre-eclampsia compared to normotensive women. This close link between the two conditions led earlier clinicians to conclude that chronic hypertension is extremely dangerous when combined with pregnancy. It is now clear that the particular risks of chronic hypertension are entirely attributable to the increased chance of developing superimposed pre-eclampsia. The majority of chronically hypertensive women who do not get pre-eclampsia can expect a normal and uncomplicated perinatal outcome. In other words, the dangers of chronic hypertension in pregnancy have been over-emphasized.

Chronic hypertension can only be diagnosed with certainty during pregnancy on the basis of readings taken in the first half, preferably before 16 weeks of gestation. Without the benefit of such readings, hypertension in the second half of pregnancy cannot be interpretated because the possibility that it may represent pre-eclampsia cannot be excluded. The signs of pre-eclampsia in chronically hypertensive women are the same as in other women, except that the blood pressure increases from a higher baseline. There may be progressive hyperuricaemia, abnormal activation of the clotting system, or new proteinuria.

Treatment of chronic hypertension in pregnancy

If antihypertensive treatment has been started before conception, the patient may seek advice about the possible effects of her medication on the growth and development of her fetus. None of the commonly used antihypertensive drugs is known to be teratogenic, but this does not preclude the possibility of subtle problems that are, as yet, unknown. For this reason it is appropriate that women with no more than moderate hypertension stop treatment before conception. By the 12th week of pregnancy, the normal fall in blood pressure is such that treatment may no longer be needed, at least until the beginning of the third trimester. Although angiotensin converting enzyme (ACE) inhibitors are often considered to be teratogenic, this is not the case; there is clear evidence that they are fetotoxic (causing growth restriction, oligohydramnios, and intrauterine and postnatal renal failure in the second and third trimester) but none that they are teratogenic. After 3 months of pregnancy they are contraindicated but not before.

If chronic hypertension is diagnosed for the first time in pregnancy, it is necessary to treat those in whom it presents an immediate (as opposed to a long-term) hazard. The precise levels at which this is necessary is a matter of opinion not fact; we take a cut-off point at 170/110 mmHg. In general medical practice, the purpose of treating less severe chronic hypertension (that is 140–169/90–109 mmHg) is to prevent long-term complications such as heart failure, aortic dissection, or coronary and cerebral vascular disease. These problems are so rare in pregnant women that in themselves they cannot justify treatment for the brief period of pregnancy. Thus, moderate hypertension *per se* carries no intrinsic maternal risk over the brief period of 9 months, except insofar as it may be the precursor of more severe hypertension. However, the higher the arterial pressure the greater the eventual perinatal mortality. The risks evolve through simple progression if the mild hypertension indicates early pre-eclampsia. By contrast, if the mild hypertension indicates a pre-existing problem, then the risk is of later superimposition of pre-eclampsia which is, as stated above, several times more likely in chronically hypertensive women. Antihypertensive treatment can only be useful if either it halts the progression of mild pre-eclampsia or prevents the superimposition of pre-eclampsia in women with long-term hypertension. There is no evidence in support of either possibility, indeed there is good evidence that control of moderate, long-term hypertension does not prevent superimposed pre-eclampsia but does cause mild fetal growth retardation. Thus, there are neither clear fetal nor maternal indications for treating moderate hypertension in pregnancy.

Oral antihypertensive agents that are used in pregnancy

The choice of oral antihypertensive agents in pregnancy is dictated by considerations of fetal safety (Table 7). Methyl dopa is the preferred agent because its fetal effects have been defined more clearly than those of other agents. Its antihypertensive action and side-effects are the same as in non-pregnant individuals. The usual treatment schedule is 1.0 to 3.0 g/day in divided doses. It can be supplemented by nifedipine.

Labetalol is a popular alternative. However, long-term b-adrenergic blockade extending throughout the second and third trimesters has been associated with significant fetal growth retardation and for this reason should be avoided. ACE inhibitors are contraindicated in the second and third trimesters.

In the unlikely event that diuretics are essential for good blood pressure control, they can be continued throughout pregnancy, but their use carries certain disadvantages if pre-eclampsia supervenes, as already discussed.

Hypertension in the puerperium

In relation to both chronic hypertension and pre-eclampsia, the highest blood pressures are often recorded in the puerperium, typically peaking at about 5 to 7 days after delivery. Antihypertensive treatment therefore has to be continued, in some women for 3 to 6 weeks or even longer after delivery. There is no clear evidence that treatment interferes with breast feeding (Table 8).

Long-term sequelae of hypertension in pregnancy

Severe pre-eclampsia and eclampsia can cause irreversible maternal complications, particularly acute renal cortical necrosis or cerebral haemorrhage. In the absence of these problems, there is no evidence that long-term health is impaired. However, in terms of life expectancy, pre-eclamptic women fall into two groups. Those who become normotensive soon after delivery have a normal life expectancy. Those who remain hypertensive not only tend to suffer recurrent pregnancy-induced hypertension but have a higher incidence of later cardiovascular disorders and reduced life expectancy, compatible with the diagnosis of underlying arterial disease.

Conclusions

A raised blood pressure is one of many secondary effects of pre-eclampsia on the mother. In pre-eclampsia the main differential diagnosis is from chronic hypertension, which in its pure form does not share the renal, coagulation, hepatic, and placental abnormalities of pre-eclampsia. The perinatal risks of chronic hypertension in pregnancy result from superimposed pre-eclampsia.

Extreme hypertension (³170/110 mmHg) in pregnancy, whatever the underlying cause, is as dangerous as it is in any other medical situation and demands treatment. However, there is no clear reason for treating more moderate hypertension on either maternal or fetal grounds. As far as it is known, the progression of moderate pre-eclampsia is not delayed, nor is the later superimposition of pre-eclampsia on moderate chronic hypertension prevented.

Methyl dopa is the most thoroughly tested antihypertensive agent for use in pregnancy; no significant adverse reaction has been observed. Labetolol is a popular alternative. In general, b-adrenergic blocking agents are safe for short-term use but cause significant fetal growth retardation if administered over longer periods (from the second trimester), although the clinical trial data are less complete than for methyl dopa. Diuretics should primarily be reserved for the treatment of heart failure complicating pre-eclampsia. Angiotensin converting enzyme inhibitors are contraindicated for use in pregnancy because of adverse effects on fetal renal function.

13.5 Renal disease in pregnancy

J. Firth

Changes in the kidneys and urinary tract during normal pregnancy

Anatomical

The most obvious anatomical change in the urinary tract during pregnancy is dilatation of the calyces, renal pelvis, and ureter. Contrary to popular belief, the ureters are not floppy and toneless, indeed tone is increased, but urinary stasis within the ureters may nevertheless contribute to the risk of asymptomatic bacteriuria developing into acute pyelonephritis. Ureteric dilatation can persist for 3 or 4 months after pregnancy, and long term in about 10 per cent of women who have had children. The kidney enlarges by about 1 cm in length during pregnancy.

Functional

Renal blood flow increases by 70 to 80 per cent between conception and midpregnancy, falling to a value 50 to 60 per cent above the non-pregnant level during the third trimester. Between conception and 16 weeks of pregnancy the glomerular filtration rate increases about 50 per cent above baseline and remains at this elevated level until delivery. Plasma creatinine decreases from a mean non-pregnant value of 73 µmol/l to 65, 51, and 47 µmol/l in successive trimesters.

Urinary excretion of glucose increases soon after conception and may rise 10-fold above non-pregnant values, hence glycosuria is common during pregnancy. This occurs because of decreased tubular reabsorption of glucose, but the reason for this is not known. Glucose excretion returns to normal non-pregnant levels within a week of delivery.

Plasma uric acid concentration decreases by about 25 per cent during normal pregnancy because of increased urinary excretion (the precise mechanism is unknown). In pregnancies complicated by pre-eclampsia or intrauterine growth retardation, the plasma uric acid concentration is higher than normal and serial measurements can be used to monitor progress. (See Chapter 13.4 for further discussion.)

The mean albumin excretion rate in pregnancy is 12 mg/day, with 29 mg/day the upper limit of normal (no different from that in the non-pregnant state). However, slightly increased urinary protein excretion is normal in pregnancy, such that proteinuria in pregnancy should not be considered abnormal until it exceeds 500 mg/day, which is over twice the upper limit of normal outside of pregnancy.

Pregnancy in women with known renal disease

Is pregnancy advisable?

Normal pregnancy is rare in women with serum creatinine more than 250 to 300 µmol/l, but many women who have renal disease will seek medical advice regarding pregnancy, the most typical questions being 'will pregnancy make my kidneys worse or do any long-term damage?' and 'will having kidney disease affect the pregnancy or baby?' The bottom line is that there is no strong medical contraindication to pregnancy from the 'renal point of view' if kidney function is only mildly compromised, proteinuria is not in the nephrotic range, and hypertension is nothing other than mild, although no woman can be given a 100 per cent guarantee. Table 1 gives a guide to the likely outcome of pregnancy in women with renal disease.

Women with a serum creatinine of less than 125 µmol/l usually have successful obstetric outcomes and there is no evidence that pregnancy adversely affects their renal prognosis. Some would suggest that more guarded advice should be given to patients with lupus nephropathy, mesangiocapillary glomerulonephritis, focal segmental glomerulosclerosis, and (perhaps) IgA nephropathy and reflux nephropathy.

When serum creatinine is in the range 125 to 250 µmol/l there is serious concern that pregnancy may cause immediate deterioration in renal function, severe hypertension, variable obstetric outcome, and an increased rate of decline of renal function postpartum.

Most women with serum creatinine more than 250 µmol/l are not fertile. The chances of conception, a normal pregnancy, and a healthy child are low; the risks to maternal health are high and pregnancy should be strongly discouraged. Women in this situation who are desperate to conceive should be told that their best chance of becoming pregnant and having a child is 1 year after successful renal transplantation.

Monitoring and management of pregnancy in women with renal disease

The chances of a successful outcome to pregnancy in a woman with renal disease are best if there is close co-operation between the patient, obstetrician, and nephrologist. At regular visits the following should be monitored: blood pressure, 24-h urine collection for proteinuria and creatinine clearance, urinary culture (for covert bacteriuria), and fetal development. Management of difficult cases requires achieving an acceptable balance between maternal and fetal interests, which is not always easy.

It is common for proteinuria to develop or to increase substantially during pregnancy in women with renal disease. Pregnancy can be allowed to continue as long as blood pressure is normal and renal function does not deteriorate. Reversible causes, such as volume depletion or urinary infection, should be sought if renal function does decline, but significant and otherwise unexplained deterioration in renal function is reason to recommend elective delivery.

The incidence of pre-eclampsia in patients with pre-existing renal disease is not known, hypertension and proteinuria being manifestations of both. The management of hypertension is the same, whether the cause is renal disease or pre-eclampsia, and is as discussed in Chapter 13.4, although whether or not mild hypertension should be treated in pregnant women with renal disease is a contentious issue. Blood pressure above 170/110 mmHg in the third trimester would be an indication for starting antihypertensive treatment in routine obstetric practice. By contrast, treatment of blood pressure above 140/90 mmHg in a non-pregnant woman of child-bearing age would be indicated in general medical practice to prevent long-term complications, and in those with renal disease (particularly if proteinuric) most nephrologists would recommend that arterial pressure be lowered even further than this. It is not known whether or not blood pressure in pregnancy should be treated more aggressively in women with renal disease than in those without.

Women with renal transplants

Fertility returns in women of child-bearing age after successful renal transplantation and over 90 per cent of pregnancies that survive the first trimester end successfully. It is generally recommended that women should not attempt to conceive for the first year after transplantation. Thereafter the risks are similar to those

suggested above for a woman with disease of her native kidneys; the risk of problems is low in the patient with good renal function, no proteinuria, and no hypertension, and there is no medical reason to dissuade such a woman from becoming pregnant. By contrast, the hypertensive woman with proteinuria and a poorly functioning graft is at high risk of adverse maternal and fetal outcome and should be strongly dissuaded from pregnancy. Prednisolone, azathioprine, and cyclosporin seem to be safe in pregnancy, there being no need for dosage adjustment in most cases. The presence of a renal transplant is not a contraindication to normal vaginal delivery and is not an indication for caesarean section. There is no increase in the incidence of congenital abnormalities in the infants of mothers with renal transplants.

Renal complications that can occur in pregnancy

Urinary tract infection

Asymptomatic bacteriuria

The incidence of asymptomatic bacteriuria is 2 to 10 per cent in pregnant and non-pregnant young women. If not treated, 40 per cent of women with asymptomatic bacteriuria will develop acute symptomatic infection during pregnancy, and treating pregnant women with asymptomatic bacteriuria should prevent approximately 70 per cent of all cases of symptomatic urinary tract infection in pregnancy. Untreated asymptomatic bacteriuria is associated with low birth weight and preterm delivery. Treatment is effective at clearing asymptomatic bacteriuria and reducing the incidence of pyelonephritis, preterm delivery, and babies with low birth weight.

E. coli is responsible for over 75 per cent of cases of bacteriuria in pregnancy. The choice of drug should be determined by the sensitivity of the organism isolated. Amoxicillin and cephalosporins are safe in pregnancy, as is nitrofurantoin, except in the last few weeks (it can produce neonatal haemolysis if used at term). Trimethoprim is contraindicated in the first trimester (folate antagonist) and quinolones should not be used at all in pregnancy (they cause arthropathy in animal studies). There is no good evidence to determine the first choice of antibiotic (pending culture results) or the duration of treatment. Use of single, high-dose therapy is controversial and some would recommend a 2-week course, with repeat urinary culture performed 1 week after treatment is stopped and monthly thereafter until delivery. About 25 per cent of patients will suffer recurrent infection and require a second course of treatment.

Symptomatic infection

Acute cystitis affects about 1 per cent of pregnant women. Treatment is as for asymptomatic bacteriuria, with the aim of abolishing symptoms and preventing acute pyelonephritis. A Cochrane review that included five studies of antibiotic treatment of symptomatic urinary infection in pregnancy concluded that there were no significant differences between any of the treatments studied and was unable to recommend any particular regimen.

Acute pyelonephritis presents with the same symptoms as it does in patients who are not pregnant (see Chapter 20.12), but the differential diagnosis in pregnancy includes uterine fibroid degeneration and abruptio placentae, and distinction from appendicitis can be particularly difficult. Preterm labour occurs in about 4 per cent of mild cases and 20 per cent of severe cases, where there is associated respiratory distress. Treatment is usually with intravenous antibiotics (typically amoxicillin or a cephalosporin) in the first instance, switching to oral therapy as the patient improves. Some advocate a 3-week course for acute pyelonephritis in pregnancy, but without firm evidence that this is necessary. However, since pyelonephritis recurs in up to 25 per cent of women during pregnancy it is important thereafter to monitor closely for evidence of recurrent urinary infection, with or without instigating prophylactic treatment with a bedtime dose of an appropriate antibiotic.

Acute renal failure specific to pregnancy

The priorities in dealing with acute renal failure in a pregnant woman are no different from those that apply to any other patient: treatment of life-threatening complications, fluid resuscitation (if necessary), establishing a precise diagnosis, treatment of any underlying condition (if possible), and timely provision of renal replacement therapy (if indicated). These issues are discussed in Section 20.5. There are, however, some causes of acute renal failure that are specific to pregnancy.

Obstetric acute renal failure

In the developed world, the incidence of obstetric acute renal failure has fallen dramatically over the last 40 years. In Leeds (United Kingdom), obstetric causes accounted for 26 per cent of cases of acute renal failure between 1956 and 1959, compared to 1.3 per cent between 1980 and 1988. A significant fall has also been seen in some parts of the developing world, where in Chandigarh (North India) obstetric causes were responsible for 25 per cent of cases of acute renal failure 30 years ago, compared with around 10 per cent today. By contrast, in a study from Turkey, the proportion of cases of acute renal failure due to obstetric causes changed only from 17 per cent to 14 per cent over the period 1980 to 1997. Where a decline in the incidence of obstetric acute renal failure has been seen, this is almost certainly attributable to improvements in perinatal care and a reduction in the numbers of septic abortions. Should acute renal failure develop in pregnancy or the puerperium then obstetric causes listed in Table 2 should be considered in addition to the conditions that can present in any patient (see Table 1, Table 2, and Table 3 of Chapter 20.4).

In most cases of acute renal failure in pregnancy, the clinical progress of the condition is typical of acute tubular necrosis, with full recovery of renal function if the patient survives. However, for reasons that are not known, pregnant women are particularly susceptible to acute cortical necrosis. The incidence of this has fallen in the developed world, from 1 in 10 000 in the decade from 1960 to less than 1 in 80 000 pregnancies in the decade from 1970 in one large study, but it still carries the risk of permanent renal failure, although delayed and partial recovery is not uncommon. (See Chapter 20.4 for further discussion.)

Acute fatty liver of pregnancy

Acute fatty liver of pregnancy is a disease of the third trimester or puerperium in which there is jaundice and severe hepatic dysfunction. In early series, the incidence of acute renal failure was over 50 per cent, but this is now much reduced, both as a consequence of the recognition of milder cases and through improved management of severe cases. The explanation for acute renal failure is unknown. Renal biopsy shows non-specific changes. (See Chapter 13.9 for further discussion.)

Haemolytic uraemic syndrome (idiopathic postpartum renal failure)

The haemolytic uraemic syndrome can present peripartum or at any time in the first few weeks after delivery, when it is often termed idiopathic postpartum renal failure. This can be a devastating condition (maternal mortality 5–20 per cent, fetal mortality 30 per cent), the cause of which is not known. Blood pressure can vary from low to very high. There may be severe heart failure and also neurological manifestations such as coma or epileptic fitting. The blood film shows a microangiopathic haemolytic anaemia, sometimes with a consumption coagulopathy in addition. Treatment is primarily supportive, but some authorities also recommend plasma exchange, although in this rare condition there are no randomized, controlled trials to justify its use. If the patient survives then renal function rarely, if ever, recovers completely and many remain dependent on dialysis. (See Chapter 20.10.6 for further discussion.)

Miscellaneous conditions

Acute hydroureter and hydronephrosis and the 'overdistension syndrome'

The anatomical changes associated with pregnancy can very occasionally be exaggerated, with massive distension of the ureters and renal pelvis. This is usually asymptomatic, but can rarely have clinical consequences. The 'overdistension syndrome' varies from transient, mild loin pain to recurrent attacks of severe loin or lower abdominal pain radiating to the groin. Variation in symptoms with posture and position are typical. Urine specimens are sterile, but can show microscopic haematuria. Diagnosis is confirmed by ultrasonography. Nursing in the knee–chest position often provides relief, but very uncommonly nephrostomy and/or ureteral stenting are required.

Rupture of the urinary tract

The development of severe, persistent pain or haematuria in a pregnant patient with acute pyelonephritis or the 'overdistension syndrome' suggests the very rare complication of rupture of the urinary tract. This can be retroperitoneal or intraperitoneal and is more likely to occur in those with pre-existing disease of the kidneys or

urinary tract, perhaps because mild weaknesses are exposed by the physiological changes of pregnancy. Distinction from other obstetric or abdominal catastrophes can be very difficult.

13.6 Heart disease in pregnancy

J. C. Forfar

Introduction

Up to 10 per cent of maternal deaths in the United Kingdom result from heart disease, and the proportion is higher in developing countries. Although rheumatic heart disease has declined world-wide, it remains an important and treatable condition in pregnancy. The improved survival of patients with treated complex congenital heart lesions presents difficult challenges for planning and management. Unfortunately, information on fetal and maternal risks in such situations is often inadequate, making it difficult to know what the best treatment is. Maternal involvement in the analysis of risks and benefits is of the greatest importance.

Cardiovascular changes in pregnancy

Significant circulatory changes occur during pregnancy (Table 1). Cardiac output increases by up to 50 per cent through increase in both heart rate and stroke volume secondary to a fall in systemic vascular resistance. The fall in blood pressure results from vasodilation mediated by gestational hormones, increased heat production, and the low resistance uteroplacental circulation. Pressure of the gravid uterus on the cava in the supine position can result in substantial falls in cardiac output and blood pressure in some women, causing weakness, light-headedness, dizziness, and even syncope. The supine hypotensive syndrome of pregnancy is relieved by turning to one side.

Blood volume increases early in pregnancy and more slowly from mid-pregnancy. These changes follow activation of the renin–angiotensin–aldosterone mechanism by oestrogens and secondary retention of salt and water. Increases in plasma volume (average 50 per cent) are faster and greater than red cell mass (average 25 per cent), thus accounting for the so-called 'physiological anaemia of pregnancy', when haemoglobin averages 11 g/dl.

Blood pressure, cardiac output, and oxygen consumption increase with the pain and anxiety of labour and from expansion of blood volume with uterine contraction. Despite blood loss on delivery, blood volume is effectively (although not actually) increased by the contracting empty uterus postpartum, and augmented preload acutely increases cardiac output. These changes return to normal over 24 h.

Cardiovascular evaluation in pregnancy

Assessment of heart disease in pregnancy is complicated by the functional changes described above, which may simulate or mask underlying heart disease. Routine investigative methods may be limited because of potential risks to the fetus.

Fatigue, reduced exercise capacity, breathlessness, and light-headedness are common symptoms during pregnancy. The increase in respiratory rate and reduced tidal volume may be perceived as breathlessness and this, combined with some peripheral oedema from increased blood volume and caval compression, with minor distension of the neck veins, may lead to an erroneous diagnosis of heart failure. The increased volume peripheral pulses, occasionally 'collapsing', and vasodilatation during later pregnancy can mimic aortic regurgitation or hyperthyroidism. The apical impulse is prominent and occasionally displaced, simulating volume loading. Heart sounds are commonly loud and may be palpable with exaggerated splitting. An apical S3 is not uncommon in pregnancy but S4 is less common and its presence should promote investigation for possible heart disease.

A soft systolic murmur at the base and lower left sternal edge occurs in most pregnancies and can radiate to the suprasternal notch and the neck. A continuous venous flow murmur may be audible in the neck along with a systolic or continuous murmur from increased flow to the breasts. Both murmurs decrease with stethoscope pressure and are less audible when the patient is upright. A diastolic murmur is rare in normal pregnancy and should prompt investigation. Murmurs associated with organic heart disease increase in intensity in pregnancy (from increased flow) and conclusions based on murmur intensity should therefore be made with caution.

Cardiovascular investigations in pregnancy

Electrocardiography (ECG)

Minor flattening of the T-waves and minor left or right QRS axis shift are common in normal pregnancy. Sinus tachycardia and atrial or ventricular premature beats are likewise frequent findings, particularly during labour and delivery. Exercise testing may confirm a clinical diagnosis of ischaemic heart disease or assess functional capacity. A low level protocol is recommended.

Chest radiography

Although the radiation dose is minimal, this test is best avoided unless there are clear indications. The uterus should be shielded. Straightening of the left heart border and prominence of the pulmonary conus are common findings, along with prominent pulmonary vascular markings. A small pleural effusion may be seen early postpartum and usually resolves quickly.

Doppler echocardiography

Cardiac ultrasound is safe and provides valuable anatomical and functional information throughout pregnancy. Late in normal pregnancy a small pericardial effusion can sometimes be seen. Trivial tricuspid and pulmonary regurgitation may be considered a variant of normal at this stage.

Cardiac catheterization

This should only be undertaken if an intervention is required for patient management. Balloon mitral valvuloplasty is an alternative to closed valvotomy for symptomatic severe mitral stenosis in pregnancy. Aortic and pulmonary balloon valvuloplasty have also been performed, as has coronary angioplasty. The brachial approach is preferable to minimize radiation exposure, and full shielding is appropriate. Radionuclide imaging techniques during pregnancy are best avoided because of uncertainty of the level of radiation exposure to the fetus.

Heart disease in pregnancy

Cardiac reserve (assessed by history and functional classification) is an important determinant of risk in pregnancy. Patients with heart disease and with no, or minimal, symptoms prior to pregnancy have a relatively small risk of complications. Patients with moderate or severe limitation prior to pregnancy are at much higher risk, and careful monitoring, and sometimes intervention, are required. Patients symptomatic at rest prior to pregnancy have a high maternal and even higher fetal mortality and pregnancy is contraindicated until their functional class can be improved.

It is therefore important that accurate diagnostic and functional evaluation of heart disease is undertaken in all patients prior to pregnancy, aiming to predict maternal and fetal risk as far as possible. The issues of maternal morbidity, long-term survival, and risks of fetal heart disease need to be discussed with the patient. It is preferable, in those with complex congenital heart disease, that such discussions take place well before pregnancy is contemplated so that appropriate action may be taken. Where predicted maternal mortality is above 30 per cent, sterilization or pregnancy termination may be most appropriate. The management of anticoagulant therapy before and during pregnancy requires special consideration (see below).

Congenital heart disease

This accounts for up to one-third of heart disease in pregnancy. Maternal and hence fetal outcome is determined by the nature of the disease, previous surgical repair, functional capacity, cyanosis, and the presence of pulmonary hypertension. Heart failure, arrhythmias, and systemic hypertension are more common with cyanotic congenital heart disease and when functional status is compromised. Infective endocarditis is a risk peripartum.

Fetal mortality averages 40 per cent in maternal cyanotic congenital heart disease, over twice that for the acyanotic mother with congenital heart disease. Low birth weight for gestational age and prematurity are more common in cyanotic mothers. The risk of important congenital defects in the fetus of mothers with congenital heart disease varies between 3 and 15 per cent.

Elective induction of labour at fetal maturity often allows better planning of monitoring and availability of key personnel. Caesarean section is usually performed for obstetric reasons rather than maternal status. Haemodynamic monitoring and maintenance of filling pressures minimize maternal risk. Antibiotic chemoprophylaxis is indicated during uncomplicated vaginal delivery in the presence of a valve prosthesis, a right to left shunt, or a surgical left to right shunt. In some centres, prophylactic antibiotics are used more widely.

Maternal risk can be classified according to structural diagnosis (Table 2).

Acyanotic shunt lesions

Atrial septal defect

This common lesion is usually well tolerated in pregnancy, even with a substantial left to right shunt. Antibiotic prophylaxis is not indicated for an isolated secundum atrial septal defect. Elective closure should be considered following delivery.

Ventricular septal defect

This lesion is well tolerated in pregnancy unless there is persistent pulmonary hypertension or impaired cardiac reserve.

Persistent ductus arteriosus

Percutaneous transcatheter closure of a persistent ductus arteriosus has occasionally been required during pregnancy because of the development of heart failure resistant to medical therapy, but the majority have a low risk provided pulmonary hypertension is not severe.

Acyanotic obstructive lesions

Aortic valve disease

Mild aortic stenosis can be missed in pregnancy because of the prevalence of a flow-related systolic murmur and confusion between a split first heart sound and the ejection click from a bicuspid valve. Asymptomatic patients with moderate or severe aortic stenosis may require careful haemodynamic monitoring during labour and delivery. Patients with symptomatic severe aortic stenosis should be advised against pregnancy, or should consider termination. Valvotomy and percutaneous balloon valvuloplasty have been performed successfully in the second and third trimesters for severe symptoms.

Coarctation of the aorta

Pregnancy is usually uneventful, although impaired fetal development, hypertension, heart failure, and aortic dissection have all been described. If possible, aortic coarctation should be corrected prior to pregnancy.

Pulmonary stenosis

The risks associated with pregnancy in this condition are low, although heart failure has been described. Balloon valvuloplasty or surgical valvotomy are intervention options, but clinical experience of these in pregnancy is small.

Cyanotic lesions

Tetralogy of Fallot

This is the commonest cyanotic congenital heart disease in adults. Pregnancy may cause major clinical deterioration because of augmented right ventricular pressure from increased blood volume and increased right to left shunting from reduced systemic vascular resistance. Reduced arterial oxygen saturation and a high haematocrit are worrying signs, and careful monitoring of labour and delivery is essential. Maternal and fetal risk are reduced where the defect has been surgically repaired, and this should be performed prior to pregnancy. Palliative aortopulmonary shunting leaves a significant risk during pregnancy.

Eisenmenger's syndrome

The high maternal mortality with this condition has been confirmed by several studies, although there are some isolated successes. One in four pregnancies reach term with a very high prevalence of growth retardation, prematurity, and perinatal death. Because of this, pregnancy is contraindicated and early termination should be considered. Thomboembolism is more common and anticoagulation should be considered in late pregnancy and postpartum. Intensive haemodynamic monitoring to avoid blood loss and blood pressure swings and to maintain filling pressures is appropriate.

Complex cyanotic congenital heart disease

The increasing success of palliative and corrective surgical procedures for complex cyanotic congenital heart disease has allowed pregnancy to be contemplated in those surviving to child-bearing age. Successful pregnancies have been reported with a single ventricle, corrected and uncorrected transposition of the great vessels, tricuspid and pulmonary atresia, but the risks are substantial and often inappropriate. Even in the absence of severe pulmonary hypertension, serious cardiovascular complications occur in one-third of pregnancies. The literature probably presents an underestimate of the risk because of a tendency to report success.

Rheumatic heart disease and other valve lesions

Rheumatic heart disease

Although rare in the United Kingdom, acute rheumatic fever may develop or recur during pregnancy and the associated carditis carries a substantial maternal risk. Antibiotic chemoprophylaxis has been advised throughout pregnancy in patients with a history of recurrent rheumatic fever.

Patients with rheumatic valvular disease should be managed according to disease site and severity. Careful haemodynamic monitoring may be necessary in late pregnancy, labour, and postpartum.

Mitral stenosis

This is the commonest cardiac lesion in pregnancy, with complications including heart failure, atrial arrhythmias (particularly fibrillation), and thromboembolism. Digoxin and b-blockade may be effective in controlling the ventricular rate and maintaining cardiac output when arrhythmias ensue. Diuretics reduce pulmonary congestion but hypovolaemia should be avoided. Asymptomatic or mildly symptomatic patients usually progress uneventfully. Severe symptomatic mitral stenosis can be successfully relieved by percutaneous balloon valvuloplasty or closed or open valvotomy. Both fetal and maternal risks appear to be modest with these procedures, although experience of balloon valvuloplasty is small. Systemic and pulmonary thromboembolism is a special complication in pregnancy and chronic anticoagulant therapy should be considered in those at higher risk based on standard criteria (see Chapter 13.7).

Mitral regurgitation

This lesion is usually well tolerated, presumably because of reduced systemic vascular resistance. Vasodilator therapy and digoxin may be indicated.

Mitral valve prolapse

This has been recognized in up to 15 per cent of women of child-bearing age and provided mitral regurgitation is not severe, there appears to be little risk to mother or fetus.

Aortic valve disease

Severe rheumatic aortic valve disease is uncommon in pregnancy. Aortic regurgitation is more frequent, but like mitral regurgitation is fairly well tolerated, partly because of the fall in systemic vascular resistance and tachycardia, both of which reduce myocardial work.

Cardiomyopathy in pregnancy

Hypertrophic cardiomyopathy

Pregnancy appears to be well tolerated, although symptoms of heart failure can develop or worsen at any stage. It is uncertain whether the risk of sudden death is increased by pregnancy. Careful haemodynamic monitoring may be indicated during labour and delivery, and avoidance of systemic vasodilatation, blood loss, and hypotension are essential. The role of b-blockade is uncertain, but these drugs can be useful in managing symptoms related to elevated left ventricular filling pressure and where there is an obstructive element to the condition.

Peripartum cardiomyopathy

This form of dilated cardiomyopathy causes left ventricular systolic dysfunction and heart failure in the last trimester of pregnancy or within the first 6 months postpartum. Other causes of dilated cardiomyopathy presenting in pregnancy should be excluded. The disease is rare in Europe but commoner in parts of Africa, with a prevalence of up to 1 per cent. Although the cause is unknown, the age at onset, geographical frequency variation, and substantial recovery of ventricular function in the majority of individuals suggest a unique and specific syndrome. Myocarditis, nutritional deficiency, small vessel coronary disease, and maternal immunological responses to a fetal antigen have all been proposed as mechanisms. Endomyocardial biopsy reveals inconsistent changes. The role of genetic factors is poorly defined.

Clinical examination reveals cardiomegaly, a third or fourth heart sound, and commonly functional mitral and tricuspid regurgitation. ECG abnormalities are widespread and usually non-specific, and a variety of arrhythmias have been described. The haemodynamic changes are similar to other forms of dilated cardiomyopathy.

Most patients respond to conventional management with digoxin, diuretics, and vasodilators. Angiotensin converting enzyme (ACE) inhibitors may affect fetal renal function and are not recommended. The role of immunosuppresive therapy is controversial and not established.

Fifty per cent of patients show substantial or complete recovery of ventricular function within 6 months postpartum. In the remainder, there is persistent left ventricular dysfunction and chronic heart failure. Progressive clinical deterioration and early death occur in a minority. There is a significant risk of thromboembolism and anticoagulant therapy is often appropriate.

The risk or relapse in a subsequent pregnancy is substantial (up to 40 per cent) and is greater in patients with persistently abnormal ventricular function.

Ischaemic heart disease

Symptomatic coronary artery disease in pregnancy has a prevalence of around 1 in 10 000. Conventional risk factors apply: particularly smoking and previous oral contraceptive use in combination, and hypercholesterolaemia. Peripartum myocardial infarction is occasionally associated with normal epicardial coronary arteries at subsequent angiography. Spasm, *in situ* thrombosis, dissection, and plaque rupture have been proposed as mechanisms.

Myocardial infarction is associated with a maternal mortality up to 25 per cent. Low-dose aspirin is relatively safe but use of thrombolytic drugs and percutaneous coronary intervention has not been adequately evaluated. Haemodynamic monitoring may be appropriate peripartum and elective caesarean section should be considered.

The Marfan syndrome

Pregnancy in patients with the Marfan syndrome is associated with an increased incidence of aortic dissection and death, particularly if existing cardiovascular disease is identified. An aortic root diameter of less than 4.5 cm and absence of progressive aortic dilatation and aortic regurgitation suggest a better outcome. However, selective literature reporting probably overestimates the true risk. In patients with established aortic root dilatation, pregnancy is undesirable and if root enlargement is progressive during the first trimester, termination must be considered. b-Blockade may reduce the rate of aortic dilatation during pregnancy, but clinical experience is limited. Regular monitoring of aortic root diameter is recommenced. Elective caesarean section may be preferable to vaginal delivery in those with significant aortic root dilatation.

Aortic dissection in the absence of the Marfan syndrome is rare, and occurs most frequently during the third trimester of pregnancy and peripartum. Precordial and transoesophageal echocardiography is the diagnostic investigation. Emergency measures to reduce blood pressure are required, although maternal and fetal mortality is high.

Primary pulmonary hypertension

A high maternal mortality rate (up to 40 per cent) has been reported and pregnancy is contraindicated. Haemodynamic deterioration during pregnancy is not predictable on the basis of preconception haemodynamics. Anticoagulation is recommended during pregnancy and early post partum.

Cardiac arrhythmias

Atrial and ventricular premature beats occur commonly in pregnancy and appear to have no adverse consequences. Patients with a substrate for supraventricular tachycardia, such as atrioventricular nodal or atrioventricular re-entry tachycardia, may experience symptomatic deterioration in pregnancy, or may develop symptoms for the first time. Bradycardia and heart block are rare and are usually congenital. Specific causes should be sought and, if appropriate, removed. Antiarrhythmic drug therapy should be initiated only for persistent arrhythmias threatening the mother or fetus (see below). Catheter ablation procedures should be undertaken postpartum to avoid unpredictable exposure to ionizing radiation.

Cardiac surgery in pregnancy

Although many cardiac operations have been described in pregnancy, including those on cardiopulmonary bypass, detailed evaluation of the risk–benefit balance is inadequate. There have been many reports of mitral valvotomy with low maternal and fetal mortality. In general, surgery considered essential for maternal health should be performed during the middle trimester or towards the end of the third trimester when elective or emergency delivery can be planned. Sustained uterine contraction is essential postpartum to minimize the risk from systemic heparinization during cardiopulmonary bypass. In appropriate circumstances, balloon valvuloplasty or coronary angioplasty seem attractive options.

Pregnancy and valve prosthesis

Increased cardiac output, a hypercoagulable state, deterioration of the bioprosthesis, and fetal risks from anticoagulation all potentially complicate pregnancy with a valve prosthesis. However, patients with no or minimal limitation before pregnancy usually have a favourable outcome. The risk of thromboembolic events with mechanical valves appears increased, partly related to anticoagulant control and the use of fixed-dose heparin regimens in the first trimester. Tissue valves are often recommended for women who wish to have children, but the long-term durability of heterograft valves in particular is questionable and premature degeneration from progressive leaflet calcification is more common in the young.

Cardiovascular drugs in pregnancy

All drugs should be avoided where possible during pregnancy and the risk/benefit balance carefully evaluated in terms of maternal health and fetal risk. For information on prescribing in pregnancy, see Chapter 13.18. Two specific issues will be discussed here: anticoagulation and the use of prophylactic antibiotics for those at risk of endocarditis.

Anticoagulation

There is no ideal anticoagulant in pregnancy. Use must depend on individual assessment of risks and benefits. Warfarin has been most widely used but has significant maternal and fetal side-effects. The risk of haemorrhage at delivery means that it should be discontinued approaching term. Fetal risks are derived from the transplacental passage of warfarin: there is a relatively high incidence of spontaneous abortion and stillbirth, and use during the first trimester has been associated with a 'coumarin embryopathy' in 5 to 15 per cent of infants so exposed. This syndrome includes hypoplasia of the nasal bone and epiphyseal stipling (chondrodysplasia punctata). Central nervous system disease, including optic atrophy and blindness, mental retardation, cerebral palsy, and intracranial bleeding have all been described and linked to warfarin.

Heparin, because of its molecular weight, does not cross the placenta. Its use in pregnancy is not without difficulty, although recent studies have shown satisfactory outcomes. Complications of long-term subcutaneous therapy include haematoma and abscess formation in the abdominal wall, thrombocytopenia, and osteoporosis. Self-injection of an adjusted dose of heparin subcutaneously every 12 h is a satisfactory approach. Fixed-dose regimens should be avoided. There is a consensus that intravenous heparin should be substituted close to term and discontinued at the onset of labour. Low molecular weight heparins have not been adequately studied during pregnancy. When the risk of thromboembolic complications is very high, for example with a mechanical mitral valve prosthesis continuous warfarin therapy (INR 2–3.5:1) may be a reasonable strategy.

A suggested strategy for the management of anticoagulation in pregnancy is shown in Fig. 1. In patients at moderate risk this involves early substitution of heparin for warfarin (preferably prior to conception) and return to warfarin from the end of the first trimester until 2 weeks before term. Continued heparin therapy throughout the pregnancy is an alternative widely practised in North America where litigation fears limit oral anticoagulation use. With the exception of premature infants, warfarin excretion in breast milk does not cause significant anticoagulation for the infant.

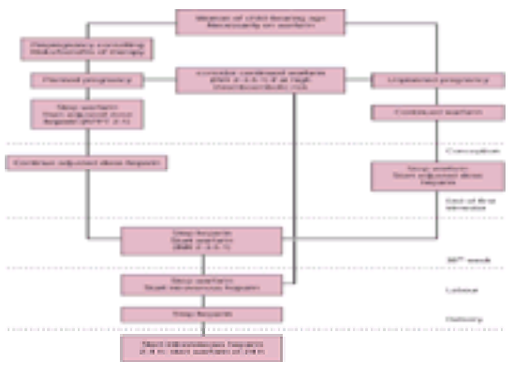

Fig. 1 A strategy for anticoagulation during pregnancy.

Prophylactic antibiotics

The incidence of bacteraemia associated with an uncomplicated vaginal delivery is low and thresholds for antibiotic chemoprophylaxis are uncertain. Routine prophylaxis is recommended for prosthetic heart valves, congenital heart disease with a right to left shunt, and when aortopulmonary anastomosis has been created with prosthetic material. Many physicians, however, also routinely administer prophylactic antibiotics to those at conventional risk from endocarditis, including valvular heart disease, ventricular septal defect, and hypertrophic obstructive cardiomyopathy. Treatment with intravenous ampicillin and gentamicin approximately 1 h prior to delivery is recommended with a second dose 8 h later. Slow intravenous infusion of vancomycin and gentamicin can be used in those who are allergic to penicillin. For patients at low risk, conventional chemoprophylaxis with oral amoxycillin is widely practised.

13.7 Thromboembolism in pregnancy

M. de Swiet

This section is concerned with thromboembolism in pregnancy, specifically deep vein thrombosis and pulmonary embolism. Arterial thromboembolism, which in pregnancy usually arises because of mitral valve disease and/or atrial fibrillation, cardiomyopathy, and the presence of artificial heart valves, is considered elsewhere. Cerebral vein thrombosis is considered in Section 15.

Significance and incidence

Pulmonary embolus is a leading cause of maternal mortality in the United Kingdom, responsible for 46 deaths between 1994 and 1996 (21 deaths per million maternities). In addition, deep vein thrombosis is a major cause of morbidity: about 80 per cent of women who have deep vein thrombosis in pregnancy have symptoms in the same leg at follow-up 11 years later. Because of the difficulties in diagnosis of non-fatal cases (see below) it is difficult to obtain precise data for the incidence of non-fatal pulmonary embolus or deep vein thrombosis. However, recent figures for the incidence of venous thromboembolism in the United Kingdom (Scotland) are 1.0/1000 maternities in women under 35 years of age and 2.4/1000 in those over 35 years. About twice as many episodes occur antenatally as in the 6-week postnatal period. Pulmonary embolism contributes 10 to 20 per cent of all cases; the remainder are deep vein thromboses.

In Africa and the Far East the condition has been almost unknown, in part due to the lower prevalence of inherited thrombophilias (see below); but those countries that have become more affluent have seen a corresponding increase in the incidence of thromboembolism.

Risk factors

It is generally believed that pregnancy itself is a risk factor for venous thromboembolism, presumably because of activation of the clotting system. Venous stasis in the lower limbs caused by obstruction of the venous return by the enlarging uterus is another factor. This effect is more marked in the left leg than the right and accounts for the fact that in pregnancy deep vein thrombosis is approximately ten times more common in the left leg than the right.

Analysis of fatal cases of pulmonary embolus shows that increasing age and parity are important risk factors: the risk of dying from pulmonary embolus in a woman aged over 40 years in her fifth pregnancy is nearly 100 times greater than in a primigravid woman aged 20 to 30 years. Caesarean section (and probably other forms of complicated instrumental delivery) increases the risk about three-fold. Oestrogen therapy to suppress lactation also increases the risk of thromboembolism and should no longer be used. Women who have had thromboembolism in the past have a 1 in 10 to 1 in 20 risk of thromboembolism in pregnancy, the risk being the same whether or not the previous episode occurred whilst taking oestrogen-containing oral contraceptives. It is not known whether previous thromboembolism in pregnancy increases the risk in subsequent pregnancies above the figures given. It is likely that prolonged periods of bed rest and obesity are also predisposing factors.

The most important specific haematological risk factors for thromboembolism are the thrombophilias. Acquired thrombophilia mainly comprises the antiphospholilpid syndromes, characterized by the presence of lupus anticoagulant and anticardiolipin antibodies, considered in Chapter 13.14. Knowledge of the inherited thrombophilias is expanding rapidly. Current estimates of the pregnancy risks of thromboembolism are as follow: factor V Leiden heterozygote: 1in 437 pregnancies; protein C deficiency: 1 in 113; type 1 antithrombin deficiency 1 in 3; type 2 antithrombin deficiency 1in 42. Increased risks that have not been accurately quantified also exist for those with protein S deficiency, the prothrombin gene mutation, and hyperhomocysteinaemia. Women with thrombophilia who have a family history of thromboembolism, and particularly those who have themselves already had an episode of thromboembolism, have a further increase in risk.

It must also be remembered that the fetus is at risk in maternal thrombophilia. The risks of miscarriage, second and third trimester loss, abruption, premature rupture of membranes, and pre-eclampsia are best characterized for acquired antiphospholipd syndrome, but they are increased in varying degree for the inherited thrombophilias as well.

Patients with any of the sickling conditions (Hb SS, Hb SC, Hb S thalassaemia) are at increased risk of developing the sickle lung syndrome in pregnancy, one component of which is probably thrombosis *in situ.* Management of haemoglobinopathies in pregnancy is considered in Chapter 13.16.

Diagnosis

The clinical features of pulmonary embolus and deep vein thrombosis are considered in Chapter 15.15.3.1. These do not differ in pregnancy, but the frequent occurrence in normal pregnancy of leg oedema, breathlessness, minor degrees of pleural effusion in the puerperium, and abnormalities of the electrocardiograph, make the clinical diagnosis even more difficult in those who are pregnant than in those who are not. Furthermore, the problems of anticoagulant therapy with its associated risks to the fetus are such that every effort must be made to make the diagnosis by objective criteria. The implications of this policy are as follows.

Deep vein thrombosis

All patients who have a history compatible with deep vein thrombosis and supporting physical signs in the legs should have a real-time ultrasound examination of the leg veins with additional Doppler blood flow studies if possible. This technique has been compared with venography in the non-pregnant state and shown to have high sensitivity and specificity for symptomatic femoral vein thrombosis. The direct comparison has not been made in pregnancy. Ultrasound is not yet accurate for calf vein thrombi, but these do not cause pulmonary emboli and the ultrasound test, being non-invasive, can be repeated to ensure that a calf vein thrombosis is not extending into the thigh. Ultrasound cannot be used above the inguinal ligament, but iliofemoral thrombosis is usually clinically obvious.

Pulmonary embolus

If a patient has a major pulmonary embolus, there is usually little doubt about the diagnosis. However, pulmonary embolus is often considered as a cause of collapse in pregnant women, particularly at the time of delivery, and the differential diagnosis of occult causes of collapse without obvious bleeding or inverted uterus is considered in Table 1. Perhaps the most important cause of confusion is intra-abdominal bleeding, with irritation of the diaphragm causing chest and shoulder-tip pain. Treatment of such a patient with anticoagulants would probably be fatal. The most important clinical features to note are the presence of abdominal signs and low jugular venous pressure in abdominal bleeding, and the raised jugular venous pressure and cardiac signs of pulmonary artery obstruction in pulmonary embolus. However, the problem of diagnosis usually arises in the patient who has pleuritic chest pain with, or without, physical signs, and either absent or non-specific signs on chest radiography. Arterial blood gas estimation may be helpful: blood samples should be taken with the patient sitting and, in cases of major pulmonary embolus, will show respiratory alkalosis with hypoxaemia. However, the definitive investigation is a lung scan, preferably a ventilation perfusion scan if there are any radiological signs in the lung parenchyma. The radiation exposure from the short-lived isotopes that are used ($^{81}Kr^{m}$ for ventilation and $^{99}Tc^{m}$ for perfusion) is trivial. If the patient

has normal blood gases and a negative lung scan, it is reasonable to exclude pulmonary embolus.

Treatment

Surgery

If the facilities and an expert team are available, the occasional patient who does not die from a massive pulmonary embolus and remains shocked and hypotensive (blood pressure less than 90 mmHg systolic, PaO_2 less than 60 mmHg, urine output less than 20 ml/h) one h after the onset of symptoms, should be considered for pulmonary embolectomy under cardiopulmonary bypass. If the patient reaches the operating theatre alive, the results are excellent. Alternatively, it may be possible to fragment the clot and improve pulmonary blood flow with a catheter introduced into the pulmonary artery. This requires only the simplest image-intensifying equipment, such as is available in most intensive care units (see Section 16).

The place of surgery (embolectomy) in massive iliofemoral thrombosis, where it might decrease the incidence of subsequent postphlebitic leg symptoms, is unclear.

Thrombolytic therapy

Streptokinase and/or urokinase treatment is probably underused for non-pregnant patients with pulmonary embolus. However, there are specific problems in pregnancy, such as bleeding, the initiation of premature labour, and the subsequent inco-ordinate uterine action associated with the release of fibrin degradation products. Therefore, in pregnancy, thrombolytic therapy should only be used in shocked patients with life threatening pulmonary embolism and as an alternative to embolectomy.

Filters

There is no substantive evidence of benefit of temporary or permanent caval interrupt devices in patients judged to be at high risk of pulmonary embolism. In pregnancy their use should be limited to those who have recurrent pulmonary embolism despite adequate anticoagulation. In practice, this happens very rarely; most recurrent pulmonary emboli occur in women who have not been adequately anticoagulated.

Anticoagulant therapy

For the reasons given above, the majority of patients will be treated with anticoagulants, the objective being to prevent further thromboembolism. As in the non-pregnant state, heparin should be used initially. Neither unfractionated heparin (UH) nor any of the low molecular weight heparins (LMWH) cross the placenta or are secreted into breast milk in significant quantities, and if heparin were to be secreted in breast milk it would not be absorbed from the infant's gastrointestinal tract, being denatured in the stomach. The only acute problem with heparin therapy is bleeding. Possible long-term problems are discussed below.

Traditionally, in the acute phase of treatment in pregnancy, heparin has been given by continuous intravenous infusion, starting at 40 000 units/24 h, adjusting the rate to double the activated partial thromboplastin time, and continuing for about 10 days. However, in the non-pregnant state clinical trials have shown that initial treatment of both deep vein thrombosis and pulmonary embolus with fixed high dose LMWH given by intermittent subcutaneous injection is as effective as intavenous infusion of UH. Typical regimens include enoxaparine 1 mg/kg 12 hourly. The advantages of LMWH regimen are considerable, in particular the lack of need for monitoring and dose adjustment, and the possibility of ambulatory treatment. It is very likely that the use of such regimen in the acute phase of thromboembolism treatment will also become standard in pregnancy, but there are concerns about this. The trials performed in the non-pregnant state have been of LMWH supported by very early additional warfarin therapy; this will not happen in pregnancy (see below), and LMWH will be used on its own for varying periods at varying intensities of therapy. Furthermore, the clotting system is activated in pregnancy, such that the doses of LMWH that have been successfully evaluated in the non-pregnant state may not be appropriate for pregnancy. Until more experience is obtained it is recommended that those using high-dose LMWH in acute phase treatment check the anti-Xa heparin assay, aiming for trough levels greater than 0.4 units/ml and peak levels less than 1.0 units/ml.

After the acute phase, the therapeutic options are oral anticoagulants, of which there is far more experience with warfarin than phenindione, and subcutaneous heparin of one sort or another. The problems with warfarin therapy in pregnancy are maternal bleeding, particularly in the puerperium, miscarriage, teratogenesis (chondrodysplasia punctata), fetal microcephaly, optic atrophy, and fetal bleeding, both retroplacental and intracerebral. The latter complications can occur with warfarin therapy at any gestational age. For these reasons warfarin should not be used in venous thromboembolism in pregnancy, although its use is necessary in those with artificial heart valves.

Once intravenous heparin has been discontinued, the patient should be given subcutaneous injections of heparin at prophylactic doses, either UH 10 000 twice daily or a LMWH such as enoxaparine 40 mg once daily. In practice, most patients receive LMWH because once daily injections are more convenient. Other possible advantages of LMWH, which remain unproven, are greater and more constant bioavailabilty, a superior risk ratio of antithrombotic activity to bleeding risk, less heparin-induced thrombocytopenia, and less bone demineralization (see below). Most patients can learn to inject themselves and administer the treatment at home. Bruising appears to be related more to the injection technique than to the type of heparin. It is not clear what degree of monitoring (if any) is necessary in this phase of heparin treatment. If the anti-Xa heparin level is less than 0.3 units/ml there should be no risk of bleeding, but the minimum heparin level for effective chronic phase or prophylactic therapy is not known. Common practice has been to check the anti-Xa heparin level at varying intervals and only adjust the dose downwards should the level be greater than 0.3 units/ml. In the absence of recurrence of thromboembolism the dose has not been increased to more than those levels recommended above. An alternative when using UH is to measure the thrombin time, which is very sensitive to excess UH (but not LMWH) activity: if it is not prolonged the patient should not be at any excess bleeding risk. In practice, when using injections of UH 10 000 twice daily or enoxaparine 40 mg once daily it is very uncommon for the anti-Xa level to be greater than 0.3 units/ml or for any of the standard clotting tests (activated partial thromboplastin time, thrombin time, INR) to be abnormal; hence the uncertainty about the need to perform these tests.

Assuming that the standard clotting tests are normal, there is no increased risk from bleeding in labour and subcutaneous heparin therapy should be continued through labour. Although there has been concern about the possibility of epidural haematoma formation in women taking subcutaneous heparin given epidural anaesthesia, this concern is not justified. Nevertheless, epidural block is often withheld until 2 h after an injection of UH or 4 h after an injection of LMWH. If an epidural catheter has been inserted similar constraints relate to its removal.

After delivery the dose of subcutaneous UH heparin is reduced to 7500 units twice daily; the dose of LMWH need not be changed. This treatment should be continued for the first week of the puerperium. After that time, the risk of secondary postpartum haemorrhage is small and patients may switch to oral warfarin therapy if that appears more desirable. Breast feeding is safe in patients taking warfarin: insignificant quantities of warfarin (though not phenindione) are secreted in the milk. Since blood-clotting parameters do not return to normal immediately after delivery, anticoagulation should be continued for some time after delivery in a patient who had thromboembolism in the antenatal period. Six weeks is often the time chosen, but the length of time is quite arbitrary.

Prophylaxis

Previous thromboembolism

Should any form of prophylactic therapy be given in pregnancy to women who have had an episode of thromboembolism in the past, granted the 5 to 10 per cent risk of recurrence? Trial data are not adequate to answer this question. Warfarin therapy is contraindicated because of the complications noted above. Some clinicians would use subcutaneous heparin throughout pregnancy, but the incidence of maternal side-effects—heparin induced thrombocytopenia (HIT) (see Chapter 13.16), alopecia, and bone demineralization—are a cause of considerable concern.

Heparin-induced thrombocytopenia is very uncommon in obstetric practice. The incidence may be less with LMWH than with UH, but patients who have had HIT with UH are certainly at risk if they take LMWH. A better alternative is the heparinoid orgaron. There are anecdotal reports of its use in pregnancy: it is also given parentally and does not cross the placenta. Clinical bone demineralization has been reported in patients taking as little as 10 000 units of heparin/day for 19 weeks, and there is evidence of subclinical bone demineralization in many patients taking heparin 20 000 units/day for more than 3 months.

If prophylaxis is to be given, the alternatives to 'standard dose' UH or LMWH prophylaxis are: the use of smaller quantities for shorter periods of time; low dose aspirin

(75 mg/day); or no prophylaxis in the antenatal period, starting heparin in labour, continuing in the puerperium for at least 1 week, and with the option of switching to warfarin for a further 5 weeks. None of these strategies has been fully evaluated.

Given the balance of risks, most clinicians would not advise prophylaxis for the patient who has simply had a single episode of thromboembolism in the past. They would, however, suggest that the patient accept the risk of prolonged subcutaneous heparin therapy if she has had more than one well-documented episode of thromboembolism, or if she has had a single episode of thromboembolism and has a known inherited or acquired thrombophilia. Patients who have had a single episode but also have a family history of thromboembolism in a first-degree relative should also receive prophylactic heparin throughout pregnancy: they may well have thrombophilia that has not yet been detected.

Thrombophilia

As indicated above, advances are being made very rapidly in this field. The risk of thromboembolism in pregnancy depends on the manner in which the condition was detected. Those found to have thrombophilia following an episode of thromboembolism are at greatest risk; those found because of a family history are at intermediate risk; and those found through population screening are at least risk.

Patients who have the antiphospholipid syndrome and have had previous thromboembolism should take prophylactic UH or LMWH throughout pregnancy and for at least 6 weeks after delivery. They are also likely to be taking low-dose aspirin for fetal reasons. If they have a particularly bad history of thromboembolism they should take LMWH in relatively high dose, granted their need to take warfarin aiming for INR 3 to 4 when not pregnant. If they have been taking heparin and aspirin in pregnancy for fetal reasons only, and have no history of previous thromboembolism, most clinicians would discontinue thromboprophylaxis at delivery unless there were other risk factors such as delivery by emergency Caesarean section.

Type 1 antithrombin deficiency has such a high risk of thromboembolism that women should take high-dose LMWH throughout pregnancy regardless of their history of thromboembolism. Antithrombin concentrate is now available and depending on the measured level of antithrombin may be given to cover labour or if the woman has an episode of thromboembolism.

It is difficult to be dogmatic about management of other forms of thrombophilia given the lack of trial data. However, patients with Type 2 antithrombin deficiency and those with homozygous factor V Leiden should probably have prophylactic low-dose heparin throughout pregnancy, whatever their past history, and if they have had a previous clot the level of anticoagulation could be increased by increasing the dose. In the remaining thrombophilias, protein C and S deficiencies, the prothrombin gene mutation, heterozygous factor V Leiden, and hyperhomocysteinaemia, heparin prophylaxis may be withheld during pregnancy but given peripartum if there is no past history of thromboembolism. Aspirin can be given to cover the antenatal period. If there is a past history of thromboembolism, prophylactic heparin should be given throughout pregnancy. Patients with hyperhomocysteinaemia should take folic acid supplements; the optimal dose is not clear, 5 mg daily should be sufficient.

Protein S deficiency cannot be diagnosed reliably in pregnancy since the levels of both free and bound protein S decrease in normal pregnancy. Genetic tests for factor V Leiden should be performed if the activated protein C resistance is low in pregnancy. However a low activated protein C resistance in pregnancy does not necessarily indicate abnormality since the activated protein C resistance is also decreased in normal pregnancy.

If a woman considering pregnancy is known to be protein C deficient, her partner's protein C status should be checked. Protein C deficiency is usually expressed in the heterozygous form. However, homozygous protein C deficiency can occur and the individual is then dependent on lifelong infusions of protein C concentrate to prevent recurrent episodes of thromboembolism.

13.8Chest diseases in pregnancy

M. de Swiet

Physiology

The pregnant woman at rest increases her minute volume by about 40 per cent within the first trimester of pregnancy. This is achieved by an increase in tidal volume rather than in respiratory rate, and is more than adequate to account for the increased metabolic rate of the mother and fetus, even in the later stages of pregnancy when maternal oxygen consumption increases by about 45 ml/min. The stimulus to increased ventilation is said to be increased progesterone secretion, but it is likely that this is not the only factor.

The majority view is that vital capacity and airways resistance do not change in pregnancy, although, surprisingly, transfer factor is reduced. The uterus enlarging within the abdomen partly accounts for a 20 per cent reduction in residual volume, but this reduction, together with change in the shape of the chest wall, occurs early in pregnancy, before there can be any mechanical effect due to the uterus. The reduction in residual volume is more marked when supine than sitting. $P\mathrm{aO}_2$ in the sitting or erect posture is unchanged in pregnancy, but falls by up to 2 kPa (15 mmHg) in patients who are supine in late pregnancy, probably due to unequal ventilation/perfusion ratios subsequent to airways closure during tidal breathing. Therefore, where possible, blood gases for diagnostic purposes should always be taken in pregnant patients when they are sitting. $P\mathrm{aCO}_2$ falls to about 4.0 kPa (30 mmHg) and plasma bicarbonate falls proportionately to about 20 mmol/l, hence there is no change in the arterial pH.

Breathlessness is a common symptom in pregnancy, presumably associated with the 40 per cent increase in ventilation that occurs in normal women. However, this cannot be the entire explanation because ventilation increases from before 4 weeks' gestation, whereas the maximum incidence of onset of breathlessness is at 28 to 31 weeks' gestation. Breathlessness is worrying for the doctor (and for the patient) because it may also be associated with cardiopulmonary disease, particularly pulmonary embolism. In the absence of other features of cardiopulmonary disease, and with normal findings on examination, useful investigations are chest radiography, arterial blood gas estimation, oximetry to determine oxygen saturation at rest and on exercise, and full lung function testing including measurement of transfer factor.

Lung disease in pregnancy—general considerations

Although ventilation does increase by 40 per cent in pregnancy, this increase is trivial in comparison to the marked increase (perhaps ten-fold) that is possible during exercise. This considerable reserve of ventilatory capacity is not greatly challenged by pregnancy and respiratory failure due to chronic respiratory disease is uncommon in pregnancy, the major problem for women with chronic conditions such as asthma or tuberculosis being the effect of therapy on pregnancy.

By contrast, acute respiratory failure is a major cause of maternal mortality: adult respiratory distress syndrome (ARDS) is the final common pathway for many obstetric disasters, carrying a mortality of about 70 per cent. Indeed, much of the practice of modern obstetrics is directed towards the avoidance of ARDS. For example the trend towards epidural rather than general anaesthesia reduces the risk of inhalation of stomach contents, and therefore of ARDS. Epidural, rather than general anaesthesia, is specifically indicated in all patients with significant chest disease.

Adult respiratory distress syndrome

The management of this condition is described in Chapter 16.5.2. Specific obstetric causes are indicated in Table 1: of these, pre-eclampsia is probably now the most common, followed by shock with or without disseminated intravascular coagulation. Some of these obstetric causes of ARDS warrant further consideration.

Inhalation of stomach contents

This only occurs in the absence of an effective gag reflex, which in obstetric practice is almost invariably associated with general anaesthesia. Most obstetric units starve their patients once labour is established, and it is a common though declining practice to give regular antacid therapy, since it is believed that the low pH of gastric contents makes them particularly harmful to the lungs, although ARDS has developed in patients given aluminium hydroxide in labour after inhalation of stomach contents at pH 6.4. Avoidance of inhalation is the single most important preventive measure. Since the maternal mortality from inhalation has fallen from 6 per cent of all maternal deaths in England and Wales in 1976 to 1978 to only one death in the United Kingdom in 1994 to 1996, current measures are probably having some effect.

Amniotic fluid embolism

This catastrophe occurs because amniotic fluid and other material of fetal origin enters the maternal circulation. Usually, though not invariably, it occurs at the end of a vigorous labour with intact membranes, generally with some obstetric intervention. Important elements in the pathogenesis are widespread deposition of platelet and fibrin thrombi, and disseminated intravascular coagulation (DIC) caused by the very high thromboplastin activity of amniotic fluid. The initial presentation is with profound hypotension and cyanosis. If the patient survives this, she is at risk of dying from haemorrhage due to DIC, and if she survives the DIC she is at risk from ARDS. In the anaesthetized patient, differentiation from inhalation is important. Bronchospasm is common in inhalation, but very rare in amniotic fluid embolus. DIC is an early presenting feature in amniotic fluid embolus, but it occurs late after inhalation. The differential diagnosis of other causes of collapse in pregnancy is considered in Table 1 of Chapter 13.7.

The diagnosis of amniotic fluid embolus can only be confirmed by finding fetal material, that is squames or hairs, in the maternal blood (from central venous pressure lines), in the sputum, or in the lungs at autopsy. However, even the finding of fetal material in maternal blood is not specific, since this has been reported in some normal women having Swann Ganz catheterization in labour. There is no specific treatment.

Asthma

Bronchial asthma is the commonest chest disease in pregnancy, with prevalence of 3 to 5 per cent. In keeping with the lack of change in airways resistance in normal pregnancy, there is little evidence that pregnancy consistently affects the clinical course of asthma. Those studies that have been performed suggest that airways responsiveness to a metacholine challenge improves during pregnancy, but this beneficial effect is trivial by comparison with the inappropriate reluctance of patients and their carers to continue normal therapy for asthma in pregnancy (see below).

There has always been concern about a possible effect of asthma on the outcome of pregnancy. Large epidemiological studies do suggest increased risks of preterm delivery, low birthweight, and congenital malformations, with relative risks of 1.3 to 2.2 compared to healthy controls. These risks almost certainly relate to poor treatment, though the cause of the birth defects is not clear. Other studies have shown no excess fetal risks when asthma specialists manage asthma in pregnancy

and achieve good control of symptoms.

It is unusual for patients to have acute attacks of asthma in labour. Perhaps the high circulating levels of endogenous catecholamines, corticosteroids, and prostaglandins are protective.

The treatment of patients with asthma does not require modification in pregnancy. Current management guidelines for asthma recommend a stepped care approach. Those with infrequent attacks should take inhaled betasympathomimetics as required to relieve symptoms, but if these are being used on a daily basis, additional regular inhaled glucocorticoids should be taken. The dose of inhaled glucocorticoid may be increased to for example beclomethasone 2000 µg per day. Alternatively a long acting b-agonist such as salmeterol or an anticholinergic drug (ipatropium) may be added. Oral prednisone should be used if these drugs do not achieve adequate control.

There is sufficient experience with all these classes of drug to recommend their use in pregnancy, but it seems sensible to use those with which there is most experience: namely oral salbutamol and inhaled beclomethasone, salmeterol, and ipatropium. Theophyllines can also be used in pregnancy, though their volume of distribution increases, making dosing difficult and emphasizing the need for monitoring of blood levels. Disodium cromoglycate has also been used extensively in pregnancy without problems, but little is used now because it is ineffective. There is insufficient experience to recommend the use of leukotriene antagonists in pregnancy.

The concern that oral steroids may be teratogenic and cause facial clefts is not supported by current studies. There is also no evidence of suppression of the fetal hypothalamo–pituitary–adrenal axis, at least with doses of up to 25 mg prednisone per day. Prednisone or hydrocortisone (by contrast with betamethasone or dexamethasone) are extensively metabolized by placental enzymes and little crosses the placenta. Women who have taken extended courses of oral steroids in the previous year should be given parenteral steroids to cover labour, as in any other situation where addisonian collapse is a possibility.

Of other drugs sometimes given to patients with asthma, aminoglycosides should only be given for more than 24 h in pregnancy if there is no alternative, and then with continuous monitoring of blood levels. This is because of the risk of damage to the fetal eighth nerve and kidney. Tetracycline should not be used because it causes permanent discoloration of the fetal teeth. Iodine-containing expectorants should not be used in pregnancy or in lactating women, since the odine freely crosses the placenta, is excreted in breast milk, and may cause hypothyroidism in the infant.

It has been suggested that ergometrine can cause severe bronchospasm in patients with asthma. Syntocinon ® should therefore be used for the management of the third stage of labour.

In summary, the management of patients with asthma requires little modification in pregnancy. In the unlikely event of an attack severe enough to require ventilation, maternal hypoxaemia should be avoided because of the associated severe fetal hypoxaemia; so also should hypocapnia (PCO_2 <17 mmHg, 2.3 kPa) and alkalosis (pH > 7.6) since these have been associated with fetal hypoxaemia, probably due to impaired placental transport.

Chronic bronchitis, bronchiectasis, and emphysema

These conditions are now very uncommon in pregnancy. Since pulmonary hypertension is poorly tolerated in pregnancy, cor pulmonale is likely to be the factor limiting maternal safety. The presence of arterial hypoxaemia puts the fetus at risk from intrauterine growth restriction.

Cystic fibrosis

Better management in childhood means that more patients with cystic fibrosis are surviving and wanting to have children. Recent analysis of 20 series concerning 217 pregnancies in 162 women indicated that pregnancy did not affect mortality, when pregnant women with cystic fibrosis were compared to non-pregnant women with cystic fibrosis. However, 24 per cent of all deliveries were preterm. Poor outcomes were associated with a pregnancy weight gain of less than 4.5 kg and a prepregnancy forced vital capacity of less than 50 per cent of the predicted value. This group is likely to produce a preterm infant and to suffer increased loss of pulmonary function and increased maternal mortality. In one small study, four out of seven women with prepregnancy FEV_1 below 60 per cent predicted died within 3.2 years of delivery, whereas all 15 women with prepregnancy FEV_1 above 60 per cent predicted survived.

Apart from high quality and intensity of obstetric and medical care, no specific measures are necessary in pregnant patients with cystic fibrosis. Most of the drugs used have been considered above. Inhaled aminoglycosides are probably safe in pregnancy.

Patients may have malabsorption due to pancreatic involvement in cystic fibrosis, and an increase in pancreatic supplements may be necessary. Diabetes mellitus can also become manifest for the first time in pregnancy, and all with cystic fibrosis should be screened for diabetes early in pregnancy, and at about 28 weeks' gestation. There is also an increased risk of pneumothorax in labour (see below).

There has been concern that women with cystic fibrosis should not breast feed their infants because of the possibility of very high sodium content of their milk (up to 280 mmol/l). This risk has probably been exaggerated, since the samples of breast milk initially analysed were taken from women who were not lactating freely, a situation in which all breast milk has high sodium content. More recent studies have indicated that once lactation has been established, the breast milk has normal sodium content. Lactation should not threaten the mother's weight providing this was reasonably maintained before pregnancy.

For couples who have had one child affected by cystic fibrosis, first-trimester prenatal diagnosis is possible on genetic material prepared from chorionic villi using linked DNA probes in at least two-thirds of cases. The prevalence of the gene in the community is said to be 1 in 20, although the overall prevalence of the disease is 1 in 2500. Therefore, women with cystic fibrosis should be counselled that there is a 1 in 20 to 1 in 44 chance that their child will have the condition if the father's status is unknown. If the father is a heterozygote, the risk is 1 in 2. All the children of affected mothers will be carriers.

Kyphoscoliosis

Mild degrees of kyphoscoliosis have no effect on pregnancy, and successful pregnancy is possible in patients with severe disease and a vital capacity of as little as 1000 ml. As in the other chest diseases, hypoxaemia and pulmonary hypertension are the limiting factors, and some with severe kyphoscoliosis become exhausted and then hypoxaemic in the last trimester. Any suggestion of excessive fatigue should be an indication for hospital admission for rest and nasal intermittent positive pressure ventilation if this is not available at home. Progressive hypoxaemia, with or without evidence of fetal compromise, is an indication for delivery. Labour and/or caesarean section are best managed with the assistance of epidural anaesthesia, which reduces the risk of atelectasis. It can be given to most patients, even those with very severe spinal abnormalities.

Pneumothorax and pneumomediastinum

There are rare complications of pregnancy (incidence less than 1 in 10 000) but they probably occur more commonly in those who are pregnant than those who are not. This is particularly so in labour, when it is supposed that the raised intrathoracic pressure due to straining is a contributing factor. However, there is often some predisposing condition such as asthma, cystic fibrosis, emphysema, or lymphangioleiomyomatosis. Cocaine use has also been implicated. Both pneumothorax and pneumomediastinum present with chest pain, and if there is a substantial leak of air the patient may be hypotensive and cyanosed (tension pneumothorax, malignant pneumomediastinum). The differential diagnosis of these and other occult causes of collapse in pregnancy are considered in Chapter 13.7. The physical signs and management of the pneumothorax are no different in pregnancy from those in the non-pregnant state, and are described in Chapter 17.12. If a patient has a past history of pneumothorax or pneumomediastinum, she should have an elective forceps delivery to prevent recurrence during straining in labour.

Tuberculosis

Before the advent of antituberculous therapy, tuberculosis was the cause of many maternal deaths, particularly in the puerperium. This is no longer so, and there should be no excess mortality from tuberculosis in pregnancy. However, a high index of suspicion is necessary to make the diagnosis in pregnancy: most centres in the United Kingdom have not screened for tuberculosis in pregnancy by routine Mantoux testing and/or chest radiographs for many years. In the future, and in areas

with high prevalence of tuberculosis in pregnancy, this policy may have to be changed.

The placenta is a very efficient filter, and intrauterine infection of the fetus almost never occurs, though neonatal infection from the mother can certainly be a problem.

None of the front line antituberculous drugs, rifampicin, pyrazinamide, isoniazid, or ethambutal, has been shown to be teratogenic despite extensive experience. However, isoniazid (and rifampicin) can cause serious hepatitis, which in the case of isoniazid seems to be a particular risk for pregnant women. Pregnant patients should therefore have regular liver function tests and receive supplementary pyridoxine when taking isonazid. A dose of 50 mg/day has been shown to give adequate blood levels in pregnancy, but the conventional dose of 10 mg/day may also be effective. Streptomycin (an aminoglycoside) should be avoided for the reasons given above. Ethionamide should not be used because of reports of multiple congenital abnormalities. Within these limitations, the pregnant patient with tuberculosis should be treated in the same manner as she would be in the non-pregnant state. In particular, patients with HIV disease or those with drug-resistant tuberculosis should be treated without regard to the pregnancy: the risk of inadequate maternal therapy is far greater than any potential risk of antituberculous treatment for the fetus.

Patients who have been adequately treated in the past for tuberculosis do not require prophylactic therapy in pregnancy. After birth, babies should only be isolated from their mothers if the mothers are still smear positive. Since modern antituberculosis regimes render the sputum sterile within 2 weeks and markedly reduce the number of organisms within 24 h, this should not occur frequently. The neonate should be treated with prophylactic isoniazid for 3 months. After this period BCG vaccination is given in the United Kingdom but not in the Unites States. It is not clear whether neonatal BCG vaccination adds any further protection to isoniazid prophylaxis. It is not without risks: skin ulceration and osteitis may occur, and occasionally disseminated disease, particularly if the mother has an immunodeficiency state. As isoniazid therapy does not affect the immunogenicity of BCG vaccine, there is no longer any rationale for the use of isoniazid-resistant BCG neonatal vaccination.

Sarcoid

This condition is rarely a problem in pregnancy. Patients who have had sarcoid in the past have no extra risk of relapse in pregnancy. Those who have active sarcoid during pregnancy tend to improve, possibly because of the increase in free as well as protein-bound cortisol levels. There is a tendency to deteriorate in the puerperium, but this should not be overemphasized. Since patients take many vitamins in pregnancy, those with sarcoid should be warned not to take vitamin D to which they may be very sensitive.

Pneumonia

Pneumonia is an uncommon complication of pregnancy, and unless the diagnosis is clear-cut, other conditions that produce chest symptoms and signs, such as pulmonary embolus, should always be considered. Bacterial pneumonia should be treated with antibiotics. For community-acquired pneumonia the antibiotics of choice in the United Kingdom are likely to be a penicillin or a macrolide such as erythromycin, both of which are suitable for use in pregnancy. Aggressive antipyretic therapy with tepid sponging, fans, and regular paracetamol should be used, because of the association between pyrexia and premature labour. During epidemics, such as the influenza epidemic in 1930, viral pneumonia has caused a high mortality in pregnancy, and clinicians should be aware that this condition should not be dismissed lightly.

Ten per cent of maternal varicella infections may be complicated by pneumonia, which has an appreciable mortality, particularly in pregnancy. All pregnant women who have close exposure to varicella-zoster virus and who have no demonstrable antibody should therefore receive zoster immune globulin. Those who develop varicella should receive acyclovir 10 to 30 mg/kg daily in three divided doses for 5 days.

13.9 Liver and gastrointestinal diseases during pregnancy

A. E. S. Gimson

Introduction

Gastrointestinal and liver disease in pregnancy includes those diseases specific to that condition, those occurring with increased frequency during pregnancy, and those already present at conception or arising coincidentally during the course of pregnancy (Table 1). Liver or gastrointestinal dysfunction is present in fewer than 5 per cent of pregnancies in Europe and the United States, but their recognition and management is important as increased maternal and fetal morbidity and mortality may result without prompt intervention.

There are significant physiological changes in hepatic function during pregnancy. Increased circulating blood volume and cardiac output are not associated with any changes in hepatic blood flow, but there is increased azygous flow, which results rarely in the formation of small oesophageal varices. Gallbladder motility is reduced and bile lithogenicity increased due to increased hepatic cholesterol synthesis and excretion into bile. Minor but important changes in laboratory blood tests occur due to haemodilution or alteration in hepatic synthesis (Table 2).

Increased gastric myoelectric activity may be manifest as nausea and vomiting, but there are few other significant changes in gastrointestinal function during normal pregnancy.

Liver disease specific to pregnancy

Hyperemesis gravidarum

Although nausea and vomiting may occur in up to 75 per cent of pregnancies, severe vomiting leading to dehydration, ketonuria, electrolyte disturbances, and nutritional deficiency is rare, developing in 2 to 16 of every 1000 pregnancies. Nutritional deficiency has been so severe as to progress to Wernicke's encephalopathy and changes in serum sodium may precipitate osmotic demyelination (central pontine myelinolysis). More common in younger women and in obesity, recent surveys do not suggest any relationship with parity or gravidity. Elevated transaminases, by two- to threefold, occur in 50 per cent of cases, with a minor rise in alkaline phosphatase and bilirubin in 10 per cent. Liver histology shows few abnormalities or hepatic steatosis only. The aetiology is unclear and may be multifactorial: positive *Helicobacter* serology has been reported in up to 90 per cent of cases, and changes in thyroid function are present in 50 per cent. An elevated free T_4 with suppressed thyroid-stimulating hormone correlates with elevated human chorionic gonadotrophin levels in these patients, raising the possibility that gestational thyrotoxicosis may also have role in pathogenesis. In some cases psychological factors are also important.

Management, which may include hospitalization, is symptomatic and includes rehydration and correction of nutritional deficiencies. Psychological support is crucial. Treatment of symptomatic gastro-oesophageal reflux is important and antiemetics are required, with metoclopramide and promethazine as effective as newer 5-HT_3 antagonists. There are uncontrolled reports of benefit with corticosteroids. In rare cases there may be recurrence in subsequent pregnancies.

Intrahepatic cholestasis of pregnancy

A cholestatic disorder of the second and third trimesters, this is the most common cause of jaundice during pregnancy, after acute viral hepatitis. Initially starting with pruritus, jaundice follows after 1 to 4 weeks in 20 to 60 per cent of cases, associated with pale stools and dark urine. Diagnosis is by history and the classic biochemical features of an elevated bilirubin (less than 100 µmol/litre) and increased aminotransferases (rarely more than 250 iu/litre), with no significant rise in alkaline phosphatase or g-glutamyl transpeptidase. Serum bile acids increase three- to 100-fold: those factors with the highest predictive diagnostic value being total bile acid concentration of more than 11.0 µmol/litre and a cholic/chenodeoxycholic acid ratio of more than 1.5 with a cholic acid percentage over 42. An ultrasound scan is necessary to exclude choledocholithiasis, and further imaging of the bile duct with magnetic resonance cholangiopancreatography will occasionally be needed. A liver biopsy is not required for diagnosis, but shows a canalicular cholestasis with no hepatocellular necrosis.

The epidemiology of intrahepatic cholestasis of pregnancy is interesting, with marked geographical variation. The highest incidence, over 10 per cent, has been recorded in Arauncanian Indians in Chile, with 2 to 3 per cent in Sweden and 0.1 per cent in Canada. It is reported to be rare in Afro-Caribbeans. Family studies have suggested a dominant mode of transmission in a few kindreds, and a non-sense mutation has been reported in the *MDR3* gene that encodes an ATP-dependent transporter of phosphatidylcholine across the canalicular membrane in one family. An association with *HLA-B8*, *HLA-B12*, and *DPB1* alleles is unconfirmed. It is more common in women with a history of contraceptive pill induced jaundice (50 per cent), those with benign recurrent intrahepatic cholestasis, where there are multiple gestations, and it may be more common in women who are positive for hepatitis C virus antibodies. In France it has been associated with use of progesterone in early pregnancy.

The aetiology is unknown, but one hypothesis suggests enhanced sensitivity of components of the bile salt excretion apparatus to oestrogen: pregnancy impairs sulphation of both monohydroxy bile salts and oestrogen, which may enhance the cholestatic potential of both compounds.

Intrahepatic cholestasis of pregnancy is associated with an increased incidence of fetal prematurity (fivefold increase), fetal distress, stillbirths, and meconium staining of amniotic fluid (1.5-fold increase), but perinatal mortality is normal with modern management. Reports of maternal morbidity from postpartum haemorrhage relate to vitamin K deficiency and are not a feature of recent series.

Treatment is symptomatic, with the bile salt ursodeoxycholic acid (10–15 mg/kg/day) the treatment of choice and better than *S*-adenosyl-methionine. Ursodeoxycholic acid relieves pruritus, reduces bile salt levels in maternal serum, and may reduce the frequency of fetal complications. Both bile salt sequestration with cholestyramine and dexamethasone have given variable results. Vitamin K should be given before delivery.

Most authors recommend early elective delivery at 38 weeks to prevent late fetal complications, and this policy has been shown to improve fetal outcome. More recently there have been suggestions that a policy of careful observation and induction of labour only for fetal distress may be used, but there is anxiety that classical

markers of fetal distress may not be adequate in this setting.

Intrahepatic cholestasis of pregnancy recurs in up to 60 to 80 per cent of subsequent pregnancies and is associated with a late increased incidence of gallstones. Oral contraceptives should be used with caution, although early reports of liver abnormalities were predominantly with high-dose pills and combined low-dose preparations may cause fewer problems.

Acute fatty liver of pregnancy

Acute fatty liver of pregnancy, a microvesicular steatosis during the last trimester of pregnancy, was first adequately described by Sheehan in 1940. Occurring in 1 in 14 000 pregnancies between the 34th and 36th weeks, it is more common in primigravidae, with male fetuses, and with twin pregnancies. Up to 40 per cent may have associated features of pre-eclampsia, with peripheral oedema, hypertension, and proteinuria, and occasionally the **HELLP** (Haemolysis, Elevated Liver enzymes and Low Platelet count) syndrome (see below). Acute fatty liver of pregnancy occurs only rarely before the third trimester, but postpartum presentations are well recorded. Initial symptoms are of headache, fatigue, nausea, and vomiting with abdominal discomfort. In severe cases jaundice develops within 14 days. This may progress to manifest all the features of acute liver failure, including coma, renal failure, and death. However, less severe cases are now described more commonly, with recent series reporting a 10 to 20 per cent fetal and maternal mortality.

The cause of many cases of acute fatty liver of pregnancy may be a fetal–maternal interaction resulting from abnormalities of mitochondrial fatty acid oxidation. Schoeman first reported a case of acute fatty liver of pregnancy associated with a defect of fatty acid oxidation in the fetus. More recently a mutation has been identified involving substitution of glutamine for glutamic acid at amino acid residue 474 of the alpha subunit of long-chain 3-hydroxyacyl-CoA dehydrogenase, an enzyme that forms one component of a trifunctional protein catalysing the last three steps in the b-oxidation of fatty acids within mitochondria. Heterozygote mothers carrying fetuses with long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency may develop either acute fatty liver of pregnancy or HELLP syndrome in up to 80 per cent of cases. Mitochondrial oxidation of fatty acids is already impaired during pregnancy, mediated by oestrogen and progesterone, and long chain 3-hydroxyacyl metabolites produced by the fetus can accumulate and be toxic to the liver. Because presentation of children with long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency may occur late after birth, with non-ketotic hypoglycaemia and sudden infant death, the early identification and treatment of such cases is important. For this reason diagnostic molecular testing is recommended on all mothers and offspring of acute fatty liver of pregnancy and HELLP pregnancies.

The important differential diagnosis is between acute viral hepatitis with liver failure, acute fatty liver of pregnancy, and hypertension-associated liver dysfunction of pregnancy. The presence of features of pre-eclampsia in up to 40 per cent may make this distinction difficult. In acute fatty liver of pregnancy transaminases are elevated to less than 500 iu/litre, in contrast to viral hepatitis where values are usually higher. Hypoglycaemia is more common in acute fatty liver of pregnancy than in pre-eclampsia, and a blood film commonly showing neutrophilia, normoblasts, thrombocytopenia, target cells, and giant platelets may also help to make the diagnosis of acute fatty liver of pregnancy. Prothrombin and partial thromboplastin times are prolonged with low antithrombin III levels. Although hepatic steatosis in acute fatty liver of pregnancy may be detected by ultrasonography, CT scanning is more sensitive with attenuation values less than half normal and less than spleen, the reverse of normal. Hyperuricaemia is present in 80 per cent, but is not pathognomonic as this may also be found in pre-eclampsia.

Despite all these biochemical and radiological tests, and because differentiation of acute fatty liver of pregnancy from acute viral hepatitis and hypertension-associated liver diseases is important in assessing the prognosis for future pregnancies, a liver biopsy may be necessary to distinguish between these three diagnoses. Histology demonstrates a microvesicular fat deposition with rare hepatocyte necrosis and minimal inflammation, a pattern similar to that seen in Reye's syndrome, tetracycline and sodium valproate hepatotoxicity, Jamaican vomiting sickness due to a toxin in unripe ackee fruit, some urea cycle enzyme deficiencies, and defects in mitochondrial fatty acid oxidation.

Other obstetric causes of renal failure that are associated with minor changes in liver blood tests rarely need to be considered. These include thrombotic thrombocytopenic purpura and haemolytic uraemic syndrome. The former is particularly associated with neurological signs, including epileptic fits, without evidence of disseminated intravascular coagulation, whereas haemolytic uraemic syndrome may occur postpartum and with microangiopathic anaemia.

After the diagnosis of acute fatty liver of pregnancy has been established, the most important component of management is early delivery of the fetus. A policy of careful monitoring has been proposed for the mildest cases, but extreme caution is required as deterioration can be sudden and unpredictable. Vaginal delivery can be tried first, but caesarean section will usually require general anaesthesia as a spinal anaesthetic in the presence of coagulation deficits may be dangerous. Hypoglycaemia is prevented by intravenous dextrose infusion; aggressive correction of coagulation abnormalities with fresh frozen plasma, cryoprecipitate, and antithrombin III has also been recommended. Liver transplantation has been used (very rarely) for cases failing to respond to early delivery and intensive care.

The risk of recurrence of acute fatty liver of pregnancy is very low, the few recorded cases most probably being due to associated recurrent metabolic defects in the fetus.

Hypertension-associated liver diseases of pregnancy

Hypertension occurs in up to 8 per cent of pregnancies and is the most common cause of maternal mortality in developed countries. Abnormalities of liver blood tests have been described in three clinical syndromes associated with hypertension in pregnancy: pre-eclampsia/eclampsia, spontaneous hepatic rupture, and the HELLP syndrome.

Pre-eclampsia/eclampsia

The development of peripheral oedema, proteinuria, and hypertension (blood pressure above 140/90 mmHg or an increase of 30 mmHg systolic and 15 mmHg diastolic pressure above pre-existing levels) occurs in up to 5 per cent of all deliveries, more commonly with primigravidae, extremes of age, multiple gestations, and family history. Pre-eclampsia is discussed in detail in section 13.04, but there are abnormalities of liver biochemistry in up to 25 per cent of mild cases and up to 80 per cent of those with severe disease, i.e. those with renal impairment, visual disturbance, headache, fits, and the onset of eclampsia. The usual abnormality is a rise in transaminases, with jaundice occurring only in the most severe cases. The alanine aminotransferase levels are usually less than 150 iu/litre, lower than in acute fatty liver of pregnancy, and bilirubin is less than 100 µmol/litre. Changes in coagulation parameters, with elevated D-dimers, reflect the intravascular activation and consumption of clotting factors. Antithrombin III levels are low. Liver histology in the early stages shows few changes except for deposition of fibrinogen within sinusoids and the space of Disse. Blockage of sinusoids by fibrin may progress to frank infarction of hepatic parenchyma, when the low levels of coagulation factors may then predispose to haemorrhage into these infarcted areas. This combination of infarcts and associated haemorrhage, often covert and without apparent clinical consequence, may be demonstrated on ultrasound or CT scan of the liver.

The management of liver dysfunction in this context is that for pre-eclampsia, with correction of hypertension and coagulation defects, early delivery being the most important aspect. Anticonvulsant prophylaxis must be considered. Very close fetal monitoring is important. Liver biochemistry improves after delivery, but a late cholestatic phase with rise in alkaline phosphatase and g-glutamyl transpeptidase is common.

Spontaneous hepatic rupture

Spontaneous rupture of the liver is fortunately rare, occurring in 1 in 100 000 deliveries. In 80 per cent of cases liver haematomas, segmental or larger infarcts, and rupture occur in patients with severe pre-eclampsia and eclampsia: the remainder occur in association with acute fatty liver of pregnancy, or underlying hepatic adenomata, hepatocellular carcinoma, haemangioma, choriocarcinoma, or liver abscess.

The classical presentation is with right upper quadrant pain, nausea, vomiting, and hypotension in an older woman with severe pre-eclampsia during the third trimester. Right upper quadrant tenderness may be associated with frank peritonism where rupture into the peritoneum has occurred. The diagnosis can be confirmed by ultrasonography or CT scanning. Current treatment is conservative if possible, starting with angiography and hepatic artery embolization, proceeding to laparotomy, use of collagen meshes, and hepatic artery ligation if necessary. Successful orthotopic liver transplantation has also been recorded, but associated coagulation abnormalities are difficult to manage. The baby should be delivered by caesarean section. Successful subsequent pregnancies are recorded, as is recurrent haemorrhage, hence careful monitoring of any future pregnancy is necessary.

Haemolysis, elevated liver enzymes, and low platelet count (HELLP syndrome)

Weinstein first described a syndrome of haemolysis, elevated liver enzymes, and a low platelet count in patients with severe pre-eclampsia or eclampsia. HELLP syndrome occurs in 10 per cent of pregnancies with severe pre-eclampsia. Strict criteria should be used for the diagnosis: haemolysis with a characteristic peripheral blood smear, serum lactate dehydrogenase greater than or equal to 600 U/litre, serum aspartate aminotransferase greater than or equal to 70 U/litre and platelet count less than 100×10^9/litre. An abnormal peripheral blood smear with fractured red blood cells (schistocytes, echinocytes, spherostomatocytes) is sensitive but not specific for HELLP, and the elevated serum lactate dehydrogenase is another indicator of haemolysis. Some cases display only one or two of the above criteria and have been labelled as having partial HELLP: these have been shown to follow a less severe clinical course. HELLP syndrome has also been classified (by Martin and colleagues) according to platelet count: class 1 platelet counts less than or equal to $50\,000 \times 10^9$/litre, class 2 more than 50 000 to less than or equal to $100\,000 \times 10^9$/litre, and class 3 more than $100\,000 \times 10^9$/litre, which is equivalent to partial HELLP.

The reason why some cases with severe pre-eclampsia progress to HELLP syndrome is not clear. Whilst the haemolysis is clearly related to intravascular deposition of thrombin and mechanical fracture of red cells, and there is fibrin deposition obstructing hepatic sinusoids, the factors causing particular damage to the hepatic microcirculation are unknown. Overt disseminated intravascular coagulation is not usually a major component; when defined as hypofibrinogenaemia (< 300 mg/dl) and elevated D-dimers (> 40 µg/ml) it occurred in 21 per cent of a series of 442 cases. Compared with other cases with severe pre-eclampsia, those with HELLP syndrome tend to be older, Caucasian, and multiparous.

Symptoms usually start in the second or third trimester, with 15 per cent starting prior to 26 weeks and 30 per cent only developing symptoms after delivery. HELLP syndrome has protean manifestations but universal early symptoms include malaise and fatigue, followed by nausea, vomiting, and headache shortly thereafter (Table 3). Epigastric and right upper quadrant pain are ominous signs, particularly when accompanied by right shoulder tip pain. Weight gain and peripheral oedema are found in 50 per cent, with diastolic blood pressure greater than or equal to 90 mmHg in all but a small minority.

The fall in platelet count and rise in transaminases usually reach their nadir in the first 2 days postpartum. Aspartate aminotransferase and lactate dehydrogenase are elevated in unison, along with other markers of hepatocellular or sinusoidal cell dysfunction, glutathione-*S*-transferase and hyaluronic acid.

Maternal complications associated with HELLP syndrome occur in up to 50 per cent of cases. Blood transfusion to correct hypovolaemia, anaemia, or coagulopathy is required in 50 per cent, with features of disseminated intravascular coagulation in 25 per cent, and pleural effusions or pulmonary oedema in 15 to 20 per cent. Renal failure due to acute tubular necrosis may occur in 3 to 8 per cent. Obstetric complications are also associated with the degree of fall in platelet counts, with placental abruption (16 per cent) and wound haematomas after caesarean section the most prevalent. Eclampsia is approximately two to three times more common in patients with class 1 HELLP than in those with milder varieties, and consistent with this the maternal mortality was 1.5 per cent in a large series, with a perinatal mortality in Martin *et al*.'s tertiary referral practice of 119/1000 infants. Overall perinatal mortality is strongly related to time of delivery, with rates as high as 30 per cent in some series, although this may be due to case selection. Mortality was 9.5 per cent in a large series assessing class 1, 2, and 3 cases. Preterm infants born before 32 weeks from mothers with HELLP syndrome had a higher frequency of severe intraventricular haemorrhage than other preterm infants. Birth weights tend to be lower in severe HELLP than in pre-eclampsia alone.

Preterm patients with HELLP syndrome should be treated at a referral centre with appropriate obstetric, anaesthetic, and haematological support. Management of the coexisting pre-eclampsia is crucial, with seizure prophylaxis using magnesium sulphate and blood pressure control with labetolol, ketanserin, or hydrallazine if blodd pressure is over 160/105 mmHg. Antenatal corticosteroids enhance fetal lung maturity if the pregnancy is of less than 32 weeks gestation. Careful fluid resuscitation is required to prevent volume overload, particularly in the presence of renal impairment, as is very close fetal monitoring.

Aside from signs of significant fetal distress, indications for urgent delivery include persistent severe right upper quadrant or shoulder tip pain, often associated with hypotension and thrombocytopenia, which indicate possible liver haematoma or impending rupture. Early delivery, at the safest time for mother and fetus, is strongly recommended in the absence of treatment that unequivocally improves the haematological abnormalities and both maternal and fetal outcome. Although arguments have been put forward for a more conservative approach in patients with mild disease—with careful monitoring of coagulation profiles, fetal growth and well being, and with the timing of delivery depending on clinical judgement—this management strategy is not without risk and has not been examined in a randomized controlled trial.

Attempts have been made to improve the outcome of HELLP with medical management alone in an effort to buy time to enhance fetal maturity and to improve the mother's clinical condition prior to delivery. Although plasma volume expansion, antithrombotic agents, plasma exchange, and corticosteroids have all been advocated, no therapies have been shown to allow safe deferral of delivery and improve outcome. In one study dexamethasone given predelivery resulted in a modest prolongation of pregnancy, whereas two other trials have shown significant improvements in haematological and biochemical parameters when given postpartum. In a trial of invasive haemodynamic monitoring, plasma volume expansion and afterload reduction, laboratory parameters improved with prolongation of gestation by 21 days, but no significant change in perinatal mortality.

Recurrence of HELLP syndrome in subsequent pregnancies is uncommon: it recurred in only 5 per cent of a series of 139 normotensive women after an index pregnancy with HELLP syndrome, despite 25 per cent developing pre-eclampsia. In hypertensive cases a further pregnancy was associated with pre-eclampsia in 70 per cent and HELLP syndrome in 8 per cent.

Differential dagnosis of jaundice during pregnancy

Many patients with acute fatty liver of pregnancy have signs of pre-eclampsia and such cases may be part of a clinical syndrome that includes hypertension-associated liver diseases. Evidence for this possibility includes the finding of microvesicular hepatic steatosis in cases with pre-eclampsia; indeed one study found fat deposition by special staining in all 41 cases studied. Histological evidence of both pre-eclampsia and acute fatty liver of pregnancy has also been demonstrated in some cases, and pregnancies associated with pre-eclampsia have been followed in the next by HELLP syndrome. Despite this there are usually features in the clinical history or laboratory findings (Table 4) that allow discrimination between these diagnoses. The size of the liver, degree of hyperbilirubinaemia, abnormalities on peripheral blood film, presence of hypoglycaemia, and disseminated intravascular coagulation are the most discriminatory tests. The differential diagnosis of jaundice and abnormal liver blood tests differs in the three trimesters of pregnancy (Table 5).

Liver diseases not specific to pregnancy

Budd–Chiari syndrome

Thrombosis in one or more hepatic veins has an increased prevalence during pregnancy and in those on the oral contraceptive pill. This relates to low antithrombin III levels and may be more common in those with an underlying procoagulant state or presence of antiphospholipid antibodies. Right upper quadrant pain, hepatomegaly, and maternal ascites should suggest the diagnosis, with confirmation by ultrasonography or hepatic venous angiography. Although hepatic venous balloon dilatation or insertion of a transjugular intrahepatic stent shunt has been recommended for Budd–Chiari syndrome, there are few data on their use during pregnancy. Maternal mortality remains very high.

Cholelithiasis

Gallbladder sludge and gallstones develop in 31 per cent and 9 per cent of pregnancies respectively, although most resolve thereafter. Prior use of oral contraceptives, increased cholesterol synthesis, reduced cholesterol carriage in bile, and impaired gallbladder motility all accounted for the increased lithogenicity of bile. Symptomatic gallstone disease should be managed in the usual way. Magnetic resonance cholangiopancreatography can accurately detect common bile duct stones without exposing the fetus to radiation, with endoscopic sphincterotomy and/or stent placement reserved for those in whom they are detected. In most cases surgery can be deferred until after delivery.

Viral hepatitis

Acute viral hepatitis is the most common cause of jaundice during pregnancy (Table 5), with no specific change to presentation, clinical course, or outcome for acute hepatitis A, B, cytomegalovirus, or Epstein–Barr virus infection.

Transmission of virus from a mother with acute hepatitis B to her offspring occurs in 50 per cent of cases, rising to 70 per cent when hepatitis starts in the third trimester. Transmission of virus from mothers with chronic hepatitis B carriage is less common, but depends on the level of viral replication. The rate is at least 90 per cent in those who are hepatitis B virus DNA positive, and who are usually hepatitis B e antigen positive, as is most common in Orientals. Following vertical transmission up to 80 per cent of offspring become chronic HBsAg carriers. Transmission of hepatitis B can be effectively interrupted by use of hepatitis B immunoglobulin at birth, with hepatitis B virus vaccination within 7 days and at 1, 2, and 12 months.

Transmission of hepatitis C from chronic carriers occurs in up to 8 per cent of cases, being higher in those with high maternal viral load. Antihepatitis C virus seroconversion of infants following transmission may take 6 to 12 months to appear, but detection of hepatitis C virus RNA by polymerase chaine reaction allows detection of transmission sooner.

Acute hepatitis E is due to an RNA virus and occurs, often in waterborne epidemics, predominantly in the Middle and Far East. In pregnancy it is associated with a mortality of up to 20 per cent due to development of acute liver failure during the third trimester, but transmission to offspring has not been recorded.

Variceal haemorrhage

Changes in splanchnic haemodynamics, increased cardiac output and azygous blood flow, and an increase in circulating blood volume have all been suggested as risk factors for variceal bleeding during pregnancy. Evidence for this remains controversial, although recent large series with non-cirrhotic portal hypertension report a haemorrhage rate of 13 per cent. Treatment of variceal bleeding during pregnancy should be with conventional endoscopic techniques, with use of transjugular intrahepatic stent shunts or surgical shunts reserved for rescue therapy.

Liver tumour during pregnancy

The first presentations of focal nodular hyperplasia, hepatic adenoma, hepatocellular carcinoma, and cholangiocarcinoma have all been reported during pregnancy. Adenomas, in some cases related to prior oral contraceptive use, may undergo vascular engorgement during pregnancy and rupture has been reported. Secondary tumours, including hepatic choriocarcinoma and ovarian teratomas, may also rupture.

Pregnancy following orthotopic liver transplantation

Fertility returns quickly following liver transplantation. Pregnancy does not alter the risks of cellular rejection, but immunosuppressive drug toxicity needs to be carefully monitored. Azathioprine may cause neonatal pancytopenia, and cyclosporin A is associated with a 40 per cent incidence of hypertension, which may be lower with Tacrolimus.

Pregnancy during chronic liver disease

Most patients with established cirrhosis are infertile, but a few remain fertile, although with a high rate of prematurity, low-birthweight babies, and stillbirths. There is little evidence that pregnancy results in deterioration in liver dysfunction in patients with cirrhosis, and improvement of inflammatory activity occurs in some cases of autoimmune chronic active liver disease. There is no increased rate of relapse after delivery. Patients with treated Wilson's disease are able to conceive and successful pregnancies whilst taking D-penicillamine or trientine have been reported.

Pregnancy during gastrointestinal disease

Only a few gastrointestinal diseases occur with altered frequency during pregnancy.

Gastro-oesophageal reflux

Symptomatic gastro-oesophageal reflux is present at some stage in up to 80 per cent of pregnancies. It is mainly due to a reduced lower oesophageal sphincter pressure rather than elevated intra-abdominal pressure from a gravid uterus. Treatment with antacid is recommended, with avoidance of H_2 antagonists or proton pump inhibitors unless symptoms and complications of gastro-oesophageal reflux outweigh potential drug toxicity. Acid-pepsin reflux combined with vomiting in early pregnancy may precipitate haematemesis, occasionally with a Mallory–Weiss tear, for which management should be as in the non-pregnant state. Upper gastrointestinal endoscopy is a safe procedure during pregnancy.

Inflammatory bowel disease

Stable inactive ulcerative colitis and Crohn's disease do not affect fertility, are not associated with increased fetal risk, and disease control is not impeded by pregnancy. There are few data on the effect of drug therapy on fertility, although sperm counts may be reduced in men on salazopyrine. The risk of relapse of inflammatory bowel disease during pregnancy has been assessed at between 30 and 50 per cent, but this is no higher than comparable non-pregnant control groups. Folate and iron supplementation are recommended, with regular monitoring of nutritional status.

Active inflammatory bowel disease is associated with involuntary infertility, and when very severe it is prudent to recommend deferring any attempt to conceive. Increased fetal loss may occur when active inflammatory bowel disease is first manifest during pregnancy, with recent reports suggesting that the site of disease activity (colonic or small bowel) does not affect outcome. Most studies have demonstrated that corticosteroids, sulphasalazine, and 5-aminosalicylic acid preparations are safe to use during pregnancy. Colonoscopy, in expert hands, can be performed during pregnancy without risk, although it is often possible to defer this procedure.

Acute appendicitis

The most common non-obstetric emergency requiring surgery, acute appendicitis occurs in 1 in 2500 to 1 in 3500 pregnancies. It is not clear if reports of a more aggressive clinical course reflect delays in diagnosis or reporting bias. Clinical management is similar to that of the non-pregnant case: surgery must not be deferred as the frequency of prematurity and perinatal mortality may be increased if perforation occurs.

Coeliac disease

Women with untreated coeliac disease have a markedly increased risk of abortion and low-birthweight babies, which can be reversed following institution of a gluten-free diet. Screening for coeliac disease should be considered in women with a previous history of abortion or unfavourable pregnancy outcomes.

13.10 Diabetes in pregnancy

Michael D. G. Gillmer

Prior to the introduction of insulin treatment in 1921, diabetes was a rare complication of pregnancy with near 50 per cent maternal and fetal mortality. Within a decade of the introduction of insulin therapy, maternal mortality had fallen to between 2 and 3 per cent, but fetal mortality remained above 40 per cent until the 1950s despite recognition that 'rigid control' of diabetes was vital to achieve an optimal pregnancy outcome. This concept has remained central to the management of the disease in pregnancy, with hindsight suggesting that the early poor fetal outcome was due to incomplete understanding of the pathophysiology of the condition, and to a lack of suitable technology for assessing adequate diabetic control.

Metabolic changes in pregnancy

Pregnancy induces substantial alterations in carbohydrate, lipid, and amino acid metabolism, which have been described as a combination of 'facilitated anabolism' and 'accelerated starvation'. From a teleological standpoint these changes appear to ensure the optimal availability of nutrients for both fetus and mother.

Carbohydrate metabolism

Fasting plasma glucose concentrations gradually decline during pregnancy by approximately 0.5 mmol/l, reaching a nadir in the third trimester. Postprandial glucose concentrations increase, despite a rise in both basal and stimulated insulin secretion. This appears to be due to peripheral insulin resistance induced by placental hormones, and to the effects of oestrogen and progesterone on the maternal pancreas.

Although insulin sensitivity appears to increase transiently during the first trimester of pregnancy in some women, there is thereafter a progressive decline which is reflected by an increased insulin:glucose ratio. Human placental lactogen, a polypeptide hormone, is one of the main causes of the insulin resistance that characterizes pregnancy. Other possible factors include increased fat stores, raised prolactin and free cortisol concentrations, sequestration of insulin by the placenta, and changes in insulin receptor affinity and number.

Serial glucose tolerance tests indicate a progressive decline in tolerance with advancing gestation. After an oral glucose load in late pregnancy there are higher peak plasma glucose concentrations, a delay in the rise to the peak concentration and an increase in the total area under the glucose tolerance curve compared with the non-pregnant state. Despite these changes pregnant women maintain efficient glucose homeostasis, but with slightly lower preprandial and higher postprandial plasma glucose concentrations following mixed meals than in non-pregnant women.

Although insulin does not cross the placental barrier, glucose crosses freely by a process of facilitated diffusion. Fetal exposure to maternal hyperglycaemia causes premature stimulation of the fetal b-cells of the pancreatic islets of Langerhans and results in fetal hyperinsulinaemia. This stimulates excessive fetal growth, leading to the macrosomia that characterizes the infant of the diabetic mother.

Lipid metabolism

Plasma concentrations of triglycerides, cholesterol, phospholipids, and free fatty acids all increase during pregnancy. During early pregnancy increased food intake coupled with moderate postprandial hyperinsulinism create ideal conditions for lipogenesis, so-called 'facilitated anabolism'. During late pregnancy food intake declines, insulin resistance is established, and in the presence of high circulating levels of human placental lactogen, lipolysis is enhanced during the fasting state, when there is also a significant increase in ketones, so-called 'accelerated starvation'. The increase in circulating free fatty acids concentrations is thought to have an important influence on maternal metabolism, providing an alternate source of maternal fuel at a time in pregnancy when fetal and maternal glucose needs are maximal.

Plasma cholesterol increases by approximately 25 per cent during pregnancy, a change which probably reflects increased synthesis and decreased catabolism. Lipoprotein triglyceride and cholesterol do not cross the placenta, but free fatty acids cross freely by simple diffusion.

Protein and amino acid metabolism

Amino acids are crucial for fetal development and fetal protein accumulation occurs rapidly in late pregnancy. Despite this there is an increase in maternal amino acid excretion in the third trimester, consisting mainly of the non-essential amino acids glycine, histidine, serine, and alanine. In addition, most amino acid concentrations fall in pregnancy, in particular ornithine, glycine, taurine, and proline, while the postprandial peak concentrations of leucine, isoleucine, serine, and alanine following a mixed meal in late pregnancy are lower than those observed in non-pregnant subjects. Starvation in pregnancy causes a two to three-fold rise in valine, leucine, and isoleucine, but a fall in alanine concentrations.

The concentration of most free amino acids is higher in fetal than in maternal plasma, indicating placental amino acid transfer against a concentration gradient.

Gestational diabetes

Gestational diabetes may be defined as '...carbohydrate intolerance of variable severity with onset or first recognition during the present pregnancy...' This definition includes not only those women in whom diabetes occurs transiently during pregnancy and regresses after delivery, but also those in whom type 1 diabetes arises *de novo* during pregnancy and persists long term.

Screening for gestational diabetes has traditionally involved performing glucose tolerance tests on all women with 'risk factors' or 'potential diabetic features'. However, these are present in 30 per cent or more women in most communities, but not all of those who develop significant glucose intolerance during pregnancy, meaning that many women are subjected to unnecessary tests, whilst others who develop gestational diabetes are missed. 'Risk factors' are therefore of limited value

for screening purposes.

Universal screening programmes based on blood glucose measurement have become popular (although controversial) in recent years. The American Diabetes Association (ADA) and American College of Obstetricians (ACOG) have both endorsed the use of a 50-g oral glucose load at 24 to 28 weeks gestation. Venous plasma glucose is measured an hour later and a value equal to or greater than 7.8 mmol/l (140 mg/dl) is recommended as the threshold for a full diagnostic oral glucose tolerance test (GTT). This screening procedure has been shown to be the most sensitive (79 per cent) and specific (87 per cent) of the screening tests available, but is probably only appropriate in populations with a high prevalence of diabetes or for those at increased risk, such as older women and those who are grossly obese. A simpler and more cost effective protocol involves a so-called 'timed' random blood glucose measurement at antenatal booking and at 28 weeks gestation, repeated whenever glycosuria occurs. A full glucose tolerance test is indicated if the plasma glucose exceeds 6 mmol/l in the fasting state or 7 mmol/l within 2 h of a meal. Screening by means of glycosylated haemoglobin or plasma protein measurements, including fructosamine, have proved to be too insensitive for use in pregnancy.

The glucose tolerance criteria for the diagnosis of gestational diabetes are controversial and this, together with the poor reproducibility of the test, may explain some of the inconsistent results of screening programmes. The American College of Obstetricians and Gynaecologists has retained the 100-g oral glucose tolerance test, but in Europe a 75-g load is used, following the World Health Organization's recommendation. It has been suggested that the criteria for 'impaired glucose tolerance' after a 75-g glucose tolerance test should be used for the diagnosis of 'gestational diabetes', but this is not universally accepted (see below). The WHO criteria are shown in Table 1, together with the ACOG standards for a 100-g oral glucose tolerance test, Oxford data from a study of the 75-g oral glucose tolerance test in 491 women at 28 to 34 weeks gestation, and data from a multicentre study of the Diabetic Pregnancy Study Group (DPSG) of the European Association for the study of Diabetes (EASD) involving 354 women in the third trimester of pregnancy.

It is apparent from these data that if gestational diabetes is diagnosed using the WHO criteria for impaired glucose tolerance (IGT), this will lead to increased diagnosis of the condition, as a significant number of women will have a 2-h venous plasma glucose in excess of the WHO limit of 8.0 mmol/l. Widespread acceptance of the WHO criteria for IGT as diagnostic of gestational diabetes could therefore explain the continued uncertainty about the adverse clinical effects of gestational diabetes on pregnancy outcome. It is suggested that the modified WHO criteria shown in Table 2 are used in clinical practice, and that a clear distinction is made between women with impaired glucose tolerance and true diabetes during pregnancy.

Medical management

In the early 1970s it was recognized that the perinatal mortality in diabetic women is positively correlated with the mean maternal blood glucose concentration during pregnancy. This finding, together with the observation that blood glucose concentrations in normal pregnant women rarely exceed 6 mmol/l, except during the hour after a meal, focused attention on the need for 'rigid control' of the maternal diabetes. Ideally, blood glucose concentrations should be measured preprandially and postprandially, as shown in Table 3, on at least 2 days each week, or more frequently if indicated, and maintained between 4 and 6 mmol/l. Measurements of glycosylated haemoglobin or fructosamine are used in many units to provide an indication of medium to long-term glycaemic control and can prove helpful, especially in non-compliant patients.

Congenital malformations

Type 1 insulin dependent diabetes preceding pregnancy is associated with a significant increase in the risk of major congenital anomalies of between 7 and 14 per cent. The precise aetiology remains obscure in most cases, but the frequency is undoubtedly increased in women with poor diabetic control preceding pregnancy and during the first trimester. The incidence also varies depending on the definitions applied in diagnosing major malformations (Table 4).

There is a three to five-fold increase in the incidence of neural tube, cardiac, and renal anomalies which account for more than a half of current perinatal deaths and are also an important cause of avoidable long-term morbidity. As the organ systems commonly affected in diabetes are all fully formed by 9 weeks gestation, that is 7 weeks after the first missed menstrual period, it is vital that all women in the reproductive age group are advised that they must make serious efforts to achieve optimal diabetic control before planning a pregnancy and that this should be maintained throughout the period of embryogenesis. In addition, all diabetic women should be advised to take folate supplements for at least 4 weeks prior to conception to reduce the risk of delivering a child with a neural tube defect.

Team care

'Team care' is an essential part of the modern management of the pregnant diabetic woman. The most important member of the team is the woman herself: she obviously has responsibility for her diabetes on a day-to-day basis, and usually has the clearest understanding of how optimal glycaemic control can be achieved. She should ideally attend a joint diabetic–antenatal clinic where she can be seen by specialist diabetic nurses, midwives, dietitians, and medical staff including an obstetrician, a physician, and a neonatal paediatrician with a special interest in this condition.

It is important to see these patients as early as possible in pregnancy, after which the frequency of clinic visits will depend on several factors, including the blood glucose concentrations achieved and the occurrence of diabetic or obstetric complications. An average two or three-fold increase in insulin requirements occurs during pregnancy. It is therefore preferable to see all diabetic women at least every 2 weeks until 34 weeks gestation, and then weekly until delivery, as this facilitates the frequent alterations of insulin dose that need to be made as pregnancy progresses and also ensures adequate dietary advice. If control is poor and more frequent advice is required, this can usually be given by telephone contact.

Diet and insulin therapy

The management of women who are diagnosed as gestational diabetics depends on their preprandial and postprandial blood glucose concentrations. If these are 6 to 8 mmol/l, a high fibre isocaloric diet is advised initially, and the woman retested. If the preprandial plasma glucose concentrations remain above 6 mmol/l on this diet or if they initially exceed 8 mmol/l then insulin therapy is commenced, using a long-acting preparation at bedtime in the first instance. Preprandial short-acting insulin is added before meals if the postprandial values remain above 6 mmol/l. Oral hypoglycaemics are not used because they cross the placenta and stimulate the fetal pancreatic b-cells causing fetal hyperinsulinaemia, the pathological process that insulin treatment aims to avoid. Non-pregnant diabetics using oral hypoglycaemic agents should ideally be changed to insulin treatment when planning a pregnancy.

Human insulin is preferred, as this produces least antibodies and reduces the theoretical risks of fetal b-cell damage or macrosomia due to the transplacental passage of injected insulin bound to antibody.

The form of insulin therapy that is currently most widely used for the control of type 1 diabetes in pregnancy is a mixture of short-acting insulin three times daily before meals combined with an intermediate or long-acting injection at bedtime. However, twice daily injections of short and intermediate-acting insulin remain popular. Fixed ratio insulin mixtures have a limited role, but in practice the patient's prepregnancy insulin regimen should only be changed if it proves impossible to achieve the desired standard of control without doing so. The pregnant diabetic is particularly prone to overnight ketoacidosis and the continuous subcutaneous insulin infusion (CSII) pump is no longer considered appropriate in pregnancy as disruption of the infusion through pump failure, catheter blockage, or disconnection can rapidly lead to ketoacidotic coma, with the risk of fetal or even maternal death.

Pregnancy is characterized by a decline in fasting plasma glucose concentrations and a plentiful supply of alternate substrates for energy requirements, including ketones derived from the b-oxidation of free fatty acids. Hypoglycaemia is therefore rare, and unlike hyperglycaemia does not appear to have any demonstrable adverse effect on the fetus. However, because of endeavours to achieve very tight diabetic control, pregnant diabetics are at increased risk of hypoglycaemia. They should therefore be provided with glucagon that can be administered by a third party in the event of severe hypoglycaemia.

Management of diabetes during and after labour

It is important to maintain normoglycaemia during labour in order to reduce the risk of neonatal hypoglycaemia. This is most easily achieved using combined insulin and dextrose infusions. Dextrose 10 per cent solution is infused at 100 ml/h and blood glucose measurements are made every hour. Insulin (6 units in 60 ml normal saline) is administered simultaneously, at an initial rate of 1 unit (10 ml) /h using an infusion pump. The insulin infusion rate is doubled or halved as necessary to maintain the blood glucose concentration between 4 and 6 mmol/l. During labour the insulin requirement may fall dramatically, presumably because of the increased

glucose demand due to uterine work, and it is frequently necessary to switch the insulin infusion off towards the end of the first stage.

After delivery the insulin infusion rate must be halved to prevent hypoglycaemia as there is a rapid increase in insulin sensitivity following the delivery of the placenta. It is also essential to return to the prepregnancy insulin dose immediately the patient resumes her normal diet: profound hypoglycaemia can occur if the dose required prior to delivery is administered at this time.

Retinopathy

Rapid reduction of blood glucose concentrations has been shown to accelerate diabetic retinopathy in both pregnant and non-pregnant subjects. There is also evidence that pregnancy and hypertension complicating pregnancy may act as independent risk factors for the progression of diabetic retinopathy. Formal retinal assessment, with dilated pupils, should therefore be performed before pregnancy so that improved diabetic control can be achieved over 3 to 9 months before a planned conception. This should avoid the need for acute improvement of the blood glucose concentrations in early pregnancy and thus minimize the risk of exacerbating proliferative retinopathy. All women should have a full ophthalmic assessment in early pregnancy to assess their retinal state and determine the possible need for laser therapy.

Nephropathy

Overt nephropathy is associated with various pregnancy complications, including pre-eclampsia, growth retardation, and fetal distress, but there is little evidence to suggest that pregnancy will hasten the progression of overt nephropathy to endstage renal failure. Patients seeking advice about pregnancy should therefore be warned that although their renal disease may have an adverse effect on pregnancy, which could necessitate prolonged hospitalization and premature delivery, possibly by caesarean section, there is usually no need to avoid or terminate pregnancy.

Obstetric management

Antenatal assessment of the fetus

Accurate information about the duration of pregnancy, fetal growth, and fetal well being are vital in the management of the pregnant diabetic. Technological developments, particularly in the use of diagnostic ultrasound, have revolutionized fetal assessment and become central to the modern obstetric management of diabetes in pregnancy.

The fetal crown–rump length should be measured during the first trimester to confirm the duration of pregnancy. In some women this technique has identified 'early growth delay' in which the fetal crown–rump length measurement is smaller than expected from the gestational age. This condition is associated with an increased rate of congenital malformations and poor fetal growth, and is thought to be due to 'less-than-optimal' metabolic compensation in early pregnancy.

A biparietal diameter measurement is also performed in the mid-trimester, ideally at 16 weeks gestation, to provide additional information about gestational age. Blood for serum a-fetoprotein should also be taken at this gestation, both to screen for neural tube defects and as part of the 'triple test' used to screen for Down's syndrome. In assessing the result of these investigations it must, however, be borne in mind that the serum a-fetoprotein and unconjugated oestriol concentrations observed in diabetic pregnancy are lower than those in non-diabetic women and a specific algorithm is required for the interpretation of these screening tests in women with type 1 diabetes.

A detailed fetal ultrasound examination to exclude congenital anomalies is performed between 18 and 20 weeks, so that termination of the pregnancy can be considered if appropriate. Further cardiac anomaly scans may be performed at 28 and 34 weeks gestation. Serial studies of growth based on measurements of the fetal head and abdominal circumferences in the second trimester provide the best means of identifying those pregnancies in which the fetus is becoming macrosomic, when it is still possible to institute optimal metabolic control and reduce the likelihood of this complication. However, although an association between birthweight and maternal blood glucose concentrations has been demonstrated during the third trimester of pregnancy, the cause of fetal macrosomia in diabetes is still uncertain and there are many examples of women who deliver infants with birthweights above the 97th centile despite excellent metabolic control in late pregnancy. However, the situation is further complicated by the finding of a two-fold increase in small-for-dates infants (birthweight below the 10th centile) in diabetics with very tight control (mean blood glucose concentration of less than 4.8 mmol/l), indicating that excessively tight blood glucose control may have a deleterious effect on the growth of the diabetic fetus, and possibly on its development.

Obstetric complications of diabetes in pregnancy

Proteinuric hypertension occurs approximately twice as often in diabetics as in normal women. Serum urate and creatinine concentrations should therefore be measured at every antenatal visit and 24-h urine protein concentrations from 24 weeks gestation. These provide the earliest biochemical evidence of proteinuric pre-eclampsia and also serve to clarify those blood pressure changes in late pregnancy which are due to pre-existing essential hypertension. Although the reason for the increased incidence of pre-eclampsia in diabetics is unknown, a link with glycaemic control has been established and the incidence of this complication is reduced with optimal diabetic control.

Polyhydramnios is one of the hallmarks of diabetic pregnancy, and occasionally the presenting feature in gestational diabetes. The cause of this complication, which has an overall incidence of approximately 15 per cent, remains uncertain, but may be due to an osmotic diuresis induced in the fetus by feto–maternal hyperglycaemia. This would be in keeping with the fact that polyhydramnios generally lessens as diabetic control improves.

Premature labour is more frequent in diabetic pregnancy and may, in some instances, be due to underlying polyhydramnios. Conventional management with intravenous b-sympathomimetic agents causes hepatic glycogenolysis and insulin resistance, predisposing to hyperglycaemic ketoacidosis. This treatment is therefore potentially hazardous in diabetic women and should be avoided whenever possible or used with extreme caution, even in non-insulin dependent patients. Use of glucocorticoids in diabetic pregnant women may necessitate the administration of very high doses (up to 30 units/h) of intravenous insulin to maintain normoglycaemia.

Fetal well being and maturity

Unexplained intrauterine death during the last 3 to 4 weeks of pregnancy has been recognized as a considerable problem in the management of diabetic pregnancy since the preinsulin era. However, the so-called 'fetal biophysical profile', a real time ultrasound technique, has revolutionized the late pregnancy management of this condition and made it unnecessary to admit diabetic women routinely for daily monitoring in late pregnancy. These assessments, which should be performed at least weekly from 36 weeks gestation, have also made it possible to prolong diabetic pregnancies to near term or beyond.

Antenatal Doppler ultrasound assessments have also been used widely in diabetic pregnancy in recent years, the results providing the reassurance necessary to prolong uncomplicated diabetic pregnancies beyond term, but unlike the biophysical profile have not proved helpful in predicting fetal demise in diabetic women, unless the pregancy is complicated by fetal growth retardation.

Timing of delivery

Poorly controlled diabetes is associated with fetal pulmonary and hepatic immaturity, predisposing to the neonatal respiratory distress syndrome and jaundice. The optimal time for delivery in uncomplicated diabetic pregnancy appears to be in the 39th week (273 days). Despite this, some authors have advocated deferring delivery until 40 weeks or later as this allows a larger number of women to enter labour spontaneously. This policy is associated with a higher incidence of macrosomic and stillborn babies and has not been shown to have any significant benefit.

Management of labour

One of the main aims in management of the pregnant diabetic woman is to achieve a spontaneous vaginal delivery. Elective caesarean section may be indicated when there is significant fetal macrosomia, with abdominal circumference greatly in excess of the head circumference, fetal malpresentation, or a history of a previous

caesarean section. Continuous fetal heart rate and contraction monitoring is advised because of the increased incidence of fetal distress. Pain relief in labour is particularly important because painful uterine contractions cause catecholamine release, leading to glycogenolysis and hyperglycaemia. Epidural anaesthesia is ideal but not vital, especially in the multiparous patient who may have a rapid and uncomplicated labour. If intravenous fluids are required for 'preloading' prior to insertion of an epidural or for the administration of oxytocin, it is essential that 0.9 per cent saline or Hartmann's solutions and not dextrose are used to avoid fetal hyperglycaemia, which predisposes to neonatal hypoglycaemia.

Efforts to predict the risk of shoulder dystocia have been conspicuously unsuccessful to date. This possibility must always be considered when the abdominal circumference exceeds the head circumference, especially if the fetus is macrosomic.

The neonate

Insulin is present in the human pancreas from 11 weeks gestation, and although the pancreatic response to insulin secretogogues is sluggish in normal infants, fetal exposure to high concentrations and large fluctuations of glucose and amino acids during poorly controlled diabetic pregnancy appears to produce premature maturation of the fetal b-cells. This causes hyperinsulinaemia, which predisposes to neonatal hypoglycaemia that may occur during the first 24 h after delivery, when high circulating insulin concentrations inhibit both glycogenolysis and lipolysis, thus depriving the infant of alternative energy sources.

Other neonatal problems include, the respiratory distress syndrome, polycythaemia, jaundice, renal vein thrombosis, hypocalcaemia, hypomagnesaemia, and cardiomyopathy, all of which appear to be related directly or indirectly to fetal hyperinsulinaemia. The incidence and severity of neonatal complications is closely related to diabetic control during pregnancy, and the infant of the well-controlled diabetic mother does not usually require admission to a special care nursery, unless a problem arises after delivery.

The puerperium and contraception

Diabetics are at increased risk of wound infection following surgery and prophylactic antiobiotics are therefore advised following both elective and emergency Caesarean section or operative vaginal delivery.

Breast feeding is encouraged, but as this reduces the insulin requirement by approximately 25 per cent an appropriate reduction must be made once lactation is established. Women who choose not to breast feed or in whom breast feeding is unsuccessful should resume their prepregnancy insulin dose after delivery.

All diabetic women should be seen for a 6-week postnatal examination and should be offered contraceptive advice at this time. The nature of the advice will depend on age, parity, and future reproductive plans. The progesterone only (mini-pill) has virtually no effect on carbohydrate or lipid metabolism and is therefore suitable for the breast feeding diabetic woman. Provided she is prepared to accept the slightly higher failure rate of this method when ovulation resumes, then it may also be used long term. Modern, low-dose, combined oral contraceptive preparations have little effect on high or low density lipoprotein concentrations or carbohydrate metabolism and can be used safely, especially in younger, insulin-dependent and gestational diabetics. Early concerns about the apparently high failure rates of copper-containing intrauterine devices in diabetics have been refuted in recent studies. The woman who has completed her family should be encouraged to consider a laparosopic sterilization.

13.11 Endocrine disease in pregnancy

John H. Lazarus

Introduction

During pregnancy the physiology of the mother and fetus changes constantly. For instance, maternal oestrogen concentrations rise and affect hepatic protein synthesis and plasma volume increases by as much as 50 per cent with consequent haemodilution. Endocrine function in the developing fetus is initially almost entirely dependent on maternal function as most endocrine glands do not produce hormones until the second trimester. Thereafter the fetus becomes less reliant on maternal hormones as the fetal glands develop and mature. This section will discuss the important therapeutic aspects of endocrine disease in pregnancy.

Pituitary disease

Prolactinoma

Pituitary adenomas are the most common pituitary disorder affecting pregnancy and prolactinomas are the most common of the hormone-secreting adenomas. Prolactinomas are a common cause of reproductive and sexual dysfunction and hyperprolactinaemia must be corrected to allow ovulation and fertility. The main concern during pregnancy is of symptomatic enlargement leading to visual impairment. There is less than a 2 per cent risk of this happening with a microprolactinoma, but a greater than 15 per cent risk with a macroprolactinoma. It is safe for patients to become pregnant following bromocriptine treatment; the prolactinomas may decrease in size, remain unchanged, or in some cases achieve complete resolution. Treatment with bromocriptine is safe during gestation, but a macroadenoma may require debulking prior to pregnancy. Cabergoline has also been used during pregnancy with no deleterious effects. The concern during pregnancy is the development of visual impairment which may occur with a macro-prolactinoma but not with a microprolactinoma.

Acromegaly

Fertility is impaired in acromegaly due to concomitant hyperprolactinaemia and decreased gonadotrophin reserve. The main aims of therapy in an acromegalic woman wishing to conceive are therefore to normalize prolactin and growth hormone levels to promote fertility. With the use of surgery as well as dopamine agonists and octreotide, many women with this condition are now able to achieve pregnancy.

The pituitary gland enlarges during normal gestation and may increase by 45 per cent during the first trimester. Pituitary adenomas can also enlarge, and pregnancy exacerbates acromegaly in about 17 per cent of cases. Patients with adenomas greater than 1.2 cm are at greater risk of visual loss during pregnancy. Management can be difficult, and risks need to be judged carefully. Those with microadenomas should discontinue medical therapy (bromocriptine or somatostatin analogues) during pregnancy and be assessed at each trimester (Fig. 1). In patients with macroadenomas removal before pregnancy leads to a greater risk of infertility, but if not resected there is a greater risk of pituitary enlargement and visual impairment during gestation. More detailed assessment during pregnancy is therefore recommended including regular visual field checks and MRI examinations in those patients with significantly large tumours at the beginning of pregnancy. However, although the metabolic and cardiovascular complications of acromegaly might be expected to result in increased risk to both mother and fetus, these potential hazards do not seem to be realized.

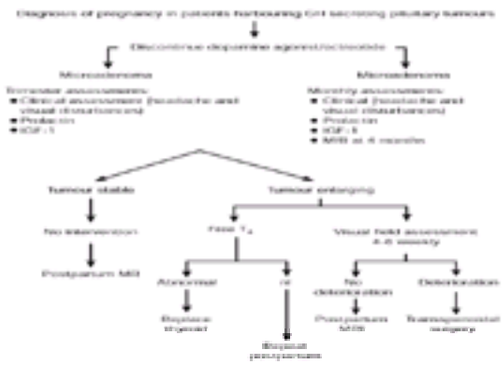

Fig. 1 Scheme for management of growth hormone secreting pituitary tumours in pregnancy (reproduced from Herman-Bonert *et al*. 1998, with permission).

Some women with apparent prolactinomas or non-functioning pituitary tumours will be found to have multiple endocrine neoplasia type 1 (MEN1). In this situation screening of the child should be offered.

Cushing's syndrome

Cushing's syndrome during pregnancy is associated with a high incidence of maternal and fetal complications, only about one-quarter of patients having an uncomplicated pregnancy. The diagnosis of the disease during gestation is difficult because many of the biochemical features, such as elevated cortisol levels and loss of the normal glucocorticoid feedback, are present during normal pregnancy. The use of corticotrophin-releasing hormone and dexamethasone testing can be helpful and MRI is valuable. Transphenoidal surgery has been successfully performed during pregnancy. This operation should be carefully considered if any pituitary tumour enlarges during pregnancy, especially when there is evidence of increasing visual field impairment.

Diabetes insipidus

Central diabetes insipidus may present during pregnancy. It is seen in women with Sheehan's syndrome, partial postpartum hypopituitarism, and associated with infiltrative disorders such as histiocytosis X. ADH deficiency is corrected using intranasal synthetic 1-deamino-8- D-arginine-vasopressin (DDAVP). During pregnancy this seems to be safe for both mother and baby. It does not affect delivery and has no adverse effects on the neonate.

Postpartum hypopituitarism

Sheehan's syndrome is caused by pituitary infarction following significant hypotension occurring at the time of delivery. Advances in obstetric care mean that it is now uncommon in the 'developed' world. However, lymphocytic hypophysitis is now increasingly recognized as a cause of hypopituitarism occurring late in pregnancy and in the postpartum period, and around 60 per cent of cases of women found to have adenohypophysitis are pregnant or have recently been delivered. They typically present with symptoms of an expanding pituitary tumour. Headaches, visual symptoms, inability to lactate, and amenorrhoea occur. Hyperprolactinaemia and elevated growth hormone levels are found. Computed tomography or magnetic resonance imaging reveals a pituitary mass mimicking an adenoma in about four-fifths of patients. Evaluation of pituitary function shows isolated or multiple anterior pituitary deficiency. Adenocorticotrophic hormone secretion is impaired, most frequently followed by that of thyroid-stimulating hormone (TSH), gonadotrophins, growth hormone, and prolactin. Histology shows lymphocytic infiltration and this may extend up to the pituitary stalk to the infundibulum. Antibodies to pituitary tissue may be present but often are not. Other autoimmune diseases, particularly postpartum thyroiditis, may be associated. In addition to the pituitary symptoms described, patients are at risk of adrenal failure and death has been reported.

Adrenal function should therefore be assessed in all patients. The diagnosis of lymphocytic hypophysitis may only be made at surgery, but if the condition is suspected beforehand, then surgery should be avoided and corticosteroids given, since these can reduce the size of the pituitary mass.

Thyroid disease

Maternal thyroid function during pregnancy

Thyroid physiology and function alter significantly during pregnancy. Thyroid volume increases in iodine deficient areas but not in areas of iodine sufficiency. There is increased synthesis of thyroxine-binding globulin, but free thyroxine decreases during the second and third trimester. During the first trimester the maternal thyroid is to some extent controlled by placental human chorionic gonadotrophin, a weak thyroid stimulator, and during this period TSH levels are suppressed.

Hyperthyroidism

Hyperthyroidism is associated with impaired fertility and the presence of thyroid antibodies is a marker for miscarriage and recurrent abortion even in those who are euthyroid. Nevertheless, hyperthyroidism occurs in 0.2 per cent of pregnancies. This is usually due to Graves' disease, but other causes include hydatidiform molar disease and gestational thyrotoxicosis due to high human chorionic gonadotrophin concentrations. Since the incidence of hyperthyroidism in pregnancy is low, and the symptoms of hyperthyroidism frequently overlap with those of the pregnancy itself, a high index of clinical suspicion is required to make the diagnosis. Further difficulties arise because thyroid function tests vary during normal pregnancy (see above) and each laboratory should ideally establish its own normal ranges for those who are pregnant. However, it is particularly important to consider whether a borderline test at this time really indicates thyroid dysfunction, and any result should be repeated before treatment is started. The diagnosis of hyperthyroidism is best made by noting an elevated serum free tri-iodothyronine in association with a suppressed TSH, the free thyroxine being elevated or at the upper limit of normal.

Untreated hyperthyroidism is associated with an increased risk of abortion and, if the pregnancy is completed, the baby may be of low birth weight and may show transient hyperthyroidism due to the transplacental passage of thyroid stimulating antibodies. Neonatal hyperthyroidism can also occur in babies born to euthyroid mothers who have been treated for Graves' hyperthyroidism in the past. It is therefore prudent to measure thyroid stimulating antibodies in the first trimester in any woman with active Graves' hyperthyroidism as well as those previously treated. If values are high, they should be measured again at 36 weeks and—if elevated—the obstetrician and paediatrician alerted to the possibility of a thyrotoxic infant.

Hyperthyroidism in pregnancy can be managed with either antithyroid drugs or surgery, the latter being optimally performed in the second trimester. Radioiodine therapy is completely contraindicated during pregnancy: non-pregnant women should undergo a pregnancy test 1 or 2 days before ^{131}I administration and be advised not to conceive for at least 4 months thereafter. If radioiodine has been administered after 12 weeks gestation (i.e. after the fetal thyroid is functional) there may be a case for therapeutic abortion. Propylthiouracil is the preferred antithyroid drug (Table) as fetal side-effects have been reported with carbimazole and methimazole. These are rare but significant, including aplasia cutis and a possible methimazole embryopathy, characterized by choanal atresia and other defects. If necessary, propylthiouracil should be continued in low dose right up to delivery and into the puerperium. An exacerbation of Graves' disease often occurs postpartum and this should be checked. Propylthiouracil does cross into breast milk but in lower concentrations than carbimazole or methimazole so that breast feeding can usually be permitted, but if breast feeding is prolonged, then thyroid function should be monitored in the neonate.

Hypothyroidism

Hypothyroidism is associated with relative infertility because of anovulation and menorrhagia. There is an increased incidence of stillbirths, congenital malformations, and maternal obstetric complications if the condition is untreated. In iodine-deficient areas the risk of neonatal brain damage is increased, resulting in cretinism in severe cases. This is due to the fact that the developing fetal nervous system is entirely dependent on T4 derived from the mother in the first trimester. Even in iodine-sufficient countries mild hypothyroidism during pregnancy is associated with impaired child development and a case for screening for maternal hypothyroidism in early pregnancy can be made. Pregnant patients with hypothyroidism of any degree should always be treated with thyroxine. In those already receiving T4 when found to be pregnant, the dose should be increased by at least 50 µg/day (and more if necessary) as it has been shown that dose requirements increase during gestation.

Fetal and neonatal thyroid dysfunction

The fetus of a mother with thyroid dysfunction during pregnancy should be regarded as a patient in its own right. Transplacental passage of maternal thyroid stimulating IgG immunoglobulins from a mother with Graves' disease may cause fetal hyperthyroidism as well as neonatal disease. Fetal hyperthyroidism is treated with propylthiouracil and the fetal heart rate monitored carefully to avoid hypothyroidism. If the mother is euthyroid, possibly with a history of previously treated Graves' hyperthyroidism, an hyperthyroid fetus may still occur due to thyroid stimulating IgGs. The fetal state is diagnosed by noting a high fetal heart rate and may be confirmed if necessary by the specialized procedure of fetal blood sampling. Treatment of the fetal hyperthyroidism in this situation is by maternal administration of high-dose propylthiouracil (300–450 mg/day). It is also necessary to give thyroxine during gestation to prevent maternal hypothyroidism.

In addition to transient neonatal hyperthyroidism, a hypothyroid state can also occur at birth due to maternal TSH-receptor-blocking antibodies. Both of these conditions are transient and the mother can be reassured. Other causes of transient neonatal hypothyroidism include maternal antithyroid drug administration, iodine deficiency, and ingestion of goitrogens by the mother.

Permanent neonatal hypothyroidism has an incidence of 1/4000 live births and is screened for routinely using whole blood TSH concentrations usually obtained by heel prick at 5 to 7 days. Recent advances in molecular biological diagnosis have revealed a number of specific hereditary gene defects (e.g. in the structure of thyroglobulin) which may require parental DNA analysis for appropriate genetic counselling.

Postpartum thyroid disease

Patients with hypothyroidism almost invariably have circulating antithyroid antibodies (usually antithyroid peroxidase (anti-TPO)). In euthyroid women, anti-TPO antibodies are found in 10 per cent at the routine antenatal booking clinic. These women are at risk of developing postpartum thyroid dysfunction (Fig. 2). Postpartum thyroiditis is a destructive process, not influenced by T4 or iodine treatment. It is characterized by transient hyperthyroidism followed by hypothyroidism, occurring in 5 to 9 per cent of anti-TPO positive women (Fig. 3). Although a minority of patients have been described with this condition who have no demonstrable immune abnormalities, the great majority have anti-TPO antibodies. Their hyperthyroidism is relatively asymptomatic but may require treatment with b-adrenoreceptor-blocking agents in some cases. Carbimazole is not effective. By contrast, the hypothyroidism is often symptomatic and thyroxine should be given. It persists at 1 year in 20 to 30 per cent of cases, and those that recover from transient postpartum thyroid dysfunction should have their thyroid function measured annually as nearly 50 per cent will develop hypothyroidism in the next 7 years. Mild depressive symptomatology is more common in postpartum women with anti-TPO antibodies than those without

these markers. Recurrent postpartum thyroid dysfunction will occur in up to 75 per cent of those women who have experienced a previous episode.

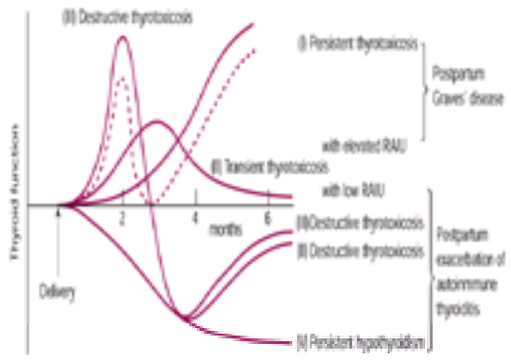

Fig. 2 Diagram to illustrate the progression to different types of thyroid dysfunction observed in the postpartum period (reproduced from Amino *et al*. 1999, with permission).

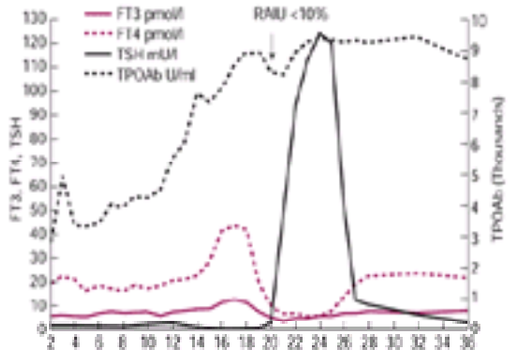

Fig. 3 Clinical chart illustrating the course of postpartum hyper- and hypothyroidism in a woman studied weekly for 36 weeks postpartum. Figures are weeks postpartum. Delivery at time 0 (reproduced from Lazarus *et al*. 1999, with permission). RAIU = radioiodine uptake.

At present, measurement of anti-TPO antibodies is not part of the routine antenatal screening performed at around 14 weeeks gestation. Such screening would predict the development of postpartum thyroiditis. Recent data also suggests that the development of children of anti-TPO positive mothers may be impaired. A case can therefore be made to support antenatal screening for anti-TPO antibodies. Similar arguments have been put forward for antenatal screening of TSH levels.

Thyroid nodules

Thyroid nodules may be clinically detectable in up to 10 per cent of pregnant women. Most of these lesions will be benign colloid nodules but between 5 and 20 per cent are true neoplasms, either benign follicular adenomas or carcinomas of follicular or para-follicular (C-) cell origin. It is often debatable whether investigation of a thyroid nodule should actually be performed during pregnancy. Many experts would pursue matters if a lump was found early on, but delay until the postpartum period if a nodule presented after 5 to 6 months gestation. Fine-needle aspiration biopsy is diagnostic in about 90 per cent of cases. In the remaining 10 per cent, ultrasound-guided biopsy may produce diagnostic tissue. If neck exploration is recommended, this should preferably be performed during the second trimester to avoid abortion in the first and premature labour in the third. Pregnancy does not adversely affect the course (generally favourable) of differentiated thyroid cancer: recurrence and distant metastases occur at the same rates in pregnant and non-pregnant women. In general, differentiated thyroid cancer should not be a contraindication to pregnancy or an indication for abortion. The position for medullary cell carcinoma is less clear cut.

Parathyroid disease

Although diseases of the parathyroid glands are uncommon in women of childbearing age, hyperparathyroidism during pregnancy can lead to acute pancreatitis, hypercalcaemic crisis, and toxaemia. There is an increased incidence of prematurity and neonatal hypercalcaemia if maternal calcium levels are high. If necessary, parathyroidectomy can be undertaken safely in the second trimester. Hypoparathyroidism is treated with vitamin D analogues, the dose of which may need to be increased to maintain normocalcaemia during gestation. Calcium levels should be monitored regularly throughout pregnancy, at least in each trimester.

Adrenal disease

The diagnosis of adrenal disease is often delayed in pregnancy. Adrenal tumours are very rare, but their pathophysiological consequences for mother and fetus are dire. In patients with phaeochromocytoma, hypertension may initially be mistaken for pregnancy-associated hypertension. This should be managed medically, as should primary aldosteronism, with surgical resection considered postpartum.

Occasionally phaeochromocytoma can be familial and screening of the child and other family members for measurable calcitonin levels, evidence of neurofibromatosis, von Hippel Lindau syndrome, or thyroid enlargement should be offered. It is also important to consider screening for multiple endocrine neoplasia type 2, associated RET mutations, and mutations in the von Hippel Lindau gene.

Addison's disease

Addison's disease is rarely diagnosed during pregnancy, but can present as a postpartum addisonian crisis. Symptoms may be attributed to pregnancy or its complications, leading to delayed diagnosis. The condition is readily confirmed by measurement of plasma cortisol, the short synacthen test, and adenocorticotrophic hormone levels. Antibodies to 21-hydroxylase should be measured to confirm the autoimmune nature of the disease, and other autoimmune conditions sought.

Congenital adrenal hyperplasia

Women with severe congenital adrenal hyperplasia have decreased fertility rates because of oligo-ovulation due to elevated androgen levels. Successful conception requires careful endocrine monitoring and possibly induction of ovulation. Problems occur during pregnancy in women with 21-hydroxylase deficiency (P450c21 deficiency),11-hydroxylase deficiency (P450c11), and 3 b-hydroxysteroid dehydrogenase deficiency. Gestational management must involve adequate adrenal steroid replacement and adrenal androgen suppression. Clinical status, serum electrolytes, and androgen levels should be measured regularly and glucocorticoid and mineralocorticoid therapy adjusted or increased as necessary. As the genetic basis of 21- and 11-hydroxylase deficiency is known, prenatal diagnosis is possible. Infants should also be evaluated clinically and, in most cases, biochemically.

Miscellaneous endocrine conditions

Gonadal dysgenesis (Turner's syndrome) is characterized by streak ovaries and infertility. Advances in *in vitro* fertilization and embryo transplantation have made pregnancy possible for some of these patients.

13.12 Neurological disease in pregnancy

G. G. Lennox

Introduction

A wide range of neurological problems occasionally complicate pregnancy and the puerperium. Pre-existing neurological diseases, such as epilepsy and myasthenia gravis, sometimes become more troublesome or, like myotonic dystrophy, pose obstetric difficulties. New neurological disorders can occur, ranging from diseases of the peripheral nerves and muscles that are relatively common but generally benign, to diseases of the central nervous system that are rare but potentially life-threatening. In all these situations the presence of the fetus influences management.

Disorders of muscle and neuromuscular transmission

Muscle disorders

Muscle cramps, particularly on waking, are extremely common in the third trimester. They are almost never a symptom of serious neurological disease and often respond to calcium supplements. Restless legs syndrome, in which there is a feeling of discomfort in the legs that is relieved by movement, is also common, especially on retiring to bed. It may respond to correction of underlying anaemia (particularly if this is due to folate or iron deficiency); otherwise management in pregnancy is aimed at promoting the rapid onset of sleep, for example by reducing caffeine intake. Drug treatment (with levodopa, clonazepam, or codeine) is best avoided. Polymyositis, although rare in young women, can deteriorate during pregnancy. Treatment with corticosteroids is thought to be safe, as is azathioprine if another immunosuppressive agent is necessary.

Most of the congenital myopathies and muscular dystrophies, apart from myotonic dystrophy, cause no special problems in pregnancy unless they are of sufficient severity to compromise ventilation, either because of respiratory muscle weakness or associated scoliosis. Such cases should ideally be assessed in a specialist unit prior to pregnancy because the cardiorespiratory demands of pregnancy, combined with the splinting effect of the fetus on the diaphragm, can lead to ventilatory failure and a temporary need for mechanical ventilation.

Myotonic dystrophy

Myotonic dystrophy is an autosomal dominant disorder due to an expanded triplet repeat in the myotonin protein kinase gene. The expansion tends to increase during transmission from mother to child, so that a mildly affected or asymptomatic mother may have a severely affected fetus. This probably accounts for the excess of polyhydramnios and perinatal death. The myotonia affects the smooth muscle of the uterus, prolonging labour and increasing the risk of postpartum haemorrhage because of uterine inertia. Moderately affected mothers may also develop symptoms of cardiomyopathy during labour. (See Chapter 24.22 for further discussion.)

Myasthenia gravis

Myasthenia gravis deteriorates, improves, and remains stable during pregnancy in roughly equal proportions of patients, but the response is neither predictable nor reproducible in subsequent pregnancies. It deteriorates during the puerperium in about half of all patients, an effect that may also occur after abortion. The mechanism of these changes is not clear. Corticosteroids, oral anticholinesterases, and plasmapheresis can all be employed in the usual manner during pregnancy. It is reasonable to continue azathioprine where this has been prescribed before pregnancy for severe myasthenia, bearing in mind the risk of inducing neonatal leucopenia. Thymectomy can be performed during pregnancy (for example where a malignant thymoma is suspected) but may take up to a year to have a therapeutic effect and ideally should be performed well before any planned pregnancy. Myasthenia does not usually influence labour, although the second stage may be prolonged by fatigue and obstetric anaesthesia is complicated by the need to avoid drugs with adverse effects on neuromuscular transmission—regional anaesthesia being preferable when possible. Acetylcholine receptor antibodies can cross into the fetal circulation, giving rise to transient neonatal myasthenia in up to 20 per cent of the babies from affected mothers. Expert paediatric support must therefore be available at delivery. (See Chapter 24.17 for further discussion.)

Disorders of nerves and nerve roots

Facial palsy

The incidence of facial nerve palsy (Bell's palsy) is substantially increased during pregnancy and the puerperium (as Bell himself described). The reason for this is not known. There have been no studies of treatment in this specific context but it is reasonable to treat promptly with prednisolone, beginning at 40 mg daily and reducing over a 2-week course.

Mononeuropathies

Carpal tunnel syndrome, due to compression of the median nerve in the wrist, is very common in pregnancy, characteristically causing pain and tingling in the hands at night and after use. Most cases can be managed with nocturnal wrist splints, although steroid injections into the carpal tunnel may tide the patient over into the puerperium, when symptoms usually remit. Diuretics are of little value. Surgical decompression during pregnancy should be reserved for cases with severe pain, weakness, or wasting, when usually there have been symptoms either before pregnancy or early in the first trimester. In troublesome cases it is worth considering delayed surgery to prevent recurrence in subsequent pregnancies, which is common.

The lateral cutaneous nerve of the thigh can be compressed as it crosses the inguinal ligament. This is particularly common in the third trimester and causes tingling, hypersensitivity, or numbness in the midlateral thigh, which may be bilateral. Usually no treatment is required, but troublesome cases may respond to transcutaneous nerve stimulation or a local nerve block. Remission after delivery is the rule.

Lumbosacral root and plexus problems

Backache is very common in pregnancy, particularly in women with a past history of back pain or occupations that involve bending and lifting. It is traditionally blamed

on changes in posture and hormonally mediated relaxation of spinal and sacroiliac joints. The pain is usually confined to the lumbar region but may radiate into the buttock or thigh. There may be tenderness over one or other sacroiliac joints. Radiological investigations are not needed if there are no abnormal neurological signs. Management is conservative.

Abrupt onset of pain that radiates below the knee with focal weakness, numbness, or reflex loss is most likely to be due to a prolapsed intervertebral disc. Provided that the signs are unilateral with no sphincter impairment, conservative management is again appropriate, with analgesia and advice to keep mobile. If this fails then magnetic resonance imaging is thought to be a safe method of investigation prior to consideration of lumbar microdiscectomy.

Obstetric nerve palsies are becoming less common with improvements in obstetric care, but still occur in cases of prolonged or complicated labour (for example due to cephalopelvic disproportion, dystocia, and primiparity), in difficult forceps deliveries, and as a result of traction or haematoma formation in caesarean section. Damage to the common peroneal nerve from incorrectly positioned leg holders is now rare.

The baby may compress the lower parts of the lumbosacral plexus during labour. This will typically give rise to focal neurological deficits depending on which parts of the plexus have borne the brunt of the pressure. Most commonly there is a unilateral footdrop, which may only become apparent when the mother starts to mobilize. Examination also reveals sensory loss that characteristically involves the dorsolateral foot and leg, distinguishing plexus damage from a common peroneal palsy where the sensory loss is confined to the dorsum of the foot. Compression of the upper lumbosacral plexus leads to weakness of iliopsoas as well as the quadriceps muscles, which distinguishes it from more distal damage to the femoral nerve. Both may give rise to sensory loss in the anteromedial thigh and loss or depression of the knee jerk. In most cases the prognosis is good, with spontaneous recovery over a couple of months. Particular care must be taken in subsequent deliveries to avoid further damage to the same nerve, as recovery after repeated injury will tend to be less complete.

Long, complicated, or instrumental deliveries may also damage the obturator or pudendal nerves. Obturator neuropathy leads to weakness of hip adduction and rotation, together with some sensory loss in the upper medial thigh. Pudendal nerve damage may be initially asymptomatic but probably contributes to the subsequent development of perineal descent and stress incontinence.

Generalized neuropathies

Chronic inflammatory demyelinating polyradiculoneuropathy can present or relapse during pregnancy, and can be treated with corticosteroids or (if necessary) intravenous immunoglobulin. The incidence of acute Guillain Barre syndrome is increased in the puerperium and can be managed in the usual ways.

The combination of the nutritional demands of pregnancy and hyperemesis gravidarum can lead to thiamine deficiency. This most commonly causes a subacute sensory neuropathy, but cases of acute Wernicke's encephalopathy (with any combination of altered consciousness, ataxia, and ophthalmoplegia, leading if untreated to death) have been described. Both conditions respond promptly to parenteral thiamine 100 mg daily.

Pregnancy can precipitate relapse in acute intermittent porphyria: abdominal pain typically precedes autonomic and sensory neuropathy, sometimes with seizures and psychiatric disturbance. Finally, lepromatous neuropathies may present or deteriorate during pregnancy, making careful clinical supervision advisable.

Disorders of the central nervous system

Headache

The most common form of headache during pregnancy (as at other times) is chronic daily headache of the tension type. This may be a continuation of pre-existing headaches or a new phenomenon, compounded by anxiety, depression, or poor sleep. Neurological examination is usual in such cases and the treatment should concentrate on explanation and reassurance, coupled if necessary with advice about relaxation techniques. Occasional paracetamol may be helpful; aspirin should be avoided in the third trimester.

Migraine usually improves during pregnancy, but approximately 20 per cent of sufferers get worse and occasionally migraine actually begins in pregnancy. No single hormonal change has been convincingly linked to these divergent responses. Whilst migraine can generally be identified accurately on clinical grounds, diagnosis is more difficult when it presents for the first time in pregnancy, particularly if accompanied by the transient focal deficits of migraine aura such visual disturbances or hemiplegia. Other potential causes of headache in pregnancy, such as eclampsia (Chapter 13.4), subarachnoid haemorrhage, cerebral venous thrombosis, cerebral infarction, intracranial tumour, and intracranial infection must be considered and excluded by careful neurological and general examination, supplemented if necessary by brain imaging (see below). Some women present in pregnancy with migraine aura without headache, which can also give rise to diagnostic difficulty: it may be necessary to exclude causes of transient ischaemic attack.

Acute migraine attacks should be treated promptly with rest and paracetamol; prochlorperazine is probably a safe treatment for vomiting. Ergot derivatives must be avoided in pregnancy (and breastfeeding), and the triptan drugs have not yet been shown to be safe. If attacks are frequent then attention should be paid to relevant lifestyle factors such as irregular sleep or meals and worry. Prophylactic drug treatment is occasionally necessary, and the greatest experience lies with propranolol which, in doses of 20 to 80 mg three times a day, appears to be both effective and safe, despite its effect on placental blood flow. Women with migraine commonly develop a dull non-specific headache of variable severity in the first few days after delivery. This usually responds to simple analgesia, particularly if the woman has been warned about the phenomenon.

Tumours

Although the incidence of cerebral and spinal tumours is probably no greater than at other times, some tumours expand during pregnancy and may present unusually rapidly. This probably reflects a mixture of hormonal and vascular factors; most meningiomas and some neurofibromas and gliomas express oestrogen and progesterone receptors and placental growth factor.

Neurofibromatosis type 1 presents particular problems in pregnancy. Women with this condition experience an increased rate of spontaneous first trimester abortions, perhaps also intrauterine fetal growth retardation and stillbirths, and have a high rate of caesarean section. Most women notice that cutaneous neurofibromas grow or appear *de novo* during pregnancy.

Meningiomas are particularly liable to expand in the third trimester, causing local mass effects such as headache, cranial nerve palsies, hemiparesis, or paraparesis, which may remit after delivery. Corticosteroids can be given to reduce surrounding oedema, and surgery can often be delayed until after delivery. Gliomas tend to present earlier in pregnancy and have a reputation for following an aggressive course. They may require early surgical intervention, and it is sometimes also appropriate to consider termination of the pregnancy. Women with known intracranial mass lesions require careful assessment prior to delivery: prolonged Valsalva manoeuvres can increase intracranial pressure and elective caesarean section may be necessary.

Choriocarcinoma is a tumour peculiar to pregnancy and the most common form of malignancy associated with pregnancy. It usually presents after molar pregnancy or abortion, but 15 per cent of cases occur during or after normal pregnancy. Neurological manifestations due to brain or spine metastases are common. The brain metastases have a tendency to invade blood vessels, giving rise to strokes through infarction or haemorrhage. Spinal metastases cause cord or cauda equina compression that may be rapid in onset. There are usually multiple pulmonary metastases on chest radiography and the serum chorionic gonadotrophin is greatly elevated. Early diagnosis and treatment (with chemotherapy and radiotherapy) improves survival, but the mortality rate of cases with neurological manifestations remains high.

The normal pituitary gland and some pituitary tumours such as prolactinomas expand during pregnancy. Their management, the possibility of pituitary apoplexy, and the postpartum differential diagnosis of lymphocytic hypophysitis are discussed in Chapter 13.11.

Stroke

There is probably an increased incidence of stroke during pregnancy and the puerperium, although it remains rare. There are some causes of stroke which seem to be more common in pregnancy, but most cases are due to one of the usual causes of stroke in non-pregnant young women. Cerebral infarction due to large cerebral

artery occlusion may be slightly more common. Possible explanations for this include the mild hypercoagulable state that develops in the later stages of pregnancy and persists for a few weeks afterwards, also the phenomenon of paradoxical embolism from the leg or pelvic veins. Cerebral infarction may occur as a result of hypoxia–ischaemia or disseminated intravascular coagulation in the context of major obstetric emergencies such as amniotic fluid embolism. Unless the cause is obvious, ischaemic stroke in pregnancy should be investigated comprehensively in the same way that it would in a young non-pregnant woman.

There is a rare syndrome of segmental cerebral vasoconstriction in the puerperium, which usually presents with headaches, seizures, or focal deficits (especially visual field defects). It has a predilection for the posterior cerebral circulation and can give rise to multiple infarcts or haemorrhages. The condition, generally termed postpartum angiopathy, can occur spontaneously but has also been described in women taking bromocriptine. There are reports of successful treatment with corticosteroids and vasodilators, but there have been no prospective studies. The condition can recur in subsequent pregnancies.

Cerebral venous thrombosis, like deep vein thrombosis of the legs, is commoner in the puerperium, and the two conditions may coexist. Classically it gives rise to headache and neurological deficit that evolves over several hours and may become bilateral, with seizures and papilloedema; other cases present with the syndrome of benign intracranial hypertension. The diagnosis can usually be made with magnetic resonance imaging, including magnetic resonance venography. Although venous infarcts frequently undergo haemorrhagic transformation, the currently available evidence favours treatment with heparin. If the patient survives then recovery may be surprisingly complete.

The incidence of aneurysmal subarachnoid haemorrhage is not increased during pregnancy but its management is difficult. In general, neurosurgical considerations take precedence over obstetric ones and the aneurysm is treated in the usual way. If it is not technically possible to isolate the aneurysm then conventional wisdom is to deliver the baby (once it is mature) by caesarean section, although there is no definite evidence to suggest an increased risk of rebleeding during vaginal delivery. Intracranial and subarachnoid haemorrhage from arteriovenous malformations is much less common but the same principles of management apply. Women with untreatable vascular malformations (including cavernomas) should be counselled about the increased risk of bleeding (perhaps due to a mixture of hormonal and vascular factors) throughout pregnancy.

Epilepsy

Most women with pre-existing epilepsy have no change in the frequency of their seizures during pregnancy, but some 30 per cent have more frequent seizures. These are often women whose epilepsy has been hard to control at other times. Anticonvulsant plasma levels tend to fall in the later stages of pregnancy through increased volumes of distribution and rates of elimination: consensus guidelines recommend that plasma levels are monitored routinely and dosage adjusted to keep these steady. This approach is not entirely foolproof because most laboratories are unable to measure the changes in protein binding that also occur during pregnancy, increasing the availability of free drug. If the dosage is increased prophylactically during pregnancy then it is important to remember to reduce the dosage again in the postpartum period.

An equally important reason for deteriorating control of seizures is lack of adherence to anticonvulsant therapy because of fear of teratogenic effects. This is best addressed by counselling well before pregnancy, which should include a discussion of the risks of uncontrolled epilepsy to both mother and fetus, although it must be admitted that this is made difficult by the lack of quantitative data. As always, the aim of treatment is to control the epilepsy using a single anticonvulsant in the lowest effective dosage, and it is reasonable to try to reduce or withdraw anticonvulsants prior to pregnancy if there is a chance that the epilepsy may have remitted. It is unwise to attempt this during pregnancy itself.

All the anticonvulsant drugs are either known teratogens or of unknown safety in pregnancy. Epilepsy roughly doubles the risk of fetal malformation and most of this risk seems to be due to the treatment rather than the epilepsy or its cause. This translates into an absolute risk in the region of 5 to 10 per cent, although many of these malformations are minor. The risk is greatest in women taking two or more anticonvulsants. In the case of more serious abnormalities, phenytoin, barbiturates, carbamazepine, and sodium valproate all appear to be associated with facial clefts, cardiac septal defects, and a pattern of craniofacial and digital dysmorphism known as the fetal anticonvulsant syndrome. Sodium valproate and to a lesser extent carbamazepine appear to be associated with neural tube defects. Some of these defects may be secondary to drug-induced folate deficiency and it is good practice to offer folate supplements (5 mg daily) routinely to all potentially fertile women who are taking anticonvulsants, especially in the 3 months prior to and the first trimester of any planned pregnancy. Carbamazepine is traditionally regarded as the safest of the anticonvulsants for which we have reasonable data, but the teratogenic effects of sodium valproate appear to be dose dependent and dosages of less than 1 g daily may be equally safe. This is important when treating women with conditions such as juvenile myoclonic epilepsy which respond much better to valproate than carbamazepine. Several registers are currently collecting prospective data on the safety of the newer anticonvulsants (lamotrigine, gabapentin, vigabatrin, topiramate, tiagabine, etc.) but, at the time of writing, these must all be regarded as of unknown safety in pregnancy.

In addition to worries about teratogenic effects (which arise in the first 8 weeks of gestation), there are growing concerns about the potential for anticonvulsants to produce more subtle adverse effects on brain development and the subsequent behaviour and intelligence of the child. Such effects have been demonstrated in relation to anticonvulsant polytherapy including barbiturates, and it is possible that they may occur with other drugs. Prospective studies are in progress, but at the moment there is no clear guidance for women with epilepsy or their doctors in relation to the magnitude of these risks.

Carbamazepine, phenytoin, and the barbiturates accelerate vitamin K metabolism and increase haemorrhagic risks. Again it is considered to be good practice to offer the mother vitamin K supplements during the last month of pregnancy and to give the baby vitamin K at birth.

Epilepsy presenting for the first time in pregnancy requires investigation in the same way as adult-onset epilepsy in general. Idiopathic epilepsy that only occurs in pregnancy (so-called gestational epilepsy) is rare. Women presenting with serial seizures or status epilepticus are particularly likely to have an underlying secondary cause such as eclampsia, stroke, tumour, or encephalitis. Epilepsy during labour is usually either iatrogenic (for example, omission of normal anticonvulsant therapy) or again symptomatic of serious intracranial disease. Eclampsia (see Chapter 13.4) is clearly the first consideration, but other possibilities include amniotic fluid embolism and cerebral venous thrombosis.

All the anticonvulsants pass into breast milk to some extent, but this need not prevent breastfeeding. Only the barbiturates occasionally cause problems with excessive sedation, but this small risk must be balanced against the problems of effectively withdrawing barbiturates by not breastfeeding. This can lead to the baby becoming irritable and jittery; impaired suckling and withdrawal seizures have also been reported.

Multiple sclerosis

Pregnancy raises complex issues for women with multiple sclerosis. Preconceptual considerations include the small risk (approximately 3 per cent) of their child inheriting the disease and the practical burdens that child care imposes upon a mother with existing and potentially progressive disability. Several epidemiological studies have shown that the incidence of relapses of multiple sclerosis falls during pregnancy itself, with a compensatory rise in the puerperium (with between 20 and 40 per cent of women reporting an exacerbation of symptoms.) It has been suggested that this reflects the production of pregnancy-associated proteins with immunosuppressive properties, such as a-fetoprotein, and changes in T-lymphocyte subsets. There is no evidence of any long-term detrimental effect on disability, and no evidence of any adverse effect from epidural anaesthesia or breastfeeding.

Relapses in pregnancy are treated in the normal way, with rest supplemented by a short course of oral or intravenous steroid if there is serious new disability. High-dose steroids given late in pregnancy can cause neonatal adrenal suppression. The manufacturers of interferon-b advise women taking it to avoid pregnancy and discontinue it during pregnancy and breastfeeding unless there are compelling reasons to continue with therapy.

Many women with multiple sclerosis have impaired bladder emptying, which predisposes to urinary tract infection. Severe spinal cord disease is a particular risk because it may mask the usual symptoms of urinary infection; regular urine culture is a sensible precaution. Paraplegia (from any cause) otherwise has little effect on pregnancy, but can lead to premature and unheralded labour, hence regular monitoring is needed in the third trimester. High spinal cord lesions can cause autonomic instability during labour; this can be blocked by careful regional anaesthesia.

Movement disorders

Pregnancy aggravates any tendency to chorea, an effect termed chorea gravidarum. This should not be regarded as a specific diagnosis, and unless there is a definite history of previous Sydenham's chorea it should prompt a search for all the usual causes of the condition, including thyrotoxicosis and systemic lupus erythematosus. Chorea can be florid and exhausting so that treatment with a small dose of a neuroleptic such as haloperidol may be required. Recurrence in

subsequent pregnancies (or with the combined oral contraceptive) is common, perhaps because of the effects of oestrogens on the sensitivity of dopamine receptors.

Parkinsonism is rare in women of child-bearing age but tends to worsen slightly during pregnancy. Preconceptual counselling is difficult because there are no useful data in relation to the teratogenicity of the drugs used in young patients; levodopa has teratogenic effects in animals. Dystonic disorders also sometimes worsen in pregnancy, the effect being especially marked in dopa-responsive dystonia where an increase in levodopa therapy may be required. Wilson's disease is an exception and sometimes improves in pregnancy. Concerns about the potential teratogenic effects of therapy with penicillamine must be balanced against the risks of catastrophic neurological deterioration if therapy is abruptly withdrawn, although in the future treatments such as zinc may turn out to be a safe alternative.

13.13 The skin in pregnancy

F. Wojnarowska

The skin undergoes profound alterations during pregnancy as a result of endocrine, metabolic, and physiological changes. Some of these are trivial and chiefly cosmetic, producing no or minor symptoms, others can be distressing and/or of major medical importance. Pregnancy will profoundly modify expression of pre-existing skin disease and there are dermatoses which are specific to pregnancy: these are described in detail below.

Common skin changes in pregnancy

Vascular changes and lesions

There is increased skin blood flow during pregnancy and this makes the skin more prone to itch and to oedema, manifest as tightening of rings and shoes. Spider naevi and palmar erythema are common, as are haemangiomas. Pyogenic granuloma may develop: this is a benign tumour with a tendency ulcerate and to bleed, and is sometimes clinically confused with melanoma. It often recurs after local destruction.

Pigmentary changes and pigmented lesions

There is darkening of the nipples, genitalia, and linea alba. The unsightly and sometimes psychologically distressing facial pigmentation of melasma (chloasma) affects many women, is worse with sunlight, and can be reduced by the use of high protection factor (SPF 25) UVB and UVA sun screens.

Pigmented naevi can increase in number, size, and pigmentation. Melanoma may occur and is associated with a poor prognosis in pregnant women (see Section 23). Any rapidly changing, irregularly shaped, or irregularly pigmented mole should be biopsied to exclude a dysplastic naevus or melanoma.

Hair changes

There is diminished shedding of hair, due to prolongation of anagen. This is perceived as thickening of the hair, which increased sebum secretion makes appear more lustrous. The synchronized shedding after parturition gives rise to the distressing postpartum telogen effluvium. Hirsutism may begin or worsen in pregnancy as there is an associated increase in androgens.

Pilosebaceous changes

The increased oestrogens of pregnancy usually improve acne, but there may be worsening of acne in some unfortunate patients, and the entire skin is usually greasier.

Striae

Striae on the breasts and abdomen are very common in pregnancy, but do not necessarily relate to either the total weight gain or the rate of weight gain. There is much individual variation.

Cutaneous infections

Candida of the vulva as well as the vagina may occur. Cutaneous and genital warts thrive in pregnancy. Treatment of genital warts is by physical destruction as podophyllin must not be used in pregnancy. Genital herpes simplex infections can pose problems as regards delivery during active infections.

The pregnancy dermatoses

There are five major dermatoses which occur in pregnancy, and some that can be precipitated by pregnancy.

Pruritus of pregnancy

Itching occurs in about 20 per cent of pregnancies. Sometimes this is in association with an inflammatory dermatosis. Often there are no physical signs, other than scratch marks, and iron deficiency must be excluded. In about 2 per cent of women itching is related to cholestasis of pregnancy, when it is termed pruritus gravidarum. The itching begins in the third trimester and affects the abdomen, palms, and soles. Liver function tests are abnormal and bile salts are raised. It resolves postpartum, but will recur in subsequent pregnancies.

Management consists of emollients and sometimes antihistamines. Chlorpheniramine is the one usually recommended for pregnancy. The non-sedating antihistamines are probably ineffective.

Polymorphic eruption of pregnancy (pruritic urticated papules and plaques of pregnancy)

This dermatosis affects 1 in 240 singleton pregnancies but is more common in multiple births, and is thus being seen more often in the context of *in vitro* fertilization. It is more common with a male foetus. The dermatosis usually begins in the third trimester and occasionally postpartum. It is most common in first pregnancies or the first multiple pregnancy.

The lesions usually begin in the striae on the abdomen and thighs, and then spread to the whole trunk and limbs, including the hands and feet. The lesions are raised red papules (Plate) and plaques, occasionally polycyclic, and rarely may blister on the lower legs. The itching can be very severe, preventing sleep. The

histopathology shows oedema, perivascular lymphocytes, and eosinophils. Immunofluorescence does not demonstrate any circulating or bound immunoreactants.

The aetiology is unknown, but there is an association with a low serum cortisol. The increased frequency in multiple births may relate to the mechanical effect of the abdominal stretching or to an increased immune complex load.

Treatment is with reassurance and emollients, for example aqueous cream and 1 to 2 per cent menthol, is helpful, but is not always sufficient. Antihistamines and moderate to very potent topical steroids, which will have significant absorption (see Table 1), and occasionally systemic steroids or induction, may be required. The condition resolves over days to weeks after delivery. It does not usually recur. The outcome of the pregnancy is not adversely affected.

Prurigo of pregnancy

This is may affect 1 in 300 pregnancies. It commences at the end of the second or beginning of the third trimester. The eruption is scattered over the abdomen and limbs, and comprises excoriated papules. There is intense pruritus. It is essential to make sure that iron deficiency is not a contributing factor.

Histopathology shows a perivascular infiltrate with thickened epidermis. Direct and indirect immunofluorescence are negative. Treatment is with reassurance and emollients, and if this is not sufficient, with antihistamines and moderate to very potent topical steroids or occlusive coal tar or icthapaste bandages, which can be applied over topical steroids to the limbs. The condition resolves in days to weeks after delivery. It does not usually recur.

Pruritic folliculitis

This is rare and most commonly affects pregnancies with a male foetus. The lesions are pruritic papules and pustules that present in the third trimester, affect the trunk, and may spread to the limbs. Topical steroids may be helpful. Pruritic folliculitis is associated with a low birth weight.

Pemphigoid gestationis (herpes gestationis)

Pemphigoid gestationis is the most severe of the pregnancy dermatoses. It occurs in 1 in 50 000 pregnancies. The name herpes gestationis is best abandoned as the herpes refers to the herpetiform grouping of the blisters rather than herpes infection. Pemphigoid gestationis commences from the second trimester onwards and quite often in the first week postpartum (range 5 weeks gestation to 4 weeks postpartum). It usually occurs in the first and subsequent pregnancies, although 8 per cent of pregnancies are skipped.

The eruption begins around the umbilicus and spreads to the whole trunk, limbs, hands, and feet, including the palms and soles, and rarely the face. The mouth and vulva may be involved. The eruption usually commences as an annular red raised plaque around the umbilicus. The lesions comprise annular lesions, papules, and plaques. Vesicles and blisters are seen (Plate 2). The mucosal lesions may be blisters or erosions. Pruritus is severe and sleep often impossible. Transplacental transmission to the fetus occurs in about 3 per cent of affected pregnancies, and the neonate develops transient self-limiting blisters (Plate 3).

Histopathology demonstrates eosinophilia, subepidermal blisters, and tear-drop vesicles within the epidermis, continuous with the subepidermal blisters. Direct immunofluorescence demonstrates that C3 component of complement and IgG1 are bound at the basement membrane zone of the dermoepidermal junction. The patient's serum has circulating IgG1 basement membrane zone antibodies that bind C3. These immunoreactants are also found at the basement membrane zone of the amnion (Plate 4). The mothers have HLA DR 3, 4, and are C4 null, and there is an association with thyroid and less commonly other autoimmune disease.

The aetiology is only partially understood. The pathogenicity of the circulating basement membrane zone antibodies is demonstrated by transplacental transmission of the disease. The major target antigen is BP180/collagen XVII (chief epitope—the transmembrane NC16A domain) and BP230 is a further antigen. Both antigens are present in skin, mucosa, and amnion associated with the hemidesmosome and adhesion complex linking epithelium to dermis/mesenchyme, and are targets in other autoimmune blistering diseases. The placenta shows increased expression of antigen presenting cells, but it is unclear why breakdown of tolerance occurs, and why normal components of amnion and stratified squamous epithelium become antigenic.

Treatment with potent or very potent topical steroids and chlorpheniramine is sometimes successful, but usually systemic steroids, for example prednisolone 20 to 80 mg daily, are required, with the dose adjusted according to disease activity. There is usually a postpartum flare, necessitating increased steroids. The disease slowly resolves postpartum, but persists for several months. There is an increased incidence of premature births and small-for-dates babies. The classical teaching is that it recurs earlier and is more severe in subsequent pregnancies, but this has not always been our experience.

Dermatoses in response to pregnancy

Urticaria (hives) and dermographism (wealing in response to pressure, for example scratching) may be precipitated by pregnancy. Erythema multiforme due to pregnancy has been described.

Dermatoses and the effect of pregnancy

Atopic eczema

Atopic eczema is the commonest skin problem presenting in pregnancy. It can be severe and life ruining, and life threatening if secondary infection with herpes simplex (eczema herpeticum) or *Streptococcus* occurs. The effect of pregnancy on pre-existing atopic eczema is unpredictable: the immunosuppression can lead to improvement, but often there is deterioration of the eczema. The eczema becomes more widespread and may result in erythroderma in the most severe cases. Secondary infection with *Staphylococcus aureus* and *Streptococcus* is a frequent complication. The skin is red, dry, and scaly with areas of excoriation and thickening or lichenification.

Treatment is a major problem in pregnancy, as there is a dilemma in balancing the need for treatment with the wish to minimize the use of potent topical steroids which will be absorbed and may affect the foetus. The use of emollients may lessen the requirements for topical steroids, and steroids should be used in the minimum quantities and strengths necessary to control the disease (see Table 1). Many topical steroids contain antiseptics and antibiotics which will be absorbed and may be contraindicated in pregnancy. The sedating antihistamine, chlorpheniramine, may help with sleep. Secondary infection often requires systemic antibiotics such as erythromycin or flucloxacillin.

Psoriasis

Psoriasis may improve or deteriorate during pregnancy. Therapy poses special problems as all the systemic treatments are contraindicated: methotrexate is a folic acid antagonist, acitretin is teratogenic, ciclosporine results in intrauterine growth retardation, and psoralens with UVA are still not proven to be safe. Topical therapy with steroids should be avoided if possible. Coal tars and dithranol have been widely used in pregnancy but are not proven to be safe, and the new vitamin D analogues are not licensed for use in pregnancy. The ideal is minimum treatment, with emollients and if necessary UVB.

A severe form of pustular psoriasis, impetigo herpetiformis, may occur in pregnancy and is best managed with bedrest and emollients.

Autoimmune dermatoses in pregnancy

Cutaneous lupus erythematosus

Cutaneous lupus erythematosus does not seem to be adversely affected or improved by pregnancy. However such patients should be screened for anti-Ro and anticardiolipin antibodies etc. (see Chapter xxx), preferably prior to conception, to identify at-risk pregnancies.

Autoimmune bullous diseases

Linear IgA disease, an autoimmune blistering disease with IgA basement membrane zone antibodies, usually improves with pregnancy, such that some patients can discontinue their dapsone therapy. Despite the deposition of immunoreactants in the amnion basement membrane zone the fetus is not adversely affected. There is usually an exacerbation 3 months postpartum.

Pemphigus vulgaris, an autoimmune blistering disease with widespread mucosal and cutaneous erosions caused by antibodies to desmosomal components, can be transmitted across the placenta, with devastating results to the fetus. This does not occur in the related pemphigus foliaceus, which is endemic in Brazil.

13.14 Autoimmune disorders and vasculitis in pregnancy

Catherine Nelson-Piercy and Munther A. Khamashta

Autoimmune diseases affect 5 to 7 per cent of the population, are commoner in women of child-bearing age, and are frequently encountered in pregnancy. Pregnancy is associated with suppressed cell-mediated immunity and enhancement of humoral immunity, but these changes revert postpartum accompanied by sudden reductions of oestrogen, progesterone, and cortisol levels. The postpartum period is therefore a time of susceptibility to autoimmune disorders and women who already have an autoimmune disorder may suffer disease exacerbation following pregnancy. Conversely, autoimmune diseases may remit or improve during pregnancy, but this is not a universal rule and autoimmune rheumatic/connective tissue diseases can flare or present in pregnancy with disastrous consequences. This chapter considers the relationship between pregnancy and rheumatoid arthritis, systemic lupus erythematosus (SLE), antiphospholipid syndrome (APS), vasculitides, and scleroderma, and how pregnancy affects treatment of these disorders. The management of these conditions during pregnancy provides the obstetrician and physician with particular challenges and concerns related to not only the mother but also the fetus.

Rheumatoid arthritis

The adult form of the disease is more common in women (female to male ratio = 3:1), and approximately 1 in every 1000 to 2000 pregnancies are affected.

Effect of pregnancy on rheumatoid arthritis

Up to 75 per cent of women with rheumatoid arthritis experience improvement during pregnancy. Originally it was thought that this was the result of raised cortisol levels but these do not correlate with symptoms. Another hypothesis is a maternal immune response to fetal paternally inherited HLA class II gene products, supported by the finding that maternal–fetal disparities for HLA DQA were observed in 78 per cent of women whose rheumatoid arthritis went into remission during pregnancy, but in only 25 per cent in those whose disease remained active. Other theories attribute the improvement to high oestrogen levels, although ethinyl oestradiol given to postmenopausal women with rheumatoid arthritis is not effective. Pregnancy specific proteins such as a $_2$-glycoprotein (PAG) have also been implicated, and in experimental models a$_2$-glycoprotein improves arthritis. Removal of immune complexes by the placenta is another postulated mechanism.

Improvement usually begins during the first trimester, when rheumatoid nodules may also disappear, but 90 per cent of those who experience remission suffer postpartum exacerbations. The largest study of disease activity in pregnancy in 140 women with rheumatoid arthritis confirmed improvement in joint swelling and pain in two-thirds of subjects by the third trimester. However, only a minority had no joints with active disease, disability as assessed by the Health Assessment Questionnaire changed little compared to prepregnancy, and only 16 per cent went into complete remission. Disease response in a previous pregnancy was predictive of response in the index pregnancy. An increase in the mean number of inflamed joints was seen postpartum, but this could not be predicted from previous puerperal relapse. In women without the condition, there is an increased incidence of rheumatoid arthritis onset in the postpartum period.

Effect of rheumatoid arthritis on pregnancy

Unlike SLE, there seems to be no adverse effect of rheumatoid arthritis on pregnancy, and neither the fertility rate or spontaneous abortion rate is significantly altered. However, the infants of woman who have anti-Ro antibodies are at risk of neonatal lupus (see below). Atlantoaxial subluxation is a rare complication of a general anaesthetic for a caesarean section, and very rarely limitation of hip abduction is severe enough to impede vaginal delivery. The main concerns relate to the safety during pregnancy and lactation of the medications used to treat rheumatoid arthritis, although only 20 to 30 per cent of pregnant women with rheumatoid arthritis will require medications to control flares or systemic disease.

Treatment of rheumatoid arthritis (and other rheumatic disorders) in pregnancy

Paracetemol should be the first line analgesic, and there are no known adverse effects in pregnancy. Aspirin and non-steroidal anti-inflammatory drugs (NSAIDs) are not teratogenic, but salicylates (in analgesic doses) and NSAIDs may increase the risk of neonatal haemorrhage via inhibition of platelet function. NSAIDs may also lead to oligohydramnios via effects on the fetal kidney, and as they are prostaglandin synthetase inhibitors may cause premature closure of the ductus arteriosus (because prostaglandin E_2 relaxation of pulmonary vessels is inhibited) with neonatal primary pulmonary hypertension. They are usually avoided in pregnancy, especially in the last trimester, but the risk to the ductus arteriosus may have been exaggerated since premature closure has not been encountered when indomethacin is used for the treatment of premature labour. Impairment of ductal flow is rare before 27 weeks and resolves within 24 h of NSAID discontinuation. Oligohydramios is also reversible. In occasional circumstances, and especially prior to 28 weeks gestation, NSAIDs may be used for control of arthritic pain if there are relative contraindications to steroids, for example in patients on heparin. They should be discontinued at least 6 to 8 weeks prior to delivery. The recently introduced cyclo-oxygenase type-2-selective (COX-2) NSAIDs, although currently contraindicated in pregnancy, have been reported to show only minor renal and no ductal effects on the fetus when used to prevent premature labour.

Corticosteroids may be continued during pregnancy and are preferable to NSAIDs if paracetemol is insufficient to control symptoms in the third trimester. Prednisolone is metabolized by the placenta and very little (10 per cent) active drug reaches the fetus, unlike dexamethasone and betamethasone which cross the placenta more readily. Exceedingly large doses of cortisone are associated with an increased incidence of cleft palate in rodents, and one case–control study has suggested an increased risk of cleft lip following first-trimester exposure. There are many other studies supporting no increased risk of abortion, stillbirth, congenital malformations, adverse fetal effects, or neonatal death attributable to maternal steroid therapy. However, in women with antiphospholipid syndrome, treated with high doses of prednisolone throughout pregnancy, an increased frequency of premature rupture of the membranes has been reported. Although suppression of the fetal hypothalamic–pituitary–adrenal axis is a theoretical possibility with maternal systemic steroid therapy, there is no evidence that this occurs. Corticosteroid usage in pregnancy increases the risk of gestational diabetes, infection, and osteoporosis. If a woman is on long-term maintenance steroids, parenteral steroids should be administered to cover the stress of labour and delivery. Prednisolone is safe in breast-feeding mothers since <10 per cent of active drug is secreted into breast milk.

The alkylating agents cyclophosphamide and chlorambucil, and the folic acid antagonist methotrexate, are all teratogenic and fetotoxic and are contraindicated in pregnancy and lactation. Methotrexate should be discontinued at least 3 months prior to conception and folic acid supplementation given preconceptually. Azathioprine, the commonest cytotoxic used in rheumatoid arthritis and SLE, seems safe based on its successful use in large numbers of renal transplant mothers and women with SLE. However, neonatal immunosuppression has been noted and conflicting information exists regarding breast feeding while taking azathioprine. Cyclosporin has been associated with a higher rate of intrauterine growth restriction (IUGR) than azathioprine in renal transplant patients and should be avoided if possible.

D-penicillamine, a chelating agent used particularly in the management of the extra-articular features of rheumatoid arthritis, crosses the placenta and is teratogenic, with a 5 per cent risk of congenital collagen defect. It should therefore be stopped before conception in women with rheumatic diseases, but continued use is crucial for successful outcome of pregnancy in Wilson's disease, where there are about 90 reported cases. Gold salts are teratogenic in animals, but there is no conclusive evidence for such an effect in humans. They can therefore be continued during pregnancy if they are controlling disease, although most would avoid initiation of treatment during pregnancy.

Antimalarials, such as hydroxychloroquine, used in rheumatoid arthritis and particularly in subacute cutaneous lupus, are safe in doses used for malarial prophylaxis. There has been concern over larger doses, when concentration in the fetal uveal tract may result in retinopathy. Nevertheless, in 215 pregnancies in women exposed to chloroquine the congenital abnormality rate was no higher than background. There is also increasing experience of the use of hydroxychloroquine in pregnant women with SLE. It seems to have no adverse effect on the neonate, and should be continued through pregnancy for two reasons. Firstly, cessation may precipitate a flare of lupus. Secondly, it has a very long half-life, such that discontinuation will not prevent fetal exposure.

Sulphasalazine, another second-line agent, has been used extensively in the treatment of inflammatory bowel disease in pregnancy and appears to be safe. It may be continued throughout pregnancy, although concomitant folate supplementation is recommended.

Systemic lupus erythematosus (SLE)

SLE is much more common in women than men (ratio 9:1), particularly during the child-bearing years, (ratio 15:1). The prevalence is approximately 1 per 1000 women and may be increasing. The fundamental issues concerning the effect of SLE on pregnancy are the presence or absence of anti-Ro/La and antiphospholipid antibodies (see below), the activity of the disease, and the presence or absence of hypertension and renal involvement.

Effect of pregnancy on SLE

SLE flares may be difficult to diagnose during pregnancy since many features such as hair fall, oedema, facial erythema, fatigue, anaemia, raised ESR, and musculoskeletal pain also occur in normal pregnancy. Whether pregnancy exacerbates SLE and increases the likelihood of flare postpartum is controversial. Six controlled studies have addressed this issue. These differ in the ethnicity of the populations, the criteria for flare, and the SLE activity scales employed. Three found no increased risk of deterioration in pregnancy; three, including the most recent study from St Thomas', suggested that SLE was more likely to flare during pregnancy and the puerperium. The studies are consistent in showing that 58 to 70 per cent of women flare during pregnancy. Steroids do not prevent these flares, and it is not our practice to prescribe prophylactic steroids or increase steroid dosage prophylactically during pregnancy or postpartum.

In 242 pregnancies in 156 women with lupus nephritis, kidney function was unchanged in 59 per cent, transiently impaired in 30 per cent, and permanently deteriorated in 7.1 per cent. As in all types of renal disease, there is a greater risk of deterioration in patients with hypertension, heavy proteinuria, and high baseline serum creatinine.

Effect of SLE on pregnancy

SLE is associated with increased risks of spontaneous abortion, fetal death, pre-eclampsia, preterm delivery, and IUGR. A prospective study of 108 pregnancies in 90 lupus patients showed a live birth rate of 82 per cent, a 43 per cent incidence of prematurity, and a 30 per cent incidence of IUGR. Most of the fetal losses were in association with secondary antiphospholipid syndrome. Pregnancy outcome is particularly affected by renal disease. Even quiescent renal lupus is associated with increased risk of fetal loss, pre-eclampsia, and IUGR, particularly if there is hypertension or proteinuria. For women with SLE in remission, and without hypertension, renal involvement, or the antiphospholipid syndrome, the risk of problems in pregnancy is probably no higher than in the general population.

Management of SLE in pregnancy

When possible, this should begin with preconception counselling. Knowledge of the anti-Ro/La antiphospholipid antibody, and renal and blood pressure status allows prediction of the risks to the woman and her baby (see below). The outlook is better if conception occurs during remission. Pregnancy care is best undertaken in multidisciplinary, combined clinics where physicians and obstetricians can monitor disease activity and fetal growth and uterine and umbilical artery Doppler blood flow regularly.

Disease flares must be actively managed. Corticosteroids are the drug of choice (see above for discussion of anti-inflammatory agents and immunosuppression in pregnancy). Hydroxychloroquine should be continued since stopping may precipitate flare. Azathioprine is also usually continued, since this acts as a 'steroid-sparing' agent. Differentiation of active renal lupus from pre-eclampsia is notoriously difficult and the two conditions may be superimposed. Since hypertension, proteinuria, thrombocytopenia, and renal impairment are all features of pre-eclampsia, diagnosis of lupus flare requires other features, such as a rising anti-dsDNA antibody titre, the presence of red blood cells or cellular casts in the urinary sediment, or a fall in complement levels. Elevation of complement split products, particularly Ba and Bb, often accompanies flares so high ratios of CH50/Ba may differentiate pre-eclamptics from those with active lupus. The only definitive investigation to reliably differentiate a renal lupus flare from pre-eclampsia is renal biopsy, but this is rarely undertaken in pregnancy.

For control of hypertension, the drug of choice is methyl dopa, with nifedipine or hydrallazine as second-line agents.

Neonatal lupus syndromes

These conditions are models of passively acquired autoimmunity. Autoantibodies directed against cytoplasmic ribonucleoproteins Ro and La cross the placenta causing immune damage in the fetus. Several clinical syndromes have been described, of which cutaneous neonatal lupus is the most common, and congenital heart block is the most serious. They rarely coexist. More than 90 per cent of mothers of affected offspring have anti-Ro antibodies, and 50 to 70 per cent anti-La antibodies. About 30 per cent of patients with SLE are anti-Ro positive, and in such women the risk of transient cutaneous lupus is about 5 per cent and the risk of congenital heart block about 2 per cent. The risk of neonatal lupus is increased if a previous child has been affected, rising to 16 per cent with one affected child and 50 per cent if two children are affected. It is important to recognize that not all Ro-positive mothers of neonates with congenital heart block have SLE. A large proportion are asymptomatic, but 48 per cent of these developed symptoms of connective tissue disease in a mean of 2.6 years in one study. Mothers of babies with neonatal lupus have a higher frequency of HLA-DR3, often with A1 and B8. There is no correlation between the severity of maternal disease and the incidence of neonatal lupus.

The cutaneous form of neonatal lupus usually manifests in the first 2 weeks of life. The infant develops typical geographical skin lesions similar to those of adult subacute cutaneous lupus, usually of the face and scalp, which appear after sun or UV light exposure. The rash disappears spontaneously within six months, suggesting a direct antibody-mediated mechanism. Residual hypopigmentation or telangiectasia may persist for up to 2 years, but scarring is unusual. Sunlight and phototherapy should be avoided.

Congenital heart block appears *in utero*, usually around 18 to 20 weeks, and may be fatal. The mechanism of damage is not fully understood. There is no treatment that reverses congenital heart block, although salbutamol given to the mother may be beneficial if bradycardia is causing fetal heart failure. Dexamethasone and plasmapheresis have been used to treat non-immune hydrops resulting from myocarditis and pericarditis, but have no effect on the conduction defect. Perinatal mortality is increased with one-fifth of affected children dying in the early neonatal period, but most infants who survive this period do well, although two-thirds require pacemakers.

Antiphospholipid syndrome

Anticardiolipin antibodies and lupus anticoagulant (LA) are overlapping subsets of antiphospholipid antibodies. The combination of either of these with one or more of the characteristic clinical features (thrombosis, recurrent pregnancy loss, or adverse pregnancy outcome—premature birth before 34 weeks due to pre-eclampsia or IUGR) is known as the antiphospholipid syndrome (APS). Other associated features include thrombocytopenia and haemolytic anaemia, livedo reticularis, cerebral involvement (particularly epilepsy, cerebral infarction, chorea, and migraine), heart valve disease (particularly of the mitral valve), systemic and pulmonary hypertension, and leg ulcers. APS was first described in patients with SLE, but it is now recognized both that most patients with APS do not fulfil the diagnostic criteria

for SLE, and that those with primary APS do not usually progress to SLE. Although the clinical features of primary and SLE-associated APS are similar, and the antibody specificity is the same, the distinction is important, and patients with primary APS should not be labelled as 'lupus'.

Recurrent pregnancy loss, typically in the second trimester, is one of the most consistent features of APS. Fetal death is typically preceded by IUGR, oligohydramnios, and features of pre-eclampsia. Fetal loss represents one part of a spectrum of fetal compromise and a wide range of pregnancy morbidity has been reported in APS including recurrent first trimester miscarriage, second and third trimester loss, severe early-onset pre-eclampsia, IUGR, placental abruption, and prematurity. Since the classification criteria for APS have recently been amended, a patient with adverse pregnancy outcome may now be labelled as APS without a history of fetal loss. The risk of fetal loss is directly related to antibody titre, particularly the IgG anticardiolipin antibodies, although many women with a history of recurrent loss have only IgM antibodies. Quantifying the risk is difficult, and the presence of antiphospholipid antibodies does not preclude successful pregnancy. The antibodies should be regarded as markers for a high-risk pregnancy, but previous poor obstetric history remains the most important predictor of fetal loss in these women.

The prevalence of antiphospholipid antibodies in the general obstetric population is low (<2 per cent), so universal screening is not warranted. However, the prevalence of antiphospholipid antibodies is increased in women with pregnancy complications including severe early-onset pre-eclampsia, abruption, intrauterine fetal death, or IUGR without hypertension. In one study, 29 per cent of women with severe early-onset pre-eclampsia were found to have anticardiolipin antibodies compared with 2 per cent of controls.

The pathogenesis of fetal loss in these patients is not fully understood, but there is typically massive infarction and thrombosis of the placental and decidual vessels, probably secondary to spiral artery vasculopathy. One hypothesis is that anticardiolipin antibodies cause thrombosis by binding to co-factor b $_2$-glycoprotein, an endogenous coagulation inhibitor. Platelet deposition and prostanoid imbalance may be implicated, as they might be in pre-eclampsia.

Studies on pregnancy outcome in women known to have APS show differing rates of obstetric complications depending on their presentation. Those found to have APS as a result of recurrent miscarriage have lower rates of complications (see Table 1) than those discovered because of late losses, thrombosis, or other systemic manifestations.

Management of antiphospholipid syndrome in pregnancy

The management of pregnancy in women with APS is the subject of much debate. Aspirin inhibits thromboxane and may reduce the risk of vascular thrombosis, but its use as a single agent in APS pregnancy has only been subjected to randomized clinical trial in low-risk women. It was not found to be beneficial. There are several non-randomized studies in women with fetal loss suggesting that it is effective, and it can prevent pregnancy loss in experimental APS mice. Most centres now advocate low-dose aspirin (75 mg) for all women with APS, some even prior to conception, in the belief that the placental damage occurs early in gestation, and that aspirin prevents failure of placentation. We also advocate intra and postpartum (3–5 days) prophylaxis with heparin, especially in the event of caesarean section.

APS is the most frequent cause of acquired thrombophilia. However, unlike the congenital thrombophilias, thrombosis can be arterial or venous, and affects vessels of all sizes. The risk of recurrent thrombosis in patients with APS may reach 70 per cent, and women with APS and previous thromboembolism are at extremely high risk in pregnancy and the puerperium. Warfarin should be stopped and heparin started before 6 weeks gestation to avoid warfarin embryopathy. Subcutaneous unfractionated (10 000 u twice daily) or low-molecular weight heparin (enoxaparin 40 mg once daily; dalteparin 5000 once daily-twice daily) should be continued intrapartum and postpartum until warfarin has been reintroduced. It is occasionally necessary to use warfarin in women with previous arterial thromboses if heparin proves inadequate to prevent further transient ischaemic events.

Opinion is divided about the best antenatal therapy for those with recurrent pregnancy loss, but without a history of thromboembolism. Treatment with high-dose steroids (in the absence of active lupus) to suppress lupus anticoagulant and anticardiolipin antibodies, in combination with aspirin, was initially recommended because of improved (50 per cent) fetal survival compared to historical controls. However, high doses of prednisolone caused considerable maternal morbidity, and subsequent studies have failed to demonstrate better fetal outcome. Whether this can be improved by adding heparin to low-dose aspirin in women with recurrent miscarriage but without a history of thrombosis has been the subject of several studies, but remains controversial. Many centres have traditionally reserved the addition of heparin for those women with previous late losses or intrauterine deaths, and using such strategies live birth rates of 70 to 75 per cent can be achieved. However, two studies in different populations of women have suggested that aspirin and heparin can improve the live birth rate from about 40 per cent to about 70 to 80 per cent in woman with a history of recurrent miscarriage. In both, the excess losses in the aspirin alone group occurred prior to 13 weeks, after which outcomes were similar. This suggests that the beneficial effects of heparin occur before 13 weeks and raises the possibility that heparin may be stopped after this time if there is no history of thrombosis or a late loss. A more recent randomized controlled trial demonstrated no increase in live birth rate with aspirin and LMWH compared to aspirin alone.

Immunosuppression with azathioprine, intravenous immunoglobulin, and plasmapheresis have all been tried, but the numbers treated do not allow firm conclusions regarding efficacy. Trials of intravenous immunoglobulin in recurrent miscarriage have been stopped prematurely because of its cost and lack of obvious benefit.

Pregnancy complicated by APS requires expert care and a team approach by obstetricians, physicians, and haematologists. Close monitoring of both mother and fetus is essential. Ultrasound monitoring of fetal growth and uteroplacental blood flow is crucial, allowing for timely delivery. Uterine artery waveforms are assessed at 20 and 24 weeks gestation and those pregnancies with evidence of an early diastolic notch are monitored very closely with 2-weekly growth scans because of the high risk of IUGR. Where there are no notches, we recommend 4-weekly assessment of growth and amniotic fluid volume. Doppler flow studies of the umbilical artery may be used, as in other pregnancies at high risk of fetal compromise through uteroplacental insufficiency.

Vasculitis

Since the primary vasculitides occur principally in the post child-bearing years and are commoner in men, pregnancy is very uncommon in patients with Wegener's granulomatosis, polyarteritis nodosa (PAN), or Churg–Strauss vasculitis. Less than 50 pregnancies have been reported in total. In general, maternal and fetal outcome are dependent on disease activity. Reported cases would suggest that disease onset or flare is more likely during pregnancy or postpartum. Maternal death occurred in two of 20 pregnancies in women with Wegener's granulomatosis, none of seven pregnancies (in four women) in Churg–Strauss, and in all of seven women in whom PAN was diagnosed during pregnancy. Fetal outcome is usually successful in controlled or remitted disease, but active disease is associated with fetal demise. In the 20 pregnancies in Wegener's granulomatosis there were two intrauterine fetal deaths (both in women with active disease), four elective terminations, and the other infants survived. Despite the high maternal postpartum mortality in PAN, there were only two intrauterine deaths and nine surviving infants. Neonatal cutaneous vasculitis, resolving with treatment, has been reported in infants of mothers with cutaneous PAN.

In view of the significant maternal and fetal morbidity and mortality associated with active disease, it is important to adopt an aggressive approach to treatment with immunosuppression in the case of flare. Azathioprine is the drug of choice in pregnancy if immunosuppression with corticosteroids is insufficient, but life-threatening disease may necessitate the use of pulsed cyclophosphamide despite the risks.

Scleroderma

Although a rare disease, scleroderma is more common in women (female to male ratio = 3:1) and this is especially so during the reproductive years (10:1). Previously it was thought that fertility may be impaired in women with or destined to develop scleroderma, but more recent studies have demonstrated normal pregnancy rates in scleroderma. Indeed pregnancy may have an aetiological role: persistent fetal microchimerism being more common in women with scleroderma than controls, leading to the hypothesis that fetal antimaternal graft–versus–host reactions may be involved in pathogenesis (see Chapter 18.11.3).

Effect of pregnancy on scleroderma

Early case reports highlighted the risk from renal crises, even in women without a prior history of renal involvement, and renal disease was the commonest cause of death in these pregnancies. However, more recent case series and case–control studies have reported far fewer renal crises. A retrospective study of 86 pregnancies found no change in symptoms in 88 per cent, improvement in 5 per cent, and deterioration in 7 per cent. Ten-year survival of women with scleroderma, with or without pregnancy, was similar. A prospective series of 89 pregnancies in 58 women found stability in 61 per cent, improvement in 20 per cent, and worsening in 19 per cent. There were only five cases of renal crisis in these two series and all occurred in women with early diffuse scleroderma—the highest risk group for renal crises even outside pregnancy. Progressive cutaneous disease is unusual during or immediately after pregnancy. Raynaud's phenomenon usually improves in pregnancy as a

result of vasodilation and increased blood flow. Reflux and oesophagitis often worsen related to the decreased lower oesophageal tone of pregnancy. Arthralgias also worsen. There is no evidence that pregnancy worsens cardiac or respiratory disease, although those with severe pulmonary fibrosis and pulmonary hypertension are at extremely high risk of postpartum deterioration, as with pulmonary hypertension from any cause.

In general, women with limited scleroderma without organ involvement do better than those with diffuse disease. The extent of diffuse disease and systemic involvement (particularly lung, cardiac, and renal) influences prognosis, but there are no absolute rules. Those with early (less than 4 years) disease, diffuse disease, or antitopoisomerase (anti-ScL-70) antibodies are at greater risk of having more active aggressive disease than those with long-standing disease and anticentromere antibodies. Women with renal involvement often have associated hypertension and rapid deterioration is possible.

Effect of scleroderma on pregnancy

Although early literature suggested an increased risk of miscarriage in scleroderma, case–control studies found no increase when women with scleroderma were compared to those with rheumatoid arthritis or normal controls. A more recent, prospective study did find a 22 per cent incidence of miscarriage (compared with 13 per cent in controls) in women with diffuse disease. There is an increased risk of premature delivery (24 per cent in limited disease and 33 per cent in diffuse disease, versus 5 per cent in controls) and IUGR, but overall success is now reported to be 70 to 80 per cent. The risks of adverse outcome are highest for women with early diffuse disease. There is no increased risk of pre-eclampsia in the absence of hypertension or renal involvement.

Management

Women should be assessed prior to conception for the extent of organ involvement. Those with renal impairment, severe cardiomyopathy, severe restrictive lung disease or pulmonary hypertension should be advised against pregnancy. Those with early diffuse disease should delay pregnancy until the disease stabilizes. Disease-remitting drugs such as D-penicillamine and cyclosporin A should preferably be discontinued before conception if disease is stable, although inadvertent first trimester exposure should not cause undue concern.

High-level, joint obstetric and medical care is appropriate with frequent and regular multidisciplinary monitoring of disease activity and fetal growth. Particular attention to blood pressure monitoring is essential: hypertension may indicate a renal crisis. Coincident renal impairment or microangiopathic haemolytic anaemia should prompt the initiation of an ACE inhibitor. These drugs have revolutionized the management and survival in renal scleroderma and should not be withheld in pregnancy. They are usually contraindicated, but in scleroderma the benefit outweighs the risk of fetal renal toxicity.

Management of scleroderma during pregnancy is largely symptomatic. Calcium antagonists may be used for Raynaud's phenomenon and histamine blockers and proton-pump inhibitors for reflux. NSAIDs are best avoided, as previously discussed, and corticosteroids (more than 15 mg/day) must also be avoided in early diffuse scleroderma since they can precipitate a renal crisis. Caution is needed if b-adrenergic agonists are required for preterm labour since scleroderma patients may have silent myocardial damage making them more vulnerable to ischaemia and pulmonary oedema. Venepuncture, venous access, and blood pressure measurement may be difficult because of skin or blood vessel involvement. General anaesthesia may be complicated by difficult endotracheal intubation, and regional anaesthesia may also be difficult. Early assessment by an obstetric anaesthetist is advisable and epidural anaesthesia and analgesia is encouraged as vasodilation improves skin perfusion of the extremities. Other measures to reduce problems related to Raynaud's phenomenon include warming of the delivery room and any intravenous fluids as well as socks and gloves.

Close observation must continue in the immediate postnatal period, particularly in those with cardiac, pulmonary, or renal involvement. The most recent data, although derived from retrospective postal questionnaire, suggest that outcomes are not significantly worse than controls, provided pregnancy is well-timed and carefully monitored. Clinicians are therefore becoming more optimistic in counselling women with scleroderma considering pregnancy.

13.15 Infections in pregnancy

Mark Herbert and Lawrence Impey

Introduction

Maternal immunity is suppressed in pregnancy and the fetal immune system is developmentally immature, thus infections in pregnancy can be devastating both for the mother, as is occasionally seen with varicella, and for the fetus, as is exemplified by congenital infections such as those caused by toxoplasmosis, syphilis, rubella, and cytomegalovirus (CMV).

Infections in pregnancy can be divided into four groups:

- Maternal illness made more severe by the pregnant state;
- Congenital infections acquired transplacentally, including *Toxoplasma gondii*, *Treponema pallidum*, rubella, CMV, *Listeria monocytogenes*, *Falciparum* spp., and *Trypanosoma* spp.;
- Fetal infection arising secondary to ascending maternal infection with preceding chorioamnionitis, caused by *Streptococcus agalactiae* and *Escherichia coli*;
- Neonatal sepsis acquired perinatally, such as HIV, HBV, and *Chlamydia trachomatis*.

Preterm delivery is an important cause of long-term handicap, and clinical evidence of infection in the placenta or neonate further increases the risk. Even with term delivery, maternal infection is associated with an increased rate of neonatal encephalopathy and cerebral palsy. This association is poorly understood. Chorioamnionitis is polymicrobial, and even *Candida* spp. have been implicated. It usually presents after preterm rupture of the membranes, but subclinical infection, usually ascending, may cause cervical changes and amniotic damage. Abdominal pain, fever, maternal and fetal tachycardia, and an offensive discharge are classic presentations, but chorioamnionitis is frequently asymptomatic in the early stages. Its management involves intravenous antibiotics and delivery, whatever the gestation.

In this chapter, we list the most important infective organisms in pregnancy, describe their maternal and fetal effects, and discuss their prevention, identification, and treatment. Detailed discussion of their pathology and features in adults is described elsewhere in the book.

Human immunodeficiency virus (HIV)

In the United Kingdom, the prevalence of HIV in pregnant women in inner London has risen from 0.04 per cent in 1989 to 0.4 per cent in 2000; in the rest of the United Kingdom, it is about 0.02 per cent. In parts of Africa, the seropositive rate among pregnant women exceeds 20 per cent, and an estimated 2.4 million HIV-infected women deliver every year.

Almost all HIV in infancy is acquired intrapartum or during breast feeding. Vertical transmission is highest in underdeveloped countries, if there are concomitant sexually transmitted diseases, in preterm delivery, and where the CD4 count is low and the viral load is high, as in early and late disease. Transmission rates are 15 to 20 per cent in Europe and North America and 25 to 35 per cent in Africa, India, and Thailand. Women with HIV are at greater risk of other sexually transmitted diseases and other coexisting disease, and consequently an increased vertical transmission rate and poorer obstetric outcomes. One-third of infected neonates die in infancy.

In the United Kingdom, viral antigen ELISA screening for HIV is offered to all pregnant women. Ideal management requires interdisciplinary co-operation, screening for other sexually transmitted diseases, and regular CD4 counts. Depending on the resources available, there are several drug regimens that are known to decrease vertical transmission, including:

- The PACTG 076 protocol: oral zidovudine 100 mg five times per day from 14 to 34 weeks gestation until labour; intravenous zidovudine in labour, 2 mg/kg intravenously over 1 h followed by 1 mg/kg per h until delivery, and oral zidovudine 2 mg/kg four times per day given to the infant for 6 weeks. Oral zidovudine given only to mother in late pregnancy, 300 mg two times per day from 36 weeks gestation, then every 3 h throughout labour.
- The HIVNET regimen of a single oral 200 mg dose of nevirapine given to mothers in labour and a single 2 mg/kg dose given to the infant at 48 to 72 h old. In sub-Saharan Africa, 110 000 HIV-positive births could be prevented over the next 5 years by this regimen.

Zidovudine and lamivudine together, from early second trimester are probably better than AZT alone. Occasional severe adverse effects in neonates have been reported. Antiretroviral therapy, elective caesarean section, and avoidance of breast feeding together reduce vertical transmission to less than 1 per cent. It is uncertain if elective caesarean section confers benefit in addition to retroviral therapy if the viral load is less than 1000 HIV copies/ml blood. Even in women on treatment there is a small but definite transmission rate with breast feeding, which should be avoided.

Rubella

A world-wide pandemic of rubella between 1962 and 1964 hastened the impetus for developing a vaccine, which has had a dramatic impact on the incidence of the congenital rubella syndrome. However, 10 to 20 per cent of the adult population in North America remain susceptible and small outbreaks still occur.

The incubation period is 16 to 18 days (range 14–21). There is a 1 to 5-day prodrome of low-grade fever, headache, malaise, anorexia, mild conjunctivitis, coryza, sore throat, cough, and lymphadenopathy (suboccipital, postauricular, and cervical) before the onset of a rash that lasts for 1 to 5 days. Arthritis and arthralgia occur in up to 70 per cent of adult women after the rash. Rare complications are thrombocytopenia, acute postinfectious encephalitis, myocarditis, Guillain–Barré syndrome, relapsing encephalitis, optic neuritis, bone marrow aplasia, and progressive panencephalitis.

The major sequelae in the fetus are cataracts, deafness, mental retardation, and heart disease, especially pulmonary arterial hypoplasia, patent ductus arteriosus, and coarctation of the aorta. The risk of the congenital rubella syndrome is greatest in early pregnancy: 90 per cent of infants will be affected before 11 weeks gestation, falling to 24 per cent at 15 to 16 weeks gestation. At 25 weeks, transmission to the fetus is approximately 25 per cent rising to 100 per cent at term, but the congenital rubella syndrome does not usually occur after the first trimester. Embryo resorption may occur in very early gestation, or abortion in later pregnancy.

Parvovirus B19

Parvovirus B19 binds to the P antigen present on erythrocytes, erythroblasts, and myocardium and can cause fetal anaemia (haemolytic and aplastic) and cardiac dysfunction. About 0.25 per cent of pregnant women are infected, but respiratory-borne epidemics, particularly in spring, may increase this fourfold. Half of adults are immune. Pregnancy does not alter the symptoms; 20 per cent are asymptomatic; the rest have a rubelliform or characteristic 'slapped cheek' rash, and 80 per cent with rash have arthralgia or arthritis.

Infection in pregnancy carries a 9 per cent fetal mortality rate, mainly arising from infection before 20 weeks gestation, and 3 per cent develop hydrops fetalis characterized by generalized fetal oedema, particularly ascites (Fig. 1). Two-thirds recover without intervention.

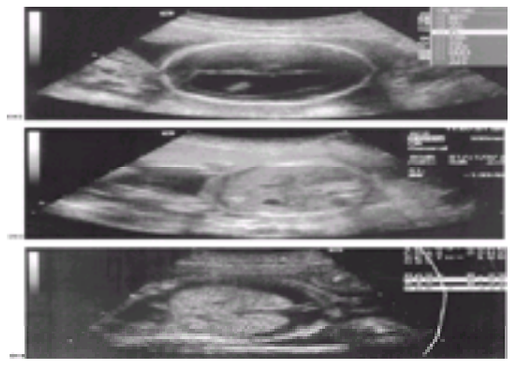

Fig. 1 Antenatal ultrasound scans: (a) fetal head showing ventriculomegaly secondary to congenital toxoplasmosis; (b) fetal abdomen showing intrahepatic calcification (marked with +) as seen in congenital varicella infection; (c) fetal abdomen showing ascites in parvovirus infection.

Maternal anti-B19 IgM antibody indicates recent infection. Ascertaining fetal involvement is more difficult because invasive sampling has a 1 per cent miscarriage risk and fetal IgM is not present before 22 weeks gestation. PCR for viral DNA can be performed on amniotic fluid, fetal blood, or other tissue. After diagnosis, regular ultrasound examination aids identification of fetal disease, and *in utero* transfusion of red cell concentrate via the umbilical vein is used to treat severe fetal hydrops. Adverse fetal effects are very rare more than 18 weeks after infection, thus regular ultrasound examinations are continued for this period.

Herpes simplex virus (HSV)

Genital herpes is predominantly caused by HSV-2, but up to 30 per cent of cases are due to HSV-1. Approximately 20 per cent of women in developed countries have been infected with HSV-2, but 90 per cent of these give no history. Primary infection in pregnancy occurs in 2 per cent of susceptible women. This is usually asymptomatic, but primary herpes may be characterized by genital pain and ulceration, discharge, dysuria, lymphoedema, and systemic symptoms. Acyclovir may be helpful in reducing the severity and frequency of recurrences. A rare but severe manifestation of HSV infection in pregnancy is isseminated disease, with necrotizing hepatitis, thrombocytopenia, leukopenia, disseminated intravascular coagulopathy, and more than 50 per cent mortality.

True congenital HSV is extremely rare in the West, but is important because of very high neonatal mortality. It occurs in an estimated 1 in 200 000 pregnancies, accounting for 3 per cent of all neonatal herpes. Neonatal infection following viral shedding in labour occurs in up to 30/100 000 in parts of North America, but is often much lower in other countries. Transmission is almost 50 per cent in active primary infection, but nearer 1 per cent with active recurrent herpes because of passive fetal immunity. Most neonatal herpes occurs in women without a history.

Caesarean section is advised for intrapartum primary herpes. If vaginal delivery is unavoidable or the membranes have been ruptured for more than 4 h, then the infant should be treated with acyclovir. With recurrent active herpes the risks of caesarean section probably outweigh the benefits. Caesarean section is not indicated if lesions are absent at the onset of labour.

Cytomegalovirus (CMV)

CMV is the commonest congenital infection in developed countries. Seventy five per cent of pregnant women are immune; less in higher socioeconomic classes or in developing countries. Around 1 to 4 per cent of women acquire primary infection in pregnancy; this may be asymptomatic, but commonly produces an infectious mononucleosis-like illness.

Transplacental transmission follows 40 per cent of primary infections and less than 1 per cent of secondary recurrences. After primary infection, 5 to 15 per cent of neonates are symptomatic, and of these more than 80 per cent develop severe neurological sequelae including mental impairment and sensorineural hearing loss. Even asymptomatic infants have a 5 to 15 per cent risk of hearing impairment. The outcomes of CMV infection in pregnancy are shown in Fig. 2.

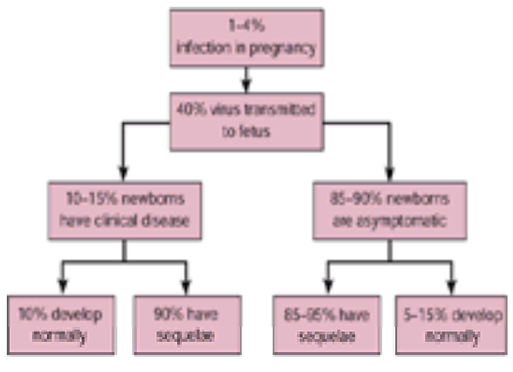

Fig. 2 The outcome from CMV infection in pregnancy.

In pregnant women, a diagnosis made by IgM or rising IgG titres can be confirmed by amniotic fluid PCR taken at least 6 weeks after maternal infection. High viral load and abnormal prenatal ultrasound findings such as intra-abdominal or cranial calcification, cerebral ventriculomegaly, and cardiomegaly, are associated with, but do not accurately predict, a poor long-term prognosis. Termination of pregnancy may be offered. There is no effective therapy. The chance of normal childhood development without evidence of fetal damage is approximately 75 per cent. Intravenous ganciclovir given to the infant reduces hearing loss in the most severely affected. CMV screening may be valuable in the future when orally available drugs are marketed.

Herpes zoster (VZV)

The varicella zoster virus incubation period is 10 to 21 days, infectivity being from 2 days before the rash appears to when all the vesicles are covered. Eighty five per cent of adults in the West are immune, infection only occurring in 1 in 2000 pregnancies. A much higher proportion of adults in developing countries are non-immune. The presence of maternal IgG indicates immunity, whilst IgM indicates primary infection. Invasive fetal testing is not often helpful.

Primary infection in pregnancy may be severe, with pneumonia in 10 per cent and occasional maternal death. Before 20 weeks, 2 per cent of fetuses develop the congenital varicella syndrome, characterized by neurological, optical, and limb anomalies. Ultrasound findings 5 weeks after infection include polyhydramnios and

echogenic foci in the fetal liver (Fig. 1).

Varicella zoster immunoglobulin (**VZIG**) should be given, preferably within 72 h of contact, to pregnant women who are non-immune as determined by serology. Women who develop varicella after 12 weeks gestation should be given acyclovir, intravenously if pneumonia develops. Specialist referral is advised with respiratory symptoms, dense lesions, or if new vesicles are still appearing after 6 days. Neonatal zoster may occur if maternal infection occurs 5 days before to 2 days after delivery; this is associated with up to a 30 per cent neonatal mortality. Babies born to mothers who develop perinatal chickenpox should be given intramuscular VZIG.

Hepatitis B

Ten per cent of hepatitis B infected adults become chronic carriers, compared to 90 per cent of infants following vertical transmission. Detectable hepatitis B surface antigen (HepBsAg positive) in blood indicates infectivity and is present from 4 to about 24 weeks after infection; thereafter its presence is associated with chronic infection. Individuals with hepatitis B surface antibodies (HepBsAb positive) are immunologically cured. Detectable hepatitis B e antigen (HepBeAg positive) indicates high infectivity.

In the West, less than1 per cent of pregnant women are HepBsAg positive, although the incidence is rising; in parts of Africa and Asia, the rate is 25 per cent. The risk of perinatal transmission relates to maternal viral antigen status. In HepBsAg positive/HepBeAg negative mothers the risk is 5 to 20 per cent, whereas in HepBsAg positive/HepBeAg positive it is 70 to 90 per cent. Targeted screening only identifies about half of chronic carriers, hence universal screening has been advocated in the West.

Vertical transmission can be reduced by more than 90 per cent by active immunization, with 0.5 ml hepatitis B vaccine, of all infants born to HepBsAg positive mothers, with additional passive immunisation (200 IU of hepatitis B immunoglobulin within 12 h of birth) for infants born to HepBeAg positive or HepBsAb negative mothers. Unfortunately, compliance with this regimen is often poor, and the WHO recommends universal vaccination in countries with high prevalence.

Hepatitis C

Approximately 3 per cent of pregnant women world-wide are infected with Hepatitis C. In inner London, the rate is 0.8 per cent, but it is 30 per cent in HIV positive women. Hepatitis C leads to chronic hepatitis in about 80 per cent. Progression is insidious and most pregnant women are asymptomatic. Liver transaminases may be normal, but if elevated, tend to reduce during pregnancy.

Vertical transmission of HCV occurs in approximately 6 per cent if HCV is detectable by PCR in the mother; otherwise the risk is negligible. Coexisting HIV infection increases the rate of vertical transmission to 23 per cent. Infected infants usually remain viraemic and prone to chronic hepatitis. Antibody levels are usually detectable within 3 months after infection. The ELISA has a sensitivity of 95 per cent, but should be supplemented by a recombinant immunoabsorbant assay (RIBA). PCR is used to confirm infection in infants.

Interferon-a reduces disease activity but is not recommended in pregnancy, although it may be used postpartum. Elective caesarean section, formula feeding, or administration of immune globulin do not reduce vertical transmission to the neonate.

Bacterial vaginosis

An overgrowth of anaerobic organisms such as *Gardnerella vaginalis* and *Mycoplasma hominis* causes this condition, which is characterized by excessive Gram-negative bacilli and cocco-bacillary organisms compared to lactobacilli on Gram staining. Bacterial vaginosis is not sexually transmitted, but is associated with sexually transmitted diseases and is rare before the onset of sexual activity. The prevalence varies from 5 to 20 per cent, depending much on the diligence with which the diagnosis is sought. Three of four Amsel's criteria are required for diagnosis: a thin white homogeneous discharge, clue cells, raised vaginal pH (>4.5), and a positive 'whiff test' (fishy odour when adding 10 per cent KOH to the discharge). At least 50 per cent of women with bacterial vaginosis have no symptoms, but an offensive, thin white discharge is often found. Its presence is strongly associated with a history of, and an increased risk for, late miscarriage and preterm birth. As prematurity is the major cause of neonatal mortality and morbidity in developed countries, the condition is extremely important. Bacterial vaginosis usually responds to metronidazole or clindamycin. Antibiotics reduce but do not eliminate the risk of prematurity. The role of screening for bacterial vaginosis in pregnancy is controversial.

Streptococci

Group A streptococci (*Streptococcus pyogenes*) remain an important cause of puerperal sepsis world-wide, but this is now rare in the West. Group B streptococci (*Streptococcus agalactiae*) usually cause less severe maternal disease. Overall, 12 to 26 per cent of pregnant women are colonized by Group B streptococci, particularly in the urine, and its presence is associated with preterm delivery. Ascending infection with chorioamnionitis and fetal infection may occur following rupture of the membranes. Intrauterine infection may cause stillbirth.

Early-onset neonatal streptococcal sepsis has a mortality of 6 per cent and occurs in 0.5 to 3.7 per 1000 live births. Risk factors include prematurity, prolonged rupture of the membranes, intrapartum maternal fever, heavy colonization, low maternal antibody levels, and a previously affected infant. Although 70 per cent of neonates born to carriers are colonized, only 1 to 2 per cent will develop disease.

Intrapartum penicillin greatly reduces early-onset neonatal disease. Preventative strategies are based on risk factors, either alone or in conjunction with screening. With the former, women are treated if they have a previous history, intrapartum fever, are in preterm labour, or where the membranes have been ruptured for more than18 h. By treating 18 per cent of women, 70 per cent of neonatal sepsis is prevented. In a combined screening and risk-based approach, third trimester vaginal and anal swabs are taken, and treatment of 27 per cent of all pregnant women can prevent 86 per cent of sepsis.

Listeria monocytogenes

Listeria monocytogenes is a Gram-positive bacillus that can cause serious disease in pregnant women, fetuses, and newborns. Infection is from salads contaminated with animal faeces, undercooked meats, unpasteurized milk, soft cheeses, and pates. In the United Kingdom, the incidence has been as high as 5 cases/100 000 live births, but world-wide the incidence has fallen as a result of public health campaigns about the likely source of infection.

Maternal disease manifests as bacteraemia, with fever, sore throat, headache, and chills. Diarrhoea, pyelitis, and back ache may occur. Symptoms generally recede without treatment, although a few mothers develop meningitis. Transplacental infection of the fetus is the most likely route of acquisition rather than ascending infection. Infection before 24 weeks gestation usually results in abortion; still birth or prematurity occurs after this gestation. The fetus may die, become macerated and then seed bacteraemia to the mother. Apparent meconium staining of liquor in preterm birth is highly suggestive of listeriosis. Two patterns of disease are seen, granulomatosis infantiseptica, in which the baby and the placenta are covered in miliary granulomata, and pneumonia without granulomata. Meningitis may coexist.

Listeria is resistant to all cephalosporins. The accepted treatment, based on animal model testing, is ampicillin with an aminoglycoside for synergy. There is little human data to support the view that ampicillin is better than penicillin G, but the usual practice is to change to ampicillin when listeriosis is confirmed.

Syphilis

The prevalence of *Treponema pallidum* infection in pregnancy is 0.2 per cent in London and 0.02 per cent in the rest of the United Kingdom, but in Africa, South East Asia, and Russia it is endemic. Pregnancy does not alter the clinical manifestations. Vertical transmission is predominantly transplacental, and occurs in up to 90 per cent of untreated women, particularly those with early disease. Most affected pregnancies result in congenital syphilis, miscarriage, preterm delivery, stillbirth, or neonatal death. Ultrasound appearances of the infected fetus may be normal or show hepatomegaly and other abnormalities. At birth, babies exhibit rhinitis, osteitis, and skin bullae. Hutchinson's triad of abnormal teeth, interstitial keratitis, and sensorineural deafness arise later in the untreated child.

Non-treponemal tests (e.g. VDRL) are usually employed for screening. Sensitivity is highest in secondary syphilis and lowest early in the infection, and false-positive

results occur with concomitant infections or autoimmune disease. The diagnosis should be confirmed with a specific treponemal test (e.g. FTA-ABS). Screening in pregnancy is cost effective, even where the disease is rare, and 121 women were identified by antenatal screening in the United Kingdom in 1994 to 97, meaning that 18 600 tests needed to be performed to detect one case.

Two intramuscular doses of benzyl penicillin, 2.4 MU 1 week apart, are given to treat syphilis in pregnancy. In true penicillin allergy, a 5 to 10-day regimen of high dose oral ceftriaxone is recommended. Treatment will prevent congenital infection in 98 per cent of cases. The rare Jarisch–Herxheimer reaction to treatment may precipitate preterm labour. VDRL titres should fall until undetectable or less than 1 in 4, otherwise retreatment is necessary.

Chlamydia trachomatis

The incubation period of *Chlamydia trachomatis* infection is 7 to 21 days. It is one of the commonest sexually transmitted diseases world-wide, and infects about 5 to 7 per cent of pregnant women. Endocervical swabs are best for screening, though urine testing may be easier. PCR has the highest sensitivity and specificity, followed by culture and then ELISA.

Chlamydia infection is mostly asymptomatic in pregnant women. Pelvic infection is very rare during pregnancy, but after delivery endometritis and salpingitis may lead to tubal damage and infertility, and 12 per cent of induced abortions are followed by pelvic infection. Maternal infection, particularly that which is recently acquired, is associated with prematurity, chorioamnionitis, and possibly stillbirth. Treatment reduces but does not eradicate these risks. Neonatal conjunctivitis occurs in up to 50 per cent exposed newborns and later-onset pneumonia in a smaller proportion.

Tetracyclines are contraindicated in pregnancy and erythromycin is not well tolerated. A single dose of azithromycin 1 g ensures compliance. Concerns about this drug in pregnancy remain unsubstantiated. Sexual contacts should be screened, and as reinfection rates are high, repeat testing is advised after at least 3 weeks to ensure a cure has been achieved. Screening or even prophylaxis of all mothers following abortion is cost effective.

Gonorrhoea

Neisseria gonorrhoea infection is endemic in many developing countries, but is declining in the West. Cervical culture will detect most infections, whereas PCR testing is expensive and does not enable antibiotic sensitivity testing. As with non-pregnant women, 80 per cent are asymptomatic in pregnancy. Pharyngeal and disseminated systemic infection with fever, rash, and septic arthritis are more common in pregnancy, but salpingitis is rare. Gonococcal cervicitis is associated with chorioamnionitis and a fourfold increase in prematurity. Ophthalmia neonatorum arises in 40 per cent if mothers are untreated. Gonococci have also been implicated in postpartum and postabortion endometritis and salpingitis. Penicillinase-producing strains are common, and treatment with 250 mg single dose intramuscular ceftriaxone, or 400 mg oral cefixime is recommended. Disseminated infection warrants intravenous therapy. The patient should be screened for other sexually transmitted diseases; indeed, antichlamydia therapy is often given at the same time. A test of cure should be taken at least 3 days after antibiotics.

Mycobacterium tuberculosis

In 1990, the WHO estimated that 90 million people developed tuberculosis and 30 million died from it. The highest rates of infection are in young adults, hence exposure during pregnancy must be common.

The pathogenesis and course are similar in pregnancy as in women who are not pregnant. The main additional concern is spread to the fetus, either through maternal disseminated disease and transplacental spread, or through direct extension of maternal genitourinary tuberculosis. Genital tuberculosis often has a long and indolent course with potential involvement of the fallopian tubes (90–100 per cent of women with genital infection), uterus (50–60 per cent), ovaries (20–30 per cent), and cervix (5–15 per cent). Genital infection is more likely to manifest as sterility and therefore is unusual as a cause of congenital infection.

Chemotherapy of tuberculosis during pregnancy provides the same excellent outlook as treatment in any other person. Providing proper treatment is received, there is no adverse effect of pregnancy, birth, the postpartum period, or lactation on the course of tuberculosis, and tuberculosis has little effect on the pregnancy outcome. Pregnancy is an opportunity to screen for tuberculosis. Women coinfected with HIV may have suppressed skin test reactivity and there is good argument for thoroughly investigating these women in pregnancy when they opportunistically present to health carers.

Congenital tuberculosis is very rare, but its incidence is increasing because of coinfection with HIV in pregnancy.

Toxoplasmosis

Toxoplasma gondii is a protozoan parasite acquired from eating uncooked meat or contaminated salad. The incubation period is 5 to 18 days. The prevalence of congenital toxoplasmosis is less than 0.1 per cent in most parts of the developed world.

Toxoplasmosis is frequently asymptomatic, but 10 to 20 per cent of mothers have lymphadenopathy or a flu-like episode. Microcephaly, hydrocephalus (Fig. 1 and Fig. 3), cerebral cystic lesions and calcification, and chorioretinitis are the severe sequelae in the fetus, leading to mental retardation and blindness. The risk of vertical transmission increases with gestation, but the severity of disease decreases, hence the highest risk for congenital toxoplasmosis with poor outcome is when maternal infection occurs between 10 to 24 weeks gestation. Congenital toxoplasmosis may rarely result from maternal infection up to 6 months prior to conception.

Fig. 3 MRI head of a 20-day-old baby with congenital toxoplasmosis, showing severe ventriculomegaly from hydrocephalus.

Diagnosis is difficult because serological tests have poor sensitivity, so much so that in proven cases no antibody may be detectable. Conversely, IgM may persist for months after infection and its identification should prompt a repeat test 3 weeks later. Screening is not advised in low prevalence countries. Confirmation of fetal infection is best achieved using PCR of amniotic fluid.

Treatment in pregnancy is with 1 g spiramycin three times per day until the diagnosis has been definitively made, but this is not of proven benefit in established congenital toxoplasmosis. Most authorities are now using pyrimethamine (50 mg/day), sulfadiazine (1 g three times/day), and folinic acid (50 mg/week) until delivery, but not starting this regimen until the second trimester onwards.

Cerebral ventriculomegaly or intracranial calcification on antenatal ultrasound examination may predict a worse outcome, and termination of pregnancy may be offered; yet normal development, including reversion of brain calcification and hydrocephalus, are possible following treatment of the neonate with pyrimethamine and sulfadiazine for 1 year.

Malaria

Millions of women world-wide are at risk of malaria during pregnancy each year. Parasitaemia is more frequent and the parasite load is higher in pregnancy, especially in primiparous women and during the second trimester; and cerebral malaria, pulmonary oedema, and renal failure occur more commonly. Severe malarial anaemia of pregnancy and placental infection cause spontaneous abortions, stillbirths, and intrauterine growth retardation. Malaria is one of the few preventable causes of low birth weight.

Congenital malaria from transplacental spread occurs in approximately 1 per cent of infected pregnancies. The newborns have fever, respiratory distress, pallor, anaemia, hepatomegaly, jaundice, and diarrhoea.

Controlled trials of antimalarial chemoprophylaxis during pregnancy demonstrate little risk and good benefit. Treatment of identified cases rather than chemoprophylaxis is not the best practice as most infected women are not diagnosed antenatally. In areas with sensitive plasmodium, chloroquine is recommended, but in many parts of the world mefloquine is preferable.

Trypanosomiasis

Trypanosoma cruzi (American trypanosomiasis; Chagas' disease) infection in pregnancy in Central and South America accounts for 1 to 10 per cent of all abortions. Infection occurs from insect bites or blood transfusions, with parasitaemia and fever occurring 2 to 3 weeks later. Congestive heart failure from myocarditis is more likely in pregnancy, and overall the disease has 10 to 20 per cent mortality; miscarriage, intrauterine growth retardation, or preterm delivery may also occur. Congenitally infected babies may have jaundice, anaemia, hepatosplenomegaly, encephalitis, pneumonitis, and hydrops fetalis from cardiac involvement. Diagnosis is through placental histology or blood smear examination for parasitaemia. There is no safe and reliable treatment in pregnancy.

T. brucei gambiense and *T. brucei rhodesiense* (African sleeping sickness) have similar adult mortality as American trypanosomiasis. Congenital trypanosomiasis is rarely described, but this is probably an under-reporting phenomenon.

A guide to the general safety of antimicrobial drugs in pregnancy is given in Table 1. The reader is advised to check current recommendations on every individual drug, for instance from the British National Formulary, before commencing any therapy in pregnancy. Table 2 gives brief notes on a few other infections in pregnancy.

13.16 Blood disorders in pregnancy

E. A. Letsky

The physiological changes of pregnancy result in profound changes in the maternal haematological system. Plasma volume increases progressively, reaching a peak during the third trimester that is about 45 per cent or 1250 ml above non-pregnant values. Total red cell mass increases by about 20 to 30 per cent, resulting in haemodilution and hence a decline in haemoglobin concentration, packed cell volume, and red cell count. In the absence of iron deficiency the mean cell haemoglobin concentration remains at non-pregnant values and there is a slight increase (approximately 4 fl) in mean cell volume. As a result of these changes, anaemia cannot be diagnosed in pregnancy using criteria applied to non-pregnant individuals.

The changes in blood volume and haemodilution are so variable that the normal range of haemoglobin concentration can lie between 10.0 and 14.5 g/dl in healthy pregnancy at 30 weeks' gestation in women who have received parenteral iron. However, haemoglobin values of less than 10.5 g/dl in the second and third trimesters are probably abnormal and require further investigation. The World Health Organization (WHO) recommends that the haemoglobin concentration should not fall below 11.0 g/dl at any time during pregnancy.

Iron-deficiency anaemia

Effects of iron deficiency on the blood

The expansion of red cell mass represents the largest single demand for iron in pregnancy, amounting to a net gain of about 500 to 600 mg. In addition, 250 to 350 mg is needed for transfer to the fetus by active transport across the placenta, mainly in the last 4 weeks of pregnancy. Daily requirements for iron increase three- to four-fold and are met by an increased rate of absorption from the gut, together with mobilization of maternal iron stores. The mean serum iron concentration of healthy pregnant women is about two-thirds of the levels for non-pregnant individuals. Total iron-binding capacity is increased because transferrin levels more than double as pregnancy advances. In consequence, the saturation of iron-binding capacity is, in healthy pregnancy, lower (at about 25 per cent) than is normal for other situations. Serum ferritin (reflecting iron stores) declines during the first half of pregnancy to a nadir of about 15 to 20 µg/l, where it remains until delivery. Many women enter pregnancy with low or depleted iron stores even if the haemoglobin concentration is normal, and the majority of those who do not receive supplements have no stores at all at the end of pregnancy.

The anaemia of iron deficiency is the most common haematological problem in pregnancy. The earliest effect of iron deficiency on the erythrocyte outside pregnancy is a reduction in cell size, which appears to be the most sensitive index of underlying iron deficiency. This, however, is a very poor indicator of iron deficiency during pregnancy because of the established larger population of younger red cells. A fall in red cell haemoglobin concentration (mean corpuscular haemoglobin, mean corpuscular haemoglobin concentration) or the concentration of circulating haemoglobin is also a relatively late development in iron deficiency and is preceded by depletion of iron stores followed by a reduction in serum iron levels. A state of iron deficiency can be diagnosed before anaemia has developed by finding a serum ferritin of less than 30 µg/l and a serum iron of less than 10 µmol/l, with less than 15 per cent saturation of the total iron binding capacity. In recent years, serum ferritin, uninfluenced by recently ingested iron, has largely replaced serum iron and total iron-binding capacity as a non-invasive indicator of iron status.

Serum transferrin receptor (TfR) provides a new and allegedly reliable method for assessing cellular iron status. TfR is a transmembrane protein, present in all cells, that binds transferrin iron and transports it to the cell interior. Any reduction in iron supply results in an increase in TfR synthesis and, like serum ferritin, TfR has been shown to circulate in the plasma in small amounts which reflect the total body mass of TfR. As soon as cellular iron deficiency is established, the serum TfR rises in direct proportion to the degree of iron lack. This rise precedes the reduction in mean corpuscular volume and is therefore particularly valuable in identifying tissue iron deficiency in pregnancy. In combination with serum ferritin, serum TfR will give a complete picture of iron status, the serum ferritin reflecting iron stores (in the absence of chronic inflammatory disease) and the TfR reflecting tissue iron status. A bone marrow examination is now very rarely necessary to assess iron status during pregnancy.

Non-haematological effects of iron deficiency

Iron deficiency causes more than just anaemia and treatment with oral or parenteral iron results in improved well-being long before the haemoglobin rises significantly. The various effects of iron deficiency on cellular function may be responsible for the reported association between iron deficiency during pregnancy and preterm birth, and effects on neuromuscular transmission may underlie the anecdotal reports of increased blood loss at delivery in anaemic women.

Effects of iron deficiency on the fetus

The fetus derives its iron from maternal serum by active transport across the placenta in the last 4 weeks of pregnancy. The concentration of ferritin in cord blood is substantially higher than that in the mother's circulation at term and falls within the normal adult range, whether or not the mother is iron deficient. However, babies born to iron-deficient mothers have lower cord ferritin levels that those born to iron-replete mothers, and this has an important bearing on iron stores and development of anaemia in the first year of life when iron intake is very poor.

There have also been suggestions of behavioural abnormalities in children with iron deficiency, and iron deficiency in the absence of anaemia is associated with poor performance in the Bayley Mental Developmental Indices. Moreover, poor performance of 12- to 18-month-old iron-deficient, anaemic infants in mental and motor development can be improved to the level of iron-sufficient infants by treatment with ferrous sulphate.

Even more far-reaching effects of maternal iron deficiency during pregnancy have been suggested. A correlation has been shown between maternal iron-deficiency anaemia, high placental weight, and an increased ratio of placental weight to birthweight. This suggests that maternal iron deficiency results in poor fetal growth compared to that of the placenta. High blood pressure in adult life has been linked to lower birthweight and with those whose birthweight was lower than would be expected from the weight of the placenta. Prophylaxis of iron deficiency may therefore have important implications for the prevention of adult hypertension.

Giving iron in pregnancy

Because anaemia it is a late sign of iron deficiency, pregnant women are frequently given iron supplements prophylactically. The justification for doing this is still debated, although there is no question that iron deficiency is prevented. This is likely to be more important in poor than in developed countries, where controlled trials have demonstrated the effect of routine oral iron supplements on maternal well-being and perinatal outcome.

The main argument in favour of routine iron supplementation in pregnancy is that if iron deficiency is detected in the third trimester there may not be time to correct it by either oral or parenteral supplements. There is no haematological benefit in giving parenteral as opposed to oral iron and the maximal response to be expected in pregnancy is a rise in haemoglobin of approximately 0.8 g/l weekly. The main advantage of intravenous infusion is that it ensures adequate iron for response and avoids any undesirable side-effects associated with oral preparations, but parenteral iron is not without its risks. Otherwise, blood transfusions may be needed, with their associated hazards. On alance, a small daily supplement of oral iron given routinely, from the sixteenth week of pregnancy, seems the more sensible approach. It need not be considered as mandatory, but side-effects, which are most commonly bowel upsets, particularly constipation, are usually overcome by simple nutritional measures.

In iron-deficient women it may take more than a year after delivery for the haemoglobin to return to prepregnancy levels. By contrast, if iron supplements are given the haemoglobin is in the normal prepregnancy range 5 to 7 days after delivery, providing blood loss is not excessive.

Folic acid deficiency

Effects of folate deficiency on the blood and its treatment

When the diet is inadequate, pregnancy can lead to a state of negative folate balance. The pregnant woman needs approximately twice as much folic acid, 200 to 250 µg daily, as do non-pregnant individuals. The increase meets the needs of the growing uterus and conceptus and the expanded red cell mass. As pregnancy advances, serum folate falls to about half the non-pregnant value at term. The red cell folate content shows a slight decline over the same period.

Megaloblastic anaemia in pregnancy is usually the result of dietary folate deficiency. Its incidence is therefore variable, dependent on the socio-economic status of the population and whether or not folic acid supplements are given routinely as part of antenatal care. It occurs more frequently in multiple pregnancies, with about half of cases presenting in the third trimester and the remainder after delivery.

Deficiencies of iron and folate are often combined, with folate deficiency revealed by the failure of a patient to respond to iron supplements. The diagnosis can be difficult to make. The peripheral blood film may be unhelpful because the expected macrocytosis is masked by iron deficient microcytosis. Hypersegmentation of the neutrophils can also be seen in pure iron deficiency. Measurements of serum and red cell folate concentrations, as well as the excretion of formiminoglutamic acid after a histidine load (which is increased in normal pregnancy), can all be difficult to interpret because the results need to be related to the normal range that is expected for healthy pregnant women and not those derived from non-pregnant subjects. The diagnosis can only be confirmed by examination of a bone marrow aspirate.

There is a strong case for prophylaxis during pregnancy, particularly in countries where overt megaloblastic anaemia is frequent. Women with a poor diet should be given 300 µg of folate daily. The risk of adverse effects is very small because vitamin B_{12} deficiency in pregnancy is rare (see below): subacute combined degeneration of the cord has never been reported in these circumstances. Folic acid should be given with supplemental iron. If gastrointestinal megaloblastic changes are established, oral supplements will have no effect and absorption in general will be impaired. This situation can only be reversed by administration of intramuscular folic acid.

Non-haematological effects of folate deficiency

It is still argued to what extent folate deficiency may alter the outcome of pregnancy. Claims of an association between folate deficiency and placental abruption, abortion, and pre-eclampsia have not been substantiated. It has been shown that the incidence of prematurity and low birthweight can be reduced by giving supplements in poorly nourished populations, but has no effect in well-nourished women.

Effects of folate deficiency on the fetus

There is an increased risk of megaloblastic anaemia in the neonate of a folate-deficient mother, especially if delivery is preterm. There are also data suggesting an association between periconceptional folic acid deficiency, harelip, cleft palate, and, most important of all, neural tube defects. The latter has been confirmed by a multicentre, controlled trial of prepregnancy folate supplementation by the Medical Research Council.

In the United Kingdom, it is recommended that women contemplating pregnancy should take folate supplements of 400 µg daily. It has also been shown in Hungary, in a large, randomized trial, that periconceptional supplement of 800 µg of folic acid prevented the first occurrence of neural tube defects. The prevalence of harelip with or without cleft palate was not reduced by this supplementation.

Vitamin B_{12}

Maternal vitamin B_{12} stores, which are of the order of 3000 µg, are largely unaffected by pregnancy. The stores in the new-born infant are about 50 µg. The concentration of serum B_{12} falls during pregnancy from non-pregnant levels of 205 to 1025 µg/l to 20 to 512 µg/l at term, associated with preferential transfer of plasma B_{12} to the fetus. The recommended intake of vitamin B_{12} is 2.0 µg daily in the non-pregnant and 3.0 µg/day during pregnancy. This will be met by almost any diet that contains animal products, however deficient in other essential substances. Strict vegans, who will eat no animal produce whatsoever, can have a deficient B_{12} intake and should be given oral supplements during pregnancy. Recently, B_{12} deficiency associated with megaloblastic anaemia has been found in a proportion of women in Malawi whose main diet is maize and who eat little or no animal protein.

Vitamin B_{12} deficiency in pregnancy is very rare. Addisonian pernicious anaemia does not usually occur during the reproductive years, associated as it is with infertility. Pregnancy is only likely to occur after the deficiency has been corrected.

Haemoglobinopathies

It is important to recognize the genetic defects of haemoglobin structure and synthesis early in pregnancy, or preferably before conception, because:

- the clinical effects may complicate obstetric management and appropriate precautions can be taken
- it is now possible to offer prenatal diagnosis to those women carrying a fetus at risk of a serious defect of haemoglobin synthesis or structure at a time when termination of pregnancy is feasible (Fig. 1).

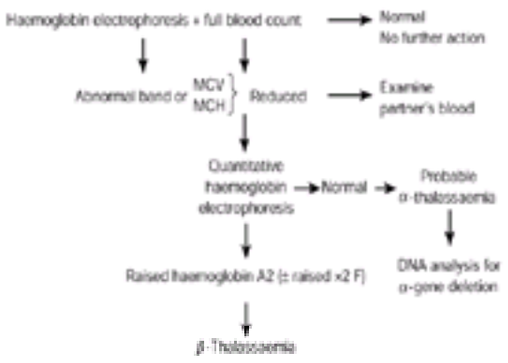

Fig. 1 Screening for haemoglobinopathies.

The two clinically significant groups of haemoglobinopathies, the sickle-cell syndromes and the thalassaemias, are described in detail in Section 22. Only special problems related to pregnancy will be discussed here.

Screening procedures vary from location to location and often only involve 'high-risk' populations. The most difficult situations arise in the United Kingdom, Europe, or the United States in antenatal obstetric units that care for a significant proportion of mothers from varying racial backgrounds. Figure 1 is a scheme that has been used with success in an obstetric unit serving a cosmopolitan population. This involves examination of red cell indices, haemoglobin electrophoresis, and, where indicated, quantitation of HbA_2 (and HbF) on every sample of blood taken at booking. If a haemoglobin variant or thalassaemic indices are found, the partner is requested to attend so that his blood can also be examined. By this means the chances of a serious haemoglobin defect can be assessed early in pregnancy, allowing counselling of the parents and the possibility of offering them prenatal diagnosis by fetal blood sampling or transabdominal chorion villus sampling, even though this will result in a late termination of pregnancy if indicated and desired. A recent audit of prenatal diagnosis, the first in 10 years in the United Kingdom, has shown that take-up is poor, particularly in Asian communities, and that at least six couples have sued their obstetrician for failure to inform them of the possibility of severe haemoglobinopathy in offspring.

Sickle-cell syndrome

It is essential to identify sickle-cell haemoglobin and the particular syndrome involved in the affected pregnant woman. The preferred procedure is to determine if there is an abnormal band on electrophoresis at booking (see above) and to perform a sickling test only on those cases where there is such a band, to confirm that this is sickle haemoglobin. The distinction between sickle-cell trait (HbA/S), sickle-cell anaemia (HbS/S), and HbS/C disease is then immediately apparent and nine out of ten unnecessary sickling tests are avoided in women of relevant racial groups.

Women with sickle-cell trait have no difficulties from overt sickling in pregnancy, but care is needed if a general anaesthetic is required during labour. There is an increased risk of pre-eclampsia, and tissue infarction can occur, even in the sickle-cell trait, if an adequate oxygen level is not maintained or if there is severe dehydration or shock.

Women with sickle-cell disease present special problems in pregnancy. Fetal loss is high, thought to be due to both impaired oxygen supply and sickling infarcts in the placental circulation. Abortion, severe pre-eclampsia, preterm labour, and other complications are more common than in women with normal haemoglobin. Although many women with sickle-cell disease have no complications, the outcome in any individual case is always in doubt.

Increasing numbers of obstetric units have adopted prophylactic transfusion regimes designed to maintain the proportion of HbA at 60 to 70 per cent of the total, but the benefit of such prophylaxis remains to be proven by a large multicentre trial with contemporary controls. A small, controlled trial in the United States suggested that the outcome is similar in women transfused prophylactically compared to those transfused only when indications arise. Prophylactic regimens are expensive and time consuming and may not be applicable in developing countries where the problem is widespread. In addition, there can be problems of alloimmunization to minor blood group red cell antigens: these have resulted in severe, delayed, and sometimes fatal haemolysis in the mother, and haemolytic disease of the new-born in some cases, not to mention the other hazards of blood transfusion.

Against this background of uncertainty, a reasonable compromise, particularly where blood transfusion facilities are limited, is to supervise pregnant women with sickle-cell anaemia with care throughout the pregnancy and to administer regular folate supplements. If they become severely anaemic or have crises during the second half of pregnancy, an exchange transfusion is appropriate. Alternatively, if they present with haemoglobin values of less than 7 g/dl it is also acceptable to transfuse them up to a level of 12 to 14 g/dl, since this will reduce the level of HbS to a safe value without the need for exchange transfusion. During labour, management is directed towards preventing dehydration and acidosis. There is some controversy concerning the safest form of anaesthetic during labour or to cover delivery, but if regional, rather than general, anaesthesia is used, precautions must be taken to prevent venous pooling in the lower limbs. In view of the non-functioning spleen, it is also sensible to give twice daily penicillin to protect against pneumoccocal infections even if pneumovax has been administered.

Special mention should be made of the problem of HbSC disease (see Section xx) in pregnancy. Many women with this disorder go through pregnancy with no complications, but occasionally there may be severe sickling episodes, either late in pregnancy or early in the puerperium, which may lead to maternal death due to massive infarctive crises, particularly in the lungs. Any woman with this disorder who develops a painful crisis late in pregnancy, or who develops symptoms and signs suggestive of a chest infection or small pulmonary embolus, requires urgent exchange transfusion. Examination of the stained blood film in the so-called chest syndrome will show large numbers of nucleated red cells. Cerebral sickling infarcts are not unusual and if not fatal may result in long-term morbidity.

As regards the fetus or neonate, most centres have developed programmes for antenatal diagnosis of sickle cell anaemia using DNA analysis of amniotic or chorionic cells, or of fetal blood. If these are not available, it is important to identify homozygous infants by agar gel electrophoresis or isoelectric focusing immediately after birth. The first 2 years of life are particularly hazardous for an infant with sickle-cell anaemia. Death due to infection and splenic sequestration is common, hence mothers must be advised to present the infants early with any unusual symptoms.

Thalassaemia syndromes

The clinical and haematological manifestations of the a- and b-thalassaemias are described in Section 22. Only certain points relevant to pregnancy will be discussed here.

a-Thalassaemia

The homozygous state for a-thalassaemia produces Bart's haemoglobin hydrops syndrome. Pregnancy with an a-thalassaemia hydrops is associated with severe, sometimes life-threatening, hypertension and proteinuria, the so-called mirror syndrome (of severe rhesus haemolytic disease). Vaginal deliveries are associated with obstetric complications resulting from the large fetus and bulky placenta and the small stature of the mother (usually of Far-Eastern origin).

If routine screening of the parents shows that the mother is at risk of carrying such a child, then she should be referred as early as possible for prenatal diagnosis so that termination of an affected fetus can be carried out before these severe obstetric problems occur. Although this is not yet a common problem in the United Kingdom, it may well become more frequent if there is an influx of immigrants from Hong Kong and the Far East, as has already occurred in the United States and Australia. Transfusion *in utero*, which has been successful in only a handful of cases, is not recommended. The fetus is usually not viable and may have a variety of associated physical defects.

b-Thalassaemia

Pregnancy is extremely rare in transfusion-dependent homozygous b-thalassaemics but is now being seen with increasing frequency in women with b-thalassaemia

intermedia. These patients may become profoundly anaemic and require regular transfusions during pregnancy.

Perhaps the most common problem associated with haemoglobinopathies and pregnancy is the anaemia developing in the antenatal period in women who have thalassaemia minor, heterozygous b-thalassaemia. They can be identified by examination of the blood sample taken at booking (see Fig. 1). The level of haemoglobin in early pregnancy may be normal or slightly below the normal range. Many women with thalassaemia minor enter pregnancy with depleted iron stores, hence they require the usual oral iron supplements in the antenatal period. Oral iron for a limited period will not result in significant iron loading, even in the presence of replete iron stores, but parenteral iron should never be given. A serum ferritin estimation can be carried out early in pregnancy, and if iron stores are found to be high then iron supplements can be withheld.

Folic acid, 5.0 mg daily, is recommended to cover the requirements of ineffective erythropoiesis. Blood transfusion may be indicated if the anaemia does not respond to oral iron and folate, the latter given parenterally as well as orally.

All women with mixed racial background should be screened for b-thalassaemia early in pregnancy. The partners of those who are found to be carriers should also be screened so that prenatal diagnosis can be offered where there is a risk of conceiving a homozygous child.

Miscellaneous anaemias specific to pregnancy

Many systemic medical conditions may further complicate the physiological haemodilution of pregnancy: these are discussed elsewhere.

A rare form of haemolytic anaemia appears to be specific to pregnancy. It remits after delivery but recurs in about half of affected women in later pregnancies. Although no autoantibody has been identified, the condition responds to corticosteroids or to infusion of human immunoglobulin (see below). The infant may be affected in about 20 per cent of cases.

There is a rare form of aplastic anaemia that occurs for the first time in pregnancy, remits after delivery, and then recurs again in subsequent pregnancies. The cause is unknown. It does not respond to any form of bone marrow stimulant or corticosteroid therapy and the management is symptomatic.

Disorders of haemostasis

Normal pregnancy is accompanied by major changes in the coagulation and fibrinolytic systems. There are significant increases in the procoagulant factors V, VIII, and X, and a very marked increase in plasma fibrinogen. In uncomplicated pregnancy, there is no change in antithrombin concentrations during the antenatal period, a fall during delivery, and then an increase 1 week postpartum. Protein C levels appear to remain constant or increase slightly, but protein S activity falls significantly during normal pregnancy.

The result of these physiological changes is to alter the usual balance between the procoagulants and anticoagulants in favour of the factors promoting blood clotting. In addition, fibrinolytic activity appears to be reduced during healthy pregnancy but returns to normal rapidly after separation of the placenta and completion of the third stage of delivery. This effect is mediated by placentally derived plasminogen activator inhibitor type II.

These changes in the haemostatic systems, together with the increase in blood volume, help to reduce the chances of abnormal haemorrhage at delivery, but they also convert pregnancy into a hypercoagulable state that may carry special hazards for both the mother and fetus. These hazards include a spectrum of haemostatic disorders, from thromboembolism through to the many conditions associated with disseminated intravascular coagulation.

Disseminated intravascular coagulation

This is associated with a wide variety of complications of pregnancy. It may be well compensated, with little change in tests of haemostatic function and no bleeding, as seen in prolonged retention of a dead fetus and mild pre-eclampsia, or it may result in intractable haemorrhage with gross consumption of coagulation factors and platelets and raised levels of fibrin degradation products, as seen classically in abruptio placentae (see Table 1).

Other complications of pregnancy in which disseminated intravascular coagulation may take a part include amniotic fluid embolism; septic abortion and intrauterine infection; hydatidiform mole; placenta accreta; pre-eclampsia and eclampsia, and prolonged shock from any cause (see Fig. 2).

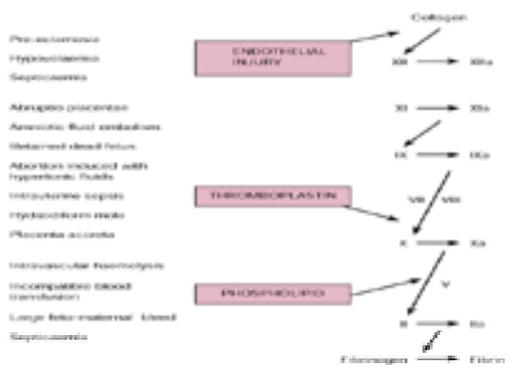

Fig. 2 Trigger mechanisms of disseminated intravascular coagulation during pregnancy. Interactions occur in many of these obstetric complications.

Disseminated intravascular coagulation in pregnancy is always a secondary process. Useful and rapid screening tests include the platelet count, partial thromboplastin time (intrinsic coagulation), prothrombin time (extrinsic coagulation), thrombin time, fibrinogen concentration, and levels of fibrin degradation products. Aside from standard supportive care (see Section 22) and removal of the triggering mechanism where this is known, management of the obstetric patient with disseminated intravascular coagulation should also seek to achieve an empty and contracted uterus.

Pre-eclampsia and haemostatic changes

Pre-eclampsia may be associated with marked changes in the normal physiological response of the haemostatic mechanisms during pregnancy (Table 2). The combination of a reduced platelet lifespan and a fall in the platelet count without platelet-associated antibodies indicates a low-grade coagulopathy. Once the disease process is established the most relevant haemostatic abnormalities appear to be the platelet count, factor VIII coagulation activity, and serum fibrin degradation products. Those women with the most marked abnormalities in these parameters suffer the greatest perinatal loss. It has been shown that if the platelet count is above 100×10^9/l there are no disturbances in haemostatic function and therefore no need for coagulation screening tests.

Rarely, in very severe pre-eclampsia, the patient develops microangiopathic haemolysis. This causes profound thrombocytopenia and leads to confusion in differential diagnosis between pre-eclampsia, HELLP syndrome, haemolytic uraemic syndrome (HUS), and thrombotic thromboctyopenia (TTP). The recent identification of deficient metalloproteinase in TTP, either due to an IgG antibody in the acute form or to a genetic defect in the chronic relapsing form, will help to distinguish this condition from severe pre-eclampsia, HELLP syndrome, and HUS, which is essential if appropriate management with fresh frozen plasma is to be applied. In relation to pregnancy, haemolytic uraemic syndrome usually presents in the postpartum period with renal failure.

Platelet disorders

Thrombocytopenia is a common haematological abnormality in pregnancy and can have important implications for both mother and fetus. It may occur as part of the

pathophysiology of pregnancy itself, or pregnancy may be superimposed on a background of haematological disease.

Incidental thrombocytopenia

As pregnancy advances there is a progressive small, but significant, fall in the platelet count in individual patients, probably due to haemodilution. Approximately 8 per cent of healthy pregnant women have thrombocytopenia at term, with platelet counts between 90 and 150×10^9/l. These women have no history of pre-eclampsia or immune thrombocytopenia and there is no increased incidence of thrombocytopenia in their offspring.

Thrombocytopenia and disseminated intravascular coagulation

Low-grade disseminated intravascular coagulation, as observed in pre-eclampsia, may be associated with further decrements but the platelet count rarely falls below 50×10^9/l, even in acute defibrination syndromes. Clearly, thrombocytopenia and platelet consumption represent only one aspect of this condition (see above) and will be corrected quickly when haemostatic mechanisms return to normal, usually without the use of, or need for, platelet transfusion.

Idiopathic thrombocytopenic purpura

Idiopathic thrombocytopenic purpura (ITP) is a rare condition, but relatively common in women of reproductive years. Patients in remission may still have elevated levels of platelet-associated IgG (PAIgG), especially following splenectomy. This is important in pregnancy because of the possibility of placental transfer of antibody resulting in fetal thrombocytopenia. Measurement of maternal platelet count, serum platelet antibody, and PAIgG are useful diagnostic tools but are not predictive of neonatal thrombocytopenia.

In the past, analysis of the literature gave an overall incidence of neonatal thrombocytopenia of 52 per cent with significant morbidity in 12 per cent, but we know now that this incidence was distorted because only symptomatic women were likely to have been investigated and reported. More recent analyses show an incidence of fetal thrombocytopenia of around 10 per cent, with severe thrombocytopenia (platelets fewer than 50×10^9/l) in less than 5 per cent overall. Fetal and neonatal morbidity and mortality is negligible even in the face of severe thrombocytopenia. Thrombocytopenia in the neonate tends to become more severe in the first few days of life and measures can be taken to correct this at birth before the nadir is reached, if indicated.

Pregnant women with ITP nearly always have the chronic form of the disease. The main clinical difficulty is that effects of treatment have to be considered in relation to the progress of pregnancy in both mother and fetus. The mild condition may require no treatment, but if the platelet count falls below 50×10^9/l, or there is clinical evidence of bleeding, then prednisolone is required (60 mg daily, reducing rapidly to the lowest possible dose that maintains the platelet count above 50×10^9/l). The prevalence of pre-eclampsia, gestational diabetes, postpartum psychosis, and osteoporosis are all increased by corticosteroids, hence the dose and duration of treatment should be the minimum needed to reduce the risk of bleeding or to raise the platelet count of any asymptomatic woman at term, allowing her to have epidural or spinal analgesia if desired or indicated.

The introduction of treatment by intravenous monomeric polyvalent human IgG has altered the management options in pregnancy dramatically. Used in the original recommended dose of 0.4 g/kg for 5 days by intravenous infusion, a persistent and predictable response is obtained in approximately 80 per cent of cases. There is no doubt about the value of this treatment in selected cases of severe symptomatic thrombocytopenia, but it cannot be advocated indiscriminately in view of its high cost and unproven benefit in milder cases. Analysis of recent reports indicates that the postulated beneficial transplacental effect on fetal platelets is unreliable and that exogenous IgG may not cross the placenta.

Splenectomy is now hardly ever indicated in the pregnant patient with ITP, but remains an option if all other attempts to increase the platelet count to safe levels fail. It is best carried out in the second trimester because surgery is best tolerated then and the size of the uterus does not make the operation technically difficult.

Mode of delivery

The most contentious problem in pregnancy associated with maternal ITP is the mode of delivery of the fetus. Even if the mother has to deliver in the face of a low platelet count, she is unlikely to bleed from the placental site once the uterus is empty, but she is at risk of bleeding from surgical incisions, soft-tissue injuries, or tears. Platelets should be available for transfusion but not given prophylactically.

The major risk at delivery is to the thrombocytopenic fetus, which as a result of birth trauma may suffer intracranial haemorrhage. Maternal platelet count, maternal platelet-associated IgG, splenectomy status, and history may give a crude indication of the likelihood of fetal thrombocytopenia but cannot be used in an individual case to predict the fetal platelet count. It is, however, unlikely for the fetus to have severe thrombocytopenia if the mother has no history of ITP before the index pregnancy and has no detectable IgG platelet antibody.

Platelet counts in blood obtained by transcervical fetal scalp sampling prior to, or early in, labour have been used to make a decision about the mode of delivery. However, this mode of sampling is not without risk of significant haemorrhage in the truly thromboctyopenic fetus, often gives false positive results, and demands urgent action to be taken on the results obtained. In addition, by the time that results are available the fetus may have already descended so far in the birth canal that caesarean section is technically difficult and traumatic for the fetus. The only way a reliable platelet count can be obtained is by a percutaneous transabdominal fetal cord blood sample, but this is not widely available and not without its difficulties, including a risk of approximately 1 per cent for the fetus. Decisions concerning the mode of delivery often have to be taken without knowledge of the fetal platelet count.

There is no good evidence that caesarean section is less traumatic than uncomplicated vaginal delivery, although this mode of delivery allows more overall control and there are usually no unpredictable complications. At the time of writing the emphasis of management is to return to a non-interventional policy of sensible monitoring, supportive therapy, and a mode delivery determined mainly by obstetric indications and not primarily by either the maternal or fetal platelet count.

Alloimmune thrombocytopenia

Fetal and neonatal alloimmune thrombocytopenia develops as a result of maternal sensitization to paternally derived fetal platelet antigen, the pathogenesis being analogous to that of Rh haemolytic disease of the new-born. The mother is not thromboctyopenic but the fetus can have a very low platelet count and is at risk of spontaneous intrauterine intracranial haemorrhage. This results from a specific antibody interfering with glycoprotein-binding sites and profoundly altering platelet function, particularly, aggregation. The most common platelet antigen involved is HPA-1, but a platelet incompatibility does not invariably result in alloimmunization. The maternal immune response appears to be restricted to those women with HLA-B8 and HLA-DR3 antigens. Thus, although 1 in 50 pregnancies are incompatible with respect to HPA-1 antigens (98 per cent prevalence of HPA-1a in the United Kingdom), only 1 in 5000 births are affected.

The children of first pregnancies (unlike rhesus disease) are often affected and the disease process can begin in early fetal life. Management is aimed at identifying the fetus at risk and correcting the thrombocytopenia *in utero*. Screening of women for HPA-1a status is not established. Investigation of neonatal intracranial haemorrhage or unexplained intrauterine death should include screening of parental blood for platelet antigens and maternal platelet antibodies. The approaches to the management of this problem are all controversial. One protocol involves fetal blood sampling at 20 to 22 weeks gestation and treating the mothers with thrombocytopenic fetuses with intravenous IgG 1 g/kg/week, with or without steroids, until delivery. This has been reported as successful in some units but not others. The overall results of multicentre trials of the efficacy of maternal intravenous IgG administration are variable, with more successful reports from North America and general scepticism from European centres. Another approach is to administer weekly compatible platelet transfusions to the fetus. This has been successful in a number of cases but involves frequent hazardous procedures. Whatever approach is used, immediate predelivery administration of compatible platelets to the fetus is recommended. The accepted management when the diagnosis is established shortly after birth is to transfuse specially prepared HPA-1a negative platelets from preselected blood-bank donors or, if facilities are available, washed platelets from the mother.

Inherited defects of haemostasis

Von Willebrand's disease

Von Willebrand's disease is the most frequent of all inherited haemostatic abnormalities and is therefore the most likely coagulopathy to affect women in pregnancy.

In normal pregnancy, a rise in both VIIIC and von Willebrand factor is observed. Patients with all but the severest forms of von Willebrand's disease show a similar but variable rise in both these factors during pregnancy, although there may not be a reduction in the bleeding time. After delivery, normal women maintain an elevated level of VIIIC for at least 5 days. In women with von Willebrand's disease the duration of this elevation seems to be related to the severity of the disorder. The general consensus is that the most important determinant for abnormal haemorrhage at delivery is a low factor VIIIC level. Appropriate factor VIII concentrates, containing von Willebrand factor activity as well as factor VIIIC, should be standing by to cover delivery but are rarely required to achieve haemostasis. Cryoprecipitate, with all the hazards of a fresh plasma product, is no longer recommended. There is virtually no place for desmopressin in obstetric practice, except perhaps in the puerperium. Any rise in factor VIII attributable to desmopressin will have been achieved under the influence of pregnancy itself. By contrast, desmopressin has a valuable place in women undergoing gynaecological or other surgery.

Haemophilia

The risks in pregnancy for the female carrier of haemophilia are two-fold:

1. She may, due to lyonization (random deletion of the X chromosome), have very low VIII or IX levels and be at risk of excessive bleeding, particularly following a surgical or traumatic delivery.
2. Fifty per cent of her male offspring will inherit haemophilia. This has important implications now that prenatal diagnosis of these conditions is possible.

It is important to identify carriers prior to pregnancy, not only to provide appropriate management for the rare case with pathologically low coagulation activity but also to provide genetic counselling. Changes in factor VIII complex may make the identification of carriers more difficult during pregnancy. Clinical problems occur more often in carriers for Christmas disease, since factor IX does not rise in response to healthy pregnancy in the same way as does factor VIII. Appropriate heat-treated concentrates are available to treat abnormal haemorrhage: cryoprecipitate and fresh frozen plasma should never be used unless heat-treated concentrates are not available.

It is possible to make an accurate prenatal diagnosis of haemostatic disorders. A fetal blood sample suitable for coagulation factor assays can be obtained from 18 weeks' gestation onwards and used to diagnose or exclude deficiencies of factors VIII and IX in male fetuses. In many cases at risk it is now possible to make rapid, early diagnosis of these conditions by DNA analysis of chorion villus samples or amniotic fluid cells obtained earlier in pregnancy. However, some few families remain where the recombinant DNA technology is not informative, so that fetal blood sample coagulation factor assays will continue to be of value.

Many women refuse prenatal diagnosis. If the fetus is male, scalp electrodes and sampling should be avoided during labour. Cord blood should be taken to establish the diagnosis to avoid haemostatic stress in the neonate.

Factor XI Deficiency (plasma thromboplastin antecedent deficiency)

This is a rare coagulation disorder, less common than the haemophilias. It has an autosomal recessive inheritance and therefore both men and women may be affected. Usually only homozygotes have clinical evidence of a coagulation disorder. Spontaneous haemorrhages and haemarthroses are rare but problems arise from the profuse bleeding which may follow major trauma or surgery if no prophylactic factor XI concentrate is given. The diagnosis is made by finding a prolonged partial thromboplastin time with a low factor XI level in an assay system in which all other coagulation tests are normal. Occasionally women with postpartum haemorrhage are found to have this abnormality. Fortunately the condition rarely causes problems either during pregnancy or delivery or in the newborn child. Prolonged bleeding at ritual circumcision is unusual. There is no justification in screening routinely for this condition either in the mother, fetus, or neonate. Women with factor XI deficiency should be given documentation of their defect so that appropriate measures can be taken to cover surgery or accidental trauma.

Genetic vascular disease

Ehlers Danlos Syndrome (EDS)

It is often forgotten that an essential part of the haemostatic system is healthy vasculature. The Ehlers Danlos syndrome may be associated with bleeding because of increased fragility of vessels due to defects in collagen synthesis. The disease has an autosomal dominant inheritance and has been subdivided into 10 subtypes of which type IV is the most severe and may have lethal complications, the most important of which is rupture of the long arteries. EDS IV is associated with an abnormality of collagen type III as a result of mutations in the corresponding gene COL3A1.

Surgical procedures should be avoided unless essential because the tissues are friable and massive bleeding may occur and healing of incisions may be delayed. Pregnancy and delivery will be involved with obvious potential hazards.

The diagnosis of this condition may be missed, especially in an obstetric gynaecological scenario, where many women complain of easy bruising, which is one of the main presenting symptoms, but platelet function and coagulation screening tests will yield normal results. Although there is no effective treatment or prophylaxis for this potentially lethal condition, appropriate management and precautions at least can be instituted, combined with sensitive genetic counselling regarding the autosomal dominant inheritance of this disorder.

13.17 Malignant disease in pregnancy

Robin A. F. Crawford

Introduction

Cancer is rare during pregnancy, quoted as occurring in only about 1 per 1000 live births. Most malignancies affecting this age group have been seen during pregnancy. Tumours of the uterine cervix, ovary, breast, or thyroid can metastasize to the placenta but not the fetus. Gestational trophoblastic disease arises from fetal chorion and is a malignant transformation of the placenta. Melanoma and haematological tumours, which also can invade the placenta, may cross into the fetal circulation. Pregnancy may cause enlargement of a pituitary tumour and a previously silent tumour may present with symptoms in pregnancy. Rare cases of colonic and neurological cancers developing in pregnancy have been reported in the literature. The diagnosis and treatment of the cancer may have been made prior to the pregnancy: discussion of teratogenesis and effects of treatment are also included in this chapter.

The placenta has several crucial functions. It is a fetal respiratory organ, a sophisticated endocrine unit, and a membrane that allows preferential and selective transfer of substrates from the mother to the fetus for fetal growth and development. In addition, the placenta is largely an effective barrier between the mother and the fetus. Transfer of fetal cells into the maternal circulation is common and probably occurs throughout gestation in all pregnancies. The transfer of maternal cells to the fetus, by contrast, is a relatively rare event.

Concurrence of pregnancy and cancer does raise complex therapeutic and ethical dilemmas, because the most appropriate and timely treatment for the mother may not be in the best interests of the fetus. Extra-abdominal surgery and anaesthesia during pregnancy rarely carry any risks to the fetus, and intra-abdominal surgery may be safely carried out in the second trimester. However, fetal cells divide and differentiate rapidly during the first trimester, and radiation and chemotherapy carry well-recognized risks to the fetus, including the risk of abortion, congenital abnormalities, or preterm birth. As a result, physicians may be reluctant to treat the mother aggressively at the time of initial diagnosis. Instead, in many cases they defer treatment for several weeks or months until the fetal lungs have matured. This delay, however, may substantially reduce the mother's chance of surviving the disease.

It is impossible to establish a threshold dose of ionizing radiation below which such treatment is safe for the fetus, inasmuch as exposure during the first trimester to a dose as low as 10 cGy appears to increase the risk of fetal abnormalities and exposure to 3 to 5 cGy increases the risk of childhood cancers. The risk is negligible if exposure to the fetus is less than 1 cGy. The dose of radiation, the gestational age of the fetus, and the practicability of shielding the fetus from radiation must be balanced against potential benefits to the mother.

Chemotherapy administered to the mother during the first trimester carries well-recognized risks including abortion or congenital abnormalities. Drugs that preferentially interfere with rapidly growing tissues, such as methotrexate, can harm the fetus. Use of antagonists of folate, purine, or pyrimidine synthesis during organogenesis results in congenital malformations in up to 25 per cent of fetuses, although this figure is much lower if the mother only receives therapy with a single agent. Treatment after the first trimester, when structural development is largely complete, is reasonably safe in many diseases and more appropriate than postponement of treatment. Chemotherapy after the first trimester has been associated with slight increases in the incidence of preterm birth and fetal growth retardation and, when administered shortly before delivery, with transient neonatal myelosuppression. Nevertheless, the long-term outcomes of the children of women who received chemotherapy during the second or third trimester are generally good.

In practical terms, acute leukaemia is virtually the only condition requiring immediate chemotherapy in a pregnant woman. When faced with cancer in the first trimester, the available information should be explained to the woman and her partner, who should give informed unhurried consent before treatment starts. In the majority of these situations, a consensus decision is reached between the woman, her partner, and the responsible physician to proceed with chemotherapy. However, the ethical issues are very complex and decisions have to be made on an individual basis.

As there is increasing success with the treatment of childhood cancers, more women will enter the reproductive age group having survived cancer treatment. There appears to be no overall increased risk of either congenital malformations or childhood cancers in the offspring of cancer survivors based on series of several thousand children. An increased incidence of spontaneous abortions, low-birth-weight babies, and neonatal deaths has been described for women with Wilms' tumour who had received at least 20 Gy abdominal radiation. Survivors of Hodgkin's disease who had received both radiation and chemotherapy (but not either alone) also appear to be at increased risk of spontaneous abortions.

Gestational trophoblastic disease

Gestational trophoblastic disease is a group of diseases which arise in the fetal chorion during various types of pregnancy. Histologically they are categorized as one of two types of hydatidiform mole (partial or complete), gestational choriocarcinoma or placental site trophoblastic tumour. Gestational trophoblastic disease is notable for several reasons. Firstly, the tumours are genetically different from the host, having antigens derived from the male partner. Secondly, apart from the placental site tumour, they secrete human chorionic gonadotrophin in amounts proportional to the viable tumour volume, allowing human chorionic gonadotrophin to be used as an ideal tumour marker. Thirdly, even metastatic disease can be cured with chemotherapy, the use of methotrexate in the early 1950s having shown reproducible results.

Complete and partial hydatidiform moles present as abnormal pregnancies ending in first or second trimester abortions. The complete mole is diploid (of paternal origin), is commonly diagnosed on ultrasound, and has no fetal elements present. The partial mole is triploid with paternal and maternal origin, has fetal elements present, and is usually diagnosed after the products of conception are examined pathologically. Gestational choriocarcinoma is a highly malignant tumour derived from syncytial and cytotrophoblastic cells. When villi are present in association with malignant trophoblasts, it is classified as a molar pregnancy. If there is diagnostic doubt about the possibility of combined molar pregnancy with a viable fetus, then the ultrasound scan should be repeated before intervention. If the twin pregnancy is associated with a partial mole, it should be allowed to proceed. If the twin pregnancy is associated with a complete mole, it may proceed after appropriate counselling. These pregnancies are associated with a reduced live birth rate of 25 per cent and are at risk of pre-eclampsia and haemorrhage. The subsequent need for chemotherapy in these rare cases is about 20 per cent, and is the same whether the pregnancy is terminated spontaneously or therapeutically, or allowed to proceed to term.

Gestational trophoblastic disease arises in various types of pregnancy, most of which are clinically recognized as abnormal. The incidence is 1.54 per 1000 live births. The most common are molar pregnancies, but gestational trophoblastic disease can also arise following abortions, ectopic pregnancies, or even after normal full-term pregnancies. Clinical surveillance of patients who have had a molar pregnancy is the only practical method of detecting and preventing gestational trophoblastic disease. In the United Kingdom, all patients with a histological diagnosis of a molar pregnancy are registered and followed up at one of three screening centres (Charing Cross Hospital in London, Sheffield, and Dundee). Only 7.5 per cent of women with hydatidiform mole require chemotherapy in the United Kingdom, and more than half of the patients who require chemotherapy for their gestational trophoblastic disease have a preceding molar pregnancy. Patients who develop gestational trophoblastic disease after an abortion or full-term pregnancy are more difficult to detect. They present with symptoms attributable to metastases. Sites of initial metastases (in order of frequency) are lung, vagina, brain, liver, gastrointestinal tract, and kidney. The interval between pregnancy and the development of metastatic gestational trophoblastic disease may be years. Because these tumours are rare, many clinicians do not consider gestational trophoblastic disease as part of any differential diagnosis.

Any woman of reproductive age who has an undiagnosed tumour or unexplained bleeding from any organ other than the uterus should have a human chorionic

gonadotrophin estimation to exclude the highly treatable gestational trophoblastic disease.

Patients with gestational trophoblastic disease are classified as having a low or high risk depending on a scoring system devised at Charing Cross Hospital and now modified by the World Health Organization. The score relies on factors such as age, the antecedent pregnancy, the interval between presentation and the previous pregnancy, the human chorionic gonadotrophin level, the blood group, the size of the largest tumour, site and number of metastases, and whether the patient had received prior chemotherapy. In the United Kingdom the low-risk group will be offered methotrexate with folinic acid rescue. The high-risk group and those low-risk patients who have resistant or persistent disease will be offered combination chemotherapy. The initial diagnosis may be made by surgical excision or biopsy of a suspicious lesion, but surgery otherwise has little role, excepting rarely to remove a cerebral metastasis to prevent a cerebral bleed.

The overall survival for patients with gestational trophoblastic disease is now about 94 per cent. Women should be advised not to conceive for 6 months after a negative human chorionic gonadotrophin reading. The risk of further molar pregnancy is low (1:74).

Cancer of the cervix

Carcinoma of the cervix may be diagnosed during pregnancy with an incidence of approximately 1 in 2200 pregnancies. In the United Kingdom, with the recent success of the cervical screening programme, the incidence is probably lower. Pregnant women with cervical cancer generally present with early stage disease and the prognosis is similar to that of non-pregnant patients.

The presenting symptom is usually vaginal bleeding. It is therefore important to check the cervix with a visual examination when pregnant women present with irregular vaginal bleeding. There is a tendency to assume that vaginal bleeding in early pregnancy is related to miscarriage, organize an ultrasound to check for fetal viability, and forget vaginal examination. In the case of an obvious cancer, a wedge biopsy under general anaesthetic is appropriate for diagnosis and staging. If there is any doubt, colposcopy can be used to assess the cervix. There is an increased risk of bleeding when taking a biopsy from the pregnant cervix, but there is no increased rate of fetal loss.

Patients with cervical intraepithelial neoplasia can be managed expectantly until after delivery. There is no contraindication for a vaginal delivery for women with cervical intraepithelial neoplasia. Indeed, there are several series which suggest that vaginal delivery is associated with a higher rate of regression of severe dysplasia than is usually seen. Standard practice would be to review with colposcopy at approximately 3 months after delivery. Management of women with microinvasion of the cervix is usually via cone biopsy under a general anaesthetic, allowing the pregnancy to continue.

When cervical cancer is diagnosed in early pregnancy, treatment options include immediate radical hysterectomy or to delay treatment until the fetus is viable, followed by classical caesarean section (scar in the upper segment of the uterus) and radical hysterectomy. This is appropriate for stage 1B cases, where the tumour is confined to the cervix and is less than 4 cm in diameter. In one series there was no difference in survival between the two modes of treatment. Typically, women diagnosed in the first trimester will be offered immediate surgery. Women diagnosed after 24 to 28 weeks' gestation are usually managed expectantly until after 32 weeks' gestation and then delivered by caesarean radical hysterectomy. Steroids are usually given to accelerate fetal lung maturity. The outlook may be worse for patients who deliver vaginally across a cervical cancer, but this has not been substantiated.

Cancer of the ovary

The stated incidence of adnexal masses occurring in pregnant women is from as rare as 1 in 2500 to as frequent as 1 in 81 live births. With the use of routine early ultrasound, the true incidence of adnexal masses is closer to the latter figure. Most of these (more than 95 per cent) are benign. Complications of a benign adnexal mass include pain due to torsion, rupture, and haemorrhage, obstruction of the pelvic outlet, and infection. Most cysts are managed conservatively, avoiding surgery. When necessary, surgery to remove cysts is usually performed in the second trimester. The advantage of waiting until the second trimester is that most cysts resolve spontaneously and that the rate of fetal loss is reduced.

The rationale for removing persistent adnexal masses is to exclude malignancy. Ovarian cancer in pregnancy is rare, with a reported incidence of 1 case per 17 000 to 38 000. This is because the usual age of childbirth is greater than the peak incidence of germ cell tumours and substantially less than the usual age of those with epithelial cancer. In addition, pregnancy protects against ovarian cancer. Two-thirds of the cancers detected are epithelial and the remaining are germ cell (usually dysgerminoma) and stromal cell types. Cysts which are simple on ultrasound and less than 5 cm in diameter have almost no malignant potential. Larger cysts with nodules, septa, or rapid growth are more likely to be malignant. Tumour markers are not helpful in pregnancy: CA 125 can be raised by pregnancy, as can a-fetoprotein and human chorionic gonadotrophin.

The management of the ovarian cancer is similar to that in the non-pregnant woman. Appropriate surgical staging is required: the author's preference being that removal of the cyst, taking of peritoneal washings for cytology, biopsy of the contralateral ovary, and biopsies of any abnormal areas are sufficient at the primary operation. It is also preferable to wait 48 h for a definitive diagnosis from paraffin sections, rather than expect the pathologist to give an immediate result from frozen section. This delay also allows the woman and her partner to consider the implications of the diagnosis. Most of the women seen with a malignant diagnosis in pregnancy will have early stage epithelial cancer: FIGO stage 1A or B, meaning well or moderately differentiated tumour confined to one or both ovaries, or to have borderline histology. No further therapy would then be necessary. Therapeutic termination is not required and pregnancy *per se* does not worsen outcome. Fuller staging may be considered 6 to 12 weeks after delivery. The decision to use chemotherapy postoperatively depends on the stage and differentiation of the tumour, the gestational age of the fetus, and the wishes of the mother. The treatment of malignant germ cell tumours can be carried out without affecting the pregnancy in the second two trimesters, especially if alkylating agents are avoided.

Cancer of the breast

Gestational breast cancer is defined as a breast cancer presenting either during pregnancy or up to 1 year postpartum. It was originally thought that pregnancy-related cancer carried a worse prognosis, but this has not been substantiated. Although breast cancer is regarded as a hormonal-dependent tumour, termination of pregnancy and oophorectomy do not provide a better outcome for the woman. Women becoming pregnant after treatment for breast cancer have a similar or better survival when controlled for age and stage.

Breast cancer is often diagnosed at a late stage as breast lumps may be difficult to detect against a background of pregnancy-related hypertrophy. Consequently, investigation of masses is often delayed. Mammography is not harmful to the fetus with appropriate shielding. When a breast mass is found, the most important step is to make a histological diagnosis. If the diagnosis of breast cancer is made, treatment is the same as for the non-pregnant woman. Obviously, chemotherapy in the first trimester is associated with risks for the developing fetus.

Suppression of lactation as a therapeutic manouevre is not necessary, with two exceptions. Firstly, if breast surgery is required during the puerperium, suppression of lactation can decrease the size and vascularity of the breast, allowing for a safer surgical procedure. Secondly, suppression of lactation is recommended in women receiving chemotherapy as some of the drugs can reach the breast milk and cause neonatal neutropenia.

Melanoma

The incidence of melanoma in pregnancy is between 0.14 to 2.8 cases per 1000 deliveries. Melanoma in pregnancy is unusual in that it can metastasize to the placenta and to the fetus. As this is a rare phenomenon, therapeutic abortion is not indicated, but careful examination and follow-up of the baby is warranted. Current evidence suggests that the clinical outcome for pregnant patients is similar to that of non-pregnant patients. Early detection and biopsy are performed as usual, and the surgical management is the same. Since most recurrences of melanoma occur in the first 3 years following initial diagnosis, it may be appropriate to delay further pregnancies until this time period has elapsed.

Thyroid cancer

It is not uncommon to find thyroid nodules which require further investigation during pregnancy. Most cancers are well differentiated with a very good prognosis. When a diagnosis is made, treatment proceeds as normal, with the exception that radio-iodine is contraindicated. Cancers discovered early in the pregnancy can be treated surgically in the second trimester. Tumours discovered in later pregnancy can have their investigation and treatment delayed until after delivery. Thyroxine is given to

reduce the level of thyroid-stimulating hormone. There is no evidence to suggest that pregnancy alters the outcome for thyroid cancer. Thyroid cancer is not an indication for termination of pregnancy.

Lymphoma

As Hodgkin's disease is a disease of young adults (mean age 32 years), it is not surprising that there are more cases diagnosed in pregnancy than there are of non-Hodgkin's lymphoma (mean age of diagnosis of 42 years). The reported incidence of Hodgkin's disease in pregnancy is between 1 in 1000 and 1 in 6000 deliveries.

Although historically believed to be exacerbated by pregnancy, there does not seem to be any influence of pregnancy on the outcome for Hodgkin's disease. If treatment is required, most patients can be managed without compromise to mother or fetus. Patients presenting with localized Hodgkin's disease relatively late in pregnancy may be observed with limited staging and not treated until after delivery.

By contrast, in non-Hodgkin's lymphoma, patients with Burkitt's lymphoma in pregnancy appear to have a highly aggressive disease involving the breast or ovary. The outlook for pregnant women with non-Hodgkin's lymphoma may be bleak, some dying prior to delivery.

Leukaemia

Leukaemia in pregnancy is rare, with an incidence of 1 per 100 000 pregnancies. This may be because the majority of cases of acute lymphoblastic leukaemia occur before reproductive age and the majority of cases of acute myeloid leukaemia occur afterwards. Chronic lymphocytic leukaemia is a disease of the elderly, hence chronic myeloid leukaemia constitutes 90 per cent of the cases of chronic leukaemia seen in pregnancy.

Since the introduction of intensive chemotherapy, the survival of pregnant women with leukaemia is similar to that of non-pregnant women. It does not appear that intrauterine exposure to antileukaemic chemotherapy produces detrimental late effects to the resulting children. Women treated with non-alkylating agents have no apparent decrease in fertility, although this is reduced by 33 per cent when alkylating agents are used.

Cancer of the colon

The reported incidence of colorectal cancer in pregnancy of 1 per 50 000 pregnancies may now be an underestimate as a reflection of the trend for women to delay pregnancy until later in life. A more recent study has reported an incidence of 1 per 13 000 live births. With increased awareness of inherited genetic traits and the availability of genetic testing, more and more patients at risk (for example those with familial adenomatous polyposis and hereditary non-polyposis coli) are undergoing screening. This may reduce the numbers of pregnant women diagnosed with colon cancer.

It appears that colorectal cancer in pregnancy is particularly common in the rectal region, below the peritoneal reflection. The importance of this is that 88 per cent of tumours are within reach of the flexible sigmoidoscope, allowing detection with a minimum of inconvenience to the patient and no risk to the fetus.

Presenting symptoms are similar to those in non-pregnant women. However, the combination of altered bowel habit, abdominal pain/swelling, and anaemia is common in pregnancy, such that these symptoms are frequently ascribed to the pregnancy itself. Assessment of the pregnant patient with colorectal cancer is similar to that of the non-pregnant patient. Radiological imaging is avoided in the first trimester. Carcinoembryonic antigen is not affected significantly by pregnancy and so can be used as a marker.

Patients younger than 40 years generally have a poorer prognosis due to delayed diagnosis and advanced stage at presentation. Pregnant women are no different in this respect. The overall fetal prognosis is relatively favourable as the diagnosis is usually made close to term and the fetus can be delivered coincident with the surgery for the colon cancer.

13.18 Prescribing in pregnancy

P. C. Rubin

Introduction

Prescribing in pregnancy is essentially about balancing risks. The damage that a drug may cause to the fetus must be weighed against the harm that may befall the mother and her unborn child if a disease goes unchecked.

While knowledge in most therapeutic areas has grown rapidly in recent decades, information on the use of drugs in pregnancy has developed sporadically, with case reports being more usual than large, prospective clinical trials. The reasons are not surprising and largely relate to concern about teratogenesis.

Thalidomide is a name inescapably associated with prescribing in pregnancy. Drug-induced fetal abnormality did not begin with thalidomide: there is an Old Testament exhortation to have 'no strong drink, neither eat any unclean thing' during pregnancy. However, the scale of the thalidomide tragedy brought to the general public for the first time the realization that drugs could harm the developing baby. Thalidomide was marketed in Germany in 1956 and subsequently in other countries as a sedative and hypnotic which had the particular attraction of being safe in overdose. Indeed, the drug was considered so safe that in some countries it was available without prescription. Then between 1960 and 1961 Germany experienced what amounted to an epidemic of phocomelia, a birth defect involving absence of the long bones with hands and feet being attached directly to the trunk. What had previously been an extremely rare condition (no cases had been reported in the 10 years to 1959) was being seen almost commonly. Various causes—viral, radioactivity, food preservatives—were considered as culprits, until one doctor retrospectively questioned his patients and found that 20 per cent had taken thalidomide in early pregnancy. On repeat questioning, asking specifically about the drug, 50 per cent admitted taking thalidomide, many having not mentioned it before since the drug was so obviously innocent. In fact, around 80 per cent of women who took thalidomide in the first trimester had a deformed baby. More than 10 000 such babies had been born before the drug was removed from the market.

The thalidomide experience had far-reaching ramifications. Drug regulation as we know it stems largely from the disaster. Doctors and their patients recognized that there is no such thing as a safe drug. In addition, the pharmaceutical industry has largely avoided obtaining systematic information on drug use in pregnancy. The reasons are obvious and understandable, but for the prescribing doctor the statement that 'the safety of this drug in pregnancy has not been established' is not helpful when faced with a woman who is, or may become, pregnant.

Identifying teratogenic drugs

Information on drug-induced fetal abnormality comes from case reports, case studies, and epidemiological studies. Case reports are a two-edged sword. Describing a single association between a drug and a fetal abnormality can be very useful in first identifying a real problem: warfarin was first linked to teratogenesis in this way. However, the problem with case reports is that they may be showing nothing more than a chance association, because fetal abnormalities occur in around 2 per cent of pregnancies, and caution must be exercised in their interpretation. This is well demonstrated by the Debendox® saga.

Most cases of morning sickness do not require treatment. However, some do, and the drug for which most information is available was withdrawn from the market in 1983 in view of mounting public concern about its safety. This drug was a mixture of doxylamine succinate and pyridoxine hydrochloride and was marketed as Debendox® or Bendectin®. Despite having been used by over 30 million pregnant women over a quarter of a century, and notwithstanding carefully designed clinical trials suggesting that the drug was not teratogenic, individual case reports linking the use of the drug to fetal abnormality were given considerable publicity and led to its withdrawal. In view of the extremely high number of exposures, many chance associations between drug use and fetal abnormality were inevitable. This episode illustrated that in an emotional area such as the use of drugs during pregnancy, well-chosen and carefully presented anecdotes can be more powerful than a substantial body of scientific data carefully accumulated over many years.

Case studies are more secure in that they describe several patients where the same drug and malformation were linked: phenytoin and the retinoids were found to be teratogenic in this way. Epidemiological studies are of two major types: cohort studies, which prospectively study exposed and unexposed groups, and case-control studies, which retrospectively compare the pregnancies of abnormal and normal offspring. So far as teratogenesis is concerned, case-control studies are the norm because of the size and expense of cohort studies. The relationship between diethylstilbestrol use in the first trimester and vaginal adenocarcinoma in teenage offspring was found in a case-control study.

The effect of drugs on the fetus

A drug can harm the fetus only if it crosses the placenta, but most drugs do. The placenta offers a lipid barrier to the transfer of drugs, and the rate at which a drug crosses from mother to baby will depend on its lipophilicity and polarity. However, with the exception of drugs administered acutely around the time of delivery, the rate of transfer is of little importance, and for any course of drug treatment it should be assumed that transfer will occur. The only notable exceptions are heparin—including low molecular weight preparations—and insulin.

Drugs can adversely affect the developing fetus in different ways depending on the gestation at which exposure occurs. For this reason it is appropriate to consider organogenesis, fetal growth and development, the breast-fed infant, and childhood growth and development separately.

Prescribing in the first trimester

Organogenesis occurs between 18 and 55 days of gestation and it is during this time that drugs can cause anatomical defects. A drug can cause a teratogenic effect only if it is present in the embryo during organogenesis, and even a definite teratogen will not cause a structural defect if it is given following this period. These seemingly obvious statements become relevant in prepregnancy counselling and in providing advice when exposure to a possible teratogen has occurred during pregnancy. Being present in the embryo during organogenesis is not necessarily synonymous with being prescribed during this period. The retinoids are stored in adipose tissue and released slowly, so a teratogenic effect can occur long after the course of treatment has been completed. It is important to recognize that teratogenic effects are not seen in all cases: on the contrary, most first trimester exposures to teratogenic drugs will not harm the baby. Clearly there is more to drug-induced fetal abnormality than simply the drug: the genetic make up of the baby is important too. Some drugs that are definitely teratogenic in the human, together with approximate risks, are listed in Table 1.

Preventing drug-induced teratogenesis—short of the obvious solution of not taking the drug—is difficult. Where there is a risk of neural tube defect, folic acid 5 mg daily should be prescribed from the time that pregnancy is planned. No direct evidence currently exists to support this approach, but the approach is logical: folic acid is known to be effective in the secondary prevention of naturally occurring neural tube defect, and anticonvulsants lower folate levels. Some reports have also claimed a direct relationship between dose and fetal abnormality. For example, one meta-analysis involving over 1000 babies exposed to sodium valproate found a higher risk of abnormality at doses above 1 g per day compared with less than 600 mg daily. In epileptic pregnancies, polypharmacy is accompanied by a greater risk of fetal abnormality, but since these women are likely to have the more severe forms of the disease, cause and effect is hard to establish. Many of the abnormalities caused

by these drugs can be detected by detailed ultrasound scanning at 18 to 20 weeks' gestation. However, the defects caused by warfarin involve mainly soft tissue and do not fall into this category.

Table 1 is not comprehensive and includes only those drugs commonly encountered in general medical practice. Some drugs used in specialist areas are teratogenic, for example several drugs used in cancer chemotherapy. Many more drugs may be teratogenic in a small percentage of exposures, but definitive information is not available because both prediction and detection of human teratogens is difficult. Predicting the effect of a drug in the human usually depends on studying its pharmacology in experimental animals. This is not fruitful in the area of teratogenesis because species variation is so great. For example, thalidomide causes phocomelia only in primates, while lithium causes cardiac abnormalities in humans at doses that produce no effect in the rat. Detecting teratogenic effects is complicated by the normal occurrence of fetal abnormalities, hence if a drug is teratogenic very occasionally it can be very difficult to distinguish its effects from those arising naturally.

Even if a drug is a teratogen, the balance of benefits and risks may still be in favour of its use. For example, chloroquine and proguanil are indicated for malarial prophylaxis in areas where *Plasmodium falciparum* remains sensitive. Currently available evidence suggests that chloroquine may cause a very small increase in birth defects: in one study 169 infants whose mothers took chloroquine-base 300 mg once weekly were compared with 454 children whose mothers took no drug. Abnormal babies were born to 1.2 per cent of the treated group, compared to 0.9 per cent of the controls: not a significant difference, but the study was too small to detect anything less than a fivefold increase in abnormality rate. By contrast to the possibility of this small increase in risk, malaria presents a major risk to the health and life of both mother and baby, particularly when an expatriate woman is travelling in an endemic area. The argument in favour of using prophylaxis is therefore overwhelming—but not so overwhelming as the advice for pregnant travellers to avoid malarial areas!

Similar arguments apply to corticosteroids, which have acquired a reputation for causing oral cleft defects. The evidence in support of this effect is at best conflicting and is easily outweighed by the benefits of steroids in conditions such as severe asthma, inflammatory bowel disease, systemic lupus erythematosus, or organ transplantation. The placenta inactivates around 90 per cent of prednisolone, whilst corticosteroids, such as betamethasone, that are used to accelerate fetal lung maturity have much greater penetration to the fetus.

Prescribing later in pregnancy

Beyond organogenesis, the fetus undergoes growth and development. The scope for producing anatomical defects has largely passed, exceptions being premature closure of the ductus arteriosus caused by indometacin and bleeding into the fetal brain produced by warfarin. Growth and function tend to be the targets of drug adverse effects for the remainder of the pregnancy.

The possible effects of some commonly used drugs later in pregnancy are shown in Table 2.

Drugs and breast feeding

Most women now elect to breast feed their babies, and the majority will take a drug during this time. Iron, mild analgesics, antibiotics, laxatives, and hypnotics are the most commonly used. Much work has been performed on the pharmacokinetic aspects of breast feeding, but systematic studies on the effect of drug ingestion by the mother on her breast-fed baby are lacking.

Milk consists of fat globules suspended in an aqueous solution of protein and nutrients. Drugs move from plasma to milk by passive diffusion of the unionized and non-protein-bound fraction. Since breast milk has a slightly lower pH than plasma, drugs that cross most extensively into breast milk are lipid-soluble, poorly protein-bound, weak bases. However, even for drugs that do cross readily into breast milk, considerable dilution has already occurred in the mother. Thus, when the concentration of a drug in breast milk and the volume of the milk consumed by the baby are translated into a dose, it is often the case that the baby receives too little drug to have any detectable pharmacological effect.

Some of the more commonly used drugs that, on the basis of experience, have a good safety record in breast-feeding mothers are listed in Table 3. It will be seen from this that many of the drugs that would be indicated for common medical problems in this context are safe to use. However, some qualification is needed about two of the drugs listed in Table 3. Oestrogen-containing oral contraceptives may suppress lactation if they are taken before the milk supply is well established, and in some women may do so even after this time: progestogen-only contraceptives do not influence lactation at any stage. Metronidazole is not harmful to the baby but is said to make the milk taste bitter and may therefore interfere with feeding.

Some drugs have been shown to affect the baby when ingested in breast milk: these are listed in Table 4. There are several other drugs for which theoretical risks exist, or for which isolated reports of serious adverse consequences have appeared. For example, aspirin is contraindicated in young children because of the possible association with Reye's syndrome, and some authorities consider that the drug should therefore be avoided in women who are breast feeding. No evidence is available to support this view, but unless the use of aspirin is considered essential in a breast-feeding woman (and such an eventuality must be rare), then it is probably best avoided. Similarly, indometacin has been associated with one case of neonatal convulsion when used during lactation: a decision with regard to its appropriateness in any given patient would depend on the likelihood of real benefit accruing from its use.

Behavioural teratology

The most obvious consequences of a drug-induced fetal abnormality occur at or shortly after birth in the form of anatomical defects, and studies in teratology have largely concentrated on immediate pregnancy outcome. However, drugs can, on occasion, cause problems that become manifest only after several years. The most striking example is diethylstilbestrol which, when given during early pregnancy, can lead to adenocarcinoma of the vagina in teenage offspring. In addition to late morphological effects, concern has been expressed that drugs given during pregnancy can influence behavioural development, although the available evidence is to the contrary.

Anticonvulsants

Several studies have claimed that the use of anticonvulsants during pregnancy is associated with impaired intellectual development of the children, but it is difficult to carry out studies in this area and the choice of control group is crucially important. When all children of treated epileptic mothers in a single hospital in Finland were studied prospectively, using the offspring of untreated epileptic women and age-matched children of the same social class as controls, no difference was found in intellectual development at the age of 5.5 years. At present it appears likely that, in the absence of any obvious morphological abnormality at birth, anticonvulsant use during pregnancy is not associated with impairment of intellectual development but studies of sufficient statistical power have not yet been performed.

Antihypertensive drugs

One of the earliest trials on the treatment of hypertension during pregnancy involved a comparison of methyldopa with no treatment. The children underwent physical and psychomotor assessment at 4 and 7.5 years. The 4-year-old children from the treatment group had a slightly smaller head circumference than their untreated controls, but there were no other physical or psychomotor differences. The evaluation at 7.5 years revealed no differences between the two groups. The reputation of methyldopa as a safe drug in pregnancy is largely based on this very well-conducted study.

The effects on childhood development of atenolol versus placebo have similarly shown no detrimental effects, a wide range of physical and psychomotor tests being performed on the children at the age of 1 year.

Effect of pregnancy on drugs

Influence of pregnancy on dose requirements

While the emphasis on what drugs can do to the pregnancy is both understandable and appropriate, the physiological changes of pregnancy can have a clinically important influence on drug disposition and effect. The plasma concentrations of some drugs fall to an extent that is clinically important during pregnancy.

Among the many physiological changes in pregnancy, the most important from the standpoint of drugs are those that influence clearance. By the third trimester renal blood flow has nearly doubled and the activity of some, but not all, liver metabolic pathways is increased during pregnancy. A further factor tending to reduce drug concentrations is an increase in body water, with around an additional 7 litres being retained by the end of pregnancy.

The importance of these changes is well illustrated by the influence of pregnancy on anticonvulsant dose requirements. The plasma concentrations of phenytoin and carbamazepine decrease as pregnancy progresses. An increase in systemic clearance is the main reason—for example, the clearance of phenytoin increases by over 100 per cent by the third trimester—with an increased volume of distribution making a further contribution. An example of the influence of pregnancy on the concentration of phenytoin is shown in Fig. 1. The reduction in anticonvulsant concentration can be substantial and, if the dose is not increased, then seizure control may be lost. The physiological changes of pregnancy resolve in the 6 weeks following delivery, and there is a progressive return to prepregnancy dose requirements during this time.

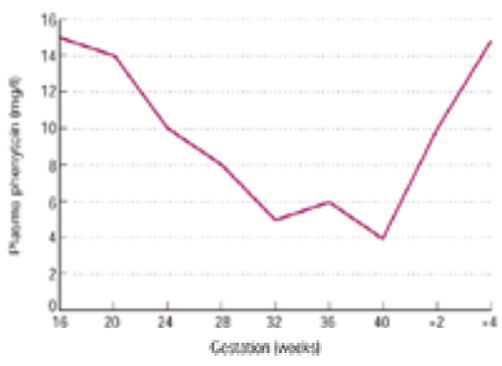

Fig. 1 Plasma phenytoin concentration during and following pregnancy in a woman who remained on a constant dose of 300 mg/day throughout. She had a seizure at 38 weeks' gestation and delivered at 40 weeks. The dose should have been increased when the phenytoin concentration began to fall.

Not all drugs metabolized in the liver show reductions in plasma concentration during pregnancy. For example, the clearance of propranolol is unchanged, presumably because this is determined by liver blood flow, which is not altered by pregnancy.

Since renal blood flow increases during pregnancy, the clearance of drugs eliminated by this route can also be expected to increase. Lithium clearance doubles during pregnancy, so that dose increases, guided by drug-level monitoring, are likely to be needed. Dose requirements fall rapidly following delivery and care must be taken to avoid the development of toxicity. The clearance of ampicillin nearly doubles during pregnancy. Formal pharmacokinetic studies have not been performed with cephalosporins, but plasma levels of around 50 per cent of those found in non-pregnant subjects have been reported. By contrast to drugs with a reasonably well-defined therapeutic range, the falling plasma levels of penicillin or cephalosporin antibiotics are of less obvious significance. However, it seems prudent to give doses at the higher end of the recommended range when using these agents to treat systemic infections during pregnancy.

Drug protein binding in pregnancy

The protein binding of drugs is also altered by pregnancy. The mechanism is not fully understood: although the concentration of albumin falls substantially in a normal pregnancy, there is no correlation between the concentration of albumin and the free fraction of the drug, at least not for all drugs. The free and pharmacologically active concentration of anticonvulsants is increased in pregnancy by 30 to 50 per cent, which has consequences for the interpretation of plasma drug levels.

Therapeutic drug monitoring during pregnancy

Epilepsy is the commonest condition for which therapeutic drug monitoring during pregnancy should be performed. This area is controversial because in non-obstetric practice therapeutic drug monitoring is considered of less value than seizure control as a guide to drug management. However, during pregnancy there is a high likelihood that drug levels will fall because of pharmacokinetic changes. In addition, measuring levels is a useful guide to poor compliance with treatment, which is a feature of the pregnant epileptic. Waiting for a seizure to occur is not without risk: women die from poorly controlled epilepsy in pregnancy. Since the free fraction of anticonvulsants increases during pregnancy, it is the unbound level that should preferably be recorded. Alternatively, saliva samples can be used to guide treatment, since these have been shown to correlate well with the plasma concentration of unbound drug.

13.19 Benefits and risks of oral contraceptives

M. P. Vessey

Introduction

The basic physiological principles underlying a hormonal approach to contraception had already been elaborated by the mid 1930s, but the development of practical methods of hormonal birth control had to await the synthesis of potent orally active steroids some 20 years later. Much of the physiological and clinical development of the 'the pill' was done by Pincus and Rock in the United States in the 1950s; great credit must be given to these two for their contribution to one of the great medical breakthroughs of the twentieth century. Indeed, in 1999 it was estimated that about 110 million women were taking oral contraceptives, 62 million of them in developing countries.

There are several different types of oral contraceptive regimen, but the most important preparations include both an oestrogen and a progestogen. In the United Kingdom, only two oestrogens have been used, ethinylestradiol and mestranol, but seven progestogens are currently available (northisterone, norethisterone acetate, ethynodiol diacetate, levonorgestrel, desogestrel, norgestimate, gestodene) while others have been used in the past (e.g. norethynodrel, chlormadinone acetate, megestrol acetate). Since the dosage of the constituent steroids may be varied (the trend has generally been downwards over the years both for the oestrogen and progestogen components), it is not surprising that the number of different oestrogen–progestogen formulations marketed currently or in the past is very large—over 100 in the United Kingdom. This adds greatly to the difficulties confronting those trying to assess safety.

Oral contraceptives have many metabolic effects, although these are fewer with modern preparations than with earlier ones. None the less, it has been said that 'almost every metabolic parameter that is capable of laboratory investigation has been reported to be altered in one way or another by some contraceptive steroid'. This implies that the results of routine laboratory tests may be altered by oral contraceptives, a point of considerable practical importance. In this chapter, however, attention will be largely concentrated on effects of the pill on morbidity and mortality, as revealed by epidemiological studies.

Until the mid 1970s, most of the available data about the benefits and risks of the pill had been derived from uncontrolled clinical trials and from case-control studies. One large-scale randomized study, including 9757 women allocated either to an oral contraceptive or to a vaginal method of contraception, had been started in Puerto Rico in 1961 by Pincus, but it proved to have serious shortcomings and contributed little to knowledge. Since the mid 1970s, an enormous amount of epidemiological information has been obtained from two large British cohort studies, the Royal College of General Practitioners Oral Contraceptive Study and the Oxford–Family Planning Association (Oxford–FPA) Contraceptive Study. Between them, these investigations recruited 63 000 women of child-bearing age (about half of whom were users of the pill and half users of other methods or no method of contraception) who have now been carefully followed up for an average of around 25 years. Many of the findings described in this chapter are derived from these two cohort studies.

Information about the benefits and risks of oral contraception in the developing world is sparse. The reader is cautioned not to extrapolate the data summarized here to parts of the world to which they clearly do not apply.

Benefits of combined oral contraceptives

High efficacy

By far the most important beneficial effect of these preparations is their remarkable efficacy which, coupled with a high degree of acceptability (at least among the young), has given many women freedom from anxiety about pregnancy. If taken conscientiously, no more than about two to four women in every thousand using a combined preparation should become accidentally pregnant each year. In practice, pills are often missed and much less satisfactory results are then obtained.

Suppression of menstrual disorders

It has long been known that oral contraceptives suppress some menstrual disorders, notably menorrhagia and dysmenorrhoea, leading to a reduction in hospital referral for diagnosis and treatment of these conditions and to a lessened risk of iron-deficiency anaemia.

Suppression of benign breast disease

Epidemiological studies have consistently shown that use of older, higher-dose oral contraceptives seems to decrease the occurrence of benign lumps in the breast, reducing the need for hospital referral for diagnosis and treatment of such lesions by up to 50 per cent. The effect is most pronounced in long-term users, appears to wear off after discontinuation of use, and is probably attributable to the progestogen component of the pill. More recent studies considering lower-dose pills have tended to find less impressive effects on benign breast disease than did the earlier studies.

Pelvic inflammatory disease

Oestrogen–progestogen oral contraceptives reduce the risk of symptomatic pelvic inflammatory disease and probably reduce the severity of the disease as well. There is, however, evidence that the protective effect of the pill is less against pelvic inflammatory disease caused by chlamydial infection than against disease caused by other organisms.

Suppression of functional ovarian cysts

Since oral contraceptives act principally by inhibiting ovulation, it is not surprising that follicular cysts and particularly corpus luteum cysts are relatively uncommon in pill users, although this may apply less to modern, very low-dose pills than to older, high-dose ones.

Suppression of ovarian cancer and endometrial cancer

Epidemiological studies reported during the past 15 years have demonstrated that the risk of both epithelial ovarian cancer and endometrial cancer is reduced by up

to 50 per cent in women who have used combined oral contraceptives for at least 5 years. Longer durations of use offer additional protection while shorter durations of use still provide some beneficial effect. The protective effect appears to persist for many years after cessation of pill use; this is important from the public health point of view since ovarian and endometrial cancer are rare in young women amongst whom oral contraceptive use is most prevalent.

Other possible beneficial effects

While the beneficial effects already described may be considered established, a number of others have been reported in some studies and deserve mention. These include a lessened risk of thyroid disease, rheumatoid arthritis, fibroids, endometriosis, and colorectal cancer. An increased peak bone mass has also been reported in long-term users. Further work is necessary before the significance of these observations can be adequately assessed.

Risks of combined oral contraceptives

Oral contraceptives are well known to cause minor side-effects such as nausea, headache, and breast tenderness. Although such symptoms are common enough and unpleasant enough to lead to discontinuation of the pill by up to 25 per cent of women, they disappear when medication is stopped and do not represent a serious threat to health.

Cardiovascular effects

The best known substantial adverse effects of oral contraceptive use are cardiovascular, comprising venous thrombosis and embolism, thrombotic stroke, and acute myocardial infarction. The evidence concerning haemorrhagic stroke is rather less convincing. All these conditions are rare in young women and the absolute risk associated with pill use is very low. The risks, in most studies, are confined to current pill users and do not depend on duration of pill use. The risk of acute myocardial infarction (and to a lesser extent stroke) in pill users seems to be concentrated in women with other risk factors for cardiovascular disease, notably cigarette smoking and hypertension.

In 1995, findings were published from a multinational study by the World Health Organization which indicated that the risk of venous thromboembolism attributable to oral contraceptive use was twice as high in women using pills containing gestodene or desogestrel as in women using pills containing older progestogens. Some additional studies have confirmed this observation while others have not, and this remains a controversial topic.

The mechanisms underlying adverse cardiovascular reactions to the pill are uncertain. However, oral contraceptives have effects on the coagulation system, on serum lipids, on carbohydrate metabolism, on blood pressure, and on the structure of vessels. Any or all of these effects might be of significance. In recent years, there has been great interest in the effect of oral contraceptive use on venous thromboembolism in women with thrombophilic disorders. Thus the risks associated with factor V Leiden and current oral contraceptive use appear to multiply, such that a woman with both these characteristics may have a risk of venous thromboembolism which is about 30 times higher than that in a woman without either of them.

Breast cancer

Large numbers of studies have been conducted on oral contraception and breast cancer, but no consensus was reached on their interpretation until a collaborative re-analysis of 54 studies was published in 1996. It was found that the relative risk of having breast cancer diagnosed in current users of combined oral contraceptives in comparison with never-users was 1.24. There was also some increase in risk in ex-users, but this was no longer apparent 10 or more years after stopping. Cancers diagnosed in women who had used combined oral contraceptives were clinically less advanced than those diagnosed in women who had never done so. It is not known whether there is an increased risk of dying from breast cancer as well as an increased risk of having breast cancer diagnosed in women using the pill.

Hepatocellular adenoma and carcinoma

Hepatocellular adenoma and carcinoma are extremely rare (but serious) conditions in women of child-bearing age. In those without exposure to the pill, the incidence might be around one per million per annum. Oral contraceptive users suffer a higher incidence than this, but there is reason to believe that the increase in risk is much less in those taking modern, low-dose pills.

Impairment of fertility

Despite a vast literature, prior use of oral contraceptives has not been incriminated either as a cause of prolonged secondary amenorrhoea (say absence of periods for more than 6 months) or of prolactinoma of the pituitary, which is sometimes associated with this condition. Many women do, however, experience some temporary impairment of fertility after stopping the pill, especially those over the age of 30 trying to have a first baby. In the majority this lasts only a month or so, but in some recovery may be much slower. It seems unlikely that oral contraceptives are ever a cause of permanent infertility.

Other possible adverse effects

A large number of studies have indicated a positive association between long-term oral contraceptive use and cervical cancer. The interpretation of this association is uncertain, mainly because cancer of the cervix is so strongly associated with sexual activity that it is extremely difficult to isolate any independent effect of the method of contraception used.

Several studies have examined the possible relationship between oral contraceptive use and malignant melanoma; they have not given consistent results. The same is true for studies of hydatidiform mole and choriocarcinoma.

In the past, there was considerable anxiety about an increase in the risk of cholelithiasis in pill users. Further work has shown the effect, if present, to be minimal. The evidence concerning chronic inflammatory bowel disease is more convincing. Many other possible adverse effects of oral contraceptives have been suggested, including depression, urinary tract infection, and fetal malformation if taken inadvertently during pregnancy. In every case, the balance of evidence is not compelling. A recent concern centres around human immunodeficiency virus (HIV) infection being commoner in pill users, with worrying findings in prostitutes in Nairobi. These results have not, in general, been replicated in other studies and there is no clear evidence of an adverse effect of pill use on the risk of HIV infection.

Progestogen-only oral contraceptives

Low doses of progestogens taken every day by mouth have been extensively investigated as contraceptives. Such preparations do not consistently inhibit ovulation and their mode of action is uncertain. Their efficacy is lower than that of the oestrogen–progestogen pill, but they can give entirely adequate protection in older women who may prefer not to use conventional pills. A major disadvantage of progestogen-only oral contraceptives is their tendency to disrupt the menstrual cycle in many women, producing irregular bleeding, whilst those who become accidentally pregnant when using them have about a 5 per cent chance of an ectopic gestation. These drawbacks probably account for the fact that progestogen-only pills represent only a small fraction of all oral contraceptives consumed. Their main advantage is that they appear to be free from the undesirable metabolic effects of combined preparations. In addition, they can be taken safely by women who are breast feeding without risking the reduction in milk production that usually occurs if combined oral contraceptives are taken.

Balance of benefits and risks

A number of authors have provided analyses of varying degrees of complexity in which they have attempted to weigh up the benefits and risks of taking the pill. Three approaches are outlined here. In the first, which uses hospital inpatient morbidity data from the Oxford–FPA study, supplemented where necessary by other epidemiological data, a comparison is made over a 1-year period of women using either oral contraceptives or a condom for contraception. The approach is fully described elsewhere (see Further reading), but Table 1 summarizes the main findings. Despite the sizeable cardiovascular risks (older 50 µg pills were used in the Oxford–FPA study) the overall results are quite favourable as far as oestrogen–progestogen oral contraceptives are concerned. Similar analyses reported from the Royal College of General Practitioners Oral Contraceptive Study have produced comparable results.

The second approach involves constructing models that consider what is known about the effects of oral contraceptives and other methods of birth control on

mortality, and estimating the balance of benefit and risk over a period of many years. This approach is too complex to describe here because of space limitations, but details are available elsewhere (see Further reading). Not surprisingly, the results obtained in such analyses depend to an important extent on whether or not oral contraceptives increase the risk of death from breast cancer (as opposed to merely increasing the rate of diagnosis of the disease), the length of time after discontinuation of oral contraceptive use that the protective effect against epithelial ovarian cancer and endometrial cancer persists, and the ages at which oral contraceptives are used. Considering the current pattern of oral contraceptive use in developed countries, which is predominantly by women below the age of 35 years, the balance of benefits and risks seems entirely acceptable.

The final approach is a more direct one. It involves examination of the mortality rates observed in the major cohort studies, comparing oral contraceptive users with non-users. Data published in 1989 from the Oxford–FPA study relating to the first 238 deaths are shown in Table 2. Although the numbers are small, the pattern of mortality reflects what is known about the effects of oral contraceptive use from other studies. Overall, the mortality ratio comparing users with non-users is 0.93 (95 per cent confidence interval 0.71–1.22). In a corresponding analysis from the Royal College of General Practitioners study including 1599 deaths, the overall mortality ratio was 1.02 (95 per cent confidence interval 0.92–1.13), while the large Nurses' Health cohort study in the United States reported an overall mortality ratio of 0.93 (95 per cent confidence interval 0.85–1.01) based on 2879 deaths. These data clearly offer considerable reassurance about the effects of oral contraceptives.

The pill has been studied extremely intensively over the past four decades. On the whole, it has stood up well to close scrutiny. It remains an excellent method of contraception for younger women. There remains some doubt, however, about its suitability for those aged over 40. Women in this age group are, however, usually well served by progestogen-only pills if a reversible method of contraception is required.

13.20 Benefits and risks of hormone replacement therapy

J. C. Stevenson

Introduction

The acute effects of female sex hormone deficiency such as vasomotor symptoms are well known, but the importance of the longer-term effects of ovarian failure have only been recognized recently. The menopause, the time of a woman's last menstrual period, is a useful marker for ovarian failure and occurs naturally at an average age of around 51 years, although it may occur at any time after puberty. A postmenopausal state can usually be inferred by the absence of menses for 12 months in a woman of appropriate age. The demonstration of elevated gonadotrophin levels may help to confirm the diagnosis in hysterectomized women.

Clinical features of menopause

A number of symptoms may arise soon after loss of ovarian function at the menopause. These include hot flushes and night sweats, and psychological symptoms such as mood swings, depression, anxiety and irritability, and difficulties with memory and concentration. Later there may be genitourinary problems such as vaginal dryness and dyspareunia, and increased urinary frequency and urge incontinence. However, it is the long-term consequences of hormone deficiency, particularly osteoporosis and cardiovascular disease, which pose a major health problem for women.

The menopause is recognized as a substantial risk factor for the development of osteoporosis, and perhaps one in every two women will have this disease by the end of their lives. The classical osteoporotic fractures are of the vertebrae, distal forearm, and proximal femur, but osteoporosis may also result in fractures of the ribs and pelvis, proximal humerus, ankle, and phalanges. Hip fracture is by far the most serious in terms of morbidity, mortality, and cost to the health service: one in five women die and at least 50 per cent of the remainder end up in institutionalized care, such that the health service costs of osteoporosis are now approaching a billion pounds annually in the United Kingdom.

Increased risk of cardiovascular disease is the most important consequence of ovarian failure. Coronary heart disease is the leading cause of death in women, and although it occurs at a later age than in men, overall more women than men die from the disease. The occurrence of coronary heart disease in women is frequently overlooked, and women are less likely than men to undergo both investigation and treatment for this disease.

It is now becoming apparent that oestrogen deficiency has profound neurological effects. Alzheimer's dementia is more common in elderly women than men, and the menopause has adverse effects on the central nervous system, including cognitive function.

Benefits of hormone replacement therapy

The main indications for the use of hormone replacement therapy are relief of menopausal symptoms and prevention of osteoporosis. Hormone replacement therapy will abolish vasomotor symptoms, often within days of starting treatment, whilst psychological and genitourinary symptoms may take weeks or even months to respond. It is therefore worthwhile persisting with therapy for several months in the absence of rapid symptomatic response, and treatment should be continued for at least several months after symptomatic relief has been obtained.

Hormone replacement therapy is well established for both the prevention and treatment of osteoporosis, and is as effective as any other agent currently available. It conserves, and to some extent increases, bone density and results in a reduction in the risk of fracture. Therapy should be offered to any woman considered at increased risk of osteoporosis, and particularly those with an early menopause. When the risk of osteoporosis is uncertain, bone density measurement can greatly aid clinical decision-making.

Hormone replacement needs to be given long-term when started in the early postmenopause, but few women are at immediate risk of osteoporotic fracture at this age. An alternative strategy is to commence hormone replacement in elderly women who are at a much greater risk for osteoporotic fracture. This approach results in a relatively rapid reduction in risk of fracture, and is thus more cost-effective. It also avoids the necessity of prolonged therapy. However, the elderly are less tolerant of the side-effects of treatment, particularly cyclical bleeding and mastalgia, and regimens that avoid bleeding are to be preferred for this age group. This includes those with lower doses of oestrogen than used in the early postmenopause, which are effective for bone conservation in the elderly. Cessation of hormone replacement therapy leads to a loss of bone density, but only at the usual postmenopausal rate, and the benefit gained by the skeleton from a suitable period of treatment persists into old age.

It is most likely that prevention of cardiovascular disease will become a major indication for hormone replacement therapy in the future. There are many mechanisms, both established and potential, whereby hormone replacement therapy might benefit the cardiovascular system, and these are summarized in Table 1. The effects vary depending on the type of oestrogen or progestogen and the route of administration. In general, hormone replacement produces a lowering of low-density lipoprotein cholesterol and an increase in high-density lipoprotein cholesterol, thus reversing the changes in lipids and lipoproteins brought about by the menopause. An improvement in glucose tolerance, due to enhancement of insulin secretion and elimination or a reduction in insulin resistance, may be seen. There are also direct effects of oestrogen on arteries, which improve their function by endothelium-dependent and non-endothelium-dependent mechanisms. Hormone replacement therapy should therefore be considered for use in women with increased cardiovascular risk, such as those with established coronary heart disease, diabetics, hypertensives, and cigarette smokers.

Population studies have shown that a reduction in the incidence of cardiovascular disease of around 50 per cent can be achieved with hormone replacement. However, a recent randomized prospective study of hormone replacement therapy for the secondary prevention of coronary heart disease failed to show any overall benefit in outcomes, although an eventual reduction in events by over one-third was observed by the end of the trial. Concerns have been raised about the reliability of these findings, due in part to certain aspects of the trial design, and further studies are awaited to clarify the position.

Therapeutic regimens

Hormone replacement therapy consists of oestrogen, which should be given continuously, with the addition of cyclical progestogen in women who have not had a hysterectomy. Progestogens are necessary to prevent endometrial hyperplasia and neoplasia, and to regulate any uterine bleeding that may occur. Oestrogen is given as oral estradiol 17b, estrone sulphate, or conjugated equine oestrogens. Alternatively, estradiol 17b can be administered transdermally through adhesive skin patches, or implanted subcutaneously as pellets. The synthetic alkylated oestrogens, such as ethinylestradiol, are not used in hormone replacement therapy because of their potency and unwanted side-effects. The progestogens used are either derivatives of 19 nortestosterone, such as norgestrel and norethisterone, or the less androgenic C-21 steroids, such as dydrogesterone and medroxyprogesterone acetate. Natural progesterone can be used but is often poorly tolerated because of drowsiness. Progestogens are usually given in the minimal dose necessary for endometrial protection for 12 or more days per month, and result in a regular uterine bleed. The usual doses of hormones are shown in Table 2.

The main drawback to current hormone replacement therapy regimens is the necessity of uterine withdrawal bleeding, although this is often fairly light, particularly in older patients, and tends to diminish with time. With a satisfactory and regular bleeding pattern, there is usually no need for endometrial screening. However, cyclical bleeding becomes less acceptable as women get older, and thus regimens that avoid such bleeding become preferable. Preparations giving continuous progestogen with continuous oestrogen are used to induce endometrial atrophy and hence abolish uterine bleeding, resulting in amenorrhoea in up to 70 to 80 per cent of women.

These therapies are less successful in younger women, where transient episodes of spontaneous ovarian activity may result in irregular bleeding.

Tibolone, a synthetic compound with oestrogenic, progestogenic, and androgenic properties, is an alternative that avoids cyclical bleeding. It relieves vasomotor symptoms and appears as effective as hormone replacement therapy for the prevention and treatment of osteoporosis, but it is not established whether it has other benefits associated with hormone replacement therapy such as desirable cardiovascular effects or effects on the central nervous system. Similarly, it is not known whether it has the same potential risks, such as for the breast.

Raloxifene is a so-called selective estradiol receptor modulator, a synthetic compound which binds to the oestrogen receptor but causes conformational changes that result in different tissue-specific actions. Thus it can act similarly to an oestrogen in the skeleton, preventing osteoporotic vertebral fractures, but like an anti-oestrogen in the breast, causing a reduction in incidence of breast cancer, at least in the short term. It does not cause uterine bleeding, but does not relieve vasomotor or genitourinary symptoms. Studies are awaited to determine what, if any, are its actions on the cardiovascular and central nervous systems.

Side-effects of hormone replacement therapy

Oestrogenic side-effects such as breast tenderness and nausea are sometimes experienced on commencing therapy, particularly by older patients who are many years postmenopause. These side-effects are transient and usually resolve after about 3 months of therapy. More commonly, side-effects are due to the progestogen and can include breast tenderness, abdominal and pelvic pain, backache, depression, irritability, and migraine.

Risks of hormone replacement therapy

The main concern about hormone replacement therapy, particularly with prolonged treatment, is the risk of breast cancer. Epidemiological evidence remains conflicting: whilst some studies show no overall increased risk of breast cancer, others show an increase with prolonged usage. However, in studies looking at mortality from breast cancer, women taking hormone replacement therapy who develop the disease appear to have a better survival than those not on treatment. It seems prudent to avoid hormone replacement therapy where possible in women with breast cancer, but the disease need not be considered a total contraindication in all cases.

Previous endometrial hyperplasia or neoplasia is not a contraindication, provided the disease has been eradicated. Similarly, endometriosis and uterine fibroids rarely cause a problem, although they may occasionally worsen. There is growing epidemiological evidence that hormone replacement therapy may result in a decrease of around 40 per cent in the incidence of colorectal cancer.

Despite previous beliefs, hormone replacement therapy does not cause hypertension, except as a rare idiosyncratic reaction. There is a small absolute increase in the risk of venous thromboembolism, although whether this is seen with non-oral low-dose therapy is not known. It is therefore prudent to exclude a pre-existing thrombophilia in patients with a relevant past or family history.

Many women gain weight after the menopause, most commonly due to excessive calorie intake, not as a result of taking hormone replacements. Weight gain may occasionally occur due to fluid retention, particularly associated with progestogen use, but increases in body fat are not caused by hormone replacement therapy, although there is a redistribution of body fat, with a reduction in the metabolically harmful central obesity.

Most of the other reputed adverse effects of hormone replacement therapy are unsubstantiated, and have largely arisen from an inappropriate extrapolation of data obtained with oral contraceptive use.

Hormone replacement therapy is a treatment with considerable benefits for many women. The choice of therapeutic agents should be tailored to suit the individual case. There are advantages and disadvantages of certain preparations and combinations, but overall the therapy used should be the one that the patient finds most acceptable. This will encourage compliance with long-term therapy, resulting in the greatest health benefits.

14.1 Introduction to gastroenterology

Graham Neale

Further reading

At the end of the nineteenth century clinical science emerged in French and German universities. The concepts generated there spread to the medical schools of North America and led to the development of academic medicine. In 1897 the American Gastroenterological Association was founded. However, clinicians were slow to apply the spirit of enquiry to their practice, and well into the twentieth century static electricity or bitter tonics were used to treat 'gastric neurasthenia'; sarsparilla and dandelion were used as 'biliary stimulants'; and colonic lavage was a popular treatment for 'autointoxication'. Few advances in the understanding of gastrointestinal physiology in the first half of the twentieth century had any direct impact on clinical practice. Before the Second World War clinicians with a special interest in abdominal disease remained general physicians, few of whom thought it worthwhile learning to use the semiflexible gastroscope. Oesophagoscopy was the province of otorhinological or thoracic surgeons; and sigmoidoscopy with rigid instruments was undertaken more often in operating theatres than in medical outpatient clinics.

After the Second World War the emergence of simple methods for obtaining biopsies of the liver and small intestine and the more rational management of inflammatory bowel disease led to the rapid development of gastroenterology as a specialty. The 1960s and 1970s brought major advances in the understanding of the pathophysiology of gastrointestinal disease which have laid the principal foundation for modern clinical practice (Table 1). This was the scientific growth period of clinical gastroenterology.

Then in the 1980s and 1990s the development of endoscopic techniques based on fibre optics revolutionized practice, taking us into the technological era of clinical gastroenterology. How long this will last is uncertain. It seems likely that gastroenterologists will become less involved in routine endoscopy. The simpler procedures will probably be undertaken by certified non-physician endoscopists (possibly with robotic instruments) and diagnostic endoscopic retrograde cholepancreatography and colonoscopy will be eliminated by improved scanning procedures. The speed of change may depend on the tenacity with which specialists in gastroenterology cling on to the simpler endoscopic techniques which often provide them with substantial earnings. However, ultimately just a few interventional endoscopists may remain, concentrating on 'high-tech' therapeutic techniques.

Moreover if straightforward curative treatments emerge for inflammatory bowel disease the role of the gastroenterologist will undoubtedly change. Already in the Western world more than half the referrals to specialists in gastroenterology are for advice on managing patients with an irritable bowel. Providers of funding for health care will get an increasing grip on cost efficiency. With better organization of medical knowledge and outcomes research, general practitioners should be able to provide the majority of routine care.

For the physician-gastroenterologist there will be a renewed emphasis on the need to develop advanced interpretative and diagnostic skills. These will underpin therapeutic decision-making and the counselling of patients—who are themselves now far better informed about health and disease. It is possible that some gastroenterologists will evolve into digestive health physicians working as members of teams involving surgeons, radiologists/scanners, pathologists, microbiologists, immunologists, and geneticists. These teams will deal with structural lesions by sophisticated minimally invasive procedures; they may control disease by new techniques of immune modification; and develop methods to correct genetic defects affecting the gastrointestinal tract and adjacent organs. They will depend on the material sciences, information technology, and new means of communication, and will be advising individuals about their health profiles. They will prescribe pharmaceuticals and work with dietitians to alter health risks and to produce health benefits. As a group, digestive health physicians will need to know a great deal about the role of nutrition in health and disease.

If these changes are to occur then educational policies will have to change. Most illnesses have multiple causes and management decisions will come to be made through sophisticated risk analysis. All clinicians should have a good background in clinical science in order to cope with the emerging information era. The sections on gastroenterology and clinical nutrition in the *Oxford Textbook of Medicine* provide such a background in an important segment of clinical practice.

14.1.1.1 Structure and function of the gut

D. G. Thompson

Introduction

This chapter provides a brief overview of the structure and function of the gastrointestinal tract (excluding the liver and pancreas). For more detail readers are referred to the Further reading list. Emphasis has been placed on those aspects of gastrointestinal anatomy and physiology which help an understanding of the nature of gastrointestinal symptoms and/or guide an approach to therapy.

Anatomy

Gross anatomy

The gastrointestinal tract is a hollow tube of approximately 5 to 6 m in length, stretching from the oral cavity to anal sphincter (Fig. 1). It is arbitrarily divided into a series of organs which serve different functions, and is joined to the liver and pancreas, the major organs of digestion.

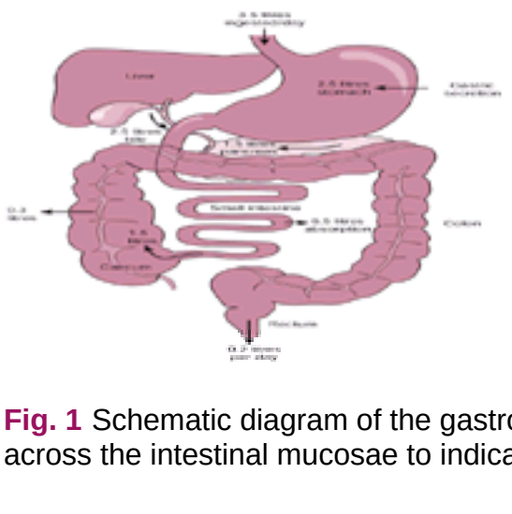

Fig. 1 Schematic diagram of the gastrointestinal tract showing the major organs of the tract and their connections. The figure also shows the average daily fluid flux across the intestinal mucosae to indicate sites and volumes of absorption and secretion in the various organs.

Anatomical structure

The gastrointestinal tract possess a broadly similar structure throughout its length (Fig. 2) with an innermost epithelium, a subepithelial lamina propria, and two muscle layers, an inner circular and an outer longitudinal layer, between which lies the myenteric plexus, the intrinsic neural control system of the musculature. While this description most accurately describes the small intestine, the other organs of the gastrointestinal tract differ only subtly from this stereotype.

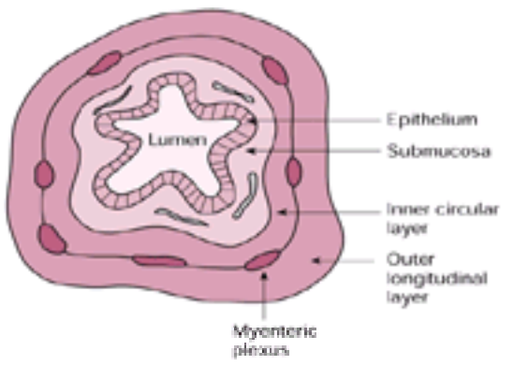

Fig. 2 A generalized structure of the intestine in cross section. A central lumen is bounded by an epithelial layer, which in turn is surrounded by a submucosal layer containing neural and vascular connections to the epithelium. Outside the submucosae lie circumferential and longitudinal muscular layers with the controlling neuronal myenteric plexus lying between.

Oesophagus

In the oesophagus, the innermost layer is a squamous rather than colomnar epithelium. The musculature in the upper third is striated and controlled directly via extrinsic neural pathways, unlike the lower two-thirds which has smooth muscle and a myenteric plexus.

Stomach

The anatomy of the stomach differs from the intestine, possessing an additional oblique muscular layer and at either end a sphincter—specialized musculature designed to act as a unidirectional valve to control the flow of luminal contents. The sphincter between the oesophagus and stomach (the lower oesophageal sphincter) lies at the level of the diaphragm. The sphincter between the stomach and small intestine is known as the pylorus.

Small intestine

The small intestine is arbitrarily divided into duodenum, jejunum, and ileum. The duodenum (so named because it is 12 fingers' breadth in length) is retroperitoneal, and possess on its medial aspect the ampulla of Vater which connects the pancreatic and common bile ducts to the duodenal lumen. The jejunum (Latin, empty, after death) is mobile and free on a mesentery. The ileum (Greek, twisted) begins indistinctly from the jejunum and ends at the caecum.

Colon and rectum

The colon differs from the small intestine in its muscular structure—the inner circular layer is similar but the outer longitudinal layer is condensed into three 'worm like' structures, the taeniae coli. At the proximal end of the colon, the caecum (Latin, blind ending) arises the vermiform appendix, named because of its worm like appearance. The ascending and descending colon are retroperitoneal whereas the transverse and sigmoid colon are freely mobile on a mesentery, extending to the pelvic floor following which it expands into the rectum.

Anal sphincter

The anal sphincter provides an important continence mechanism and has two parts, an internal sphincter of smooth muscle and an external sphincter of striated muscle.

Functional anatomy

The function of the gastrointestinal tract is closely associated with its structure.

The epithelial layer

The epithelium lies in contact with the luminal contents and ranges in permeability from being largely impermeable (oesophageal squamous epithelium) to highly permeable (intestinal epithelium). The absorptive function of the epithelial layer is modulated by a network of neurones, the submucous plexus, which receive input from the central nervous system. In addition, the neurones of the submucous plexus and the nerve terminals of extrinsic afferent nerves, particularly those running in the vagus trunk, are modulated by signals arising from the epithelium.

Neuromusculature of the gut

The striated muscle in the gastrointestinal tract (upper oesophagus and anus) is directly innervated by second order (lower motor) neurones (arising from the brainstem and spinal cord respectively) and therefore under direct central nervous system control whereas smooth muscle is largely autonomous, being controlled 'locally' by the enteric nervous system without direct innervation from the central nervous system. The central nervous system can, however, indirectly influence the muscular function of the gastrointestinal tract via its innervation of the myenteric plexus.

Immune system of the gastrointestinal tract

Throughout the gastrointestinal tract lie discreet clusters of immune cells which provide immunosurveillance and immune protection, that is Peyers patches in the small intestine and the appendix (see Chapter 14.4).

The function of the gastrointestinal tract

The function of the gastrointestinal tract is the transport, digestion, and elimination of ingested material to supply nutrients, vitamins, minerals, and electrolytes which are essential for life, together with the protection of the rest of the body from injurious or allergenic material.

Secretion/absorption

The gastrointestinal tract is responsible for movement of very large volumes across its lumen (Fig. 1). Overall, more than 8 litres enter the lumen per day. In contrast, only 200 to 300 ml is expelled per day as stool, the remainder being efficiently absorbed by the small intestine and proximal colon. The major digestive/absorptive organ of the gastrointestinal tract is the small intestine. Without the small intestine life is impossible whereas the possession of the small intestine without oesophagus, stomach, or colon is still compatible with reasonable nutrition. The various organs of the gastrointestinal tract subserve different functions to ensure that ingested nutrients are adequately digested or eliminated.

Oesophageal function

The oesophagus functions as a conduit to transport ingested food masticated by the mouth and salivary glands, through the thoracic cavity and into the proximal stomach.

Gastric function

The stomach acts as a storage, a sterilizing, and a digestive tank. Its receptive function enables large quantities of food to be eaten rapidly and stored and processed until adequately prepared for delivery to the small intestine. The presence of pathogens in food is reduced by the secretion of hydrochloric acid upon meal ingestion while the production of peptidases and lipase capable of operating in a low pH commence the process of digestion.

Small intestinal function

The small intestine is the major site of digestion and absorption. It regulates the speed of delivery of gastric contents via a sensing mechanism located in the epithelium, comprising endocrine cells sensitive to the pH, osmolarity, and chemical composition of the luminal contents, and signals both to intrinsic and to extrinsic neurones of the vagus to delay gastric emptying. This sensory signal also stimulates the delivery of bile and production of pancreatic secretion ensuring that these major digestive materials are delivered to the intestine only in the presence of nutrients.

The absorption of digesta is achieved through the intestinal mucosa. While some passes between the intestinal cells, most is actively transported through the epithelial cells via specific transporters (e.g. peptide, hexose transporters). The small intestinal is also a major absorptive organ, retrieving over 6 litres of fluid per day from the lumen (Fig. 1), the end result of which is the delivery of a small quantity of unabsorbed food (1.5 l) into the caecum.

Regional variation in intestinal absorption

The intestine shows regional differences in its absorptive function. The jejunum is responsible for the majority of nutrient and fluid absorption, whereas the ileum has additional, specific absorptive functions, in particular the absorption of vitamin B_{12} and the absorption of bile salts. Surgical resection of the ileum may thus be associated with development of B_{12} deficiency and of diarrhoea resulting from passage of bile salts into the colon where they induce secretion.

The colon

The colon's function is to salvage water and electrolyte from the small intestinal effluent, converting over a litre of material from the intestine into small pellets for elimination. In addition to its water and electrolyte absorptive function, the colon also salvages unabsorbed calories from the lumen, particularly undigested carbohydrate, for example starch polysaccharides. These are incompletely digested in the small intestine and thus pass to the colon where the anaerobic bacteria of the lumen ferment the carbohydrate to short chain fatty acids, which are absorbed to provide a secondary nutrient source.

The rectum

The rectum provides a storage function, enabling the elimination of colonic residue (defecation) to be restricted to times of personal convenience.

Neural control of gastrointestinal function

For the greater part of the time, the gastrointestinal tract is controlled by its own nervous system—the enteric nervous system. The enteric nervous system is not entirely autonomous however, and requires some local and central nervous system 'reflexes' for adequate co-ordination of functions along its length. For example the co-ordination of the passage of luminal contents into the small intestine from the stomach requires sophisticated control, which is provided by a vagally mediated reflex operating via the brainstem. This circuitry alters the gut from its fasted state to the fed state, that is gastric relaxation, the induction of gall bladder emptying, and pancreatic secretion, thus ensuring the provision of digestive enzymes at the appropriate time. An additional relay function is provided by prevertebral ganglia where visceral afferent neurones synapse with efferent relay neurones to integrate contractile patterns and contraction force.

The intrinsic nervous system

The intrinsic nervous system acts as a local control system with its own 'programmes', examples of which are the peristaltic reflex and the migrating motor complex.

Peristaltic reflex

This basic 'programme' responds to local luminal distension by an ascending muscular excitation pathway and descending inhibition (Fig. 3) which ensures aboral propulsion of luminal contents. This reflex is best seen in the oesophagus where it is known as secondary or non-swallow-related peristalsis. While the reflex can be induced in the small intestine or colon, it is not a major factor for luminal transit.

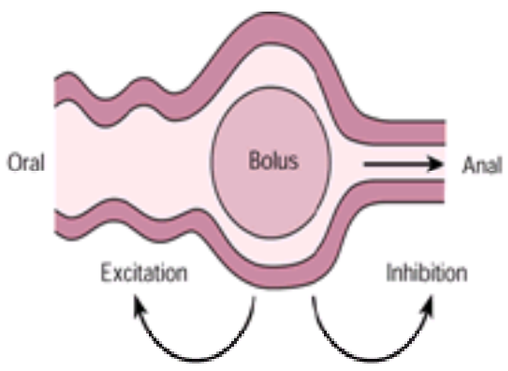

Fig. 3 Peristaltic reflex. The peristaltic reflex is the mechanical response of the intestine to the intraluminal distension. Note the presence of proximal motor excitation and distal inhibition which together propel the distending bolus from mouth to anus.

The migrating motor complex

This comprises a triphasic pattern of aborally propagating contractions in the distal stomach and small intestine during the fasted state which probably serve to maintain an empty lumen and reduce bacterial growth. Periods of quiescence are followed by irregular contractile activity which then terminates in a aboral migrating burst of regular contractions, which slowly migrate from the distal stomach down to the terminal ileum. This pattern, which characterizes the fasted state, is interrupted on food ingestion by a vagally mediated reflex which converts the pattern into a fed one.

The immune function of the gut

Being the major route of nutrient absorption, the gastrointestinal tract is also a potential portal for pathogen entry. The gastrointestinal tract therefore requires a sophisticated immune surveillance system together with a process for eliminating intestinal pathogens and the ability to either tolerate or eliminate ingested antigens. Details of this process are more fully dealt with in Chapter 14.4.

Disturbances of local physiological control mechanisms and origins of symptoms

Disturbances of local neuromuscular function are associated by the disturbances transit and elimination or secretion and absorption. An example of disturbed transit resulting from disturbed neuromuscular function is achalasia or slow transit constipation. Examples of disturbance of secretion and absorption are secretory diarrhoeas or the hyperacidity associated with *Helicobacter pylori* infection. Examples of symptoms which follow damage to extrinsic neural control are exemplified by the symptoms of truncal vagotomy, that is rapid transit and impaired nutrient–enzyme mixing result in poor digestion and an osmotic diarrhoea.

The relationships between gastrointestinal symptoms and the central nervous system are relevant to the understanding of functional gastrointestinal 'disorders'; it is well recognized that psychological disturbances, for example anxiety or depression combined with local disturbances of gastrointestinal physiology produce pain, nausea and vomiting, and altered bowel habit.

14.1.1.2 Symptomatology of gastrointestinal disease

Graham Neale

The skilful analysis of symptoms indicating disorders of the digestive system is an integral part of the practice of internal medicine. Many patients with abdominal symptoms do not have easily defined organic conditions. The traditional skills of taking a careful history and examining the patient thoroughly are invaluable in managing patients who have functional disorders such as 'irritable bowel', non-ulcer dyspepsia, non-specific diarrhoea, recurrent abdominal pain, and somatization disorder. One might suppose that the enormous advances in endoscopic, scanning, and other techniques will have made clinical diagnosis less important, but this is not so: most gastrointestinal disorders are minor self-limited disorders of uncertain cause or are functional in nature, thereby often eluding definition by these procedures. Moreover the early suspicion of life-threatening disease and prompt referral of patients for investigation depends on clinical judgement.

Disorders of swallowing

Pharyngeal disease

Difficulty in swallowing is an important symptom that requires prompt resolution. Oropharyngeal disorders cause difficulty in initiating swallowing, regurgitation through the nasopharynx, a sensation of sticking in the throat, or the feeling of a lump in the throat on or after swallowing. Coughing and choking on swallowing is usually a symptom of pharyngeal disease and indicates failure to close the larynx. More rarely it is a sign of an obstructive lesion in the lower gullet which allows food and secretions to accumulate and spill into the larynx, especially at night. This symptom needs urgent attention to reduce the risk of aspiration pneumonia. Painful lesions of the oropharynx are usually demonstrated quite easily by simple inspection.

Patients with neurological disorders such as Parkinson's disease, motor neurone disease, myaesthenia gravis, and dermatomyositis only rarely present with disorders of swallowing and the clinician has only to be aware of the way in which known illnesses may affect the swallowing process. Oropharyngeal dyskinesia is common in the early phase of recovery after a stroke and may be persistently troublesome in patients with brainstem lesions.

Patients with the sensation of a lump in the throat on or after swallowing require an imaging technique to look for a pharyngeal pouch, a postcricoid web, or carcinoma and rarely pressure from a large osteophyte as a result of cervical spondylosis. It is unwise to submit patients with suspected pharyngeal lesions to conventional fibre-optic oesophagoscopy as a first examination because of the risks of perforation. Patients with a persistent feeling of 'a lump in the throat' without any demonstrable disease ('globus hystericus') usually respond well to the taking of a careful history, a single scanning procedure, and firm reassurance. They are more often women than men and they nearly always show signs of an anxiety state.

Oesophageal pathology

Dysphagia

Oesophageal dysphagia causes a sensation of food sticking in the gullet and is nearly always due to organic disease. The symptoms vary from discomfort to severe pain and the patient is rarely able to localize the site of the obstruction accurately. Associated symptoms such as regurgitation, vomiting, and coughing or choking are common. Oesophageal dysphagia is caused by obstructive lesions or more rarely by neuromuscular disorders. The common intrinsic lesions are inflammatory strictures secondary to reflux or tumours. Extrinsic compression may occur as a result of mediastinal lesions or vascular disorders (for example an aortic aneurysm). Neuromuscular disorders such as diffuse oesophageal spasm and dystrophia myotonica are much less common than obstructive pathology. The duration, progression, and frequency of symptoms help determine the likely nature of the pathology. Steady progression of dysphagia over a few weeks suggests malignant obstruction whereas association with a long history of heartburn suggests an inflammatory stricture. The dysphagia of neuromuscular disorders is usually confined to solids, and progresses, whereas that of achalasia is initially episodic and in the early stages often wrongly attributed to a functional disorder.

Heartburn

Heartburn is an extremely common symptom. It is an episodic lower retrosternal or epigastric burning that radiates upwards. It is caused by gastro-oesophageal reflux and commonly occurs an or hour or two after meals (especially if these are fatty or spicy); it may be precipitated by heavy physical work and bending. Symptoms often occur on lying down and are characteristically relieved by the ingestion of antacids. Most pregnant women suffer heartburn.

Oesophageal pain

Odynophagia is oesophageal pain felt within 15 s of swallowing and may be associated with the impaction of a lump of food at a site of mechanical blockage or a hold-up with oesophageal spasm. Odynophagia without hold-up occurs with intrinsic inflammatory disorders (such as reflux or candidal oesophagitis) and extrinsic disorders (such as mediastinitis). Hot liquids and alcohol may cause odynophagia in a normal gullet (the so-called 'tender oesophagus').

Oesophageal pain not clearly related to swallowing is characteristically retrosternal, often has a crushing quality, and may radiate to the jaw thereby mimicking cardiac pain. Patients with these symptoms are usually investigated for angina before being referred to a gastroenterologist: some will be shown to have reflux-associated chest pain or a primary disorder of motility (e.g. diffuse oesophageal spasm). High-amplitude contractions of the distal oesophagus are often discovered in patients with attacks of chest pain of uncertain cause and these are believed to be related to psychological stress.

Dyspepsia, nausea, and vomiting

Dyspepsia, nausea, and vomiting are extremely common symptoms which can be produced by a wide range of conditions from the most serious (such as end-stage neoplastic disease) to the most trivial (such as over-indulgence in food or alcohol). Patients may speak of indigestion (to describe any low-grade upper abdominal discomfort) and sickness (to describe either nausea or vomiting).

Dyspepsia

Dyspepsia is upper abdominal or lower chest discomfort or pain related to eating which may be described by the patient as a burning, a heaviness, or an aching and is often accompanied by other symptoms such as nausea, fullness in the upper abdomen, or belching. Although the symptoms of upper gastrointestinal disease are imprecise and non-specific, care in taking the clinical history will often facilitate making the correct diagnosis quickly and limit unnecessary investigation. All too often,

an over-stretched, relatively inexperienced clinician will spend a few minutes talking to the patient and then arrange a battery of blood tests, gastrointestinal endoscopy (and biopsy), ultrasonic examination of the abdomen, and some conventional radiology before telling the patient that he can find nothing wrong (and possibly implying that the patient is too ready to complain). Certain aspects of history-taking yield important clues:

- How clearcut is the patient's description of symptoms? Peptic ulcer often gives well-localized pain in the epigastrium. In about 40 per cent of patients with dyspepsia this comes on after a meal and wakes the patient at night. Attacks of central abdominal pain which cause the patient to double up may indicate gallstones although, if there is associated cholecystitis, the pain is more likely to be in the right upper quadrant (often radiating to the right shoulder).
- For how long has the patient had symptoms and how constant are they? A short history makes organic disease likely.
- Has the patient any associated diseases and what drugs are being taken? Many drugs cause upper abdominal symptoms especially aspirin and non-steroidal anti-inflammatory drugs.
- Has the patient lost significant weight? Are there associated symptoms? Vomiting suggests organic disease, alcoholism, or pregnancy.
- Has the patient any worries or anxieties that may be related to dyspepsia of recent onset (especially in women and in the young)? Sometimes patients will deliberately conceal their worries for fear that the clinician will too readily accept them as the cause of their symptoms.
- Details about dietary habits, smoking, and intake of alcohol should be obtained and it may be necessary not to take what the patient says at face value.

For the older patient (over 45 years) with dyspepsia of recent onset, gastroscopy is nearly always indicated in order to identify early gastric cancer. By the time the patient has the classical triad of symptoms of this disease—loss of appetite, loss of weight, and loss of strength—it is usually too late to achieve a surgical cure. Regrettably the early symptoms of gastric cancer are usually mild and non-specific.

The symptoms of patients known to have infection with *Heliobacter pylori* by serological testing are difficult to assess. Most infected patients are symptomless and most of those who have dyspeptic symptoms without ulceration are not cured by treatment with appropriate antibiotics.

Nausea

The term nausea should be restricted to the feeling of being about to vomit. Acute nausea is usually accompanied by hypersalivation. Nausea is caused by labyrinthine stimulation (as in motion sickness); distension of hollow viscera, or any severe somatic pain and by some drugs, especially opiates and those used in chemotherapy for malignant conditions.

Again the clinician has to define carefully what the patient means by nausea. It may be used to describe anorexia, an aversion to food, abdominal fullness, or a sinking feeling in the abdomen. In the absence of a recognizable cause persistent or frequent nausea without vomiting often proves to be psychologically determined.

Vomiting

Vomiting is the forceful ejection of gastric contents through the mouth by the co-ordinated contraction of abdominal and gastric muscles with relaxation of the lower oesophageal sphincter. Non-productive vomiting is called retching. Vomiting occurs with peptic ulceration, especially when there is delayed gastric emptying (pyloric stenosis), and with advanced gastric cancer. It occurs with disorders of the biliary tree (especially as a result of gallstones) and with acute pancreatitis (in which it is a prime symptom). It is an important symptom of intestinal obstruction, especially with lesions above the ileocaecal valve, and it may occur with any cause of peritoneal inflammation such as appendicitis. Metabolic causes of vomiting include diabetic ketoacidosis, hypoadrenalism, and uraemia. Drugs which cause vomiting include opiates, some antibiotics (for example erythromycin), and chemotherapeutic agents. Alcoholism, raised intracranial pressure, and pregnancy are important causes of early morning vomiting.

Effortless vomiting without a definable cause may be psychogenic. This is usually a disorder of young women many of whom have suffered psychological trauma (such as sexual abuse). It is not related to the vomiting of bulimia, a condition that is part of the anorexia nervosa syndrome (see Chapter 26.5.5). Rumination has to be distinguished from vomiting. Rumination is the repetitive regurgitation of gastric contents into the mouth after meals, the regurgitated material then being reswallowed. It is not associated with nausea, heartburn, or discomfort and often appears to be simply an acquired habit.

Abdominal pain

Pain in the 'acute abdomen'

Most patients with acute abdominal pain are promptly referred to a surgeon. However, this does not always happen and the end-result may be disastrous. Thus all clinicians should be able to assess a patient with acute abdominal pain. The site of the pain is usually helpful, but it is diffuse or atypical in at least 25 per cent of patients with acute gastrointestinal pathology. It is important to determine whether movement or coughing aggravate the pain as in appendicitis and generalized peritonitis (including perforated peptic ulcer and pancreatitis). Pain exacerbated by inspiration points to pathology in the upper abdomen (especially cholecystitis) or adjacent to the diaphragm. A detailed analysis of the type of pain is usually unhelpful but it is useful to know if it is intermittent, colicky, or constant. Some pain radiates in a characteristic manner—urological (loin-to-groin), gynaecological (to the back or thigh), and cholecystitis (to the shoulder tip). In contrast, the pain of appendicitis and diverticulitis does not radiate. The pain of intestinal obstruction is colicky and often associated with vomiting. Severe pain without physical signs and with normal routine tests (laboratory and simple radiological) raises the possibility of mesenteric vascular occlusion especially in patients over the age of 50 years or those known to be at risk of thromboembolic disease. Acute porphyria is the other condition to consider. The pain is diffuse and severe and most frequently occurs in the third decade with females being much more frequently affected than males. Tenderness is almost always absent but tachycardia and anxiety are prominent. During the attack the urine will contain excess †-aminolaevulinic acid and, usually, porphobilinogen.

Upper abdominal pain

Pain in the upper abdomen has been considered under the heading dyspepsia. Upper abdominal discomfort is so common that its presence alone is of no value in distinguishing between those patients with organic disease and those with a functional disorder. Moreover patients with an irritable bowel, diverticular disease, and occasionally with other colonic pathology may have discomfort in the centre of the abdomen which they may describe as indigestion. In such circumstances there is usually also a history of some change in bowel habit that will indicate the true nature of the condition. Disease in the small intestine is proportionately rather uncommon and is frequently misdiagnosed as an irritable bowel. Symptoms are rarely specific but should be reinterpreted in the light of screening investigations (such as the blood count, a straight radiograph of the abdomen, and assessment of serum markers of inflammatory disease).

Lower abdominal pain

With lower abdominal pain analysis of symptoms often does not help to determine the cause. Indeed inflammatory and neoplastic colonic disorders often may not give rise to pain and when pain does occur, it is usually diffuse and central. However, focal pain and tenderness in the left iliac fossa often indicates diverticulitis and, more rarely, colonic cancer. Focal pain in the right iliac fossa may be a marker of Crohn's ileocaecal disease. The passage of stool or flatus will often relieve the pain of colonic disease and an irritable bowel; in contrast it tends to exacerbate the pain of local rectal conditions. A history of recent-onset lower abdominal pain in patients over the age of 40 years is an indication for prompt investigation.

Proctalgia fugax is a very painful paroxysmal perineal pain occurring unexpectedly often at night and may last for up to half an hour. The pathogenesis is uncertain and it is unassociated with any signs of disease. The condition is often recurrent but is self-limiting.

Diarrhoea and constipation

The general public knows well what is meant by 'an attack of diarrhoea' or 'being constipated' but these conditions are not easy to define in medical terms. First one must recognize that to a lay person, constipation means passing a stool less often than normal and usually with difficulty. But 'normal' may be anything from two or three times a day to two or three times a week. Moreover the mass and consistency of a normal stool varies considerably depending on diet, gender, and individual factors. Subjects eating a Western diet pass 80 to 200 g of stool each day with more women at the lower end of this range. To add to the difficulty of assessing bowel function, the frequency of bowel habit may bear no relation to the volume of faecal material passed nor to the amount of stool in the colon. Thus care must be taken to define exactly what is happening and it is advisable to take the common-sense view that a change in normal bowel habit is significant. Two warnings are appropriate:

first, most people are loath to mention incontinence (they will usually say that they have diarrhoea and will have to be asked specifically about soiling); secondly in those with persistent unexplained diarrhoea, it is best to examine the stool because patients' descriptions of their faeces are often uninformative.

Diarrhoea

The clinician needs to understand some basic gastrointestinal physiology in order to understand the mechanisms of diarrhoea and to make sense of a patient's symptoms (Table 1). Most cases of diarrhoea can be diagnosed quite simply from the history, an examination of the stools, and, when appropriate, direct examination of the rectal mucosa. Acute infective diarrhoea is recognized by its recent onset, sometimes preceded by nausea or vomiting and a general systemic upset. Abdominal pain often occurs with *Campylobacter* infection, and although passage of blood and mucus can occur with any severe infection, it is more common with *Shigellosis* and infection with *E. coli* 0157.

In assessing chronic or recurrent diarrhoea, it is worth trying to distinguish diarrhoea of large bowel origin from that of the small intestine. Large bowel diarrhoea characteristically occurs on rising, may be associated with pain which is relieved by defaecation, and often contains mucus and sometimes red blood. The differential diagnosis usually rests between inflammation and neoplasm. Small bowel diarrhoea occurs at any time, and although often watery, the stool may also contain excess fat. Steatorrhoea occurs in coeliac disease, pancreatic insufficiency, stagnant loop syndromes, and massive intestinal resection. Drugs (such as beta-blockers, diuretics, antacids, and antibiotics) as well as excess intake of beer may also cause diarrhoea.

In assessing diarrhoea that otherwise remains unexplained, it may be worth distinguishing between osmotic and secretory mechanisms. This is done by measuring the concentration of the major cations (sodium and potassium) and stool osmolality. If the measured osmolality is little more than the sum of the cations multiplied by two (to allow for the unmeasured anions), then the patient has a secretory diarrhoea. In contrast, if there is a significant osmolar gap then there must be another solute in the stool. Unfortunately this test may be unreliable if the volume of stool is less than 500 to 600 ml per day.

Constipation

Each year about 1 per cent of the population consult their family doctor complaining of constipation. The mode of presentation ranges from the acute onset of colonic obstruction to a lifelong disability. The most common causes of constipation are shown in Table 2. In taking a clinical history it is important to determine exactly what the patient means by constipation. A relatively sudden change in bowel habit without any significant change in dietary habit or medication suggests an organic disorder. A desire to defaecate, especially if associated with colicky discomfort, suggests organic obstruction. Constipation from a young age increasing slowly with time indicates a disorder of normal colonic function, a condition that is much more common in women than men. Colon physiologists distinguish between 'slow transit' and 'outlet obstruction' constipation (Fig. 1) but this distinction is of limited value in management. 'Low fibre' diets (as ingested by many young people living away from the family home for the first time), some drugs (especially opiates and drugs with anticholinergic activity such as antidepressants), metabolic disorders, and neurological disease must be considered—although in most cases no cause can be established. In women it is also necessary to consider the obstetric history and to consider the possibility of pelvic floor dysfunction. Straining at stool over a prolonged period may lead to rectal prolapse and incontinence and it may be necessary to ask the patient specifically about such symptoms.

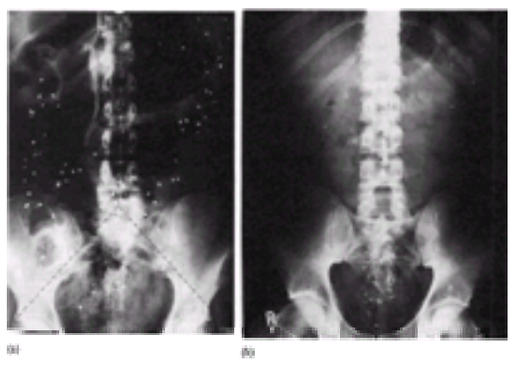

Fig. 1 Functional constipation illustrated by the use of markers (patient takes one marker capsule daily for 14 days, each capsule containing 10 radio-opaque pellets). (a) Abdominal radiograph of a 58-year-old woman with 'slow transit' constipation (colonic inertia). Seventy three pellets were retained after 14 days equally distributed between right and left colons (mean transit time 7.3 days, median normal for women 3.0 days). (b) Abdominal radiograph of a 30-year-old man who, a year previously, had an emergency laminectomy for an acute prolapsed disc. He complained of constipation since the operation and was shown to have 'outlet obstruction' presumably due to impaired rectoanal reflexes. Fifty seven pellets were retained with nine in the right colon, nine in the left colon, and 39 in the rectosigmoid segment (mean transit time 5.7 days, median normal for men 2.3 days). 14.2.1 Colonoscopy and flexible sigmoidoscopy

Christopher B. Williams and Brian P. Saunders

Development

Colonoscopes are similar to gastroscopes, but with greater flexibility to pass loops in the bowel. Early instruments had limited angulation and relatively clumsy characteristics. Colonoscopy was therefore initially looked on as a second-line procedure, time-consuming and potentially traumatic. Polypectomy was introduced in 1972 and this, coupled with recognition of the accuracy of the technique and (with biopsies) in diagnosing or excluding inflammatory disease or neoplasm, started an explosion of demand. Development of video-colonoscopes in the 1980s added high quality videotaping and prints which, with improved and more agile instruments, has contributed to making colonoscopy acceptable both for routine clinical use and for well-person surveillance and screening.

Colonoscopes range from 60 to 70 cm flexible sigmoidoscopes, thin very flexible paediatric instruments also used in adults with fixation or stricturing, up to 165 cm long colonoscopes with different flexibility characteristics and instrumentation channel sizes. Further technical improvements include higher resolution and zoom-magnification, better control ergonomics, adjustable shaft flexibility and electronic means of imaging shaft loops on-screen without fluoroscopy. Ultrasound colonoscopes, thin ultrasound probes for use with conventional instruments and magnetic resonance-compatible scopes are also being evaluated.

A large range of accessories can be introduced through the suction/instrumentation channel of a colonoscope, including biopsy or grasping forceps, washing, spraying or deflation tubes, cytology brushes, and injection needles. Therapeutic accessories include insulated forceps, polypectomy snares and retrieval devices, coagulating probes and argon plasma coagulating catheters, laser light guides, haemostatic clip and nylon loop applicators, dilating balloons, and metal stent introducers. It is also possible to preload onto the tip means of applying constricting loops or bands. Use of an external 'overtube' allows a looping instrument to be stiffened or exchanged for another without having to recommence the procedure. CO_2 insufflation apparatus is available which, since the gas is exhaled within 10 to 15 min, ensures that patients are not left distended after the procedure.

Cleaning and disinfection

As for all flexible endoscopes, skilled maintenance, regular checks, and meticulous cleaning are essential. All parts, including air, water, and instrumentation channels must be accessed during cleaning. It is not possible to sterilize a colonoscope but, after scrupulous mechanical cleaning and 'high level disinfection' (usually in an automated washing machine with 2 per cent glutaraldehyde solution and subsequent rinse cycles), all viral agents (including HIV and hepatitis B) and bacteria are inactivated. It takes at least 30 min to clean and disinfect an instrument so, allowing for repairs, three or more colonoscopes are needed to provide a routine service. Mycobacterial spores require even longer (60 min) exposure; prolonged disinfection is therefore recommended before and after examination of AIDS patients, not only because of patient susceptibility to infection but also their increased likelihood of harbouring mycobacteria. Accessories may be disposable or require autoclave sterilization or high-level disinfection, as directed by the manufacturers.

Patient preparation

Flexible sigmoidoscopy preparation is normally by disposable enema (hypertonic phosphate or similar) given or self-administered 10 to 15 min before the procedure. Some patients prefer to avoid the indignity of an enema by taking full oral preparation and this is also advisable in any patient with a colon narrowed by pronounced diverticulosis or stricturing.

Full bowel preparation is usually the most unpleasant part of colonoscopy. Oral preparation must be preceded by dietary restrictions, which include stopping iron or constipating agents in the preceding days, and taking low fibre diet (with no nuts, mushrooms, or iron-containing red wine) for 24 h.

Purgative preparation is cheap and generally best tolerated, but some individuals can suffer considerable cramping, explosive incontinence, or vasovagal reaction. A senna preparation on the afternoon or evening before exam is followed 2 to 3 h later by an osmotic purge (commonly magnesium citrate, sodium phosphate, or mannitol 10 per cent). The last dose should be taken only a few hours before the procedure to avoid the solidifying action of the proximal colon. Large quantities of clear fluids (including alcohol in moderation) are encouraged up to the time of examination to avoid adherent residue, which is difficult to flush or aspirate.

Fluid overload is the alternative approach, achieved by ingestion of 3 to 4 l of isotonic solution, usually polyethylene glycol (PEG)–electrolyte solution which avoids the electrolyte losses that occur if normal saline or 5 per cent mannitol are used. This approach is ideal for patients with active inflammatory bowel disease. Commercial PEG–electrolyte preparations can be prepacked for postage and are flavoured. Around 10 per cent of patients become nauseated, vomit, or become distended and stop drinking, any of which results in poor preparation, especially in the proximal colon.

If there is any possibility that the patient is obstructed, full oral preparation is contraindicated because of the possibility of perforation; a smaller volume should be given, supplemented by enemas. In the presence of massive bleeding it may be preferable to proceed direct to colonoscopy and rely on the purgative effect of blood, rather than waste time on preparation. In extreme cases of overwhelming blood loss peroperative 'caecostomy lavage' has been described, but nasal-tube lavage is a more usual compromise before emergency colonoscopy.

Psychological preparation of the patient should not be forgotten, since most of those scheduled for colonoscopy are apprehensive, whether through embarrassment, expected discomfort, or fear of colorectal cancer. Explanatory literature and a friendly telephone manner at the time of booking the exam can help a great deal. Equally, a warm and reassuring atmosphere on reception, whilst obtaining 'informed consent' and also during the procedure, can help transform colonoscopy from an ordeal into a reasonable and well-tolerated experience.

Medication

'Conscious sedation' is offered to most patients, unless they are likely to be easy to examine (flexible sigmoidoscopy, with a previously easy examination, or sigmoid resection or stoma) or are motivated to try without medication. The unpleasant gnawing quality of 'visceral pain' caused by the inevitable stretching of colon or attachments during insertion are tolerable for a few spells of 20 to 30 s. Prolonged examinations or the lowered pain threshold of patients presenting with features of irritable bowel syndrome or diverticulosis can be made considerably more pleasant with a minimal dose of a sedative–analgesic combination. Combing a low dose of benzodiazepine (typically, midazolam 2–3 mg, intravenous), with an opiate analgesic (pethidine 25–50 mg, intravenous) reduces discomfort and anxiety and gives the patient a well-deserved feeling of euphoria. Low-level sedation of this kind does not inhibit conversation, the ability to complain of pain or to change position when necessary. Smaller doses should be given in small, elderly, and sick patients but incremental larger doses (especially opiate) can be needed in apprehensive, younger ones. Pulse oximetry monitoring is routine and nasal oxygen, resuscitation equipment, and reversal agents (flumazenil, naloxone) should be immediately accessible. Sedated patients must be accompanied home. On-demand, self-administered nitrous oxide/oxygen inhalation has been shown by some to be equally effective for skilled endoscopists, giving rapid recovery and allowing return home without escort.

General anaesthesia is rarely needed and generally best avoided, since in an unconscious patient position change is made more difficult and removal of the warning given by pain may tend to more aggressive technique. For the few patients with particular reasons for general anaesthesia and an expert encoscopist, propofol anaesthesia gives excellent results and also more rapid recovery than after high doses of conventional sedatives. In certain countries with enough anaesthetists

available (France, Australia) this approach is commonly employed, whereas in others (Germany, northern Italy, Japan, China) unsedated colonoscopy is routine.

Antispasmodics are decried by many, on the basis that they are thought to elongate the colon and make insertion more difficult. In randomized trial, we have shown this to be untrue and routinely use them (hysocine-*N*-butyl bromide) both in order to speed insertion and to optimize the view for greater accuracy.

Antibiotics are only given to those with immunosuppression or immunodepression, previous endocarditis, heart valve prosthesis, septal defects, recent vascular prosthesis, or ascites.

Flexible sigmoidoscopy

Flexible sigmoidoscopy is the kindest and most logical means of examining proximal to the rectosigmoid junction (15 cm) whereas the rectum and the anal canal are better seen with the appropriate rigid instrument. Paradoxically the sigmoid colon, especially the sigmoid-descending colon junction, is the most difficult part of colonoscopy. In the presence of severe diverticular disease it may be impossible to reach even mid-sigmoid without expertise and a thin endoscope; after hysterectomy it may be cruel to examine without sedation. For this reason, although flexible sigmoidoscopy is both better tolerated and more accurate and effective than aggressive, rigid proctosigmoidoscopy, depth of insertion should be limited to what is tolerable by the individual patient. Some endoscopists mistakenly attempt to 'reach the splenic flexure' routinely. This is potentially unkind and also a mistaken concept. Without fluoroscopy or the use of newer means of imaging, even expert endoscopists can be completely mistaken between sigmoid-descending junction and splenic flexure. At 60 cm of insertion the 'scope tip can be anywhere between mid-sigmoid and caecum, and there are no positive localizing landmarks.

Insertion of the 'scope tip usually follows digital lubrication with jelly, the blunt tip of the instrument being gently inserted as the sphincters relax. Thereafter the 'scope is coaxed in as gently as possible, without haste or force, steering and 'cork-screwing' around bends with twisting movements. Blind insertion with 'red-out', guesswork, or 'push through' are all avoided as far as possible. Any small polyps (up to 5 mm) that may be adenomas are normally snared or destroyed at once, as they may be difficult to see on withdrawal or if left for subsequent colonoscopy. Because of the remote possibility of explosive gas concentrations after limited preparation, either repeated suction with air reinflation or use of CO_2 should precede electrosurgery; alternatively 'cold snaring' with physical removal of the polyp can be employed. If in doubt a biopsy can be taken, both to give some idea of the size of any lesion against the open forceps and to give partial histology.

Total colonoscopy

In expert hands, and in the absence of obstruction, a severely ulcerated colon, or other contraindication, total colonoscopy is possible in over 99 per cent of cases, with little sedation or suffering and virtually no complications. In less expert hands 'total colonoscopy' or 'completion' rates as low as 33 to 45 per cent have been reported and 75 per cent is common. The principle difference in technique between expert and inexpert is the ability, whilst keeping sufficient orientation for steering purposes, to pull-back and crumple the looped segment of colon already traversed, whilst simultaneously straightening the way or bend ahead. The ideal is to keep the colonoscope as straight as possible and to pleat or 'concertina' the colon over it, avoiding the unnecessary loops and pain by caused by pushing too hard or too long. The ideal is not always immediately achievable, so patience and determination—tempered by humanity—are essential qualities for the colonoscopist.

Paradoxically a freely mobile colon, without the conventionally fixed segments in the descending and ascending parts, can be as difficult to traverse as one with adhesions. This is principally because atypical loops may form, sometimes uncontrollable until the instrument tip eventually reaches a fixed point, giving a 'hold' and allowing the shaft to be straightened back. Happily, this type of long and mobile colon, whilst being a nightmare for the endoscopist, typically also has long enough attachments that the patient experiences little discomfort.

From the point of view of the patient, colonoscope stretch discomfort is frequently felt as 'wind pain', rapidly relieved as soon as the causative loop can be straightened. True over-distension is easily removed by aspiration. Further distress may be produced by the unpleasant illusion of incontinence given when the body-warmed and lubricated shaft is withdrawn through the sensitive anal canal; it is kind to prewarn the patient of this phenomenon and to preserve decorum by aspirating any fluid found during insertion through the rectosigmoid.

Once the colonoscope has successfully passed into the descending colon and has been straightened back to remove sigmoid colon looping, it is likely that the rest of the insertion phase will be considerably easier. When the 'scope shaft is straight it feels responsive and free, as do the angling controls—whereas the more looped the colonoscope is the more 'snarled up' everything becomes, and the more the patient suffers. Avoiding looping and responding to pain are the basis for successful, kind, and safe insertion. It also minimizes instrument repair bills and maximizes accuracy and ease of targeting lesions, since a straight instrument handles better.

This practical philosophy underlies the reason for simple but effective 'tricks of the trade' such as position change. It is obvious that in left lateral position there will be pooling of any fluid in the left colon; the transverse colon will also tend to sag down and so make the splenic flexure more acute. It therefore follows that, at the splenic and any flexure where there is a poor view or difficulty in insertion, position change may improve matters (to supine or right lateral at the splenic, but back to left lateral again for hepatic flexure). Adding only the simple principles of pulling back as often as possible to straighten each loop before tackling the next, avoiding over-distension to keep the bowel reasonably deflated and supple, and trying assistant hand-pressure whenever an unavoidable loop may be accessible (sigmoid and transverse colon) and the 'art of colonoscopy' is explained. Insensitivity, impatience, aggression result in the endoscopist being too muscular and tense to handle the shaft and controls sensitively, and so cause needless looping, pain, failure, and complications.

Contraindications, risks, and limitations

There are few contraindications to colonoscopy. It is, however, a relatively strong vasovagal assault with potential for arrythmias and so is contraindicated for 2 to 3 months after myocardial infarction. The tip, shaft, and air pressure involved in insertion have potential to exacerbate any existing risk of perforation. Colonoscopy is thus contraindicated in the acute phase and 2 weeks after an episode of diverticulitis, and also in severe acute or deeply ulcerated colitis of any variety (ulcerative, Crohn's, ischaemic, or infective). Patients with acute localized or rebound tenderness of the abdomen, free air, or dilated colon on radiograph should not be submitted to colonoscopy without special reason, due consultation, and by an expert endoscopist—who may decide to abandon the procedure.

The risks of diagnostic colonoscopy, as implied above, are to a great extent related to the training, personality, and handskills of the endoscopist. Regrettably large-scale audit shows figures of around 1 perforation in 1500 examinations, although this can be balanced against avoidance of the considerably worse complications of surgery. Therapy inevitably increases the likelihood of complications, principally bleeding but occasionally perforation after polypectomy or dilatation. Perforation may be actual (needing surgery) or threatened as the 'postpolypectomy syndrome' (managed conservatively with rest and antibiotics). Immediate bleeding can occur in around 1 per cent of polypectomies but is usually easily stopped by submucosal adrenaline injection (5–20 ml of 1/10 000 dilution, which is safe because of portal drainage) or by local electrocoagulation, clipping, or nylon loop application. Delayed haemorrhage can occur for up to 10 to 14 days after removal or local coagulation of even small polyps; it is usually self-limiting, but can be substantial and require admission to hospital and transfusion. Aspirin has been implicated as a risk factor in some series and should ideally be stopped for a week before and after polypectomy. Anticoagulants and other antiplatelet agents should similarly be withdrawn if possible or special measures instituted.

The greatest causes of colonoscopy-related mortality (1 in 10 000 exams) are patients referred (not always correctly) for surgery following endoscopic complications and deaths directly due to over-sedation, usually in the elderly. There have been unnecessary deaths when an internist has persisted in conservative management without involving a surgeon in management of suspected perforation. Surgical fatalities or major morbidity have resulted in others found at operation to have only a point perforation which would clearly have sealed spontaneously. In managing suspected perforation, due consultation between endoscopist and an endoscopically-aware, preferably laparoscopy-oriented, surgeon is essential. The need to modify sedation is described above and the endoscopist should also not be too proud to abandon an examination which is proving unreasonable, rather than to 'flatten' the patient. CT colography ('virtual colonoscopy') can image the proximal colon during the same visit.

The major limitations of colonoscopy relate to the fact that it is dependent on hand-skills and that tortuous, angulated, and haustrated colonic anatomy results in some 'blind spots' for the endoscopist. Areas that the endoscopist sees are extremely accurately evaluated, with a resolution of under 1 mm. The percentage of mucosa unseen is uncertain but is probably around 10 to 15 per cent overall. The likelihood of larger and 'significant' lesions being missed is much lower than this because colonic neoplasms are usually protuberant. Paradoxically, pathology can be missed in the capacious distal rectum or the anal canal, which can be avoided by retroverting the endoscope and/or examining with a rigid proctoscope as well.

Indications

The indications for colonoscopy are wide and constantly expanding, and are likely to continue to do so until alternative and less invasive techniques ('virtual colonoscopy' or genetic tests) are perfected. Where there is a shortage of endoscopic personnel, skill, or facilities it is possible to reduce the load of 'total colonoscopy' either by cross-referring for radiographs or related imaging techniques. It is also possible to combine these with prior flexible sigmoidoscopy on the same visit on the basis that limited colonoscopy covers the highest yield area, which is also the most prone to 'misses' or over-diagnosis.

High-yield indications include patients with bleeding, anaemia, or occult blood loss. Persistent bleeding, especially if dark or 'mixed-in' with the stool, is of sinister import, although it can be due only to local mucosal traumatization in diverticular disease. Good clinicians may select out for sigmoidoscopy alone patients with obviously fresh bleeding on defecation or with spotting 'on the paper'. However, the presence of blood in a patient of 50 years or more (so at-risk for colorectal neoplasia) is increasingly used as an excuse for the reassurance of a whole colon screening examination. Of all patients with blood loss referred for colonoscopy, around 10 per cent will have a 'significant' lesion, either a neoplastic polyp of 1 cm diameter or greater or malignancy. Colonoscopy is considered the investigation of choice for major bleeding, being readily available and offering immediate therapy and a high degree of diagnostic accuracy. Angiodysplasia, small ectatic vascular lesions in the proximal colon of elderly subjects with bleeding or anaemia, are relatively rare but are an example of a condition easily diagnosed and treated by colonoscopy—but by virtually no other method.

Chronic diarrhoea or known inflammatory disease is accurately and easily assessed by endoscopy and biopsy. The terminal ileum can be accessed or biopsied in over 80 per cent of cases by an experienced endoscopist. Endoscopic differential diagnosis between the focal or 'apthoid' (mouth-like) ulcers with intervening normal mucosa in Crohn's disease and the generally reddened surface of ulcerative colitis is easy and definitive in around 90 per cent of cases. A few remain as 'indeterminate colitis' and differential diagnosis can be more difficult in severe or chronic cases. The possibility of infective colitis, including tuberculous or amoebic, must be borne in mind and extra specimens taken for microscopy and culture if in doubt. Biopsies typically show somewhat greater extent of inflammation than is visible to the eye, and so must be taken at intervals around the colon in any patient with bowel frequency, to exclude 'microscopic colitis' or the related phenomenon of 'collagenous colitis'. Chronic inflammatory disease affecting more than half the colon carries an increased long-term risk of cancer or mucosal dysplastic (precancerous) change, and so indicates annual or 2-yearly surveillance from 8 to 10 years after onset of symptoms. Ischaemic colitis, typically affecting a short segment around the splenic flexure, can show changes ranging from mild reddening to marked ulceration or even near gangrene.

Polyps of almost any size can be removed endoscopically, leaving for transanal proctological management only very large, sessile rectal polyps up to 12 cm from the anal verge. Around 5 to 10 per cent of polyps will contain focal, high-grade dysplasia or invasive carcinoma. Even 'malignant polyps' or 'polypoid cancers' having no adenoma present can be managed conservatively by endoscopy alone if complete removal is confirmed histologically by a margin of 1 mm between the limit of invasion and the plane of excision, and the tumour is also well or moderately differentiated. Placing one or more India ink tattoos near the polypectomy site gives a permanent marker for endoscopic follow-up, or localizes it if surgery or laparoscopy is indicated. Lasers have been used for ablation of the postpolypectomy remnants of sessile polyps, but the newer alternative technique of argon plasma coagulation is cheaper, easier, and safer.

Cancer prevention or surveillance colonoscopy gives a strong guarantee to the patient even when negative, both because of the accuracy of colonoscopy and the generally slow time-course of development of colonic neoplasms. Follow-up at 3 to 5-year intervals after polypectomy does yield further adenomas in 30 to 50 per cent of patients, especially those with three or more or large polyps on the initial examination. A large series has suggested that the incidence of colorectal cancer is reduced by polypectomy and follow-up. Patients at genetic risk merit colonoscopic surveillance, especially those with a first-degree relative with colorectal cancer under 45 years of age, two or more affected first-degree relatives, or those assessed genetically as belonging to a 'hereditary non-polyposis colon cancer' family with autosomal dominant risk (see Chapter 14.15). Follow-up, ablating minute or 'flat' adenomas, is scheduled at 1 to 5-year intervals according to perceived individual risk.

Abnormalities on other diagnostic methods are ideally checked colonoscopically. Abnormalities seen on scanning frequently turn out to be spurious, presumably faecal, and the majority of positive occult blood tests prove to be 'false' for neoplasm. Supposed 'strictures' on barium enema often prove to be due to spasm or uncomplicated sigmoid diverticulosis. Others, such as anastomotic strictures, typically after Crohn's resection, are usually easily and effectively balloon-dilated. Even patients with typical malignant 'apple-core' strictures should ideally have preoperative total colonoscopy to exclude other synchronous neoplasms, if necessary using a small-diameter instrument (sometimes a paediatric gastroscope). If this proves impossible, endoscopy should be rescheduled within 6 months after resection. Colonoscopy has effectively supplanted 'diagnostic laparotomy'; it also avoids the numerous resections previously performed in diverticular disease when radiographs could 'not exclude the possibility of malignancy'—which the endoscopist can in a few minutes.

There are low-yield indications for colonoscopy, where alternative investigations such as flexible sigmoidoscopy, barium enema, 'virtual colonoscopy', or other approaches may be justified. These include patients with simple constipation of long standing, bloating, left iliac fossa discomfort, or combinations of these symptoms suggesting 'irritable bowel syndrome'. Where the patient is young, the extra accuracy of 'one-off' colonoscopy may be justified. In elderly patients, the greater likelihood of diverticular disease and difficult (and so more hazardous) colonoscopy may be a further disincentive, although these patients find the distension and manoeuvres of barium enema more unpleasant than sedated colonoscopy.

Cost effectiveness and relationship to other techniques

Flexible endoscopy seems superficially expensive and is demanding of professional time. However, modern colonoscopes are surprisingly robust and, properly handled and maintained, will perform thousands of examinations without expensive repairs.

Newer teaching methods, including use of computer simulation to improve handskills, should help to improve standards and speed training of doctors in colonoscopy and nurse practitioners to undertake flexible sigmoidoscopy.

Sigmoidoscopy provides rapid, unsedated examination, so allowing 'one-stop' patient management and avoiding the need to return for prepared exam–whether colonoscopy, radiography, or scanning. Flexible endoscopy has the general advantage that it leaves only gas (air or CO_2) in the colon, and so can be followed by any other modality if complete, whereas barium takes several days to clear.

Total colonoscopy, its accuracy increasing to near microscopic levels with newer and more agile instruments, is likely to remain the diagnostic 'gold standard' for the foreseeable future. Other, newer methods such as 'virtual' colonoscopy and genetic screening, may have an invaluable screening and selection role, but are unlikely to provide definitive tissue diagnosis or therapy. Endoscopy, providing that the bowel is prepared appropriately, can follow immediately to check or treat patients with a positive scan. It is therefore possible that colonoscopy will, in future, relinquish some of its present front-line role, but it is highly likely that requirements for it will increase if population screening for the prevention of colorectal cancer becomes routine.

14.2.2 Upper gastrointestinal endoscopy

Adrian R. W. Hatfield

Background

Subsequent to the pioneering work on the transmission of light down flexible optic fibres by Professor Hopkins in 1954, 'gastro-cameras' were replaced by early, flexible, fibre optic endoscopes in the mid-1960s, which led to the development of gastrointestinal endoscopy as we now know it. A major disadvantage of fibre optic endoscopes has been the deterioration of the fibre bundle with time leading to poor images. The recent availability of cheaper, miniaturized colour chips has led to the development of video endoscopes, providing an excellent, clear view which does not deteriorate with the age of the endoscope. With appropriate improvements in software, the endoscopic video image can be magnified and modern instruments will zoom up to 25 × magnification and the mucosal detail can also be enhanced electronically so that small lesions of a few mm can be seen quite clearly. The modern video endoscope image can be instantly printed out and archived digitally on a computer system.

The external specifications and handling of the new video endoscopes are similar to their previous, fibre optic counterparts and thus the techniques for disinfection and endoscopy are similar for both ranges of equipment. The disadvantage of the modern equipment is that the video endoscopy system needs considerable hardware. In most instances a video monitor, light source, and processor are located in an endoscopy unit and not easily moved to a different location such as an operating theatre for emergency endoscopy. In the acutely bleeding patient, the presence of blood in the lumen of the gastrointestinal tract diminishes the efficiency of the video chip and the image obtained is often poor. In this situation, a conventional fibre optic endoscope will often give a much better view and will be more easily taken into the operating theatre for such an emergency.

Endoscopy units and disinfection techniques

It is now well recognized that the care of the instruments and other equipment, together with the important aspects of patient safety, are greatly improved by having a purpose built endoscopy unit staffed by experienced endoscopic nursing staff who are trained in handling and disinfecting endoscopes and patient safety during and after intravenous sedation.

Most endoscopy units have a purpose built disinfecting machine which can take single or multiple instruments and, after suitable mechanical cleaning, a disinfecting agent will be automatically pumped through the channels of the instrument for a given period of time and flushed out afterwards. The choice of disinfecting agent varies between units but the trend has been away from hazardous agents such as glutaraldehyde (Cidex) to less harmful agents, such as Nu-Cidex or Tristel, that do not need sophisticated extraction and ventilation.

For routine, simple diagnostic upper gastrointestinal endoscopy many patients are now routinely endoscoped without sedation, after local anaesthesia to the throat only. 'No sedation endoscopy' is suitable for busy units with long lists of day cases. However, large numbers of endoscopies, particularly in apprehensive or sick inpatients and those needing more complicated procedures, are still performed under intravenous sedation.

There are now clear guidelines, drawn up by the British Society of Gastroenterology, as to the practice of administering intravenous sedation for endoscopic procedures. Patients are now monitored with pulse oximetry and oxygen is given routinely to the ill or elderly and to other patients if oxygen saturation falls during the procedure. The precise choice of sedation will vary between units and will depend on the patient and the type of procedure performed, however diazemuls and midazolam remain the two most common sedative agents used, often combined with pethidine for more lengthy or invasive procedures. It is not uncommon to reverse the effect of the benzodiazepine sedation with flumazenil (Anexate) and any opiate sedation with naloxone (Narcan). On rare occasions general anaesthesia will need to be used for endoscopy, usually for children or adults with ventilatory problems.

Specific risk of infection with endoscopy

Patients with heart murmurs were routinely given antibiotics to cover endoscopic procedures in the past. It is now recommended that only patients with prosthetic valves need be given routine prophylactic antibiotic cover, with a single parenteral dose of a broad-spectrum penicillin before the procedure.

Current disinfecting agents and schedules will cope with hepatitis B and C and HIV infection. All endoscopic staff wear disposable gloves and the nurse nearest the patient's mouth will usually wear a visor to cover eyes, nose, and mouth, particularly with a patient of known infective risk. As there is no effective way of sterilizing an endoscope against prions (at present thought to be the transmissible agent in Creutzfeldt–Jakob disease), the current Department of Health Guidelines make it clear that all equipment used on patients with suspected Creutzfeldt–Jakob disease should be destroyed afterwards. Patients with suspected Creutzfeldt–Jakob disease are not therefore endoscoped and alternative ways of diagnosis or treatment are usually sought.

Diagnostic endoscopy in the gastrointestinal tract

Endoscopy has now become the investigation of choice in patients with retrosternal or upper abdominal symptoms where, previously, barium radiology would have been employed. The advantages of detecting grades of inflammation and erosive change, rather than radiologically obvious ulceration, are obvious. Equally, the ability to take samples from the gastrointestinal tract with brush cytology or biopsy greatly enhances the diagnosis, not just in differentiating between benign and malignant ulcers and strictures, but also in assessing degrees of inflammatory change and in detecting dysplasia, for example in Barrett's oesophagus.

Endoscopy will detect oesophageal varices in patients with liver disease at an early stage. In the symptomatic patient with liver disease and gastrointestinal bleeding, endoscopy is particularly important as the site of bleeding may be variable and the management very different. Bleeding oesophageal varices can be managed endoscopically in a number of therapeutic ways.

In the last 10 years, it has become routine to take gastric biopsies in patients with peptic problems to detect the presence of *Helicobacter pylori*. The routine use of a simple CLO test, where mucosal biopsies are inserted into a gelatine well containing a colouring agent that turns yellow to red in the presence of *Helicobacter* urease, will be satisfactory. In some patients, gastric biopsies are necessary in this situation for culturing the bacteria to ascertain sensitivity in patients with infection resistant to multiple eradication therapies. In younger patients where malignant disease is less of a concern, serum, faecal, or breath test analysis is an acceptable alternative to establishing *Helicobacter* infection and thus such patients could be treated initially without endoscopy and gastric biopsy.

Most gastric cancers in the United Kingdom are diagnosed when the patient is symptomatic and thus the finding of a mucosal cancer is rare. Most lesions are straightforward to diagnose endoscopically and biopsies are usually confirmatory. Cancers that infiltrate the wall of the stomach below the mucosa are difficult to diagnose endoscopically as endoscopic biopsies are usually quite superficial. In this situation a 'double punch' type technique is useful, where a second biopsy is taken from the deeper submucosa through the small defect of the first biopsy. 'Linitis plastica' is difficult to assess endoscopically, particularly where Buscopan may have been used routinely to inhibit peristalsis at the start of the endoscopy. In such patients, a barium meal may help in the diagnosis by showing the lack of gastric motility.

Small bowel endoscopy (enteroscopy)

For many years, routine upper gastrointestinal endoscopes were not of sufficient length to pass beyond the duodenojejunal flexure into the small bowel. Enteroscopes are now made that can be advanced under direct vision down the upper small intestine or, alternatively, a thinner endoscope is allowed to pass down the small bowel spontaneously and then the bowel lumen is visualized on withdrawal. Such endoscopic procedures are lengthy and difficult and will not necessarily view the entire small bowel. A more comprehensive view is sometimes obtained, particularly in the hunt for obscure bleeding lesions, by passing a standard upper gastrointestinal endoscope up and down the small intestine through small enterotomies at the time of laparotomy, with a surgeon concertinering the small bowel over the shaft of the endoscope. Recently a video capsule has been developed which, when swallowed, transmits a good view of the entire small bowel during transit through the gut.

The rather lengthy, tedious, and unpredictable techniques of small bowel biopsy using a Crosby capsule have been largely superseded by routine upper gastrointestinal endoscopy with biopsies from the distal duodenum. Such biopsies have been shown to be very representative of the upper jejunal mucosa. This technique is now used routinely in the diagnosis of coeliac disease.

Therapeutic endoscopy in the upper gastrointestinal tract

Over the last 20 years, a wide range of therapeutic manoeuvres have been developed for use in various situations in the upper gastrointestinal tract.

Gastrointestinal bleeding

Oesophageal varices can be injected through the mucosa with ethanolamine oleate under direct vision. Paravasal injection is best avoided as it can lead to secondary bleeding from mucosal ulceration and sometimes later oesophageal stricture formation. Endoscopic sclerotherapy can be repeated at weekly or monthly intervals until the varices have been obliterated. Bleeding gastric varices can also be injected but these are more difficult to obliterate. More recently, endoscopic banding techniques have been employed, both in the acutely bleeding patient and the chronic situation. Single or multiple bands could be put on varices in the oesophagus or, sometimes, in the fundus of the stomach. The addition of thrombin into gastric varices after banding may enhance successful eradication and reduce the risk of bleeding if the bands slip off too early.

Bleeding erosions and ulcers can be injected with dilute adrenaline (1:10 000). This may be satisfactorily in reducing bleeding in the short term and can always be repeated if necessary. Endoscopic laser therapy can be employed around a visible vessel in the base of an ulcer. A similar effect can be obtained by the use of multicontact diathermy probes or heater probes. Bleeding vascular abnormalities, such as angiodysplasia, can be treated with thermal probes but more satisfactorily with non-contact laser which does not pull off a coagulum and has the extra benefit of destroying vessels just below the mucosa.

Benign oesophageal strictures

Commonly, a peptic stricture above a hiatus hernia secondary to reflux will produce dysphagia but benign strictures due to other causes, such the swallowing of corrosive substances and postsurgical anastomotic strictures, can be treated by the same endoscopic techniques. In the past, bougies of increasing size were passed over a previously endoscopically placed guidewire and the stricture slowly dilated. More recently, high pressure dilating balloon catheters, passed over the wire under radiological screening or directly through the scope under direct endoscopic vision, can be used more efficiently and safely with better patient tolerance.

Achalasia of the cardia can be treated with balloon dilatation using a larger balloon of 30 to 40 mm diameter, where the aim is to rupture muscle fibres to weaken the circular muscle sphincter. Alternatively, botulinum toxin can be injected through the mucosa into the muscle sphincter circumferentially at the time of endoscopy. The improvement in swallowing after this procedure is limited and may need to be repeated every 6 months.

Malignant gastro-oesophageal strictures

Most of patients with non-operable tumours of the stomach or oesophagus producing dysphagia are palliated by the insertion of some sort of oesophageal stent. By and large, silicone rubber prostheses have been replaced by self-expanding metal stents which can be very easily and safely placed through a malignant stricture without the need for prior dilatation, thus reducing the risk of perforation. Most of these stents now have a membrane to prevent tumour ingrowth through the mesh but this will sometimes occur at one or either end. Such tumour overgrowth can be treated with endoscopic laser therapy. Brachytherapy can be given via an endoscopically sited tube through the stricture prior to stenting.

Removal of foreign objects

Most solid objects such as marbles, rings, and coins should pass spontaneously and the need for removing foreign bodies is usually because they are sharp and may cause damage if left *in situ*. Most objects can be snared or trapped in a basket and removed intact. Sharp objects can be pulled into a endoscopic overtube to protect the oesophagus during withdrawal.

Polyps and small tumours

Most gastric polyps are entirely benign and do not need removing. Leiomyomas of the stomach or duodenum can be watched if small, but if over 5 cm in size should probably be removed. Often such patients will go directly to surgery but newer endoscopic techniques using submucosal resection can tackle lesions that do not infiltrate beyond the submucosa. Careful prior assessment with endoscopic ultrasound is usually needed to make sure that a small tumour can be technically removed in this way.

Assisted nutrition

There are now many types of enteral feeding tube that can be sited in the upper gastrointestinal tract. Although most fine-bore feeding tubes can be passed on the ward or under radiological control, the prior passage of an endoscopic guidewire into the stomach which is then rerouted through the nose, can allow feeding tubes to be positioned accurately, often through an oesophageal stricture or difficult anastomosis, or positioned in the duodenum in patients with gastric stasis. The endoscopic positioning of a nasojejunal feeding tube, beyond the duodenojejunal flexure, is now becoming a common alternative to intravenous feeding in patients with complicated pancreatitis where 'pancreatic rest' is needed.

Techniques for placing a gastrostomy tube endoscopically (PEG) are now simple and straightforward. After transabdominal puncture into a distended stomach under direct endoscopic vision, a PEG tube with diameters from 8FG to 24FG can be pulled back down the oesophagus through the stomach and a flange, balloon, or button will allow the tube to be anchored firmly up against the gastric mucosa. In patients where there is gastric stasis or in pancreatitis, a small jejunal extension tube can be inserted through the PEG and positioned endoscopically into the distal duodenum or beyond the DJ flexure (PEJ).

Endoscopic ultrasound

Special endoscopes are available with a dual capability of endoscopic and ultrasound imaging. Either a rotating or a fixed linear array transducer will provide an ultrasound image at a point where the endoscopist can accurately direct the probe in the lumen of the oesophagus, stomach, or duodenum. Although CT scanning will stage most larger tumours of the upper gastrointestinal tract, pancreas, and bile duct, endoscopic ultrasound is particularly useful in staging small tumours and particularly mucosal tumours. The linear array ultrasound endoscope can be used for needle biopsy of tumours in the wall of the gastrointestinal tract or head of

pancreas and sometimes adjacent lymph nodes. Although endoscopic ultrasound is still developing in the United Kingdom, it is used more commonly elsewhere in Europe where gastroenterologists are routinely trained in abdominal ultrasound.

Endoscopy and disorders of the pancreas and biliary tree

Diagnostic endoscopic retrograde cholangiopancreatography

The development of side-viewing duodenoscopes in the 1970s allowed endoscopic visualization of the papilla of Vater and cannulation of the pancreatic and biliary duct systems, endoscopic retrograde cholangiopancreatography (ERCP). For many years ERCP was the gold standard of investigating pancreatic and biliary disorders but, with the advent of CT and MR scanning, the need for diagnostic ERCP has diminished. ERCP is still extremely useful in the diagnosis of patients with gallstones, sclerosing cholangitis, and biliary tumours where scanning is normal or equivocal, in the absence of overt jaundice. A tissue diagnosis can be obtained with brush cytology and endoscopic biopsy within the bile duct, avoiding the need for percutaneous biopsy.

Diagnostic ERCP is still useful in the assessment of patients with pancreatitis, congenital abnormalities, such as pancreas divisum, and in some patients with a pancreatic mass on scanning where the diagnosis is not clear. Most patients with a carcinoma of the pancreas will present with obstructive jaundice and will need a therapeutic procedure, others without jaundice will usually be diagnosed on ultrasound or CT scanning.

In specialized centres, biliary and pancreatic manometry is performed to assess patients with pancreatobiliary pain with no apparent structural abnormalities. At ERCP, a perfused catheter can be inserted into the bile duct and into the pancreatic duct and pull-through manometry performed. This will show whether elevated basal and peak pressures indicate sphincter of Oddi dysfunction.

Therapeutic endoscopic retrograde cholangiopancreatography

Gallstones

The endoscopic removal of common bile duct stones at the time of ERCP is the treatment of choice for patients presenting with pain, abnormal liver function tests, jaundice, or cholangitis. Following previous cholecystectomy, about 10 per cent of patients will ultimately represent with bile duct stones and endoscopic management is far safer than further surgical exploration of the bile duct. Prior to laparoscopic cholecystectomy, it is particularly important to investigate and to endoscopically clear the bile duct of stones, if suspected. Failure to do so may increase the likelihood of postoperative bile duct leaks. At the time of ERCP if stones are located in the biliary tree, a small diathermy cut is made into the bile duct through the papilla and, through the sphincterotomy, stones can be extracted with a balloon or basket. If the stones are too numerous or too large to extract at the first procedure, small pigtail stents are inserted into the bile duct to guarantee good drainage without stone impaction and therefore reduce the incidence of postprocedure cholangitis.

Most large stones can ultimately be removed using a mechanical crushing basket (lithotripter) or sometimes with the help of extracorporeal shock wave lithotripsy, following which fragments can be removed from the bile duct at follow-up ERCP. In experienced hands, the technical failure rate is low and thus the need for surgical reintervention is uncommon. Only in patients with very large bile duct stones, intrahepatic stones, or stones above biliary strictures is there a need for further procedures, such as intraduct choledochoscopy, using small endoscopes with direct contact lithotripsy using a pulse dye laser or an electrohydraulic probe. Very elderly or frail patients with large bile duct stones can be managed long-term by simple placement of an endoscopic stent beside the stones for drainage to prevent jaundice and/or cholangitis. Such stents can be changed over the years as per necessary.

Benign strictures

Postoperative anastamotic strictures or those following bile duct damage at the time of cholecystectomy can initially be managed with intermittent biliary balloon dilatation at the time of ERCP or simple endoscopic stent placement. In the young patient after a trial of dilatation or stenting for a reasonable length of time, about 1 year, surgical reconstruction of the bile duct might be needed if it is clear that endoscopic treatment is not leading to resolution of the stricture. In patients with primary sclerosing cholangitis, there may be single or multiple strictures in the intrahepatic and extrahepatic biliary tree, often in association with pigment stones, which can be difficult to dilate or stent. A variable proportion of patients with primary sclerosing cholangitis develop a cholangiocarcinoma and this can be very difficult to prove even with good ERCP, biliary cytology, CT, and MR scanning.

Malignant bile duct obstruction

Pancreatic and bile duct cancer and carcinoma of the ampulla of Vater can all produce stricturing of the biliary tree at different levels. At ERCP the stricture can be dilated and then an endoscopic 10 or 12FG polyethylene stent placed to relieve jaundice. These stents are cheap and usually stay patent for 4 to 5 months. In pancreatic cancer, about one-third of patients will survive long enough to occlude their stent, in which case a further procedure is performed to remove the blocked stent and replace it with a new one. Self-expanding metal stents offer a way of palliating patients for longer as they have a lumen of 10 mm which gives excellent long-term drainage. At present, biliary metal stents have an open mesh and tumour infiltration may occur, causing recurrent jaundice and/or sepsis. In that situation, a plastic stent can be inserted through the blocked metal stent to achieve drainage. Membrane-covered metal stents are now becoming available which should avoid the problem of tumour ingrowth and hopefully remain patent for longer.

In some patients with cholangiocarcinoma at the hilum of the liver, separate obstruction to right and left main ducts or subsegments may be found. In such a situation, more than one stent may be necessary to relieve jaundice or sepsis. Brachytherapy for cholangiocarcinoma can be administered endoscopically using an iridium wire source inserted down an endoscopically placed catheter inside the stent within the cholangiocarcinoma. Photodynamic therapy (PDT) can also be administered using a diffuser laser fibre, endoscopically sited within the malignant biliary stricture(s).

Pancreatitis

In patients with acute, relapsing and chronic pancreatitis a variety of endoscopic therapies can be performed. After pancreatic sphincterotomy, stones can be removed from the pancreatic duct, strictures can be stented, and drainage of the dorsal duct in pancreas divisum can be achieved. Peripancreatic fluid collections and pseudocysts can also be managed by pancreatic duct drainage or direct endoscopic cyst puncture and stenting techniques. Pancreatic endotherapy is difficult and can be associated with complications. Nevertheless, in selected patients it may be very valuable and avoids difficult and complex pancreatic surgery.

Gastric outlet obstruction

About 10 per cent of patients with pancreatobiliary tumours will develop gastric outlet obstruction as a late complication as tumour infiltrates the duodenum. Conventionally, a surgical gastric bypass has been unavoidable and this has carried a substantial morbidity/mortality as these patients are often very frail in the latter stages of their malignant disease. A large-diameter, self-expanding metal 'enteral' stent can now be placed in the stomach and duodenum at the time of endoscopy. This rapidly relieves symptoms of gastric outlet obstruction and allows the patients to eat a reasonable diet, without vomiting, thus avoiding the need for bypass surgery.

Hazards and complications

Diagnostic endoscopy carries very few risks. With careful attention to nursing techniques and sedation protocol, cardiovascular problems during endoscopy and aspiration pneumonia after are extremely rare. Direct damage to the upper gastrointestinal tract during insertion and subsequent inspection down to the duodenum is extremely unusual but rarely the cricopharynx, lower oesophagus above the cardia, and duodenal cap are sites of direct perforation with the endoscope, more commonly with inexperienced endoscopists. An unrecognized pharyngeal pouch represents a real hazard during insertion of the endoscope and might lead to a perforation if undue force is applied.

Most complications of endoscopy occur during therapeutic procedures and are specific to the type of procedure being performed.

The perforation rate following oesophageal dilatation is extremely low now that techniques and equipment have improved. The development of self-expanding stents

in the oesophagus avoids the need for forceful dilatation of malignant strictures and this has radically lowered the postprocedure complication rate of perforation. Due to the size of the balloon used in dilating achalasia of the cardia, perforations can be seen. Anybody who develops pain or discomfort after oesophageal dilatation should be assumed to have developed perforation, a chest radiograph should be obtained and if there is evidence of mediastinal air or surgical emphysema, conservative management with nil-by-mouth, parenteral antibiotics, and intravenous feeding is advocated. Many patients will settle conservatively without the need for surgical intervention.

The complications of ERCP are well known and more frequent than those of other endoscopic manoeuvres in the upper gastrointestinal tract. Even with diagnostic ERCP, up to 2 per cent of patients may develop postprocedure pancreatitis after either manipulation at the papilla or the injection of contrast into the pancreas. Such pancreatitis is usually self-limiting and mild although the serum amylase may reach extremely high levels. Some patients have a very elevated amylase without any pain. After endoscopic sphincterotomy and any therapeutic manoeuvre in the pancreatic or biliary tree, pancreatitis and bleeding can occur. Between 2 and 5 per cent of patients may have some degree of bleeding, but only a small proportion of these will need a blood transfusion or, rarely, surgical intervention. With the use of periprocedure antibiotics and the routine use of biliary stents after incomplete gallstone clearance within the bile duct, the incidence of postprocedure cholangitis is minimal.

14.2.3Radiology of the gastrointestinal tract

Alan Freeman

The widespread introduction of endoscopic techniques has lessened the need for radiological examination of the intestinal tract, and has completely replaced it in the examination of the stomach. There is, however, still a major radiological role in the investigation of the small and large bowel; the small bowel will be considered first.

The small intestine

The small intestine may be examined by a number of radiological means which include: plain films, barium contrast studies, ultrasound, CT, nuclear medicine, and MR. Plain film radiography performed in cases of suspected small bowel obstruction typically include films taken with both vertical and horizontal beam, the object being to demonstrate dilated loops and air–fluid levels. This role, however, is increasingly replaced by CT and apart from this, plain films have no other function. Barium studies of the small bowel have been the mainstay of examination for almost a century and, correctly performed, provide good morphological detail of the bowel. There are two types of examination; the first is the so-called barium follow through wherein the patient drinks a quantity of barium sulphate and then sequential films are taken of its passage through the small bowel. The second is the small bowel enema or enteroclysis and in this technique a tube is passed into the third part of the duodenum and barium sulphate is continuously infused, thus outlining the small intestine. This latter technique can also be used to provide a double contrast effect by infusing methyl cellulose, which provides a negative contrast against the positive contrast of barium sulphate.

Both techniques have advantages and disadvantages. The follow through is simple to perform and of course is more comfortable for the patient. However, it is imperative that fluoroscopy is performed at regular intervals together with abdominal compression so that all loops of small bowel are outlined. Enteroclysis by its very nature means that the barium column is observed in a continuous fashion and any minor obstruction or abnormality is thus more likely to be observed. Proponents of enteroclysis therefore argue that it is a more accurate test, but it is difficult to make a direct comparison as it is obviously difficult to perform both techniques on a cohort of patients. Given the relatively low incidence of disease of the small intestine, it seems reasonable in most instances to perform a follow through study in the first instance and to reserve enteroclysis for unresolved problems, subacute obstruction, etc.

Both types of contrast study suffer from the fact they only demonstrate the mucosal surface of the bowel and disease in the wall of the bowel or outside of it may be easily overlooked. In this situation, some form of cross-sectional imaging, typically ultrasound or CT, may well give more information.

Ultrasound, to date, has not found a huge role because it is highly operator dependent and requires considerable time. Its advantage of course is that it is radiation free. Usually, a high frequency ultrasound probe, in the order of 5 mHz, is used and the whole abdomen is carefully covered quadrant by quadrant with graded compression. Dilated, fluid-filled loops of bowel are relatively easy to examine, but the presence of excess gas within bowel loops, deep pelvic loops, and patient obesity all provide major impediments to full examination by ultrasound.

These factors, however, provide no problem for CT which, despite its use of ionizing radiation, is finding an increasing role in the investigation of small bowel disease. This particularly applies to acute small bowel obstruction where it provides not only confirmation of the diagnosis but often demonstrates the site and the nature of the obstructing lesion. As the images are usually enhanced by means of intravenous contrast agents, they can provide useful information as to the viability or otherwise of the obstructed loops. Thickening and infiltration of the bowel wall is readily appreciated at CT, as is the demonstration of exophytic tumours such as leiomyomas and lymphoma.

Nuclear medicine studies, which involve the injection of a radio-labelled substance, have major roles in the demonstration of inflammatory conditions involving the small bowel and for the demonstration of potential bleeding sources from the small bowel. In the former, the patients white blood cells are extracted and then labelled with Tc 99m pertechnetate. These white cells are then reinjected into the patient. The cells concentrate at the site of inflammation and this activity is demonstrated on a gamma camera. The technique is known as labelled white cell scanning. Alternatively, indium may be used as the isotope when a longer half-life is required and this particularly applies in the diagnosis of possible intra-abdominal abscess. This does involve a higher radiation dose to the patient.

If bleeding from the small bowel is the problem, then the patient's red blood cells are extracted and again labelled with Tc 99m pertechnetate. The labelled cells are reinjected into the patient and the abdomen is scanned under a gamma camera. A bleeding source of more than approximately 0.5 ml/min, can be identified as a hotspot, indicating the probable site. A more specific bleeding source is a Meckel's diverticulum and if this is symptomatic it is likely to contain ectopic gastric cells which may be demonstrated by the simple injection by pertechnetate by itself.

Magnetic resonance imaging (MR) of the small bowel holds huge promise and is likely to become the most important technique in the future. It has major advantages in that it involves no radiation and image reconstruction can be performed in almost any plane. Indeed, image reconstruction is so fast that in effect, MR fluoroscopy of the bowel can produce images similar to those obtained at barium fluoroscopy. Because of the lack of ionizing radiation, areas of interest or difficulty can be 'revisited' time and again until fully evaluated. To obtain these images, the bowel does need to be distended which usually involves passing a nasoduodenal tube and utilizing water or methyl cellulose as the distention and contrast agents.

Anatomy of the small bowel

Strictly speaking, the small bowel commences at the pylorus and includes duodenum, jejunum, and ileum. However, the first part of duodenum, proximal to the superior duodenal flexure, is usually more closely aligned to the stomach in relation to pathology and investigation and for practical purposes, this chapter will discuss small bowel from mid-descending duodenum onwards. The third part of the duodenum commences at the inferior duodenum flexure and passes across the midline at roughly the level of L3 to ascend to the duodenal–jejunal junction. This is marked by the peritoneal ligament of Treitz. At this point, the small bowel emerges from the retroperitoneum to become an intraperitoneal structure. It is then divided roughly into equal lengths of jejunum and ileum, with jejunal loops occupying the left upper quadrant and ileal loops the right lower quadrant. The ileum terminates at the ileocaecal junction where it again becomes a retroperitoneal structure. Morphologically, jejunum can be distinguished from ileum both by its size (it is usually about 1 cm larger in diameter) and by the presence of valvulae connivente or plicae semilunaris. The latter gives it its characteristic fold pattern on contrast studies as opposed to the relatively featureless ileum.

Pathology of the small bowel

Coeliac disease and malabsorption states

Coeliac disease, caused by a sensitivity to gluten, is characterized by atrophy of the small intestinal villous pattern. The definitive diagnosis thus rests with duodenal or jejunal biopsy, but radiology retains a role in evaluating complications as well as excluding other causes or malabsorption.

Barium follow through studies have been the mainstay and demonstrate changes which include dilatation of jejunal loops (to more than 3.5 cm), flocculation of the barium suspension, thickening of the fold pattern (particularly if there is associated hypoproteinaemia), and delayed transit. Many of these features are very subjective and thus radiology cannot be used as a test to exclude coeliac disease. Marked mucosal effacement typically involving the duodenum, but sometimes the whole of the jejunum, may be a prominent feature leading to the so-called 'moulage' appearance which is specific for coeliac disease and for the rare graft-versus-host syndrome

(Fig. 1). Likewise, transient intussusceptions occurring during the examination are only seen with coeliac disease.

Fig. 1 Severe coeliac disease showing moulage phenomena. There has been complete obliteration of the small bowel fold pattern such that the barium follow through appearances resemble toothpaste squeezed from a tube, leading to the alternative term of 'tube of toothpaste' sign. This particular study was performed because the patient was thought to have a carcinoma of the stomach and thus illustrates one of the very varied ways in which coeliac disease can manifest.

Complications, such as the development of lymphoma, may be demonstrated by both barium studies and CT, whilst stricture formation following ulcerative jejunitis, often regarded as a prelymphomatous condition, is best assessed by barium studies.

Other causes of malabsorption include jejunal diverticulosis and short bowel syndrome, plus infiltrative causes such as intestinal lymphangectasia, Whipple's disease, eosinophilic gastroenteritis, amyloidosis, and mastocytosis:

- Jejunal diverticulosis causes malabsorption because of intestinal stasis and subsequent bacterial overgrowth. The diverticula usually protrudes through the mesenteric border of the jejunum and can be demonstrated on small bowel series as a number of sac-like structures containing barium, particularly if erect views are taken.
- Short bowel syndrome results if extensive lengths of small bowel have been resected, often either as a result of vascular accidents or following complications of Crohn's disease. The bowel will adapt by increasing its diameter, but an overall length of less than 50 cm is usually incompatible with life. This situation is particularly severe if the terminal ileum has been resected because of its specialized function in the absorption of vitamin B_{12} and in the enterohepatic circulation of bile salts.

The various small bowel infiltrations are rare:

- Intestinal lymphangestasia is characterized by the presence of dilated lymph vessels in the mucosa which cause protein and lymphocytic loss into the small bowel. It may be primary or secondary, with the secondary form being caused by conditions which obstruct the bowel lymphatics, such as lymphoma, carcinoma, postradiation changes, and occasionally in association with heart failure and constrictive pericarditis. High-quality barium studies may demonstrate the dilated lymphatics as very fine, mm-size nodules, mainly in the jejunum (Fig. 2).

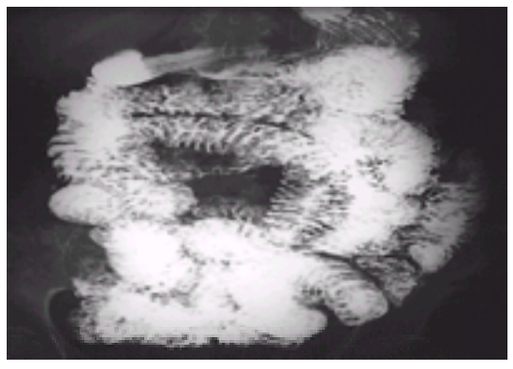

Fig. 2 Intestinal lymphangiectasia demonstrated by thickening and straightening of the fold pattern together with a faint granular background due to the dilated lymphatics. In this case lymphangiectasia was secondary to an underlying lymphoma.

- Whipple's disease is caused by a bacillus resulting in a syndrome of steatorrhoea, abdominal pain, and arthralgia. It has a male predominance. Barium studies show thickened folds together with slight dilatation of the bowel lumen. In addition, CT may demonstrate bowel wall thickening together with mesenteric lymphadenopathy, the lymph nodes usually being of low attenuation.
- Eosinophilic gastroenteritis—in this condition, the wall of the bowel is infiltrated with eosinophils and there is usually a peripheral eosinophilia as well. Often, there is a history of atopy and the triad of eosinophilic gastroenteritis, asthma, and mononeuritis multiplex comprise the Churg–Strauss syndrome. Symptoms resulting from small bowel involvement depend on the major site of location of eosinophilic infiltration, which may be either mucosal or serosal. With the former diarrhoea, malabsorption, and protein loss are dominant, whereas the latter is characterized by ascites. Barium studies in cases of mainly mucosal involvement show fold thickening together with nodular filling defects, whereas serosal involvement is better assessed by CT, which shows both the bowel wall thickening and ascites.
- Amyloidosis and mastocytosis are very rare causes of malabsorption with infiltration in both cases, causing thickening of the valvulae connivente. Amyloidosis is characterized by the deposition of amyloid fibres in the small bowel and may be primary or secondary (Fig. 3).

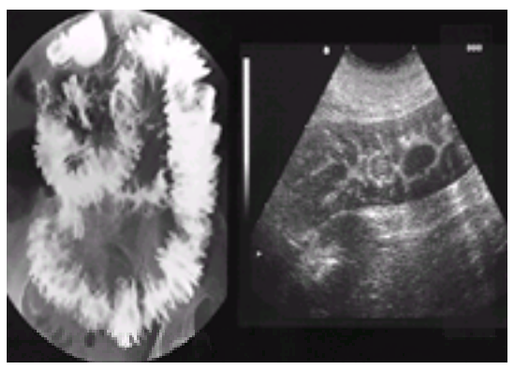

Fig. 3 Amyloidosis of the small bowel shown on a barium follow through (a) and ultrasound examination (b). There is complete disorganization of the normal small bowel fold pattern (a) and the degree of thickening of the small bowel wall is best appreciated on the ultrasound (b).

Tumours of the small intestine

These may be benign or malignant and are relatively uncommon:

- Benign tumours include leiomyomas, haemangiomas, and adenomas. Bleeding or intussusception are the commonest presentations, particularly from leiomyomas. These tumours may grow into the bowel lumen, but often have a significant exoenteric mass, in which case they can grow to a very large size without causing clinical symptoms. They may, therefore, be demonstrated on barium studies as a filling defect, sometimes with a central ulcer which results from necrosis, whereas CT is the best method for demonstrating the exocentric component. A number of syndromes include small bowel polyps as part of their features and these include Peutz–Jegher's with small bowel hamartomas, Gardener's with adenomas, and Cronkhite Canada with retention polyps. Many of these have an association with periampullary carcinoma.

Malignant tumours of the small bowel include carcinoid, carcinoma, lymphoma, and metastases:

- Carcinoid typically arises in the distal ileum and presents as a smooth, submucosal mass. At this stage, they behave like a benign tumour. Later, local infiltration occurs causing extensive tissue thickening and a desmoplastic reaction. This may be severe enough to cause bowel obstruction. Once the tumour has reached a size of 2 cm or more, it is likely to display true invasiveness, metastasizing via the portal vein to the liver. Radiological assessment is best by CT, which can show evidence of local infiltration into the mesentery typically with a central spiculated mass, and later very vascular liver metastases.
- Adenocarcinoma of the small bowel is rare with an approximate incidence of 1 in 100 000. These tumours are most commonly found in the jejunum. The usual macroscopic appearance is that of an annular, concentric tumour which gives rise to an apple-core appearance on barium studies or sometimes a large mass (Fig. 4). Prognosis is poor as the majority of tumours have metastasized at the time of surgery.

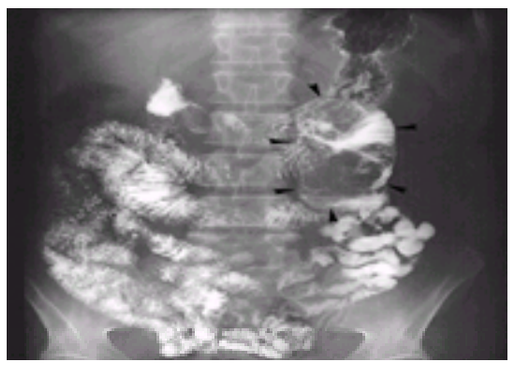

Fig. 4 Adenocarcinoma of the jejunum. This follow through examination in an anaemic patient demonstrates the large mass (arrowheads) arising from the proximal jejunum at a site just distal to the ligament of Treitz—a common position. Note also the normal small bowel pattern distal to this tumour when compared to the abnormal patterns shown on Fig. 1, Fig. 2, and Fig. 3.

- Lymphoma may involve the gastrointestinal tract and indeed is the most common location for extra nodal disease. In contradistinction to carcinoma, the ileum is more frequently involved than the jejunum. A number of macroscopic forms are seen including: (1) multiple nodular defects; (2) diffuse infiltration (Fig. 5); (3) the infiltration may destroy the muscularis propria leading to the so-called aneurysmal form with bowel dilatation; (4) large endoexoenteric masses with excavation; (5) large extraluminal masses. The latter is a particular feature of HIV-associated Burkett's lymphoma.

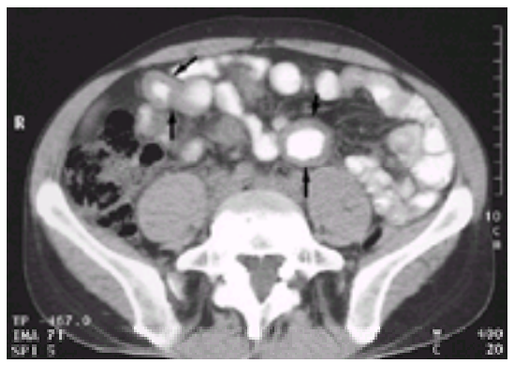

Fig. 5 Lymphoma of the small bowel as shown at CT examination. Several loops are involved demonstrating marked thickening of the bowel wall to a width of 5 to 6 mm (arrows).

- Metastatic disease to the small bowel may arrive by either transcoelomic spread or via the haematogenous route. Common tumours to seed across the peritoneal cavity are from the colon, pancreas, and stomach with the addition of the ovary in females. The commonest source for haematogenous metastases to the small bowel is malignant melanoma which produces characteristic submucosal masses with a central umbilical-type ulcer. Carcinoma of the bronchus and breast also are major causes of haematogenous metastases.

Crohn's disease and inflammatory small bowel conditions

Crohn's disease is the commonest inflammatory condition to affect the small bowel in Western populations and is characterized by a chronic course of progression with spontaneous remission. The cause remains unknown and despite the presence of non-caseating granulomas on biopsy, extensive investigation into infectious agents has so far proved inconclusive. It may involve any part of the gastrointestinal tract, but in the great majority of cases the small bowel demonstrates most macroscopic change, and when involved the terminal ileum is the usual site.

The disease starts with mucosal ulceration which then becomes transmural with fissure ulcers. Healing is accompanied by fibrosis and stricture formation and there is considerable thickening of the bowel wall. Skip lesions may occur affecting considerable lengths of small bowel. Fistulation is a characteristic of the disease and these may be enteric, enterocutaneous, or extend into the muscles of the abdominal wall and pelvis. Intra-abdominal abscesses also characterize severe disease. Radiological assessment is by means of Tc99m white blood cell scanning, barium follow through studies, CT, and MR. White cell scanning is used as the initial test for a patient with symptoms and signs of possible Crohn's disease (Fig. 6). It is also used to document disease activity and response to therapeutic measures. It is highly sensitive but may produce false positive results from other conditions which cause terminal ileal inflammation. Barium studies are then performed to demonstrate morphological detail. These may show the earliest change of Crohns disease which is an aphthoid ulcer resulting from ulceration on the tip of a lymphoid follicle. Next comes distortion and thickening of the fold pattern which in some instances becomes completely effaced. Finally, development of deep, interlacing, linear ulcers give rise to the characteristic cobblestone pattern due to oedema of mucosal islands between the ulcers. If stricture formation occurs, this is best appreciated by barium studies and if there is a long segment of stenosis, this is sometimes referred to as the string sign. The demonstrations of fistula is also shown by barium studies, but this is now increasingly in the realm of spiral CT which can also demonstrates intra-abdominal abscesses and abnormal intra-abdominal fat. The role of MR imaging in Crohn's disease is also evolving rapidly because this can demonstrate the thickened bowel wall, inflammatory changes in the mesentery, and, in particular, the presence and anatomy of fistula formation.

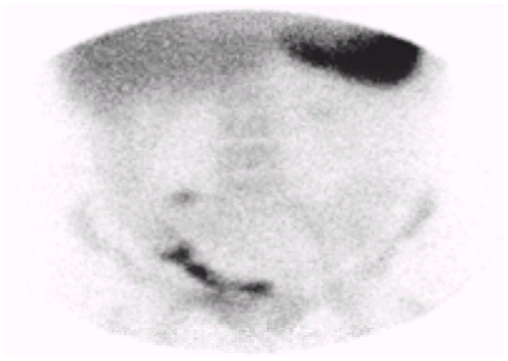

Fig. 6 Crohn's disease of the small bowel as demonstrated by a technetium 99m labelled white cell scan. There is grade III activity in the right iliac fossa indicative of highly active Crohn's disease in the terminal ileum. Note the normal accumulation of isotope in the spleen. (By courtesy of Dr Jane Dutton.)

Other inflammatory conditions of the small bowel include infection, such as *Yersinia enterocolitica* and tuberculosis. The former is associated with changes of terminal ileitis and is usually self limiting. The latter may affect any part of the gastrointestinal tract, but typically the ileocaecal region. Now that bovine tuberculosis has largely disappeared, the bacillus in most cases has arrived from swallowing infected sputum. Barium studies usually demonstrate changes in both the terminal ileum and caecum, a helpful point in distinguishing this from Crohn's disease, although the appearances can be very similar. There may be two type of appearance—the ulcerative form and the hypertrophic form. The latter is characterized by thickened and matted loops of bowel in the right iliac fossa. In addition, tuberculous enteritis may present as ascites from tuberculous peritonitis.

Postradiation enteritis and bowel ischaemia

Postradiation enteritis is considered here because the pathophysiology is one of endarteritis obliterans. This may follow any form of radiotherapy, either external beam or cavity therapy, and is most commonly encountered in female patients who have had therapy for carcinoma of the cervix. Thus, it typically involves small bowel loops which lie deep in the pelvis and these are made more susceptible if there is adhesive disease which fixes them in this position. Initial changes are of mucosal oedema but major problems from fibrosis and stricture formation occur later, in some instances after a latent period as long as 25 years. Sinuses and fistulae can be particularly problematic if there has been previous surgery to the radiation-damaged bowel. These changes are well appreciated at barium follow-through studies.

Bowel ischaemia and infarction may result from both arterial and venous occlusion. Arterial thrombosis of the superior mesenteric artery results in catastrophic infarction of most of the small bowel and carries a dismal prognosis. On the other hand, multiple, small emboli may cause episodes of non-occlusive ischaemia from which the bowel makes a good recovery. These typically are shown as areas of narrowing due to oedema with an abrupt transition to normal small bowel between the involved segments. Venous occlusion may result from volvulus of the bowel, blood dyscrasias, and malignant infiltration in the mesentery.

The colon

Colonoscopy has revolutionized imaging approaches to the colon because of its therapeutic as well as diagnostic role. However, it is not without risk, and barium enema examination still remains a much used alternative. CT is an increasingly used technique particularly since the advent of spiral CT allows three-dimensional reconstruction and thus so-called virtual colonoscopy.

For all three techniques a completely clean and empty colon is a prerequisite. This is achieved by colonic lavage, usually using an oral preparation the day before the examination, such as Picolax or Klean prep. For barium enema examination, the patient is placed on a fluoroscopic table and barium sulphate is run into the colon up to the level of the transverse colon. The excess is then drained out and air or carbon dioxide is insufflated into the colon to achieve a so-called double contrast effect, that is luminal distension with air and mucosal coating by barium sulphate. Up to 12 images are then taken of the colon with the patient in different positions so that the entire bowel is demonstrated in double contrast.

For CT examination, no positive contrast is used but the colon is simply distended with air, usually after the administration of a spasmolytic drug such as Buscopan. So-called volume rendering of the data following spiral CT examination permits a three-dimensional reconstruction of the lumen of the colon, thus allowing the operator to apparently 'fly' through the colon in a manner similar to colonoscopy, hence the term virtual colonoscopy.

CT without bowel preparation has also been used in the detection of gross colonic abnormalities in elderly patients, thus sparing them the discomfort of bowel preparation and a barium enema, both of which are likely to be less than optimal in this group.

Anatomy of the large bowel

The colon commences with the caecum and appendix in the right iliac fossa and these structures lead into the ascending colon which is a retroperitoneal structure. After the hepatic flexure the transverse colon is again intraperitoneal, suspended by the transverse mesocolon. The splenic flexure marks the transition to descending colon which is again retroperitoneal. Finally, the sigmoid and proximal rectum are intraperitoneal with the peritoneal reflection sited at the junction of the mid and lower third of rectum.

Pathology of the colon

Diverticular disease and irritable bowel syndrome

Diverticular disease and its complications are one of the commonest conditions to affect the colon. It results from raised intraluminal pressure causing a bleb of mucosa to herniate through the bowel wall at points of potential weakness, where the nutrient artery pierces the wall to supply the colon. This is accompanied by hypertrophy of the circular muscle fibres in the bowel wall, which is the first sign of this condition. Diverticula by themselves may not cause symptoms and indeed they are said to be present in one-third of the population over the age of 60. They may, however, become inflamed, resulting in a number of complications which include local and segmental abscess formation, perforation and fistula formation, stricture formation, and colonic bleeding. The usual location is the sigmoid colon which, with severe diverticular change, may become very distorted. A barium enema is the best technique for demonstrating the presence and extent of diverticulosis and these are shown as small barium-filled out-pouchings from the bowel wall. Most of the complications of diverticular disease, however, are best appreciated at CT. This demonstrates the marked thickening of the bowel wall as well as the presence of fistulae and abscesses. The latter are shown as soft tissue areas of fluid density either within or immediately adjacent to the wall of the bowel (Fig. 7). Stricture formation, however, is best assessed at barium enema and will usually require colonoscopy for biopsy purposes as the distinction between benign diverticular stricture and one secondary to malignancy is often difficult.

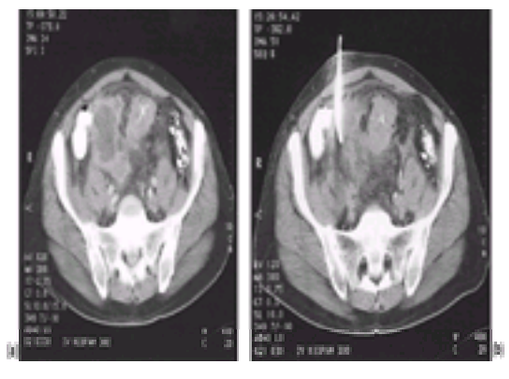

Fig. 7 Diverticular disease and its complication as shown at CT examination (a) demonstrating the marked thickening of the sigmoid wall and to the right of this is a fluid collection demonstrated by a low attenuation mass. This has been drained under CT control with the drainage catheter shown in position (b).

The diagnosis of irritable bowel syndrome is not radiological but clinical. However, in many instances the distinction from diverticular disease and colonic carcinoma is impossible and therefore a further examination, usually a barium enema, is indicated to exclude these diseases.

Colorectal cancer and polyp formation

Colorectal cancer is the second most common cause of death from cancer in the Western world and early detection can have a profound effect on prognosis. It is now clear that colorectal cancer arises as a result of a n umber of mutations resulting in a chromosome instability pathway. The first macroscopic change is the formation of an adenomatous polyp which over time, often two or three decades, will eventually become a frank carcinoma. The percentage of polyps, which, if left alone will become a carcinoma is unknown, but any attempt to reduce the mortality from colorectal cancer starts with their detection and subsequent removal. Polyp detection is achieved by both barium enema and CT colonography.

At barium enema, a polyp may be demonstrated as a filling defect in the barium column or as a ring of increased density on the air contrast views. They may be sessile or pedunculated.(Fig. 8). The size of the polyp is significant as lesions under 5 mm in size have little or no statistical association with an increased risk of cancer. Any polyp over the size of 10 mm should be removed and once they reach 20 mm they will almost certainly be malignant. For obvious reasons, their detection requires a colon that is completely clean as residual faecal material can readily be misinterpreted as polyp.

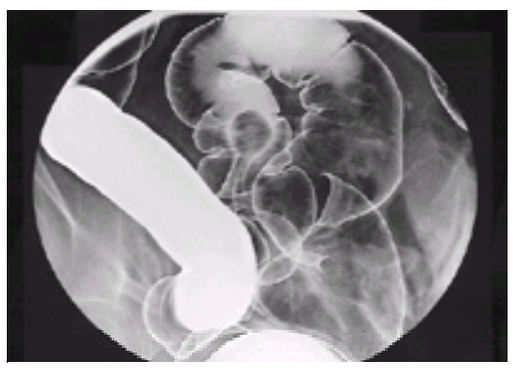

Fig. 8 Colorectal polyp in the mid sigmoid as shown on a barium enema. This is a pedunculated polyp and with the presence of a such a long stalk is likely to be benign. A sessile polyp of this size would have to be regarded as definitely suspicious and possibly malignant.

Carcinoma of the colon has several macroscopic appearances including annular stricture, a proliferative type, a large polypoid type, and schirrhous. Both barium enema and CT examinations detect of all of these.

CT colonography has two major advantages. First, if a tumour is demonstrated, then it can be formally staged at the same examination, that is by looking for involvement of the lymph nodes or the presence of liver metastases. Second, if a further clarification or a therapeutic manoeuvre is indicated, then colonoscopy may be performed immediately after the CT as only air has been insufflated into the colon.

Inflammatory bowel disease

The two main causes of idiopathic inflammatory bowel disease are ulcerative colitis and Crohn's disease with an approximate ratio of 3:1. Ulcerative colitis invariably starts in the rectum and spreads proximally, whereas Crohn's disease more commonly involves the right colon. Both conditions are best appreciated at barium enema, though the complications of Crohn's disease, that is fistulae and abscess formation, are best demonstrated by CT. The radiological appearances reflect the pathophysiology. Ulcerative colitis results in fine mucosal ulceration which always involves the rectum and then may spread proximally to involve the entire colon. There is loss of the haustral pattern and the mucosa demonstrates a fine granular appearance. Crohn's disease in contradistinction demonstrates more discreet and deep ulcers. The latter represent fissure ulcers which may extend throughout the whole thickness of the bowel wall. There is discontinuity of involvement as well as asymmetry. The picture is completed by terminal ileal involvement. An unusual feature of Crohn's disease is its earliest appearance, which is that of aphthous ulceration caused by ulcers appearing on the surface of hypertrophied lymphoid aggregates.

Other causes of colitis include pseudomembranous (caused by an overgrowth of *Clostridium difficile* often following antibiotic usage) as well as the various infective colitides, for example shigella, campylobacter, or CMV. The last named is usually only a problem in the immunocompromised patient. Postradiation colitis typically affects the sigmoid colon, for example after treatment for carcinoma of the cervix.

14.2.4 Investigation of gastrointestinal function

Julian R. F. Walters

Digestion and absorption of food by the gastrointestinal (**GI**) tract is achieved by the integration of multiple steps: the complex foods taken in through the mouth are digested into simpler molecules which can be transported across mucosal epithelial cells into the metabolic pool of the body. The contents of the gastrointestinal tract also need to be moved to regions where specialized digestive and absorptive functions can take place, and physical and immunological barriers must be maintained to prevent injury from toxic or immunologically active substances and bacteria.

These functions are assessed clinically in a variety of ways. Much can be learnt indirectly from techniques not principally aimed at defining GI function. Patients will describe appetite, dietary intake, weight changes, and the frequency and nature of their bowel movements. Clinical examination may reveal malnutrition—either generalized or specific. Many blood measurements of absorbed dietary components (such as iron, folate, vitamin B_{12}, cholesterol, and triglycerides), or their metabolic products (such as haemoglobin, albumin) can be abnormal when GI function is impaired, and their serial changes can be used to follow improvements with treatment. Radiological studies (see Chapter 14.2.3) can demonstrate functional changes as well as anatomy, and physiological measurements are central to studies of motility disorders (Chapter 14.12). Tests aimed at giving specific measurements of GI function are described below.

Intake and output

Nutritional assessment

The dietary history is a critical part of the investigation of GI function. For instance, a high intake of milk in a patient of African ethnicity will suggest that diarrhoea may be due to lactase non-persistence. Vitamin B_{12} deficiency in a vegan is most likely to be due to dietary deficiency rather than malabsorption.

Patients may not accurately recall what they eat. Assessment can be improved by keeping a detailed diary with formal recording of the diet over a week, this will enable the usual intakes of a full range of nutrients to be calculated. Total calories, fat, protein and nitrogen, water, electrolytes, individual vitamins, minerals, and trace elements can all be assessed in this way.

Assessment of nutritional status can indirectly provide evidence of gastrointestinal dysfunction. Calculation of the body mass index (kg/m ^{2}) gives a measure of obesity, and hence fat stores. More detailed estimates of body composition can be made by anthropometry, measuring skin-fold thickness, or body density. Dual-energy, X-ray absorptiometry will assess the percentage of fat, and bone mineral density as a measure of calcium stores.

These estimates of nutritional status can change over time. If the intake of any particular nutrient exceeds the losses, the body is in positive balance, as occurs during growth. If the losses are greater, the result is a negative balance. Losses from all sources must be included. Urinary loss is obvious for water, electrolytes and minerals, and nitrogenous compounds. Carbon dioxide and heat losses reflect metabolism and calorie consumption: research calorimetric techniques can estimate these accurately. Absorption by the GI tract is a major factor is determining overall balance—with unabsorbed nutrients and excreted matter being egested in faeces.

Faecal output

Stool weight and volume can vary in the healthy individual, but averages about 200 g/24 h. This volume increases in diarrhoea or other forms of malabsorption, and may be as high as several litres/24 h in patients with secretory diarrhoea, such as that due to cholera. Accurate measurements of faecal volume and electrolyte composition are then helpful in maintaining an accurate fluid balance.

Patients may complain of diarrhoea but mean urgent, frequent, or unformed stools, rather than an increase in volume. Stool charts, recording frequency and volume, help to define the change in the nature of the stools. Changes in frequency and volume with simple changes such as fasting help to differentiate osmotic diarrhoea from secretory or inflammatory causes. Stool electrolytes and osmolarity are also helpful here: a large osmotic gap suggests an unabsorbed ion from, for example, magnesium salts taken as laxatives, or the products of unabsorbed carbohydrate fermentation. Stool pH is low after carbohydrate malabsorption, as in lactase deficiency (non-persistence) or sucrase–isomaltase deficiency.

Faecal fat output is increased in most forms of generalized malabsorption and results in steatorrhoea. Patients frequently describe stools that float or are foul-smelling, but to be sure that this is due to fat, qualitative and quantitative estimations need to be performed. Fat droplets in the stool can be detected microscopically after staining with lipid-soluble dyes. Accurate estimation of the loss of fat in the faeces requires a 3-day collection of stools while the patient is on a defined fat-intake diet. An average output of more than 5 g/24 h for a 70 to 100 g daily fat intake is abnormal. Patients and clinical and laboratory staff dislike this test for obvious reasons.

Gas, wind, explosive stools, and foul odours are frequent complaints. Although volumes of flatus and the presence of various gases have been measured in research studies, these have not been adopted as routine clinical investigations.

Stool microscopy for faecal leucocytes can be helpful in diagnosing inflammatory diarrhoea. Detection of bacterial pathogens, parasites, ova, or toxins may show the cause.

Digestive secretions

In patients with possible malabsorption, who have an adequate dietary intake but large volume stools, an important clinical decision is whether digestion is at fault (such as pancreatic exocrine insufficiency) or whether absorption is the problem (as in coeliac disease). Often this is rapidly established by employing tests with high positive-predictive-values for common individual diseases, such as endomysial serology for coeliac disease or imaging studies for chronic pancreatitis (see Chapter

14.18.3.2).

Intubation of the lumen to collect the contents for measurements of secretory rates and composition is the definitive way to study digestive juices produced by the stomach, pancreas, liver, and intestine. Though necessary for basic physiological and pharmacological studies, tube tests are now rarely performed in a clinical setting. Endoscopes are generally now used, which enable direct vision and biopsy of anatomical lesions, and can, on occasions, also provide functional information.

A large number of tubeless tests have been developed to indirectly measure digestion and absorption, or to help differentiate between the two types of disorder. Many involve small doses of radionuclides. Other tests use markers of breath hydrogen or urinary excretion (Table 1). Selection of these tests in clinical practice depends on their predictive values, reliability, cost, and ease of use.

Gastric secretion

The gastric mucosa secretes acid, pepsin, and some other products such as intrinsic factor. Measurements of acid output have historically been important in diagnosing the cause and response to treatment of acid-related diseases such as duodenal ulceration. This has become less relevant with the discovery of *Helicobacter pylori* and potent acid suppression with histamine H2-receptor antagonists and proton-pump inhibitors.

Intubation of the stomach with a nasogastric tube allows the gastric contents to be sampled. Tube positioning is important. Swallowed salivary secretion will raise the pH and so will refluxing duodenal contents, common after retching. The yellow colour of bile will indicate duodenal reflux into the stomach. After an overnight fast, gastric aspiration allows the volume of resting secretions to be measured and the pH determined. Normal resting volumes are less than 50 ml. pH values above 4 suggest impaired acid secretion, as in the gastric atrophy and achlorhydria found in pernicious anaemia, or as the result of acid-suppressant drugs. Gastric pH can also easily be measured at endoscopy.

Estimation of basal and peak acid output requires continuous sampling and titration of the aspirate with sodium hydroxide. A marker can be infused to correct for loss of gastric contents into the duodenum. A basal acid output of about 5 mmol over 1 h is normal. Low values are found in achlorhydria. The detection of a high basal output is important in making the diagnosis of Zollinger–Ellison syndrome. However, this clinical decision is now usually made after finding a high serum gastrin level in a patient treated with a proton-pump inhibitor, who because of symptoms is unable to discontinue therapy.

Peak acid output following pentagastrin stimulation quantifies the ability of the stomach to maximally produce acid. There was considerable interest in the use of this test for research purposes before the aetiology of duodenal ulcer became clear. However, it is of little clinical use now that our understanding of pathophysiology and therapeutics has advanced.

Biliary secretions

Bile samples, mixed with pancreatic secretions and other duodenal contents, can be collected from the duodenum at upper endoscopy (or after intubation). Endoscopic retrograde cholangiopancreatography (**ERCP**) allows bile to be collected from the bile ducts. Microscopy of bile can detect cholesterol crystals. The proportions of bile acids, phospholipids, and cholesterol are relevant in the study of biliary cholesterol saturation and gallstone formation, but have little clinical use.

Bile secretion by the liver is not easily measured directly. Clearance from the circulation can be determined for a number of compounds normally secreted into the bile. Apart from measurements of bilirubin, such tests have found little clinical use. The nuclear medicine **HIDA** (hepatoiminodiacetic acid; lidofenin) scan gives a measure of biliary secretion as well as helping define functional anatomy. The gallbladder function of contraction in response to a meal, or cholecystokinin (**CCK**), can be measured by imaging techniques, of which ultrasound is the most convenient.

Pancreatic secretions

Pancreatic secretion of a large number of digestive enzymes and bicarbonate is crucial for the digestive process. Duodenal intubation allows their collection for assay of the activities of some of the key enzymes such as trypsin, lipase, and amylase; however, these duodenal contents will be mixed with bile and duodenal secretions, or with those from the stomach. Pure pancreatic juice can be collected at ERCP.

Although a number of stimulation tests have been used to diagnose pancreatic exocrine insufficiency, their clinical usage is very limited: virtually all patients can be managed without the need to resort to these function tests. The duodenum is intubated, usually under fluoroscopic control. Secretin, which stimulates bicarbonate secretion, or CCK, which stimulates enzyme secretion, are given intravenously, either alone or in combination. The contents of the duodenum are then aspirated for assay of bicarbonate and enzyme concentrations. The Lundh meal is an alternative standardized stimulus to pancreatic secretion.

Several indirect, tubeless pancreatic tests have been developed and are much simpler and more convenient to perform. The pancreolauryl test relies on the hydrolysis of fluorescein dilaurate by pancreatic esterases. The fluorescein is absorbed and excreted in the urine where it can be assayed easily. The test is administered on 2 days, each time with a standard breakfast and similar urine collections. On the first day, a test capsule containing fluorescein dilaurate is given, and on the second, a control capsule of non-esterified fluorescein. To diagnose pancreatic insufficiency, the ratio of fluorescein recovered in the urine with the dilaurate test substance will be less than 20 per cent of that with the control. Another test uses *N*-benzoyl-L-tyrosyl-*p*-aminobenzoic acid (**NBT-PABA**) as an alternative substrate. Following a similar principle, pancreatic chymotrypsin activity releases *p*-aminobenzoic acid (**PABA**), which is assayed in the urine. This test seems to be less reliable than that with pancreolauryl.

A different type of indirect test for pancreatic exocrine dysfunction involves the determination of proteolytic enzymes in the faeces—these enzymes are produced by the pancreas and are stable during passage through the intestine. Chymotrypsin activity has been used as a test for many years. An improved method using an immunological assay for human-specific elastase I has recently been developed.

All these indirect tests are generally reliable in patients with severe exocrine pancreatic insufficiency causing steatorrhoea, where they can have adequate specificity for pancreatic disease if borderline test results are repeated or ignored. Many patients with severe intestinal disease will have somewhat abnormal results. The sensitivity of the tests is such that patients with lesser degrees of pancreatic functional impairment will be missed and considerable pancreatic damage may have occurred before the tests become abnormal.

Intestine

The role of brush-border enzymes in digestion is clearly important. Individual enzyme activities (e.g. sucrase–isomaltase) can be measured directly in small-bowel biopsies, obtained at endoscopy or using a capsule or biopsy tube. Indirect tests of intestinal digestive enzyme function are closely linked with those of absorption and are described below. Intestinal secretions, such as those from the Brunner's glands in the duodenum or from the crypts in secretory diarrhoea, are not directly measured.

Absorption

Carbohydrates

The xylose absorption test has been used for many years as a simple measure of absorption and malabsorption. Xylose does not need to be digested, is absorbed by the jejunum, does not undergo significant metabolism, and is excreted efficiently by the kidney. Urine is collected for 5 h after oral administration of the sugar to a fasted subject. Usually 25 g is given and more than 17 per cent should be recovered in the urine. A smaller dose of 5 g causes less diarrhoea. The test measures the area of functioning mucosa and has reasonably good sensitivity for intestinal mucosal abnormalities such as coeliac disease. The measurement of blood levels is said to improve accuracy. False-positive low levels of xylose excretion can occur with delayed gastric emptying, ascites, and with insufficient urinary output. As described elsewhere, serological tests are now available that are simpler, more specific, and more sensitive in screening for coeliac disease.

Lactose tolerance testing can be performed to diagnose lactase deficiency. This is similar to the glucose tolerance test, except that 50 g of lactose is given instead of glucose. Blood glucose levels are measured, and should increase if brush-border lactase is present to split the lactose in to glucose and galactose. In subjects without

brush-border lactase, the lactose is not digested or absorbed and the blood glucose level does not rise. The lactose passes through the small bowel to the large intestine where it is then broken down by bacteria, thereby causing symptoms of gaseousness and diarrhoea.

The breath-hydrogen test for lactose intolerance is based on this principle (Fig. 1). Hydrogen is only produced in the body from the bacterial fermentation of carbohydrates in the gut. Hydrogen diffuses into the blood and is excreted in the breath. Breath hydrogen can be measured simply and relatively cheaply to an accuracy of a few parts per million (**p.p.m**). Colonic bacteria produce a background level of breath hydrogen from the fermentation of unabsorbed colonic contents. After taking oral lactose, breath hydrogen is measured every 30 min. An increase greater than 20 p.p.m. implies that, rather than being absorbed in the small intestine, the sugar has been broken down by bacteria in the colon. As described below, bacterial overgrowth in the small intestine elevates breath hydrogen after glucose administration, and can also do this when lactose is given. Similar breath-hydrogen tests can be performed with other sugars when fructose or sucrose malabsorption is suspected.

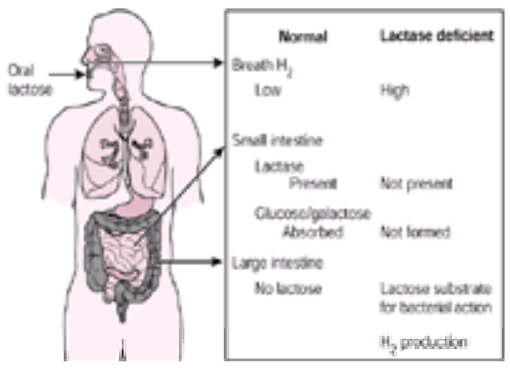

Fig. 1 Lactose-hydrogen breath test for lactase deficiency.

Fat

The estimation of non-absorbed fat, that is faecal fat, is discussed above. A tubeless test, which does not require faecal collection, is the [^{14}C]triolein test. This has been advocated as a simple method to determine lipid absorption. After digestion and absorption of the labelled triglycerides, metabolism in the liver produces ^{14}C-labelled CO_2 which s detected in the breath. This test is not widely used and is only sensitive to large changes in fat absorption.

Bile salts

Bile salts, critical for lipid absorption, undergo an enterohepatic circulation where the conjugated bile salts (such as glycocholate and taurocholate) are reabsorbed in the ileum. Failure to reabsorb these salts increases their concentrations in the colon where they produce a secretory diarrhoea. Tests have been developed to look for evidence of bile salt malabsorption.

The SeHCAT test uses radiolabelled selenohomocholic acid as the taurine conjugate. This is given orally and whole-body retention is measured with a gamma camera after 7 days. Low values result from an excessive loss of bile salts. Bile salt malabsorption, often producing SeHCAT retention values of less than 5 per cent, is found after ileal resection, with ileal disease such as Crohn's, and in idiopathic bile salt malabsorption due to transporter defects. Small intestinal bacterial overgrowth results in deconjugation of the bile salts, which will also impair absorption and retention.

Vitamin B_{12} and the Schilling test

Absorption of vitamin B_{12} (the cobalamins) is particularly complex. Vitamin B_{12} deficiency is common, and, if not nutritional, is due to one of several GI disorders. Intrinsic factor, produced by the stomach, binds cobalamins in the intestine. The intrinsic factor–vitamin B_{12} complex interacts with a receptor in the brush-border membrane of the terminal ileum and is taken up by the cell. Vitamin B_{12} is stored in the liver. Pancreatic enzyme activity is necessary to release dietary vitamin B_{12} from R-proteins in the diet so that it can bind to intrinsic factor. Bacterial overgrowth in the small intestine can split the intrinsic factor–vitamin B_{12} complex before it can be absorbed.

The Schilling test uses radioisotopes of cobalt to label cobalamin. A two-part test is usually performed, with two isotopes, ^{57}Co and ^{58}Co, simultaneously. One isotope is used to label free vitamin B_{12} and the other to label a complex of intrinsic factor and vitamin B_{12}. After an overnight fast, both are given together by mouth, and unlabelled cobalamin is given by intramuscular injection to ensure that binding sites are occupied. Absorbed radiolabelled vitamin B_{12} is excreted in the urine. This is collected for 24 h and should normally contain more than 10 per cent of the ingested dose, with an equal ratio of the two isotopes. In gastric disease, such as pernicious anaemia, or after gastrectomy, absorption is reduced when vitamin B_{12} is given alone but not when it is given with intrinsic factor. In terminal ileal disease, or after resection, absorption of both forms is low. Small-bowel bacterial overgrowth mimics ileal disease, but antibiotic treatment restores vitamin B_{12} absorption to normal.

Gastrointestinal transit

Physiological function tests have been developed to measure the motility of the gut in propelling the contents of the diet through the areas involved in digestion and absorption. These are described in full in Chapter 14.12.

Oesophageal function

Peristalsis in the oesophagus, with appropriately timed relaxation of the upper and lower oesophageal sphincters, is necessary for efficient and comfortable swallowing, without symptoms of dysphagia. Gastro-oesophageal reflux through the lower sphincter will produce heartburn. Oesophageal manometry, with multiple fine tubes passed through the nose and connected to sensors, will measure the pressures in the oesophagus and at the sphincters at rest and during swallowing. Disordered peristalsis, spasm, achalasia, nutcracker oesophagus, and conditions associated with reflux can be diagnosed (see Chapter 14.6).

Monitoring gastro-oesophageal acid reflux with pH-sensitive electrodes over 24 h is useful in diagnosing the severity of gastro-oesophageal reflux disease (**GORD**), and in relating atypical symptoms to episodes of reflux. A small, portable recording device allows the times of symptoms, meals, and sleeping to be recorded, so they can be analysed together with episodes of low pH. A composite score can be calculated, reflecting the severity of reflux. A bile-sensitive electrode is also available, and may be of use in patients with adequate acid suppression but who still suffer symptoms from duodenogastric and gastro-oesophageal reflux.

Gastric emptying

This can be measured by a range of imaging tests, of which radionuclide labelling of liquid and solid food is probably the most effective technique. Tracer quantities of technetium and/or indium are incorporated into simple foods. Gamma scanning over the stomach allows the time course of gastric emptying to be determined. These measurements are useful in conditions such as diabetic gastroparesis or after gastric surgery where bloating, nausea, or vomiting are problems. Radiological measurements of barium emptying, although widely available, are less reliable unless the contrast is incorporated into food. Ultrasound and magnetic resonance imaging (**MRI**) have also been used.

Intestinal transit

Radionuclide techniques, as used to measure gastric emptying, can also determine small-bowel transit by timing the appearance of counts over the caecum.

Estimates of transit times through the large intestine can be obtained with further imaging.

Mouth-to-caecum transit times can be estimated simply with breath-hydrogen testing. As described above, breath hydrogen is derived from the bacterial metabolism of unabsorbed carbohydrates. Lactulose, a non-absorbed sugar, is given by mouth and breath hydrogen sampled every 15 to 30 min. A rise in breath-hydrogen values indicates that the lactulose has reached the caecum. A rapid rise will occur if there is bacterial overgrowth in the small intestine.

Dye markers taken by mouth will give an estimate of the whole-gut transit time when they are detected in the stool.

Radiological markers, small differently shaped pieces of radio-opaque plastic, can be useful in determining transit through the large intestine. These are taken daily for several days. A plain abdominal radiograph shows the number remaining and their distribution in the parts of the colon.

Defecation and anorectal physiology can be measured with manometry in response to balloon inflation in the rectum.

Tests of gastrointestinal integrity and barrier functions

Several tests examine other aspects of GI physiology not discussed above. Evidence for infection, structural damage, or loss of barrier functions can be obtained.

Infection

Helicobacter pylori infection of the stomach is common and can be detected at endoscopy by microscopy, culture, or the biopsy urease test. The urea breath test, an indirect test, is now one of the commonest breath tests performed to look at gastric pathophysiology. Either radiolabelled [^{13}C]- or [^{14}C]urea is given by mouth to fasting subjects. The urease activity of *H. pylori* in the stomach metabolizes this to radiolabelled CO2, which is then exhaled. A standard amount of CO_2 is collected in a breath sample and the activity of the isotope determined—by mass spectrometry for ^{13}C or scintillation counting for ^{14}C. As there are no other sources of urease activity in the body, this is a very specific test. Low-level *H. pylori* infection, as can occur when acid production is suppressed with histamine H2-receptor antagonists or proton-pump inhibitors, can give negative results and reduce the sensitivity of this test.

Bacterial overgrowth in the small intestine can be detected by the glucose-hydrogen breath test (Fig. 2). Glucose given by mouth is normally fully absorbed, but some metabolism to hydrogen will occur if bacteria are present in the small intestine. This will be measurable in the exhaled breath, which is collected every 30 min for 2 h. A positive test produces a diagnostic rise of 20 p.p.m. above a low baseline. It may be necessary to give a diet low in non-absorbable polysaccharides to reduce baseline hydrogen production. This test has a sensitivity of about 80 per cent. Alternative tests, which are less popular, involve the administration of radiolabelled compounds such as the bile salt, cholyl-[^{14}C]glycine (glycocholate), and measuring ^{14}C-labelled CO_2 in the breath (Fig. 3).

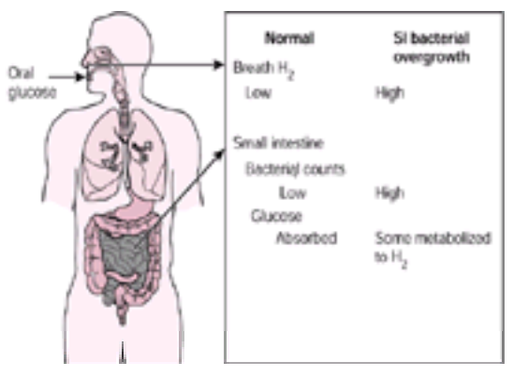

Fig. 2 Glucose-hydrogen breath test for small intestinal bacterial overgrowth.

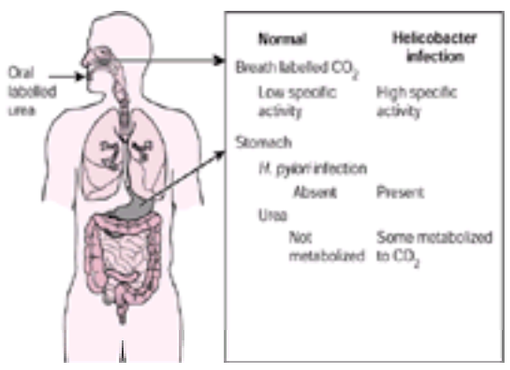

Fig. 3 Urea breath test (^{13}C or ^{14}C) for *H. pylori* infection.

Mucosal damage

Several tests will give abnormal results if the gastrointestinal mucosa is damaged. The faecal occult blood test becomes positive with a relatively small loss of blood per day. Dietary components containing blood or peroxidase can give positive tests. The presence of leucocytes in faeces suggest inflammatory causes of diarrhoea.

White-cell scanning has a role in diagnosing and assessing the activity of inflammatory bowel disease. Autologous white cells, labelled with indium or technetium, are reinjected intravenously and collect in areas of inflammation. Imaging with a gamma camera, at multiple time points, indicate white-cell accumulation at sites of diseased bowel and chemokine production. The complexity and the radiation dosage involved limits the use of this test.

Calprotectin is a calcium-binding protein found in leucocytes. It is stable in the gut lumen and so can be quantified in the stool. It can be detected in faeces in a variety of inflammatory conditions and its simplicity may make it suitable as a first-line screening test.

In patients with small intestinal lymphangiectasia, lymphocytes are lost into the lumen of the gut. The full blood count may then show a lymphopenia. Protein loss also occurs in this disorder. Many other inflammatory and ulcerative conditions can produce a protein-losing enteropathy, and several tests have been employed in attempts to quantify this loss. Since a1-antitrypsin is resistant to breakdown in the intestine, faecal measurements can provide an indication of the loss of serum proteins into the lumen. *In vivo*-labelled [^{51}Cr]albumin is also used to estimate GI protein loss.

The permeability of the intestine can be investigated using a number of different probes: usually sugars, which normally have little uptake in the gut but can enter the body in disease states. These probe substances will then be excreted and measured in the urine. Lactulose is one such sugar that is normally excluded. When administered together with another molecule which is taken up and excreted readily, such as rhamnose or mannitol, the ratio can correct for individual differences in gastric emptying or urine collection. Although the results of these tests are usually abnormal in coeliac disease, specific erological tests, such as endomysial IgA antibodies, are much more specific and sensitive for use in screening. Intestinal permeability changes have been described in other diseases but roles in their pathogenesis are uncertain.

14.3.1 The acute abdomen

Julian Britton

Most patients with acute abdominal pain are treated in the community: a minority are admitted urgently to hospital and then, usually, put under the care of a surgeon. Two-thirds of such patients, wherever they live, are suffering from either abdominal pain for which no cause is found or acute appendicitis. In the remaining one-third many disorders account for the pain and, rarely, the cause lies outside the abdomen. Sometimes patients with a surgical diagnosis present to a physician because the abdominal symptoms and signs are overshadowed or suppressed by a medical condition. Occasionally patients in hospital for another reason will develop an acute abdomen.

The management of acute abdominal pain depends on clinical skill, and investigations play only a small part. Sometimes immediate treatment must take precedence over making a diagnosis. More commonly the clinician has time to take a history, to examine the patient, and to consider a differential diagnosis.

Diagnosis

The history

An accurate history is the essential foundation for the diagnosis of abdominal pain. This requires time, patience, and skill. The doctor should give the patient his or her undivided attention and take care not to interrupt the flow of words. The way patients tell their story is as important as the story itself. Any additional questions should be short, specific, and direct and must be couched in language the patient understands. Body language and sentence construction must not suggest any particular answer. Negative findings are always as useful as positive ones. It is important to obtain sufficient but no more than sufficient information. Unnecessary or irrelevant facts can be misleading and will always add to the difficulties of analysis.

Pain

The nature of the pain is the best guide to the diagnosis. The site and any radiation of the pain may suggest which intra-abdominal organ is the source of the symptom. How and when the pain started and whether it has been constant since then are useful points for consideration. Perforation of the bowel, rupture of an aneurysm, and acute ischaemia all occur suddenly and the pain is severe from the outset. Acute inflammation starts slowly and the pain is constant and increases in severity with time. Colic comes and goes and implies an origin from a viscus containing smooth muscle. Aggravation of the pain on sudden movement is equivalent to rebound tenderness on examination and suggests local peritonitis.

Other symptoms

Nausea and vomiting often accompany abdominal pain, but not necessarily together. Retching without vomiting suggests acute intestinal obstruction with impending strangulation. Anorexia is a non-specific symptom particularly in ill children. Disturbances of bowel function are always important and the complete absence of stool or flatus implies intestinal obstruction. The urinary and the genital systems are common sources of abdominal pain and patients must be asked about the associated symptoms. Complications of previous abdominal surgery cause pain and so, sometimes, do therapeutic drugs.

Examination

General observation of the patient is important. Demeanour is a good guide to the overall severity of the illness. Patients with peritonitis lie perfectly still. Patients with colic are restless. Abdominal distension can be often observed through the sheets and jaundice or the smell of melaena are also important signs.

Pulse, temperature, and blood pressure are essential measurements and changes over time are more valuable than isolated readings. Examination of the abdomen itself follows the pattern of inspection, palpation, percussion, and auscultation. It must include a rectal and vaginal examination and examination of the urine.

If palpation causes pain it is essential to decide if guarding, rigidity, and rebound tenderness are present as well. Rebound tenderness is a reliable guide to the presence of peritonitis. A silent abdomen carries the same implication, and in the context of pain is usually a clear indication that a patient requires an urgent laparotomy. Two surgical conditions which are commonly missed are a small strangulated femoral hernia in an obese patient and pelvic appendicitis. Careful examination of the groin should identify the former. In the latter case the abdominal signs are often subdued because somatic pelvic pain is not referred to the anterior abdominal wall. Tenderness on the right side of the pelvis may be the only positive physical sign and it is critically important to overcome any reluctance to perform a rectal examination.

Investigation

With one exception, simple blood tests do not help to diagnose acute abdominal pain but they are important in managing the surgical patient. The exception is the serum amylase which should be measured in every patient with abdominal pain unless the diagnosis is otherwise obvious. High levels of amylase activity are strongly suggestive of acute pancreatitis. Unfortunately serum amylase is also elevated in patients with biliary colic, perforated peptic ulcer, ischaemic bowel, or ruptured aortic aneurysm. A false negative result is found if the blood sample is taken too late after the onset of pancreatitis because amylase concentrations return to normal within about 48 h. A raised peripheral blood leucocyte count or the presence of white cells or red cells in the urine are useful pointers to intra-abdominal inflammation

or disease of the urinary tract, but neither test is specific.

Radiology

Plain abdominal radiographs are helpful in confirming intestinal obstruction and may show calculi in the gall bladder or the renal tract. Air under the diaphragm on an erect chest radiograph is definite evidence of perforation of the bowel or stomach but does not identify the site of the perforation (Fig. 1). About one in ten patients with a perforated peptic ulcer does not show free intraperitoneal air.

Fig. 1 An erect chest radiograph demonstrating free gas under the right diaphragm. (From Britton J (2000). The acute abdomen. In: Morris PJ, Wood WC, eds. *Oxford textbook of surgery*, 2nd edn. Oxford University Press, Oxford, 1823–42.)

An ultrasound examination may show a swollen tender retrocaecal appendix. Computed tomography will confirm acute pancreatitis and acute diverticulitis.

Making a diagnosis

Even experienced doctors only make a correct diagnosis in three-quarters of patients with abdominal pain, whilst junior doctors are right only about half the time. Patterns of disease provide a useful guide: all over the world acute appendicitis and non-specific abdominal pain are the most common diagnoses in a surgical setting (Table 1). Acute cholecystitis is the third most common cause of an acute abdomen in the developed world, whilst in Africa small bowel obstruction is frequent. In a medical ward it would be unusual to encounter non-specific abdominal pain: diverticulitis, a perforation, a ruptured abdominal aortic aneurysm, or mesenteric infarction from embolism secondary to atrial fibrillation or coronary thrombosis would be more likely.

Occasionally a patient presents with all the classical symptoms and signs of a condition. More commonly the clinician has to analyse the data in a number of different ways often based on anatomy, pathology, or, sometimes, by elimination. Pragmatic doctors simply decide if the abdominal symptoms and signs justify surgery. If they do then the diagnosis becomes apparent at operation. If they do not then the patient is re-examined after a few hours. If the signs worsen then surgery is required. If the patient improves then continued observation is appropriate. The only risk of active observation is that the patient deteriorates significantly in the time spent watching, with a consequent increase in the complication rate after surgery.

Surgical causes of abdominal pain

Acute appendicitis

The incidence of acute appendicitis is declining, but the disease remains frequent and often eludes diagnosis. Periumbilical pain moving to the right iliac fossa over a few hours and accompanied by nausea and fever are the classical symptoms. Tenderness, guarding, and rebound tenderness which is worse in the right iliac fossa are the important physical signs. When all these symptoms and signs are present there is little need for investigation and the treatment is a prompt appendicectomy. Prophylaxis against venous thrombosis is important and appropriate antibiotics given before operation are known to reduce the incidence of subsequent septic complications.

Laparoscopy is valuable when the diagnosis is not clear, particularly in young women in whom the rate of appendicectomy with a normal appendix is high. Laparoscopic removal of the appendix is also possible. Whichever method of appendicectomy is adopted, drinking followed by eating may start in a few hours. Most patients stay in hospital for 24 or 48 h.

Non-specific abdominal pain

Three out of every ten patients admitted to a surgical ward with acute abdominal pain are discharged without a diagnosis. This does not mean that there is no pain or that there is no cause. Acute appendicitis can sometimes resolve.

Acute cholecystitis

This is easy to diagnose, particularly with the assistance of an ultrasound examination. Bed rest, intravenous fluids, and, for most patients, antibiotics will allow the inflammation to resolve. If there is no improvement, the gall bladder should be drained either percutaneously or surgically (Fig. 2). In most instances a cholecystectomy should be performed on the next available operating list.

Fig. 2 This abdominal computed tomography scan shows acute cholecystitis. Fluid can be seen within the thickened wall of the gallbladder. The gall bladder was subsequently drained with a percutaneously placed pigtail catheter.

Intestinal obstruction

Abdominal pain, abdominal distension, vomiting, and constipation are the typical symptoms and signs of obstruction. Adhesions, hernias, and cancer of the large bowel are common causes. Obstruction due to adhesions will sometimes resolve itself during treatment with intravenous fluids and nasogastric suction. Hernias can

sometimes be reduced. In most other instances, surgery is required after appropriate resuscitation.

Perforated peptic ulcer

Surgery to close the perforation and to lavage the peritoneal cavity is the standard treatment. Patients benefit later from treatment to suppress acid secretion and to eliminate *Helicobacter pylori*.

Diverticulitis

This presents with pain and tenderness in the left iliac fossa accompanied by fever. The diagnosis is easily confirmed by computed tomography if necessary. Bed rest, intravenous fluids, and antibiotics are the standard treatment. When colonic perforation occurs, and this can be surprisingly silent, resection of the bowel and a temporary colostomy will be required.

Acute pancreatitis

This is a capricious disease and may complicate other medical or surgical conditions. Treatment is with intravenous fluids and analgesia. Computed tomography will confirm the suspected diagnosis and also helps in the management of complications such as a pancreatic abscess or a pseudocyst.

Medical causes of abdominal pain

Pneumonia

Pneumonia may present with referred abdominal pain in the young and the old especially when complicated by diaphragmatic pleurisy. Sometimes the pneumonia results from inflammation below the diaphragm and it is important to treat both conditions.

Hepatitis

Intrahepatic cholestasis due to drugs, viral hepatitis, or alcohol is easy to confuse with cholangitis caused by extrahepatic obstruction. If the bile ducts are not dilated on ultrasound examination 1 week after the onset of jaundice then large duct obstruction is unlikely to be the cause.

Herpes zoster

Persistent severe pain precedes the rash in herpes zoster (shingles). When one of the lower thoracic or upper lumbar dermatomes is involved patients will present with abdominal pain. The diagnosis is usually impossible before the rash has appeared and is obvious once it has.

Drugs

Digoxin, non-steroidal analgesics, laxatives, and drugs which cause constipation can all cause abdominal pain. The first is notorious for causing nausea, vomiting, and abdominal pain when given to excess.

Gastroenteritis

Severe colic is sometimes a presenting feature of gastroenteritis. Diarrhoea and vomiting are not far behind and the diagnosis is rarely difficult. Patients should be isolated as soon as the diagnosis is suspected and stool cultures should be requested promptly.

Diabetes mellitus

Children with acute type 1 diabetes may complain of abdominal pain. They are always ketotic and hyperglycaemic and the diagnosis can often be made by smelling the patient's breath. A surgeon should check that some septic focus is not an underlying cause and refer the patient urgently to a physician.

Rarities

Rare causes of abdominal pain such as sickle cell crises, acute porphyria, lead poisoning, or a spinal tumour are often only made after a considerable period of time and then usually by exclusion. The diagnosis is often suggested by appropriate review of the past history and family history of the patient. Once the possibility of these rarities is considered it is a simple matter to arrange the relevant tests: since these disorders greatly aggravate the risks of exploratory surgery under general anaesthesia, prompt diagnosis and rapid referral for definitive treatment is highly desirable.

Management of the medical patient with abdominal pain

Observation

Most patients who develop acute abdominal pain on a medical ward will require the opinion of an experienced surgeon. If this is deemed unnecessary or a surgeon is not immediately available then the patient should be placed under observation and reviewed at frequent intervals.

Pain relief

Analgesia suppresses abdominal signs and is best not given until a diagnosis has been made. However, a surgeon can allow for the diagnostically confounding effects of analgesia provided it is clear which drug has been given and when; patients in pain should be given the analgesia they need.

Antibiotics

Treating undiagnosed abdominal pain with antibiotics is not recommended. They are rarely curative.

Resuscitation

Patients who may need an abdominal operation should not be given any food or drink by mouth and should be resuscitated with appropriate intravenous fluids. There will then be the minimum of delay if surgery under general anaesthesia is required.

14.3.2Gastrointestinal bleeding

T. A. Rockall and T. Northfield

Introduction and definition

Acute gastrointestinal haemorrhage is classified by its origin, from either the upper or the lower gastrointestinal tract, anatomically demarcated by the ligament of Treitz. Only when gastrointestinal bleeding is acute does it constitute an emergency. Chronic, low-volume blood loss is usually subclinical until such time as it presents with iron deficient anaemia.

Acute upper gastrointestinal haemorrhage (AUGIH)

Epidemiology

The incidence of AUGIH in the United Kingdom is approximately 1 per 1000 adults/year, of which 15 per cent of cases occur in patients already in hospital. The male incidence is twice that of the female in all age groups except the elderly, where they are similar. The annual incidence increases dramatically with age, rising to nearly 5 per 1000/year in the over 75 age group. In the United Kingdom in 1993, about one-quarter of cases occurred over the age of 80 years.

Aetiology

Many gastrointestinal lesions may result in haemorrhage but peptic ulcer is the most frequent in the United Kingdom (Table 1). Each diagnostic group has its own aetiological factors. *Helicobacter pylori* infection and ingestion of aspirin and non-steroidal anti-inflammatory drugs (NSAID) are important for ulcer disease and erosions of the upper gastrointestinal tract. Ulceration may also occur at the site of surgical enterostomies (stomal ulcers) and in association with the Zollinger–Ellison syndrome. Peptic ulceration at specific sites is associated with major haemorrhage due to the anatomical relation of major arteries—the posterior wall of the first part of the duodenum (gastroduodenal artery), the lesser curve of the stomach (left gastric artery), and posterior wall of stomach (splenic artery).

Liver disease due to alcohol and hepatitis are the principal causes in Western countries of portal hypertension, which leads to oesophageal varices; variceal bleeding may rarely affect the stomach and the remaining gastrointestinal tract. Mallory–Weiss tears are mucosal lesions at the oesophagogastric junction associated with profuse vomiting; haematemesis occurs which is usually minor and always self-limiting. The most common malignant causes of upper gastrointestinal haemorrhage are adenocarcinoma of the stomach and gastric lymphoma, but acute bleeding is an unusual presentation. Other causes include benign tumours (or those with uncertain malignant potential) such as the stromal tumours (previously described as leiomyomas) which may bleed when the mucosal surface ulcerates, angiodysplasia (and other vascular lesions), aortoduodenal fistula, haemobilia, and trauma.

Clinical features

Upper gastrointestinal haemorrhage usually presents with haematemesis or 'coffee-ground' vomiting and melaena. Frank haematemesis indicates a severe bleed. It is not always a feature but melaena will always follow a significant bleed. In rapid bleeding, symptoms of hypovolaemia may precede haematemesis or melaena. These include postural hypotension, syncope, shock, and even death. In most cases, the causative lesion will not be known until diagnostic endoscopy is undertaken. The patient should be asked about ingestion of NSAIDs and whether blood was present in the first vomit (it is usually absent in Mallory–Weiss tear). Signs of chronic liver disease may be present in patients with oesophageal varices but this does not confirm the cause of blood loss since peptic ulcer is a common synchronous lesion. Melaena is a clinical diagnosis made on the observation of black, tarry, offensive stool on rectal examination or passed spontaneously. In patients with rapid haemorrhage, usually accompanied by shock, fresh blood may be passed per rectum (haemochezia) and may thus be difficult to distinguish from lower gastrointestinal haemorrhage. A mix of fresh blood and melaena may indicate a lesion in the lower small intestine (e.g. Meckel's diverticulum).

Laboratory diagnosis

AUGIH is a clinical diagnosis. The initial haemoglobin estimation is not a useful indicator of the volume of blood lost until time for haemodilution has passed. The haemoglobin may be normal in a patient with a large, acute haemorrhage. Equally, the haemoglobin may be low in a patient with iron deficiency anaemia resulting from chronic haemorrhage who presents with a small, acute bleed. The haemoglobin and haematocrit after volume resuscitation are more useful. Platelet count and coagulation studies are important to exclude a bleeding disorder and are of particular relevance in patients receiving therapeutic anticoagulants and in those with liver disease.

Treatment

The management of acute upper gastrointestinal haemorrhage falls into four principal stages.

Assessment, resuscitation, and monitoring

Important aspects of assessment are confirmation that a bleed has occurred and the degree of hypovolaemic shock that has resulted. Resuscitation is as for any hypovolaemic patient with the immediate aim of rapidly replenishing blood. Tachycardia, vasoconstriction, sweating, hypotension (including a postural drop), tachypnoea, and a low central venous pressure all indicate hypovolaemia. Adequate resuscitation is evidenced by a normal pulse rate, blood pressure and central venous pressure, production of urine, and an improving level of consciousness. Central venous access and placement of a urinary catheter will help in the resuscitation and monitoring of the more severe cases and those with major cardiovascular and respiratory comorbidity. Once circulating blood volume has been restored, management should be aimed at monitoring the patient for continued or recurrent bleeding, replacing blood, making a diagnosis, and instituting therapy. Regular pulse, blood pressure, central venous pressure, and urine output will give a good guide. Fresh haematemesis obviously indicates further acute haemorrhage. The passage of further fresh melaena has to be interpreted in the light of the cardiovascular signs and repeated estimations of blood haemoglobin concentration.

Diagnosis and haemostasis

In most instances, the diagnosis is obscure until upper gastrointestinal endoscopy is undertaken. This diagnostic, and potentially therapeutic, procedure should be undertaken as soon as possible after resuscitation is complete. The aim of endoscopy is fourfold:

1. to make a diagnosis;
2. to assess the risk of further haemorrhage based upon the site, size, and nature of the lesion (including stigmata of recent haemorrhage);

3. to apply haemostatic therapy where appropriate;
4. to inform the surgeon as to the site of the lesion in cases requiring urgent surgery due to rapid, ongoing blood loss and to exclude varices in these cases.

Haemostasis occurs spontaneously in most cases. When bleeding continues, haemostasis can be achieved by endoscopic, surgical, or radiological means. Endoscopic haemostatic therapy may be given in the form of injection of adrenaline or sclerosants (e.g. polidocanol) either alone or in combination, or other substances such as fibrin glue. The application of heat energy in the form of laser (Argon or NdYAG), heater probe, or diathermy are also effective for peptic ulcer with active bleeding or visible vessels. There is good trial evidence that endoscopic therapy reduces the rate of rebleeding in these subgroups and one trial has shown a reduction in mortality. There is no randomized, controlled trial evidence that planned, repeated endoscopic therapy further reduces rebleeding in peptic ulcer. Repeated injection or banding have been shown to reduce rebleeding and mortality from oesophageal varices.

Surgery is indicated in massive, acute bleeding not amenable to endoscopic therapy or where endoscopic therapy fails to control active bleeding. Many units would attempt a second endoscopic therapy especially in young patients before resorting to surgery. There is some evidence that early surgical intervention in those over 60 is appropriate. There is no place for a third attempt at endoscopic therapy and surgery is indicated. In cases where endoscopic therapy has failed and surgery is deemed to be exceptionally high risk, visceral angiography may allow for embolization (e.g. the gastroduodenal artery in duodenal ulcer).

Uncontrolled variceal haemorrhage may be controlled with a Sengstaken–Blakemore tube as a temporary measure before more definitive treatment. Where endoscopic therapies subsequently fail, transjugular intrahepatic portosystemic shunt (TIPSS) is a minimally invasive method of creating a portosystemic shunt. Finally, oesophageal transection is occasionally life saving where all other attempts at haemostasis have failed.

Treatment of causative lesion

Treatment of the causative lesion should be started as soon as possible after diagnosis. There is, however, no evidence that drug therapy alters the outcome of the bleeding episode in terms of rebleeding or death. Histamine (H_2) receptor antagonists and proton pump inhibitors both heal ulcers but neither have been shown to affect the outcome of the bleeding episode. Where the causative lesion is a tumour (benign or malignant) then elective surgery may be indicated. Angiodysplasia can be treated with laser or argon beam. Specific treatments may be required for rarer causes such as tuberculosis.

Prevention of recurrence

Recurrent episodes of bleeding from peptic ulcers can be achieved by eradicating *H. pylori* infection and through the avoidance of ulcerogenic drugs. Persistent ulceration despite these measures may require long-term acid suppressive therapy and Zollinger–Ellison syndrome should be excluded. Variceal haemorrhage can be prevented through programmes of variceal eradication by injection or banding and also by TIPSS, or ultimately liver transplantation where indicated.

Prognosis

Prognosis depends on many factors including the severity of the bleed, the age of the patient, the associated comorbidity of the patient, the diagnostic category, the endoscopic features (stigmata of recent haemorrhage), and whether continued or recurrent bleeding is a feature. Overall, the crude mortality for patients presenting to emergency departments with acute upper gastrointestinal haemorrhage is about 10 per cent. Most deaths occur in the elderly and those with severe comorbidity. Death in those under the age of 60 with no comorbidity is very low (0.1 per cent) regardless of the severity of the haemorrhage. The factors that contribute to mortality have been combined in a prognostic risk score. This is represented in Table 2. The mortality associated with each risk score is represented in Table 3.

Acute lower gastrointestinal haemorrhage

Epidemiology

The incidence of lower gastrointestinal haemorrhage has not been well defined but it is common. Most (90 per cent) of acute lower gastrointestinal bleeds will stop spontaneously although 35 per cent will require blood transfusion, and 5 per cent will require urgent surgical intervention.

Aetiology

As in upper gastrointestinal haemorrhage, several pathological causes are responsible. Most causative lesions are colonic or anorectal and only 3 per cent originate in the small bowel. In the Western world, diverticular disease represents the largest proportion of cases (40 per cent), followed by inflammatory bowel disease (20 per cent, including Crohn's, ulcerative colitis, infectious colitis, and ischaemic colitis), neoplasia (15 per cent), benign anorectal disease (10 per cent), and arteriovenous malformations (2 per cent). Other lesions are rare and include radiation injury, Meckel's diverticulum, other small bowel pathology, and varices. Bleeding is not uncommonly associated with coagulopathy but studies have shown the distribution of causative lesions in these cases to be the same. In severe cases, however, generalized mucosal bleeding may occur.

Iatrogenic causes of haemorrhage include postpolypectomy bleeding and anastomotic bleeding. The risk of haemorrhage after polypectomy is estimated to be between 0.2 per cent and 3 per cent. Haemorrhage is usually immediate but may be delayed. When identified, endoscopic haemostatic techniques are usually successful (injection of adrenaline, resnaring, recoagulating, placement of a ligature or clip).

Acute colonic diverticular bleeding is common. The estimated risk of bleeding with this disease is about 15 per cent. After a single bleed, the risk of recurrence is 25 per cent and after two bleeds it is 50 per cent. Eighty per cent of all bleeds stop spontaneously and no therapy is indicated. Operative intervention should be considered after two major bleeds because the risk of further recurrence is high. However, many of these patients are frail and elderly and continuation of conservative treatment for multiple, self-limiting episodes may be appropriate. Inflammatory bowel disease often manifests itself as bloody diarrhoea but more rarely may present with profuse haemorrhage. This is more common in Crohn's disease than in ulcerative colitis because the inflammation involves the whole thickness of the bowel wall. Up to 6 per cent of patients with this disease may sustain a major haemorrhage. About 50 per cent stop bleeding spontaneously but of these 35 per cent will rebleed. For this reason, urgent surgery is usually indicated for patients with a life-threatening haemorrhage as a result of inflammatory colitis. The operation usually required is a total colectomy. The rectum is usually preserved at this stage unless this is the site of major haemorrhage. Ischaemic colitis rarely causes severe haemorrhage. Bloody diarrhoea is more usual and may be accompanied by pain.

Benign and malignant colonic tumours may present as profuse bleeding although occult blood loss and minor fresh bleeding is more common. Rarely is urgent surgical intervention required. Vascular anomalies occur with increasing frequency with age. They may originate from chronic, partial venous obstruction of submucosal veins due to incompetence of the precapillary sphincters and arteriovenous malformations. These lesions are usually multiple and are most frequent in the caecum and ascending colon. Bleeding is usually slow, intermittent, and recurrent although once again it is occasionally massive (2–15 per cent). Most (90 per cent) stop spontaneously but 25 to 85 per cent will recur. The treatment of choice is endoscopic coagulation if the lesions can be identified. Colectomy is reserved for those with repeated major haemorrhage.

Benign anorectal disease does present as lower gastrointestinal haemorrhage and a careful examination of the anorectum is imperative before initiating more invasive examinations. However, anorectal lesions are common and complete colonic evaluation is usually required even after identifying an anorectal source such as haemorrhoids.

Diagnosis and treatment

A good history from the patient may give clues as to the cause of colorectal haemorrhage. Important points include a prior history of bleeding, the presence of liver disease, and drug usage (aspirin, non-steroidal anti-inflammatory drugs, and warfarin) as well as the exact nature of the bleeding—specifically the duration, the colour of the blood, the relationship to defaecation, whether the blood is mixed with or separate from the stool, an associated change in bowel habit, or mucus discharge. Bright red blood separate from the stool suggests an anorectal cause. Diarrhoea and mucous associated with darker blood mixed in with the stool suggests colitis or neoplasm. None of these clinical features, however, is absolutely diagnostic.

Resuscitation measures are as for bleeding from the upper gastrointestinal tract. However, since most lower gastrointestinal bleeds stop spontaneously, initial

management should be conservative with transfusion and correction of clotting abnormalities. Once haemorrhage has ceased, bowel preparation and colonoscopy can be undertaken in a stable patient and with a much higher chance of detecting the pathological lesion (85–90 per cent).

In the small proportion of patients in whom active colonic bleeding continues, investigation to localize the source of the haemorrhage is indicated so that directed treatment can be administered in the form of endoscopic therapy, interventional radiology, or surgery. Colonoscopy is favoured by many clinicians but the use of bowel preparation is still debated. Some favour the use of a purgative together with distal colonic washouts before endoscopy, whilst other authors have argued that this is unnecessary because of the cathartic effect of blood in the colon. In one study, the causative lesion was identified in three-quarters of patients without preparation. This compares favourably with studies which have used mechanical preparation methods. Colonoscopy should be abandoned if massive haemorrhage obscures the diagnosis or severe mucosal or ischaemic colitis is encountered, as the risk of perforation in these cases is high.

Nuclear scintigraphy can be used to detect active haemorrhage. It is very sensitive and can detect bleeding rates of less than 1 ml/min. Tc99m labelled sulphur colloid can be used, which has the advantage of no preparation but the half-life is very short and its rapid enhancement of the liver and spleen can obscure the diagnosis. A better method is the use of Tc99m labelled red cells. Unfortunately, although sensitive, it is also very non-specific and localizes the lesion very poorly. It may be useful immediately before angiography to confirm active haemorrhage before undertaking the more invasive procedure. Whenever there is massive, active haemorrhage, however, this is unnecessary and the patient should proceed directly to visceral angiography.

Selective mesenteric angiography can also detect a rate of bleeding of 0.5 to 1.0 ml/min. The sensitivity reported in various studies ranges from 40 to 86 per cent. Once the site of haemorrhage is identified, the patient can proceed directly to surgery or there is the therapeutic possibility of arterial infusion of vasopressin or selective embolization. Vasopressin infusion has considerable side-effects including mesenteric thrombosis, intestinal infarction, myocardial ischaemia, hypertension, arrythmias, and death. Nitroglycerin may be infused simultaneously to counteract the systemic effects of the drug. There is a wide range in the reported rate of initial control of the haemorrhage, and the rebleeding rate is high (22–71 per cent).

Selective embolization using coil springs or gelfoam into the most distal vessel results in high initial rates of haemostasis and the rate of intestinal infarction is low. It is a good technique for patients with a very high predicted operative mortality.

From a practical aspect, investigation should start with examination of the abdomen and rectum, followed by proctosigmoidoscopy. If there is any suspicion of an upper gastrointestinal cause, then upper gastrointestinal endoscopy is recommended. Colonoscopy is the investigation of choice to evaluate the colon and terminal ileum. Where this fails, visceral angiography should be undertaken, which may allow the site of haemorrhage to be identified and treatment instituted.

In about 5 per cent of cases, the source of bleeding remains obscure. Additional investigations may include small bowel enteroscopy or laparotomy with on-table enteroscopy.

14.4 Immune disorders of the gastrointestinal tract

M. R. Haeney

Introduction

The gut is protected by several mechanisms. The intercellular tight junctions of the epithelial cells form an important physical barrier; these cells turn over every 24 to 96 h. Any injury to the epithelial barrier results in rapid migration of adjacent viable epithelial cells to cover the denuded area, a process called 'restitution', while lymphocytes and macrophages migrate through pores in the basement membrane to provide temporary protection. The acid pH of the stomach and the proteolytic enzyme content of the intestine are formidable chemical barriers to many organisms. A change in the normal microflora of the intestine or impaired gut motility may allow pathogenic bacteria to flourish. Microbial antigens that resist these defences and penetrate the epithelial surface encounter the mucosal immune system.

Functional morphology of the gut-associated lymphoid tissue

Lymphocytes are found at three sites within the mucosa (Fig. 1):

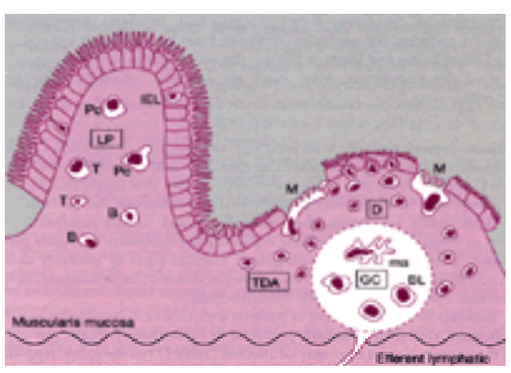

Fig. 1 Organization and structure of gut-associated lymphoid tissue. On the left, T and B lymphocytes and plasma cells (PC) can be seen in the lamina propria, with intraepithelial lymphocytes (IEL) between the columnar epithelial cells. On the right, there is a Peyer's patch covered by cuboidal epithelium with occasional 'M'cells. The Peyer's patch comprises three areas: the dome (D) of T and B lymphocytes; the thymus-dependent area (TDA); and the germinal centre (GC) containing macrophages (Ma) and B lymphoblasts (BL).

1. organized lymphoid aggregates (Peyer's patches) beneath the epithelium of the terminal small intestine;
2. lymphocytes within the epithelial cell layer (intraepithelial lymphocytes);and
3. lymphocytes scattered among other immunocompetent cells within the lamina propria.

Gut-associated lymphoid tissue is divided into two functional compartments: an afferent arm—Peyer's patches—where interaction occurs between luminal antigens and the immune system, and an effector arm—the lymphocytes of the intraepithelium and lamina propria.

Peyer's patches

These are covered by a specialized epithelium (follicle-associated epithelium) that has no microvilli but whose surface seems wrinkled or folded under the scanning electron microscope (Fig. 1). These microfold, or M, cells sample and transport particulate antigens from the lumen into the 'dome' area, where T and B cells mix freely with the microfolds of the M cells and priming of both types of lymphocyte occurs. Within Peyer's patches are specialized T cells that induce immature IgM-bearing B lymphocytes to switch isotype to IgA.

Lymphocytes are mobile: an array of cell surface receptors permits adhesion to endothelial cells and to components of the extracellular matrix. Primed B lymphoblasts, committed mainly to producing IgA antibody, migrate from Peyer's patches, via the lymphatics and mesenteric lymph nodes, to the thoracic duct and hence into the circulation. These cells return preferentially to the lamina propria, a process known as 'homing'. Once back in the gut, they mature into IgA plasma cells and are responsible for local and secretory antibody defences. The number of IgA-containing cells in the lamina propria far exceeds the numbers containing IgM, IgG, or IgE.

Intraepithelial lymphocytes

There is a similar migration pathway for T lymphocytes whereby T blasts from mesenteric nodes 'home' both to the epithelium and to the lamina propria. Intraepithelial lymphocytes are phenotypically and functionally distinct from peripheral blood lymphocytes. Peripheral T cells rarely express the human mucosal lymphocyte antigen (HML-1) but nearly all intraepithelial lymphocytes do. Human mucosal lymphocyte antigen CD103 is a novel aEb7 integrin which binds to its ligand, E-cadherin, expressed on gut epithelial cells. This interaction may direct homing of intraepithelial lymphocytes to the epithelium but is more likely to selectively retain intraepithelial lymphocytes within the epithelial compartment. Intraepithelial lymphocytes are not a homogeneous population: about 10 per cent do not express the CD3 antigen and therefore are not T cells. About 70 per cent are CD8+ and show increased expression of the g/† form of the T-cell receptor compared with peripheral blood lymphocytes (see Chapter 5.1). In experimental models, some intraepithelial lymphocytes are cytotoxic and some have natural killer activity, functions important in the control of enterovirus infection. Intraepithelial lymphocytes also seem to have a role in controlling the cell barrier function of epithelial cells, i.e. 'restitution'. However, the function of intraepithelial lymphocytes in humans is unclear.

Lamina propria lymphocytes

Large numbers of lymphocytes, natural killer cells, mast cells, macrophages, and plasma cells occur in the lamina propria. T and B lymphocytes are both found, but T cells predominate in a ratio of about 4:1. In contrast to intraepithelial lymphocytes, 80 per cent of these T cells are CD4+. They do not proliferate well after stimulation of the T-cell receptor, yet produce large amounts of cytokines interleukin 2, interleukin 4, interferon-g, and tumour necrosis factor-a. T-cell homing to the lamina propria is determined mainly by the integrin a4b7 on primed cells interacting preferentially with mucosal addressin cell adhesion molecule 1 expressed on the

microvascular endothelium in the lamina propria.

Secretory immunoglobulins

The plasma cells of the lamina propria secrete mainly IgA, which is specially adapted for its function. IgA is synthesized as a dimer with two IgA molecules linked by a smaller 'joining' peptide (the J chain), also produced by the plasma cells. The secretory component is a 70 kDa fragment of the polymeric immunoglobulin receptor synthesized by epithelial cells and is essential for transport of secretory IgA into the gut lumen. The polymeric Ig receptor binds the dimeric IgA; the complex is endocytosed and transported through the cytoplasm to the luminal surface of the cell where proteolysis of the receptor occurs. The IgA dimer is released into the gut attached to the proteolytic fragment of the receptor now called secretory component. Secretory component also protects the IgA molecule from degradation by proteolytic enzymes.

Secretory IgA predominates in the saliva and in gastric and intestinal secretions, where it tends to be concentrated in the mucous layer overlying epithelial cells. Secretory IgA neutralizes viruses, bacteria, and toxins and prevents the adherence of pathogenic micro-organisms to gut epithelium and so blocks the uptake of antigen into the systemic immune system.

Spectrum of intestinal immune responses

Ingestion of antigens can lead to local immunity, a systemic immune response, or a state of specific immune unresponsiveness (tolerance).

Local immune responses

These can occur independently of a systemic response. For example, immunization against poliomyelitis with oral Sabin vaccine gives better protection than the injected Salk vaccine, even though both induce serum antibodies. Local IgA antibody, produced in response to the oral vaccine, partly blocks uptake of pathogenic virus into the circulation.

Systemic immune responses

Macromolecules are absorbed by the intestine into the portal or systemic circulations, via either the glandular epithelium covering the villus or the M cells. Up to 2 per cent of a dietary protein load appears antigenically intact in the circulation. Sinusoidal phagocytes (Kupffer cells) of the liver destroy much of the antigen but enough passes through the liver to stimulate systemic antibody production, particularly in the spleen. Antibody formed in the spleen enters the portal circulation to complex with incoming antigen. Circulating immune complexes of IgA and dietary antigens are regularly found in normal people after meals.

Systemic tolerance

A unique feature of the mucosal immune system is its ability to downregulate immune responses to dietary antigens (oral tolerance). Native Americans knew that eating the leaves of poison ivy prevented contact dermatitis on subsequent exposure to the plant. This observation can be reproduced in animals by feeding them antigen; they become immunologically unresponsive (tolerant) to subsequent parenteral injections of that antigen. Oral tolerance can affect all aspects of the systemic immune response: a single feed of protein antigen suppresses systemic IgM, IgG, and IgE responses as well as T-cell mediated immunity. This has led to attempts to treat autoimmune diseases by feeding autoantigens to patients.

Immunological disorders of the gastrointestinal tract

Normally, the intestinal immune system steers a delicate course between the undesirable extremes of immunological incompetence, with resulting vulnerability to ingested pathogens (for instance, the gastrointestinal consequences of primary and secondary immunodeficiencies), and hypersensitivity to dietary antigens, with immunologically mediated reactions each time that antigen is eaten.

Primary immunodeficiency diseases

Immunocompromised patients are at risk from two sources of infection: common pathogens, which invade even the immunologically healthy, and 'opportunistic' agents that can invade and infect only those with weakened defences. In the compromised host, most infections are due to common pathogens that are readily identified and controlled. The difficult problems arise from opportunistic infections because these often elude isolation, may not respond to available drugs, and carry a high fatality. Indeed, the identification of certain opportunistic infections implies an underlying immunodeficiency that demands further investigation.

It is beyond the scope of this section to deal with all the gastrointestinal complications of every known form of primary and secondary immunodeficiency. Instead, attention will be focused on representative disorders.

Common variable immunodeficiency (CVI)

Common variable immunodeficiency is an example of one of the primary antibody deficiency syndromes described in Section 5.

Definition

Common variable immunodeficiency is a heterogeneous group of disorders characterized by low serum immunoglobulin levels, a normal or low proportion of circulating B lymphocytes and, in about one-third of patients, impaired cell-mediated immunity. It can present at any age and, in the United States and Western Europe, the prevalence is about 40 per million of the population. Most cases are sporadic, although some are inherited.

Clinical features

Patients present typically with recurrent sinopulmonary infections, most frequently caused by pneumococci, streptoccoci, and *Haemophilus influenzae.* Less commonly, they present with arthropathy, skin sepsis, meningitis, osteomyelitis, or other severe systemic bacterial infections (see Section 7).

With certain exceptions, these patients are not unduly susceptible to viral or fungal infections, because cell-mediated immunity is usually preserved. There are rarely any diagnostic physical signs of antibody deficiency, although examination often shows evidence of the consequences of previous infections, particularly bronchiectasis.

Between 30 and 50 per cent of patients with common variable immunodeficiency have gastrointestinal problems at some time. Virtually any part of the gastrointestinal tract may be affected (Table 1) but the most common symptoms are diarrhoea (intermittent or chronic) and weight loss. An approach to the diagnosis of these complications is shown in Fig. 2.

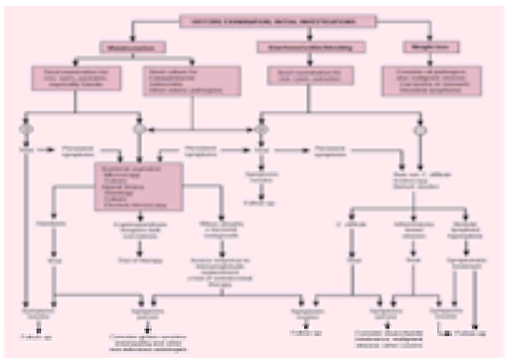

Fig. 2 A scheme for the investigation of gastrointestinal complications in patients with common variable immunodeficiency. (Reproduced from Haeney MR (1989). Gastrointestinal disease in the immunocompromised host. In: Turnberg LA, ed. *Clinical gastroenterology* by permission of Blackwell Science, Oxford.)

Stomach

Achlorhydria and pernicious anaemia

Achlorhydria is found in about 30 per cent of patients and the associated atrophic gastritis occasionally leads to a syndrome resembling pernicious anaemia except that the atrophic gastritis involves the whole stomach without antral sparing, the serum gastrin concentrations remain normal, and autoantibodies to gastric parietal cells and intrinsic factor are absent.

Gastric cancer

Patients with common variable immunodeficiency have a 47-fold increase in the incidence of carcinoma of the stomach. It is sufficiently common to warrant yearly gastroscopic examination in hypogammaglobulinaemic patients who have atrophic gastritis. The high concentrations of microbial enzymes and nitrites found in the gastric juices may lead to local production of carcinogenic *N*-nitroso compounds. Chronic active gastritis induced by *Heliobacter pylori* and overexpression of p53 may also play a role in gastric carcinogenesis.

Small intestine

Infective complications

Although infestation with *Giardia lamblia* is the most common identifiable cause of malabsorption, in many patients the cause is never found. Giardiasis is virtually confined to adults and is rarely seen in boys with X-linked hypogammaglobulinaemia. Giardiasis may also cause diarrhoea, villous abnormalities, vitamin B_{12} and folate malabsorption, steatorrhoea, disaccharidase deficiency, and protein-losing enteropathy but the pathogenetic mechanisms are poorly understood.

Examination of at least three consecutive fresh stool specimens is essential to detect the cysts of *G. lamblia* (Fig. 2). If this fails, duodenal aspiration and jejunal biopsy are needed to establish the diagnosis. In particularly difficult cases, a therapeutic trial of metronidazole can be useful, although infestation frequently recurs. Most patients show symptomatic improvement after treatment with either a 7-day course of metronidazole (2 g daily as a single dose) or mepacrin (100 mg, three times daily for 10 days). Other parasitic infestations occur. *Cryptosporidium* infection occasionally causes self-limiting diarrhoea but has a much more sinister outcome in boys with CD40 ligand deficiency (hyper IgM syndrome) and in patients with human immunodeficiency virus (**HIV**) infection.

Bacterial infections also cause diarrhoea in patients with common variable immunodeficiency and *Campylobacter jejuni* is frequently responsible. Rarely, campylobacter causes an ascending cholangitis and hepatitis. Treatment is a 2-week course of erythromycin (500 mg, four times daily) with follow-up stool culture to ensure that treatment has been effective.

Shigella or salmonella diarrhoea does not occur more commonly than normal. Similarly, while overgrowth of commensal bacteria is common, bacterial counts rarely exceed 10^5 organisms/ml, compared with counts of more than 10^6/ml in the blind-loop syndrome. Nevertheless, it is common practice to treat these patients empirically with tetracycline and metronidazole, often with symptomatic improvement.

Nodular lymphoid hyperplasia

Nodular lymphoid hyperplasia describes the presence of lymphoid nodules in the lamina propria of the gut. Although described in many disorders and occasionally in healthy individuals, nodular lymphoid hyperplasia should make the clinician suspect common variable immunodeficiency. It occurs in 20 to 50 per cent of patients but is not necessarily symptomatic. The nodules, which are 1 to 3 mm in diameter, appear as protrusions on fibreoptic endoscopy (Fig. 3 and Plate 1) and as multiple filling defects on barium studies (Fig. 4). Nodular lymphoid hyperplasia restricted to the rectum or colon can present with rectal bleeding, abdominal pain and features of intestinal obstruction, but rarely with diarrhoea.

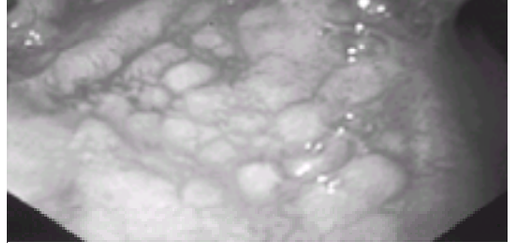

Fig. 3 The appearance of nodular lymphoid hyperplasia on upper gastrointestinal endoscopy. (See also Plate 1.)

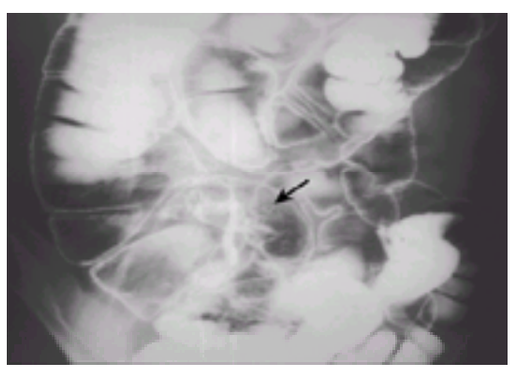

Fig. 4 A double-contrast barium enema showing nodular lymphoid hyperplasia in the terminal ileum (arrowed).

The ultrastructure of these nodules is similar to Peyer's patches, and lymphoblasts containing IgM are found in the centres of the follicles. The condition probably represents hypertrophy of the gut-associated lymphoid tissue in response to antigens in the gut lumen. In one series of nodular lymphoid hyperplasia in individuals with normal serum immunoglobulins, every patient had intestinal giardiasis, suggesting an aetiological link with persistent infestation. Although nodular lymphoid hyperplasia is not premalignant in patients with hypogammaglobulinaemia, intestinal lymphoma has been reported in apparently immunocompetent subjects with extensive small-bowel nodular lymphoid hyperplasia.

Hypogammaglobulinaemic sprue

In a few patients with unexplained diarrhoea, the mucosal lesion resembles coeliac disease or tropical sprue but with reduced or undetectable plasma cells within the lamina propria. In tropical regions, about 1 per cent of patients with 'sprue' may be suffering from a primary humoral immunodeficiency syndrome. Malabsorption in patients with hypogammaglobulinaemic sprue can improve rapidly after replacement immunoglobulin therapy.

Although extremely rare, patients with common variable immunodeficiency may have concomitant gluten-sensitive coeliac disease.

Inflammatory bowel disease

About 5 per cent of patients with common variable immunodeficiency have features of inflammatory bowel disease with radiological and histological findings of Crohn's disease. Others have proposed a specific common variable immunodeficiency enteropathy characterized by low-grade microscopic colitis, increased intraepithelial lymphocytes, and an intact crypt architecture with a good response to an elemental diet.

Non-granulomatous jejunoileitis

This is a rare feature of common variable immunodeficiency and has a poor prognosis.

Management

The cornerstone of treatment of antibody deficiency is immunoglobulin replacement; enough must be given to prevent further infections and reduce the incidence of complications. Intravenous or subcutaneous immunoglobulin therapy is the treatment of choice and is discussed more fully in Section 5.

Antibody-deficient patients respond as promptly as others to appropriate antibiotics but longer courses of treatment are usually needed to ensure complete eradication of the micro-organism.

Selective IgA deficiency (see also Section 5)

Definition

Selective IgA deficiency refers to a serum IgA concentration below the limit of detection (< 0.01 g/l). By definition, the serum IgG and IgM concentrations are normal.

Aetiology

Selective IgA deficiency is common and occurs in about 1 in 700 of healthy adults. Most cases are sporadic, but there is an association with inheritance of the HLA B8, DW3 haplotype, and with deficiencies of IgG2 and IgG4. It is sometimes linked with defects in chromosome 18, particularly in the autosomal recessive syndrome of ataxia telangiectasia. Selective IgA deficiency may also be due to drugs such as phenytoin or penicillamine.

Clinical features

Although selective IgA deficiency is associated with a range of disorders, most IgA-deficient individuals are asymptomatic, possibly because IgM-producing cells provide high local concentrations of IgM antibody or because symptomatic individuals are those who also have deficiency of IgG2 antibodies to polysaccharide antigens.

Gastrointestinal complications (Table 2)

Pernicious anaemia

Selective IgA deficiency is associated with pernicious anaemia. Unlike common variable immunodeficiency, the anaemia conforms to the classical Addisonian type in that atrophic gastritis and raised serum gastrin levels occur.

Malabsorption and steatorrhoea

IgA deficiency occurs in about 1 in 40 of patients with coeliac disease, over 15 times more frequently than in the general population. Patients with selective IgA deficiency and a flat jejunal mucosa respond to dietary gluten withdrawal in a way typical of classical coeliac disease.

Antibodies to dietary antigens

Secretory IgA helps prevent absorption of food antigens through the intestinal mucosa and there is a high prevalence of serum antibodies to food proteins in patients with selective IgA deficiency. For instance, about a third of IgA-deficient blood donors have serum antibodies to milk compared with 0.3 per cent of healthy controls. IgA-deficient subjects also tend to have autoantibodies to antigens such as collagen and IgA itself (see below).

Gastrointestinal infection

With the exception of *G. lamblia* infestation, other infections rarely persist. Even giardiasis is far less frequent than in common variable immunodeficiency. However, in the past, IgA-deficient patients were prone to develop chronic diarrhoea and malabsorption after truncal vagotomy and gastroenterostomy for duodenal ulceration. This was due to overgrowth of commensal bacteria in the upper intestinal tract, presumably because of the combined effects of deficiency of local antibody production, achlorhydria, and impaired gastrointestinal motility.

Inflammatory bowel disease

Crohn's disease and ulcerative colitis occur in patients with IgA deficiency but their frequency is difficult to judge from the widely varying published reports.

Malignant disease

Oesophageal, gastric, and colonic neoplasms have been reported but it is not certain whether the risk of malignancy is truly increased.

Management

Patients with selective IgA deficiency rarely warrant immunoglobulin replacement therapy, unless IgG2 deficiency is also present. Antibodies to IgA develop in about a third of patients with selective IgA deficiency: high titres of antibodies may cause severe reactions to plasma or blood transfusions or even the trace amounts of IgA present in intravenous immunoglobulin preparations.

Other types of primary immunodeficiency

Gastrointestinal problems occur in other types of immunodeficiency (Table 3) (see Section 5). These conditions are much rarer than primary antibody deficiency. Most defects involving cell-mediated immunity present within the first 6 months of life. Infants with severe combined immunodeficiency, for example, grow and develop normally for a few months but then fail to thrive, frequently with a clinical triad of pneumonia, mucocutaneous candidiasis, and intractable diarrhoea caused by one or more of a range of micro-organisms. Some disorders are associated with unusual gastrointestinal features (Table 3).

Secondary immunodeficiency

Secondary immunodeficiency describes conditions in which the immune defect results from underlying disease and is far more common than primary immunodeficiency. In many cases, the secondary immunodeficiency is of minor relevance to the clinical picture but occasionally its severity may mask the underlying condition. AIDS is a florid example of the gastrointestinal complications seen in patients with secondary defects predominantly involving cell-mediated immunity.

HIV and the gastrointestinal tract

The gastrointestinal tract is a major target organ in HIV infection and AIDS, irrespective of the route of acquisition of the infection. Breast feeding can transmit HIV in humans, implying that the intestine is also an important portal of entry for the virus. In a simian model, severe depletion of CD4+ lymphocytes in the lamina propria and of intraepithelial lymphocytes occurs during primary infection and persists throughout the course of the infection. These dynamic changes in intestinal T lymphocytes are more severe than those seen in blood or peripheral lymph nodes. About half of patients with HIV infection will have gastrointestinal involvement at some time, and any level of the tract, from mouth to anus, can be involved (see also Section 7).

There are three main mechanisms in the pathogenesis of gastrointestinal disease: direct infection of enterocytes by HIV; opportunistic and other infections; and opportunistic tumours (Fig. 5 and Fig. 6). A major change in the small intestine is a partial villous atrophy, detectable early in the natural history of HIV infection. Enteropathogens causing intestinal infections are of the same types as in immunocompetent subjects but the infections are much more aggressive and invasive, and elicit little host immune response, so familiar symptoms and signs may be absent. A systematic and thorough search for likely pathogens is essential (Fig. 6). Multiple infections and tumours may coexist, so the organism isolated is not necessarily the cause of the symptoms. Colonic complications increase in frequency as immunodeficiency worsens. Clinically, patients experience diarrhoea, intestinal bleeding, and abdominal pain. Toxic megacolon, intussusception, idiopathic colonic ulceration, and pneumatosis intestinalis have also been described.

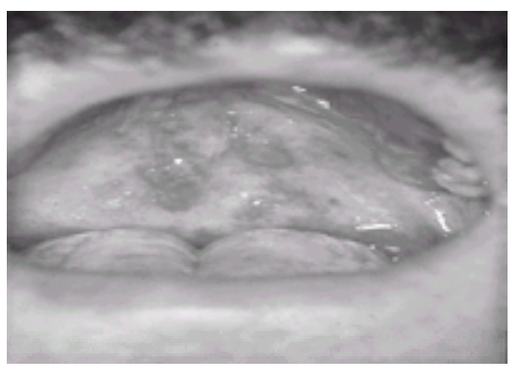

Fig. 5 Kaposi's sarcoma of the oral cavity in a patient with AIDS.

Fig. 6 Gastrointestinal consequences of HIV infection. (Redrawn from Chapel HM *et al.* (1999). *Essentials of clinical immunology*, 4th edn, by permission of the authors and Blackwell Science, Oxford.)

The clinical features of HIV infection and AIDS are discussed in detail in Chapter 7.10.21.

Immunodeficiency secondary to gastrointestinal disease

A low serum IgG concentration may be due to increased intestinal loss of immunoglobulin. A useful clue is a low serum albumin because there are no known conditions where immunoglobulin is selectively lost from the gut. The major causes of protein losing enteropathy are discussed in Chapter 14.22.

Intestinal lymphangiectasia (see also Chapter 14.15)

This immunodeficiency results from increased loss of lymphatic fluid containing immunoglobulins and lymphocytes. There is a selective loss of naive T lymphocytes expressing CD4/CD45RA. The basic defect is an abnormal dilatation of the lymphatic vessels in the intestine. There is a primary familial form in children, who present with diarrhoea, malabsorption, and growth retardation. Such children may have abnormal lymphatics elsewhere in the body causing chylous ascites, pleural effusions, and localized areas of oedema. The condition may also occur secondarily to lymphatic obstruction, for example due to intestinal lymphoma or constrictive pericarditis (see Section 15 and Section 22). The diagnosis should be suspected when there is T-cell lymphopenia, hypoalbuminaemia, and hypogammaglobulinaemia. The diagnosis is confirmed by finding dilated lymphatics in a jejunal biopsy (Fig. 7). The primary form of the disease responds well to a low-fat diet with additional medium-chain triglycerides. In secondary forms, correction of the underlying disease process is needed.

Fig. 7 A jejunal biopsy from a patient with intestinal lymphangiectasia showing dilated central lacteals.

Food allergy and intolerance

Introduction

Food allergy is one of the most controversial topics in medicine. It undoubtedly exists but extravagant claims that a staggering array of symptoms are due to food 'allergy' have confused the subject. Such claims are too rarely supported by objective, scientific observations and have provoked a sceptical response from many doctors. The major cause of confusion lies in the lack of agreement on definitions and diagnostic criteria.

Definition

Food allergy refers to a form of exaggerated reactivity (hypersensitivity) of the immune system to an ingested antigen. The term should be used only when the abnormal reaction is proved to be immunologically mediated, either by IgE or some other immune mechanism (Table 4). The term food intolerance should be used to describe all abnormal, reproducible reactions to food when the causative mechanism is unknown or is non-immunological. Food allergy and intolerance must be distinguished from food fads and psychological aversion to foods.

Aetiology

Food allergy

Although the gut provides a physical barrier to the antigen load in the lumen, up to 2 per cent of a protein meal can appear antigenically intact in the circulation. This was shown by injecting serum from a patient with known sensitivity to fish into the skin of a normal subject. A wheal and flare response at the skin test site (positive Prausnitz–Kustner reaction) was observed shortly after the normal subject ate the appropriate antigen, showing that this must have crossed the gut and triggered IgE-sensitized mast cells at the skin test site.

Atopic individuals have a higher prevalence of food allergy. The allergic components of foods are mainly glycoproteins with molecular weights between 10 and 70 kDa and most are heat stable and resistant to proteolysis, with the exception of those causing the oral allergy syndrome (see below).

In some forms of food allergy, damage involves immune mechanisms other than IgE. For instance, in coeliac disease there is strong evidence that exaggerated local T-cell mediated reactivity to dietary gluten causes the villous atrophy.

Food intolerance

Non-immunological mechanisms of reproducible, adverse reactions to food are much more common and include irritant, toxic, pharmacological, or metabolic effects of foods, enzyme deficiencies, or even the release of substances produced by fermentation of food residues in the bowel. Some foods contain pharmacologically active substances (such as tyramine or phenylethylamine) that act directly on blood vessels in sensitive subjects to produce migraine. Traces of drugs, food additives (for example monosodium glutamate), colouring agents (for example tartrazine), or preservatives (for example benzoic acid) can also cause symptoms in susceptible people by mechanisms which are ill understood, but are probably due to direct effects on mast cells.

Prevalence

The general public perceives food allergy to be a major health problem but epidemiological studies do not support this view. Food allergy affects 2 to 5 per cent of children under 5 years but only 1 per cent of adults. In one survey of 7500 households in the United Kingdom, about 20 per cent of the sample reported a food intolerance but this was confirmed by double-blind, placebo-controlled food challenge in only 1.4 per cent. However, the prevalence of peanut allergy appears to have increased significantly over the last 20 years.

Reactions to food additives, while they exist, are also not as common as most people believe. In a second population study in the United Kingdom, 7.4 per cent had symptoms suggestive of intolerance to food additives; further clinical assessment and additive challenge showed a true prevalence of 0.01 to 0.23 per cent.

Clinical features

Food reactions can be early or late, confined to the gastrointestinal tract or occur at sites remote from the gut (Fig. 8).

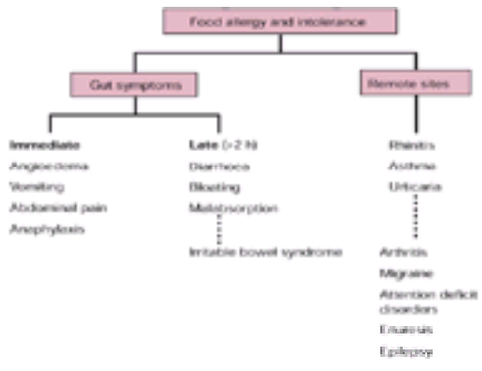

Fig. 8 Clinical spectrum of food allergy and intolerance. (Redrawn from Chapel HM *et al.* (1999). *Essentials of clinical immunology*, 4th edn, by permission of the authors and Blackwell Science, Oxford.)

Gut-related symptoms

About 75 per cent of young children, but only 10 per cent of adults, present with local gastrointestinal symptoms of food intolerance.

Early reactions

These are often 'immediate' in onset, occurring within minutes or up to 2 h after ingestion, recur on challenge testing, and include, apart from gastrointestinal disturbances, such features as perioral rash, angioedema of the lips or tongue, tingling of the throat, urticaria, asthma, or even anaphylaxis. Such acute and severe allergic reactions are mostly due to IgE antibodies to foods and are the least controversial form of food allergy. They are fairly easy to diagnose and the offending food is readily identified, usually by the parent: although any food may be responsible, 90 per cent of reactions are caused by cows' milk (in infants), peanuts, tree nuts, eggs, fish, and shellfish. Peanut is the most allergenic food known and peanut allergy is lifelong.

In some cases, anaphylaxis only occurs when the food is eaten 2 to 4 h before exercise, so-called food-dependent, exercise-induced anaphylaxis.

Allergy to latex rubber is increasingly common and several high-risk groups are recognized, notably patients with spina bifida or multiple urological procedures, and health care workers. Latex allergy may crossreact with plant defence proteins, called chitinases, in foods, typically melon, banana, avocado, chestnut, celery, passion fruit, or peach.

Oral allergy syndrome describes itching and lip swelling without involvement of other target organs. It occurs in patients with pollen allergy and is due to crossreactivity with epitopes in fresh (but not cooked) fruits and vegetables such as apples, carrots, hazelnuts, kiwi fruit, or raw potatoes.

Allergic eosinophilic gastroenteritis is characterized by intolerance to multiple foods, eosinophilic infiltration of the stomach and small intestine, peripheral eosinophilia, and positive skin prick tests and radioallergosorbent tests (see below) to foods.

Late reactions

Symptoms occurring over 2 h after food ingestion, such as diarrhoea, bloating, or a fatty stool are suggestive of food intolerance, if not allergy. Features of the irritable bowel syndrome (see below) may be accompanied by allergic symptoms elsewhere but usually occur in isolation and without any evidence of an immunological reaction.

Remote symptoms

Some patients with acute, IgE-mediated reactions to foods also experience rhinitis, asthma, urticaria, angioedema, or eczema. However, eating the implicated foods does not always cause these remote systems. Sneezing bouts, blocked nose, or asthma can also occur after taking wine or other alcoholic drinks because of the irritant effect of sulphite preservatives or other components. This is not an immunological reaction. Many patients with atopic eczema find that certain foods provoke a transient red and blotchy rash but it is mainly in children that food makes eczema worse. Elimination diets rarely improve atopic eczema in adults.

What is more debatable is whether food intolerance plays any part in remote symptoms such as hyperactivity/attention deficit disorder, enuresis, or arthritis.

Specific syndromes of food allergy

Food allergy contributes to a number of common intestinal disorders where the immunological mechanisms are not IgE mediated.

Coeliac disease

The characteristic histological lesion in untreated cases of coeliac disease (see Chapter 14.9.4) is loss of normal villi and a marked increase in the numbers of CD8+ intraepithelial lymphocytes, particularly those expressing the g/† T-cell receptor. It is believed that HLA class II molecules on antigen-presenting cells expose processed peptides from ingested wheat gliadin to immunocompetent T cells. Gliadin-specific, HLA DQ2-restricted T cells have been isolated from small intestinal biopsies of coeliac patients. T-cell infiltration of the small bowel epithelium is seen within hours of gluten exposure and resolves on treatment with a gluten-free diet, strongly suggesting that intestinal damage is due to a T-cell mediated reaction to gluten.

Cows' milk protein enteropathy

Milk proteins can cause a malabsorption syndrome similar to coeliac disease. Cows' milk protein enteropathy in babies causes failure to thrive, diarrhoea, malabsorption, and even intestinal bleeding and colitis. Jejunal biopsies show villous atrophy and lymphocytic infiltration.

Symptoms disappear when cows' milk is removed from the diet. Reintroduction of cows' milk causes a recurrence of symptoms. After a viral gastrointestinal infection, cows' milk may also be poorly tolerated for a while because of a temporary inability to digest lactose. Thus, in babies and small children with chronic gastrointestinal symptoms and failure to gain weight, trials (under medical supervision) of milk exclusion are justified and the diagnosis can usually be confirmed by food challenge. Recovery often occurs within a few months.

Recognized syndromes of food intolerance

In some conditions, a relationship to foods can be convincingly demonstrated in a proportion of patients. Sometimes, symptoms are provoked by the known irritant, pharmacological, or metabolic effects of food.

Irritable bowel syndrome

Irritable bowel syndrome is a descriptive term for several conditions that produce a similar range of abdominal symptoms (see Chapter 14.13). Irritable bowel syndrome is characterized by alternating constipation and diarrhoea, abdominal bloating, and colicky pain. In a variant of this disorder, however, constipation predominates and gastrointestinal transit times are greatly increased. Most cases are unrelated to food intolerance but in a minority of patients—usually those with predominant diarrhoea, with some bloating and pain—a relationship to specific foods can be demonstrated. Some patients who improve on a restricted diet are able to identify certain foods, notably cereals and dairy products, that provoke symptoms when reintroduced. However, not all gastroenterologists are convinced of a causal relationship between food and irritable bowel syndrome.

Lactose intolerance (see Chapter 11.3)

Many adults cannot digest lactose because of a deficiency of the enzyme lactase. In them, undigested sugar is fermented in the lower bowel, causing diarrhoea and wind. Lactose intolerance is not common in Europeans but affects up to 90 per cent of adult Africans and Orientals. It can also occur as a transient result of gastroenteritis and even as a secondary effect of cows' milk protein intolerance. This can cause confusion in diagnosis unless a lactose challenge is performed separately from a cows' milk protein challenge.

Fructose intolerance

This is discussed in Chapter 11.3.

Miscellaneous syndromes

Migraine and headache

Coffee and coffee withdrawal can provoke migraine in susceptible people. Certain cheeses cause headaches in many people, probably due to their tyramine or

phenylethylamine content. Red wines, especially port, cause headaches in susceptible people because of their content of congeners.

Asthma

Foods preserved by sulphites, particularly white wine, dried fruit, and fruit salads in supermarkets and restaurants, sometimes provoke asthma by the release of sulphur dioxide.

Urticaria

While IgE-mediated food allergy causes acute urticaria and angioedema, allergy rarely induces chronic urticaria. However, food dyes and preservatives often trigger chronic urticaria in sensitive subjects.

Chinese restaurant syndrome

Monosodium glutamate, used to enhance flavour in food and found in large amounts in Chinese food, may cause a syndrome of chest pain, sweating, nausea, dizziness, and fainting in susceptible individuals. However, double-blind studies have not convincingly demonstrated that monosodium glutamate is the culprit.

Controversial issues

Behavioural problems in children

The belief that foods and food additives can induce behavioural problems, particularly attention deficit disorder, is a controversial one. A diet free of preservatives, salicylates, and artificial flavours has been claimed to benefit up to 70 per cent of such children but most well-designed, double blind, placebo controlled challenges have failed to support a causal link. Children with behavioural disorders may improve temporarily for a few weeks when given a diet avoiding food additives but this appears to be a placebo effect. Parents who suspect food additive intolerance in their child may insist on maintaining the child on a restrictive diet, even when dietary challenges prove negative. Extreme examples have been termed 'Munchausen's syndrome by proxy'.

Psychological distress in adults

Some patients with a multiplicity of vague and variable symptoms, such as unexplained fatigue and malaise, and disturbances of sleep, appetite, or libido turn to the diagnosis of food allergy as an explanation. Only a few have clearcut psychiatric illness, others inadvertently cause symptoms by overbreathing or by somatizing their psychological distress. Having made their own diagnosis of food allergy, they have difficulty in accepting they are not allergic to foods, even though their food aversions may have resulted in a dangerously inadequate diet. They will frequently seek out practitioners who are prepared to endorse their views, whether valid or not. Early diagnosis and sympathetic management is essential if unnecessary consultations and inappropriate allergy tests are to be avoided.

Diagnosis

Food allergy should not be diagnosed without clear indications, as needless dietary restrictions can seriously disrupt not only the patient's life but also the whole family and may occasionally cause malnutrition. No test can replace a careful clinical history and thorough examination to exclude other, sometimes more likely, causes of the patient's symptoms.

Skin tests and radioallergosorbent tests

Skin prick tests and radioallergosorbent tests for detecting serum IgE antibodies are positive in about 75 per cent of patients who have IgE-mediated, acute, early reactions to foods such as nuts, egg, or fish. Usually, the offending antigen is obvious from the clinical history and confirmatory tests are needed only if there is clinical doubt. In patients with late symptoms at sites remote from the gut (Fig. 6), skin and blood tests are notoriously unreliable for many reasons:

1. Foods, as antigen sources, are poorly standardized and contain multiple, ill-defined antigens.
2. The antigen content of the food will depend on whether it is raw or cooked.
3. Some foods cause non-specific ('irritant'), positive skin reactions.
4. Patients may have IgE antibodies but no symptoms.
5. Food reactions can be mediated by mechanisms other than IgE antibodies.

For most patients with suspected food intolerance, laboratory tests are of little diagnostic value.

Elimination diets and challenge tests

In the absence of reliable laboratory tests, elimination diets and food challenge form the basis of diagnosis. To minimize bias and suggestion, the relationship between food and symptoms should be established by a placebo controlled, double blind challenge under medical supervision. In some cases, for example in chronic urticaria or when the symptoms are mild and largely subjective, it may be necessary to repeat the challenge before accepting that the association is not simply coincidental. In several series, only a quarter of reported 'adverse reactions' can be confirmed by double blind challenge. Although these rules are simple to state, they are difficult to carry out in practice. However, the alternative is that of prolonged, unsupervised, dietary manipulation, usually self-imposed or inflicted by parents on their children, with the attendant risks.

Food challenges are not without risk: there is a danger of precipitating an anaphylactic reaction. This is well-recognized in children with relatively mild symptoms of food intolerance, who develop anaphylaxis when the food, often cows' milk, is reintroduced after a period of avoidance.

Bogus or unproven laboratory tests

The absence of reliable laboratory tests has led to the promotion of controversial 'alternative' tests: these are at best misleading and at worst dangerous. New diagnostic procedures, like new drugs, require scientific validation: they must be reliable and reproducible. When presented with coded, duplicate samples, some 'alternative' laboratories in the United Kingdom were unable reliably to identify food allergies in patients known to have them; they gave inconsistent results for paired samples from the same patient; they reported many allergies in non-allergic subjects; and they often gave dubious and risky dietary advice.

Provocation-neutralization testing

This has been critically evaluated by the Royal College of Physicians of London, the American College of Physicians, and the California Medical Association: these bodies concluded that reported studies were seriously flawed and that the method lacked scientific validity. Under double blind conditions, the response of patients to active and control injections appeared to be due to suggestion and chance.

Leucocytotoxic testing

This involves incubating a patient's leucocytes with various food extracts and inspecting the cells for damage. The high number of false positive and false negative results led the American Academy of Allergy to conclude that there was no evidence that the test was effective in diagnosis of food allergy.

Other tests

Hair analysis, applied kinesiology, radionics, radiaesthesia, psionic medicine, and auriculocardiac reflex testing have never been objectively evaluated and are more a matter of gullibility and faith than science. Electrodermal (Vega) testing does not correlate with skin prick testing and cannot distinguish atopic from non-atopic

individuals.

Treatment

Dietary management

Recognition of the offending food and its elimination from the diet is the cornerstone of treatment. In patients with acute IgE-mediated reactions to a single food, such as shellfish, this is usually straightforward. Patients with anaphylactic reactions to foods need to be careful to avoid accidental exposure. A problem for such patients is the use of a food, most notably nuts, as an undeclared or 'hidden' ingredient in manufactured foods or restaurant meals. Where there remains a risk of accidental ingestion it may be appropriate for some patients to carry a preloaded syringe of adrenaline (epinephrine) for self-injection.

In less clearcut situations, certain foods or food additives are eliminated empirically because they are frequently implicated in that form of food intolerance: for example, a diet free of cereal grains and dairy products may be beneficial in certain patients with irritable bowel syndrome, while a diet free of azodyes, preservatives, and salicylates helps a proportion of patients with chronic intractable urticaria.

Patients who seem intolerant of a wide range of foods may need a very restricted diet, sometimes called a 'few-food' diet. If symptoms are improved, then foods can be reintroduced one at a time. This is both diagnostic and therapeutic, but care is essential as anaphylaxis can occur on reintroduction, especially in children. Expert advice from specially trained dietitians is essential to avoid nutritional deficiency.

Sodium cromoglycate

Oral sodium cromoglycate has been used as an adjunct to diet in selected patients with food allergy, especially those with accompanying allergic reactions in the eyes, nose, and skin. Its effectiveness is still unproven.

Immunotherapy

Although immunotherapy (hyposensitzation) is effective in wasp or bee venom anaphylaxis and in some forms of allergy to inhaled allergens, it has never been evaluated scientifically in food intolerance. There is considerable interest in future immunization with peptides containing T-cell epitopes.

'Alternative' therapies

Provocation-neutralization therapy and enzyme-potentiated desensitization are two treatments used by 'alternative' practitioners: neither is of proven value, although both induce significant placebo responses.

Food allergy seems particularly vulnerable in inducing unorthodox treatments which have not been scientifically validated by double blind, placebo controlled trials or confirmed by independent investigators. The hazard of the unconventional approach to therapy is that potentially serious problems can be misdiagnosed and mistreated.

14.5 The mouth and salivary glands

T. Lehner

Dental caries and sequelae

Aetiology

Dental decay or caries is a very common chronic disease and causes much pain and discomfort. Caries is most frequent in children and young adults. It affects the pits and fissures of the occlusal surfaces, and the enamel of the approximal surfaces of teeth. Root caries (at the neck of the tooth) occurs later in life. Caries is an infection caused by the aggregation of bacteria on the surface of the tooth, referred to as dental plaque.

The development of dental caries requires the presence of cariogenic bacteria that produce acid below the critical pH (5.5) required for dissolving enamel and sugar in the diet that can be metabolized by bacteria. *Streptococcus mutans*, *Streptococcus sanguis*, *Lactobacillus acidophilus*, *Lactobacillus casei*, and *Actinomyces viscosus* are cariogenic. However, *S. mutans* appears to be the most efficient cariogenic organism. Germ-free studies have clearly shown that *S. mutans* induces caries rapidly in the absence of other organisms; it is a facultative anaerobic, non-haemolytic, acidogenic organism, producing extracellular and intracellular polysaccharides. The organism fulfils Koch's postulates as a cause of dental caries.

The most common carbohydrates in our diet are starch and sucrose, with smaller amounts of glucose, fructose, and lactose. However, the most important substrate in humans is sucrose. Sucrose gives rise to heavy plaque formation, with considerable amounts of extracellular polysaccharide. The most important polysaccharide is dextran (glucan), which is synthesized in large amounts by the constitutive enzyme glucosyltransferase (dextran-sucrase). Dextran allows plaque to stick to the surface of the enamel.

Streptococci do not possess a cytochrome system but contain glycolytic enzymes which will convert glucose to lactic and other organic acids. The pH inside the plaque may fall within 2 to 3 min of rinsing the mouth with glucose or sucrose from a level of about 6.5 to 5; the critical pH below which decalcification of enamel

occurs is thought to be about 5.5. Caries is the end result of a complex sequence of microbial and biochemical processes terminating in acid formation.

Pathology

Caries develops as a result of acid formed by the bacterial plaque acting on sucrose. The enamel becomes demineralized and plaque bacteria penetrate along the enamel prisms. This process progresses slowly through the enamel layer, but once the dentine is reached, destruction by decalcification and proteolysis of the dentine is rapid. The pulp reacts by an acute inflammatory response that results in necrosis, as the pulp is enclosed within the rigid walls of the tooth and the exudate cannot expand to adjacent tissues. Eventually, infection and toxic materials spread from the opening of the root canal to the tissues around the apex of the tooth and induce periapical inflammatory changes, which may terminate in an acute or chronic abscess or a chronic granuloma. If epithelial proliferation takes place within the granuloma or abscess, then a cyst may develop, which will increase in size over many years before it may be revealed clinically. A dental abscess represents a mixed infection with a variety of streptococci, staphylococci, and other organisms.

The immunological changes are complex, but serum IgG, IgA, and IgM antibodies, as well as cell-mediated immunity to *S. mutans*, can be correlated with the DMF (**D**ecayed, **M**issing, and **F**illed teeth) index of caries. Salivary IgA antibodies are also found. Although humans have the potential to mount humoral and cellular immune responses to *S. mutans* under natural conditions, the immunity achieved is commonly ineffective. Immunization experiments with *S. mutans* have been successfully carried out in rats and monkeys, with a significant reduction in caries. There are two principal immunological mechanisms of protection against caries. One involves salivary IgA antibodies, which can be induced by direct immunization of the minor salivary glands or by immunization of the gut-associated lymphoid tissue, from where sensitized B cells may home to the salivary glands. Salivary antibodies may prevent *S. mutans* from adhering to the tooth surface and thereby prevent caries. The alternative mechanism involves all the humoral and cellular components elicited by systemic immunization. Antibodies, complement, polymorphonuclear leucocytes, lymphocytes, and macrophages pass from the gingival blood vessels to the gingival domain of the tooth. Bacterial colonization of the tooth can therefore be influenced by systemic immunity and an important mechanism is probably that of IgG-induced opsonization, binding, phagocytosis, and killing of *S. mutans* by phagocytes.

Clinical features

The patient complains of toothache aggravated by hot or cold drinks or food. The throbbing pain becomes progressively worse, affects the patient especially at night, and may radiate to the face and ear. If relief is not sought the pain becomes excruciating in intensity, and the tooth becomes tender to bite on. This will be followed by death of the dental pulp and the development of an acute swelling due to an abscess or cellulitis. With an acute abscess the inflammatory exudate may penetrate through the bone to the soft tissues. Whilst the pain is reduced the oedematous swelling of the face increases, and if the upper canine is involved the swelling spreads to the eyelid and may present an alarming appearance. The regional lymph nodes are tender and enlarged and there may be fever and some malaise.

Much less commonly a cellulitis or infection by b-haemolytic streptococci may give rise to a spreading infection along the fascial planes, especially of the submaxillary and sublingual spaces. The inflammatory exudate may occasionally spread along the parapharyngeal spaces into the loose connective tissue of the glottis causing oedema of the glottis and respiratory obstruction. The attendant brawny swelling of the neck and floor and the mouth, difficulty in swallowing, trismus, fever, and malaise is referred to as Ludwig's angina. An alternative chronic course is the development of a chronic pulpitis, granuloma, abscess, and eventually cyst around the apex of the offending tooth, and these may proceed without symptoms or only slight discomfort.

Although the patient may point out the painful tooth this can be misleading because the pain often radiates to adjacent teeth. The offending tooth is located by finding the caries, most commonly in the pits and fissures of the occlusal surfaces or the approximal surfaces of adjacent teeth. The tooth responds with pain on application of a hot or cold stimulus, and later is tender to percussion and may be discoloured. Dental radiographs will confirm or localize the carious tooth and, at a later stage, periapical pathological changes.

Treatment

The principles of treatment are to remove the caries, apply a non-irritant material such as zinc oxide and eugenol dressing to protect the pulp, and then restore the tooth with a filling. The most common filling material is dental amalgam which contains mercury. Public anxiety has been aroused by anecdotal evidence that amalgam fillings are toxic and can cause poor memory and lassitude or even multiple sclerosis. There is, however, no scientific evidence to justify these claims, though as a precautionary measure, the United Kingdom Department of Health recommends that mercury-containing amalgam fillings should not be used in pregnant women. The alternatives to amalgam are a number of composite filling materials. If the pulp is damaged irreversibly it will have to be extirpated and root-canal therapy instituted. The alternative to conservative treatment is extraction of the offending tooth. A dental abscess is effectively dealt with by extraction of the diseased tooth, for this removes the source of infection and drains the pus.

If the tooth is to be saved, the pus is drained by an intraoral incision and/or establishing drainage through the root canal. Antibiotics are usually given for acute abscesses and oral penicillin such as phenoxymethylpenicillin, 250 mg four times a day for about 7 days, is adequate. Cellulitis should first be treated by intramuscular penicillin in the form of benzylpenicillin, 1 megaunit (MU) four times a day. The swelling should then be incised to relieve the pressure and provide drainage; extraction of the tooth under general anaesthesia should take place as soon as the patient's condition permits.

Prevention of dental caries is best practised by careful plaque removal by the individual, and by limiting the intake of sugar, especially the frequent consumption of sweets and sweetened drinks. The type of toothpaste used matters less than the method of tooth brushing, though fluoride in toothpaste decreases the incidence of caries in children by up to 40 per cent. Water fluoridation, however, is the most effective public health preventive measure. One part per million of fluoride in the drinking water will decrease the incidence of caries in children by up to 60 per cent. There is no evidence of toxicity from water fluoridation. The ethical and scientific issues of water fluoridation are complex and have been the subject of a report by the Royal College of Physicians of London.

Differential diagnosis

Toothache occasionally needs to be carefully differentiated from sinusitis and neuralgia. Throbbing pain that is exacerbated by thermal stimuli and is more severe at night is an important diagnostic feature. An abscess or cellulitis caused by dental caries has been confused with mumps, although mumps is confined predominantly to the parotid fascia, earache may be a prominent feature, and pain is elicited by pulling on the ear lobe. A chronic granuloma or a dental cyst are usually diagnosed radiologically, unless the cyst becomes large and a swelling becomes clinically evident.

Course and prognosis

The acute sequence of events from dental caries is acute pulpitis, periodontitis, resulting in an abscess or cellulitis. If treated promptly the sequelae can be prevented, but if not treated the patient will lose the tooth and may develop facial scarring due to a discharging sinus. With slow progression of caries or incomplete removal of decay chronic pulpitis may supervene followed by chronic periadenitis, which may result in a periapical granuloma, abscess, or cyst. Dental caries is in most instances a progressive condition and can be halted only by a dental surgeon.

Gingival and periodontal disease

Aetiology

A mild inflammation of the gingiva (gum) and slight destruction of the collagen fibres of the periodontal membrane are found in most adults. Advanced destruction of the periodontal membrane, including the supporting bone, is found in about half of the middle-aged or older population. A close association has been found between accumulation of bacterial plaque and gingivitis. During this process a change occurs from a predominantly Gram-positive coccal form of plaque to a complex population of filamentous organisms, spirochaetes, vibrios, and Gram-negative cocci. Of the Gram-positive organisms, *Actinomyces viscosus* appears to be involved in the development of gingivitis. Gram-negative organisms are thought to be essential in the development of periodontal disease. *Porphyromonas gingivalis*, *Actinobacillus actinomycetemcomitans*, *Fusobacteria* and *Capnocytophaga* spp. have been implicated in this disease. The cell walls of the Gram-negative organisms contain lipopolysaccharides and those of the Gram-positive organisms have lipoteichoic acids, dextrans or levans, which may be responsible for a variety of immunological functions.

The causative factors responsible for periodontal disease are not known, but bacterial plaque is thought to be involved. There are two views concerning the microbial

aetiology: that the non-specific mixed organisms in dental plaque are responsible for the development of periodontal disease or that specific organisms are responsible. The hypothesis of specific microbial aetiology has received support from observations that *P. gingivalis* is the predominant organism isolated from periodontal disease. Furthermore, a specific but rare type of juvenile and rapidly progressing adult periodontitis is associated with *A. actinomycetemcomitans*. Invasiveness of these micro-organisms probably plays an important part in their virulence, and some of the periodontopathic bacteria can be found in the gingiva of adult as well as juvenile periodontitis. However, innate and acquired host factors may be more important than bacteria in determining the development of periodontal disease.

Dental plaque may calcify, especially in adults and the elderly, to produce calculus. This is often found on the lingual surface of the lower incisors and the buccal surface of the upper molars, i.e. opposite the orifices of the major salivary glands. Chronic gingival inflammation may persist for many years and breakdown of the periodontal membrane, with loss of the supporting bone, may follow and increase in severity over the years. This is referred to as periodontitis, or 'pyorrhoea' as it used to be called, and is the most important cause of loss of teeth after the age of 40, when the incidence of dental caries has greatly diminished. An important feature of periodontitis is that it affects many teeth, and may result in complete loss of the dentition. As mentioned above, a very rare type of rapid destruction of the supporting dental tissues is found in children or young adults and is referred to as juvenile periodontitis; one or more teeth may become mobile and may be lost before 21 years of age.

Pathology

There are four immunopathological stages:

1. The initial lesion is found in the normal clinical state, with a localized inflammatory response of polymorphonuclear leucocytes; complement activation and chemotaxis generated by plaque antigens and possibly immune complexes may account for this stage.
2. The early lesion shows a localized infiltration of predominantly T with a few B lymphocytes. In the circulation, lymphocytes are sensitized at this stage to plaque antigens.
3. The established lesion is characterized by a localized plasma cell infiltration and peripheral blood lymphocytes can be stimulated to proliferate by plaque antigens. This stage can persist for years, with early pocket formation.
4. The advanced lesion marks the transition to a destructive immunopathological mechanism, with ulceration of the pocket epithelium and localized destruction of collagen and bone.

Periodontitis is a progressively destructive process leading to loss of teeth. The immunological processes are complex, and cytokines may play a significant role, especially raised levels of tumour necrosis factor-a, interleukin 1b, interferon-g, prostaglandins, and metalloproteinases. Destruction of the periodontal ligament and bone eventually leads to loss of support of the teeth.

Clinical features (Fig. 1 and Fig. 2)

Fig. 1 Chronic gingivitis, with erythema and oedema of the gingival margin of the lower teeth and especially the upper right lateral incisor.

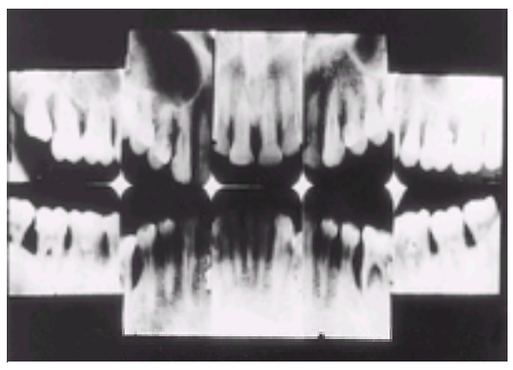

Fig. 2 Radiograph of teeth showing advanced periodontitis with loss of supporting bone of the teeth.

The symptoms of chronic gingivitis or periodontitis are usually so mild that they go unnoticed by the patient. They may, however, complain of discomfort from their teeth, bleeding of gums and associated halitosis, difficulty on eating, looseness of teeth, and occasionally abscess formation. A lack of severe symptoms allows the disease to progress to an irreversible stage before help is sought. Periodontal disease is commonly associated with diabetes. Smoking is a well-documented risk factor. Recently a significant link has been found between periodontal disease and cardiovascular thrombosis. Surprisingly, periodontal disease in pregnant women has been associated with an increased risk of low birth weight and premature birth. It is not clear whether transient bacteraemia in the last trimester might elicit a mechanism responsible for these findings.

Differential diagnosis

Chronic gingivitis can be differentiated from acute ulcerative gingivitis by the sudden onset, malaise, characteristic halitosis, pain, and ulceration of the gingiva in the latter. Herpetic gingivostomatitis occurs predominantly in children and again the onset is acute, with fever, malaise, pain, and ulceration of the gingiva and oral mucosa (see below). Desquamative gingivitis associated with bullous lesions and lichen planus may cause difficulties in differential diagnosis and the points to bear in mind are that the attached gingiva shows diffuse erosive areas and evidence of bullous lesions may be found in the oral mucosa. Periodontitis is clinically differentiated from gingivitis by the loss of connective tissue attachment to the teeth, leading to pocket formation. There is progressive bone loss, readily diagnosed by radiographic examination of the teeth, and eventually loosening of teeth.

Treatment

The aims in the management of gingivitis and mild periodontitis are to remove dental plaque and calculus by scaling the teeth, and this can be done only by a dentist or dental hygienist. Prevention is, however, much more effective by plaque control, which involves careful tooth brushing with the aid of plaque-disclosing solutions and regular use of dental floss and wood points. Chlorhexidine rinses (0.2 per cent) twice a day prevent the accumulation of plaque and decrease gingival inflammation. In some forms of periodontitis tetracycline or metronidazole can be helpful; preparations are available that can be applied locally, but these are generally used in addition to local surgical treatment. However, once deep periodontal pockets have been formed, these are treated by root planing, gingival

curettage, or surgically. It should be appreciated that the management of periodontal disease is dependent upon meticulous plaque control.

Course and prognosis

If the bacterial plaque is not removed, gingivitis may progress to periodontitis and after many years will result in increased mobility and loss of teeth. This process, however, is reversible by plaque control and, if necessary, eradication of pockets, as long as there is sufficient bone to support the teeth.

Herpes simplex and other viral infections

Herpes simplex virus type 1 is responsible for certain orofacial infections (see also Section 7).

Primary herpetic gingivostomatitis

Aetiology

Clinical or subclinical primary infections by herpes simplex virus type 1 are acquired in early childhood, probably in the second and third years of life. Primary herpetic infection in the first year is rare, because most mothers have neutralizing IgG antibodies to the virus that are transferred through the placenta to the fetus. Serum virus complement-fixing and neutralizing antibodies are found in about 50 per cent of children at 5 years of age. The disease is common in children, but is also seen, less frequently, in adults.

Pathology

Herpes simplex virus is a DNA virus and there are two types: type 1 is found predominantly in the orofacial region and type 2 in the genital region. There are three genes (a, b, g) and the b gene codes for viral glycoproteins gB, gC, gD, and gE. These viral glycoproteins have been well characterized: gB is involved in viral penetration of the cell membrane, gC constitutes the C3b receptor (binding activated C3b), and gE is the crystallizable fragment receptor for IgG. Antibodies against gD neutralize herpes simplex virus and block its penetration. Hence this viral infection generates many significant immunological molecules in the host cell, in addition to expressing a viral antigen on the cell surface.

Infection starts with the entry of herpesvirus into epithelial cells. Viral replication takes place inside the nucleus, and this is associated with the formation of intranuclear inclusion bodies and giant cells. As more epithelial cells become infected, degenerative and oedematous changes give rise to vesicle formation. The intraepithelial vesicles contain oedema fluid, with giant cells and degenerating cells with intranuclear inclusion bodies. The vesicles rupture early, resulting in ulcers that heal rapidly.

Clinical features

The disease is recognized by an acute onset of a sore mouth and often sore throat, fever, and extensive inflammation of the gums, followed by formation of vesicles and ulcers of the oral mucosa, and regional lymphadenitis. Infants display considerable fretfulness, sleeplessness, and refusal to eat. Initially there are crops of small ulcers but these coalesce to produce large, shallow, irregular ulcers with surrounding inflammation. Herpetic keratitis is not often associated with herpetic stomatitis, and herpetic encephalitis is extremely rare but may occasionally complicate herpetic stomatitis.

Diagnosis

The early phase of infection can be confused with a cold but the development of vesicles and ulcers makes that diagnosis unlikely. Recurrent aphthous ulcers may occasionally be misdiagnosed in the adult, though the important differentiating points are the acute onset, sore throat, fever, and lymphadenitis in herpetic infection. Laboratory tests can be useful in confirming the diagnosis. Direct examination of a smear from the lesion can be helpful if intranuclear inclusion bodies or giant cells are found. Culture of the virus may assist in the diagnosis, but the herpesvirus is also found in carriers. A rise in antibody titre to the virus during an infection can be a useful aid in diagnosis.

Treatment

Patients are advised to rest for 2 to 4 days; a soft diet is indicated, and an adequate fluid intake is emphasized. The mouth is cleansed by thorough rinsing with hot salt water six times daily and the teeth are cleaned with a wet flannel. In infants, special attention must be paid to the fluid intake and sleep. A useful sedative to use is promethazine elixir, given in doses of one teaspoonful (5 mg/5 ml) at night-time.

Acyclovir tablets (200 mg), two to four times daily, can be helpful if started at an early stage of infection. However, in late onset of primary herpetic infection, tetracycline mouthwash can speed up recovery; however, this should not be used in children.

Course and prognosis

The natural course of this infection is 7 to 14 days, during the initial days of which eating is usually difficult, but healing of the ulcers occurs spontaneously. Recurrence of herpetic lesions intraorally is rather rare in otherwise healthy subjects but occurs frequently in patients with cellular immunodeficiencies.

Recurrent herpetic infection

This is also called recurrent herpes labialis or cold sores.

Aetiology

The lesion is caused by herpes simplex virus type 1 and is commonly found from childhood to past middle age in both sexes. A variety of factors may precipitate the lesions: the common cold, fever, exposure to sunlight, local trauma, emotional stress, menstruation, dental treatment, and section of the sensory root of the trigeminal ganglion are among the best known. Severe herpetic infections, affecting the lips, perioral skin, and mouth, are seen in patients receiving immunosuppressive drugs.

Pathology

Primary herpes simplex infection is followed by viral latency in the trigeminal ganglion. The relation between primary infection, latency, and recurrent infection by herpes simplex virus has not been completely elucidated. However, there is evidence that primary infection induces immune responses to the virus; antibody and cell-mediated cytotoxic mechanisms kill most of the virus-infected cells. The virus is sequestrated to the nerves and will migrate along the axons to the trigeminal ganglion. Indeed, the entire herpes simplex virus genome can be found in the trigeminal ganglion, although the DNA is qualitatively different. A number of clinical precipitating factors may induce derepression of the viral genome and virus replication, which will then migrate along the axon to be shed at the nerve endings. In the presence of some defect in cell-mediated immunity acting at the neuroepithelial junction, recurrent herpetic lesions will be precipitated. Cytokine production, especially interferon-g, may be impaired, and a decrease in cytotoxic CD8 T cells is involved in recurrent herpetic infection.

Clinical features (Fig. 3)

Fig. 3 Recurrent herpes labialis vesicle on the vermilion border of the lower lip.

The lesions are usually limited to the vermilion border of the lips and adjacent skin. A single blister or a crop of blisters may develop a day after the prodromal phase. The duration of the lesion usually varies between 3 and 10 days, but secondary infection by *Staphylococcus pyogenes* commonly occurs. The lesion recurs at various intervals often at the same site for many years, and the rate of recurrence may be related to the type of precipitating factor involved. The significance of cellular immunity is highlighted by herpes simplex virus infections found in cell-mediated immunodeficiency states, such as AIDS, and in patients receiving immunosuppressive therapy.

Diagnosis

Localization to the vermilion border of the lips and the history of recurrences make this a readily recognizable condition. Laboratory assistance is rarely required but the findings are similar to those described for primary herpetic infection, except that there is an elevated initial antibody titre which does not usually increase during recurrent infection. Staphylococcal infection from the anterior nares should be excluded.

Treatment

Acyclovir (acycloguanosine) cream (5 per cent) can be effective if applied during the prodromal phase. Staphylococcal infection responds readily to mupirocin or fucidin ointment, applied three times daily. In the severe type of mucocutaneous herpetic infection in immunosuppressed patients, acyclovir tablets (200 mg) are administered two to four times daily.

Course and prognosis

The lesions heal usually within about 7 days but recurrences are difficult to prevent. If the precipitating factors are known, some preventive measures can be taken such as applying a barrier cream to the lips before exposure to the sun.

Herpes zoster infection

Herpes zoster infection of the skin of the face, innervated by the second or third branch of the trigeminal nerve, may be associated with unilateral oral vesicles. These break down early to produce ulcers along the oral distribution of the maxillary or mandibular branches.

Herpangina

This is a rare infection by the coxsackie group A viruses, usually affecting the soft palate and the oropharyngeal region. Children tend to be affected more often than adults and the mode of presentation of the disease is similar to that in primary herpetic stomatitis. The diagnosis can be firmly established only by isolating the virus from a lesion or by showing an increase in antibody titre. The disease appears to be self-limiting and specific treatment is not necessary.

Hand, foot, and mouth disease

This is another virus infection caused by coxsackie A5, 10, and 16 (see Section 7). The mouth is sore due to multiple small vesicles or ulcers, which most commonly affect the hard palate, tongue, and buccal mucosa. There are associated vesicular lesions on the hands and feet. The diagnosis is confirmed by isolating the virus from the lesion. The disease is self-limiting within about 2 weeks and no specific treatment is necessary.

Measles

This is an acute exanthematous virus infection of children (see Chapter 7.10.6). Whitish macules on the buccal mucosa, known as Koplik's spots, may precede the development of the red macular rash by 2 to 3 days.

AIDS (see Chapter 7.10.21)

Aetiology

This is an infection by the human immunodeficiency virus (**HIV-1**) affecting primarily CD4+ T cells, macrophages, Langerhans, and dendritic cells. In addition to the CD4 receptor all HIV-1 strains require the coreceptor CCR5 or CXCR4 for viral entry.

Pathology

Entry of HIV into the host is by the interaction between gp120, CD4, and CCR5 or CXCR4 on the cell membrane. The trimolecular complex enables the viral particle to enter the cell by fusion between the viral and cell membranes. Hence, the primary target of HIV is the CD4 subset of T cells which decrease in number as the cells become infected and killed, but the CD8 subset is not affected, resulting in a decrease in the CD4:CD8 cell ratio. It is not clear whether the virus kills CD4 cells directly or indirectly by an immune mechanism.

Clinical features

There are five main populations at risk:

1. Homosexual men: those with multiple sex partners and the anal-receptive partner in anogenital intercourse are at greatest risk.
2. Transmission of HIV during vaginal intercourse is common in parts of Africa and Asia; female prostitutes may carry the virus in their genital secretions.
3. Intravenous drug abusers can spread the virus via infected needles from one person to another, directly by the vascular route.
4. Those who have received a blood transfusion with HIV-infected blood, especially haemophiliacs treated with factor VIII.
5. Perinatal HIV infection of babies from infected mothers.

There is some epidemiological evidence that oral sex might lead to HIV infection, but it is unlikely that salivary transmission of HIV can occur. Comparative isolation studies of HIV from body fluids have been made and their results suggest that whilst HIV can be cultured from whole saliva, the frequency of isolation is low (up to 9 per cent) as compared with semen (21 per cent) or plasma (55 per cent). The quantity of HIV isolated from saliva is also low. The available evidence suggests that the HIV resides in the cellular fraction of oral fluid, presumably CD4+ T cells and macrophages, and not the fluid fraction originating mostly from the salivary glands.

The special significance to dentists of oral transmission of HIV is self-evident, as they work in a pool of saliva, often mixed with gingival blood. However, seropositive conversions were not found among about 1000 dental staff in the United States and the same number tested in Germany. Only 1 out of 1309 dentists in another study in the United States was seropositive and he did not wear protective gloves. This is an almost negligible prevalence of HIV seropositivity in a population of dentists, among whom more than 90 per cent admitted to needlestick injuries. The transmission of HIV during dental procedures remains a possibility, especially since a case has been documented of a Californian dentist passing HIV to his patients. However, the details of this case are most perplexing and the route of transmission has not been established.

This section will be confined to the oral manifestations of AIDS. It is of significance that oral candidiasis and hairy leucoplakia may predict the development of AIDS. A variety of opportunistic infections may develop in the mouth. Fungal infection with candida, especially *Candida albicans*, is common. All varieties of oral candidiasis have been recorded in AIDS, but it appears that the chronic hyperplastic and atrophic varieties are more frequent than the pseudomembranous variety. Other fungal lesions may occur but are rare (for example histoplasmosis and cryptococcosis).

Viral infections with herpes simplex virus give rise to recurrent oral herpetic lesions affecting the palate or gum and present as painful vesicles that ulcerate. It should be remembered that recurrent intraoral herpetic lesions are extremely uncommon in the rest of the population (unlike recurrent herpes labialis). Orofacial lesions due to herpes zoster have also been recorded but are rather rare. Epstein–Barr virus appears to cause hairy leucoplakia, which is a raised white plaque commonly affecting the tongue and is clinically similar to chronic hyperplastic candidiasis. Similar lesions have not been recorded in the general population. Papillomavirus may induce single or multiple warts in the mouth of AIDS patients.

Kaposi's sarcoma is a neoplasm of the vascular endothelial cells. Oral lesions present as red or purple macules or papules, often affecting the palate and tongue. Other neoplasias are less common but non-Hodgkin's lymphomas and carcinomas have been recorded.

Gingivitis and periodontitis may show changes similar to those of acute necrotizing ulcerative gingivitis (see below), except that these may be superimposed on rapidly progressing periodontitis. The condition can be painful and has been associated with rapid loss of soft tissue and bone support, leading to loss of teeth.

Recurrent oral ulcers are probably more common in patients with AIDS than in the general population. Enlargement of the salivary glands, especially of the parotid glands, might be caused by a viral infection.

Differential diagnosis

As oral manifestations of AIDS may occur early in the disease, oral candidiasis, herpetic infections, leucoplakia, oral or gingival ulcers, salivary gland swellings, and oral tumours should be suspected, especially in young men (and women) falling into the population groups most at risk of HIV infection.

Treatment

In addition to the general management of AIDS, the teeth and gums should receive a great deal of attention to maintain a high standard of oral hygiene. Otherwise the lesions should be treated as for any other oral condition. Routine dental treatment can be difficult to arrange in a dental practice, but most hospitals have made special arrangements for AIDS patients.

Fungal infections (see Section 7.12)

Candidiasis

This is also called moniliasis or thrush.

Aetiology

Candida is a commensal organism in the mouth found in 20 to 40 per cent of the normal population. Most normal subjects show serum-agglutinating antibodies and a cutaneous delayed hypersensitivity reaction to candida. It is not clear whether candida infection of the oral mucosa is endogenous or exogenous, but as the organism is ubiquitous, a suitable environment and impaired immune responses are the most important conditions conducive to infection by candida. Oral candidiasis can be an early manifestation of AIDS (see above). Although most species of candida can become pathogenic, *C. albicans* is most frequently found in oral infections.

Pathology

The different varieties of candidiasis have in common a superficial invasion of epithelium by fungal hyphae; it is unusual for the hyphae to penetrate the basement membrane. However, in immunodeficient patients candida may spread by the vascular route to the heart, kidneys, and brain. Raised titres of antibodies to candida are found in serum and secretory IgA antibodies in the saliva of patients with oral candidiasis. Antibodies and complement are necessary for optimal phagocytosis of candida by polymorphonuclear leucocytes or macrophages. There is evidence that serum antibodies to the 44 to 60 kDa candida antigen prevent systemic candidiasis. In contrast, cell-mediated immunity is involved in chronic mucocutaneous candidiasis, with a spectrum of cellular immunodeficiencies.

Clinical features

Oral candidiasis develops in a variety of conditions predisposing to candidal proliferation: diabetes mellitus, anaemias, cell-mediated immunodeficiencies (such as AIDS or thymic defects), broad-spectrum antibiotics, immunosuppressive drugs, and leukaemias. Local factors commonly predisposing to oral candidiasis are dry mouth due to Sjögren's or sicca syndrome, irradiation, dentures, or steroid sprays used for asthma.

Varieties of oral candidiasis

There are four main varieties of oral candidiasis.

Acute pseudomembranous candidiasis (thrush)

This disease is commonly seen in infants as well as in debilitated adults, particularly in diabetes mellitus and malignant diseases (especially leukaemia and lymphoma). Iatrogenic agents are also important predisposing factors; systemic antibiotics, corticosteroids, and immunosuppressive drugs seem to enhance candida infection. Local antibiotic and corticosteroid treatment can enhance oral candidiasis. Clinical manifestations of thrush are usually symptomless white papules or cotton-wool-like exudates that can be rubbed off leaving an erythematous mucosa.

Acute atrophic candidiasis (Fig. 4)

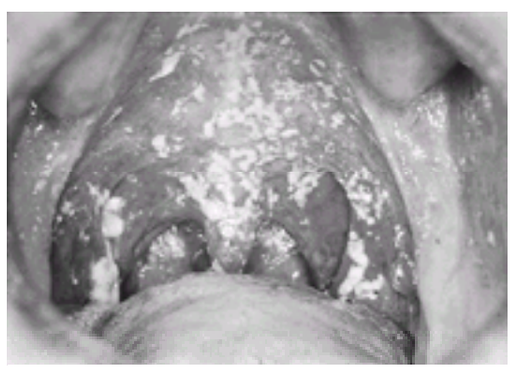

Fig. 4 Oropharyngeal thrush, following the application of a steroid spray in a patient with asthma.

This may follow acute pseudomembranous candidiasis and is usually associated with broad-spectrum antibiotic therapy; it is hence referred to as 'antibiotic sore tongue'. It is the only type of oral candidiasis that is consistently painful, showing a smooth erythematous tongue, with angular cheilitis and (less often) inflamed lips and cheeks.

Chronic atrophic candidiasis

This type of candida infection is better known as 'denture stomatitis', for it presents as a diffuse erythema of the palate limited to the denture-bearing mucosa. The denture covering the palatal mucosa predisposes to proliferation of candida. The lesion is usually symptomless but is often associated with angular cheilitis (Fig. 5).

Fig. 5 Angular cheilitis caused by candidal infection.

Chronic hyperplastic candidiasis

This lesion presents as a firm, diffuse white patch, or as numerous white papules with intervening erythema on the tongue, cheeks, or lips. The lesion may persist for many years or for life and should be distinguished from leucoplakia. This variety of candidiasis can be associated with skin lesions and there are three clinical types of mucocutaneous candidiasis:

1. Chronic localized mucocutaneous candidiasis. This starts in childhood as an intractable oral candida infection, with involvement of nails and sometimes the adjacent skin of the hands and feet. A number of other skin sites may show persistent candida infection.
2. Chronic localized mucocutaneous candidiasis with granuloma. This condition begins in infancy and the clinical manifestations are similar to those in the previous type of candidiasis, with the important additional feature of granulomatous masses affecting the face and scalp. Recurrent respiratory tract infection has been recorded in a quarter of affected children.
3. Chronic localized mucocutaneous candidiasis with endocrine disorder. This is found in children and young adults. A strong familial incidence is often found and candidiasis commonly precedes the endocrine abnormalities. The clinical features of candida infection are similar to those seen in the localized mucocutaneous variety. The association with hypoparathyroidism and Addison's disease, and less often pernicious anaemia and hypothyroidism, illustrates the relationship between cell-mediated immunodeficiencies and autoimmune endocrine disorders.

Differential diagnosis

Chronic hyperplastic candidiasis can cause some difficulties in differential diagnosis from leucoplakia and the laboratory tests are useful in this, as well as in the other types of candidiasis, in establishing the diagnosis. AIDS must be considered, particularly in homosexual males. A culture from the lesion yields candida, usually *C. albicans*, and direct examination of scrapings shows the Gram-positive hyphae and yeast cells of candida. Biopsy of the lesion in chronic mucocutaneous candidiasis is helpful, as in addition to the superficial invasion of epithelium by candida hyphae, there is usually extensive epithelial hyperplasia. The dermis shows an intense mononuclear cell infiltration with a large proportion of plasma cells.

A rise in convalescent serum antibody titre to candida may assist in the diagnosis of the acute types of candidiasis, but there may be an impaired antibody titre in the chronic type of candidiasis. Chronic mucocutaneous candidiasis usually shows some defects in cell-mediated immunity and this should be determined by investigating delayed hypersensitivity, lymphocyte proliferation, and generation of interleukins on stimulation with candida. It is essential that the endocrine function should be tested in children with chronic candidiasis of the mouth and nails.

Treatment

Oral candidiasis responds readily to topical oral treatment with antifungal drugs: sucking tablets of nystatin 500 000 IU four times a day or amphotericin B 100 mg four times a day for 1 to 2 weeks is very effective. Alternative antifungal agents, such as miconazole and fluconazole, are equally effective. Chronic mucocutaneous candidiasis, however, is often unresponsive to topical oral treatment and may necessitate intravenous administration of amphotericin B. Endocrine replacement therapy is essential if there is an associated endocrine disorder. Although almost complete eradication of the lesions can be accomplished, the disease tends to return after the drug is discontinued because of the underlying immunological defect which needs to be rectified.

Bacterial infections

Acute (necrotizing) ulcerative gingivitis

This is also called Vincent's gingivitis or acute fusospirochaetal gingivitis.

Aetiology

An infective cause of acute ulcerative gingivitis has been widely accepted, although the organisms thought to be responsible are disputed. *Fusobacterium fusiformis* and *Borrelia vincenti* have been favoured on account of their presence in large numbers in direct examination of smears from the lesions. *Bacteroides melaninogenicus* has also been implicated as the causative organism, but evidence is accumulating in favour of a mixed bacterial pathogenesis of Gram-negative organisms (fusobacteria, veillonella, bacteroides, leptotrichia), which may be responsible for the lesions due to their endotoxin activity.

Whatever role micro-organisms may play, a number of predisposing factors are recognized. Of the local factors poor oral hygiene with accumulation of dental bacterial plaque, defective restorations, and pericoronitis are most important. The prevalence of acute ulcerative gingivitis is rather high and it is seen more commonly in young adults and smokers. A lowered general resistance may also predispose to the disease.

Pathology

The gum undergoes an acute inflammatory reaction, with an intense polymorphonuclear response and fibrinous exudate. This leads soon to necrosis of the epithelium

and thrombosis of the small blood vessels.

Clinical features

Acute ulcerative gingivitis is readily recognized by the sudden onset of painful, bleeding gums and a characteristic foul breath. Except for primary herpetic stomatitis, this is the only other oral mucosal infection in which there is a rise in temperature, which may reach 39 °C, regional lymphadenitis, anorexia, and significant malaise. Oral examination reveals necrotic, punched-out ulcers, predominantly affecting the interdental gingiva. At times there are shallow necrotic ulcers affecting the oropharyngeal mucosa, which shows diffuse erythema; this has been referred to as Vincent's angina. In the presence of erupting wisdom teeth, the overlying gum can show ulceration and oedema causing partial trismus.

Diagnosis

This disease is often confused with primary herpetic stomatitis because of the acute onset. However, patients with primary herpetic stomatitis are usually younger and their breath is stale but lacks the distinct foul quality of that found in ulcerative gingivitis. First vesicles and then numerous well-defined ulcers are scattered over the oral mucosa, unlike the tendency for localization of necrotic sites to the gingiva in ulcerative gingivitis. Direct examination of a smear from the lesion reveals a large number of spirochaetal and fusiform organisms, with a decrease in the mixed bacterial flora.

Treatment

Metronidazole is very effective and should be taken 200 mg by mouth three times daily for 3 to 4 days. Phenoxymethyl penicillin, 250 mg taken four times daily for a week is equally effective in clearing the symptoms. Oxidizing agents, hydrogen peroxide mouthwash, and a variety of peroxyborate preparations are also useful. During the acute phase, patients are advised to use a soft toothbrush or a soft cloth to clean their teeth, and they are encouraged to rinse their mouths forcibly with warm saline every 3 h.

Although treatment by drugs is effective in clearing the acute phase, recurrences can be prevented only by careful attention to oral hygiene. The teeth have to be scaled and polished, and the patient is instructed as to the best method of tooth brushing and control of dental plaque. Frequent examinations by a dental surgeon are advisable.

Course and prognosis

In the absence of treatment the acute phase may gradually disappear leaving behind a partially necrosed gingiva and chronic inflammation. Inadequate treatment commonly leads to recurrent ulcerative gingivitis over many years, with halitosis, gingival bleeding, and recession.

Cancrum oris (noma)

This is a rapidly spreading gangrene of the lips and cheeks, mostly confined to children in parts of tropical Africa. It is thought to be an extension of acute ulcerative gingivitis when associated with other diseases, especially measles. Cancrum oris is very rare in the United Kingdom, but can be seen during the terminal stages in patients with leukaemia, especially when treated with a variety of cytotoxic, anti-inflammatory, and immunosuppressive drugs.

Tuberculosis

Oral tuberculosis is rare and usually associated with pulmonary tuberculosis. The presenting feature is usually a painful ulcer which may be single or multiple, often large, with a depressed, granulomatous floor and some induration of the base. The tongue, lips, and cheeks may be affected. Diagnosis is based on microscopical and cultural demonstration of *Mycobacterium tuberculosis* and a biopsy of the lesion, which will show a tuberculous granuloma. With the rise in the prevalence of tuberculosis, especially due to AIDS, oral tuberculous lesions may also reappear. Oral tuberculosis responds readily to specific chemotherapy.

Syphilis

Treponema pallidum may affect the mouth in all stages of syphilis but is uncommon (see also Chapter 7.11.33).

Primary stage

A chancre appears within 2 to 4 weeks of infection. The lesion presents on the lip or tongue as a painless, small, firm nodule that breaks down and forms an ulcer with raised indurated edges. The regional lymph nodes show discrete, rubbery enlargement. The diagnosis depends on direct observation of *T. pallidum* by darkground illumination. This stage is highly infective, but serological tests are usually negative during the initial 3 to 4 weeks.

Secondary stage

This develops 1 to 4 months after infection and presents as a generalized maculopapular rash and lymphadenitis. Shallow, snail-track ulcers affect the tonsils, tongue, or lips, and the saliva is highly infective. The serological tests for syphilis are positive.

Tertiary stage

This is delayed by 3 to 15 years after infection. Gumma and leucoplakia are the typical oral manifestations at this stage. A gumma starts as a swelling of the palate, tongue, or tonsils; it undergoes necrosis and results in a painless, punched-out, deep ulcer, with a 'wash-leather' floor. The lesion may heal by scarring, or give rise to perforation. Leucoplakia usually affects the dorsum of the tongue as an irregular, diffuse white patch that cannot be rubbed off.

The treatment of oral syphilis is the same as that used in other sites, but the response in the tertiary stage is rather poor.

Oral ulceration

In view of the great variety of oral ulcers a classification will be given first (Table 1). Only recurrent oral ulcers will be dealt with fully and the other types of ulcer will be considered predominantly under differential diagnosis.

Recurrent oral ulcers

Three types of ulcer will be described: minor aphthous ulcers, also known as aphthae; major aphthous ulcers, also referred to in the literature as periadenitis mucosa necrotica recurrens; and herpetiform ulcers. Aphthous stomatitis is another term used to describe these ulcers.

Aetiology

These are the most common lesions affecting the oral mucosa and the prevalence varies between 10 and 34 per cent in the population. Although a number of causes has been suggested, the aetiology of recurrent aphthous ulcers has not been fully established. Trauma is unlikely to play an essential role, though it might precipitate ulceration, as is seen following dental treatment. There is no evidence that vitamin deficiency or food allergy is involved. Infection by the herpes simplex virus has been excluded as a cause of this type of ulceration. Whilst emotional stress may often influence the pattern of the disease, it is unlikely to be the direct cause. A family history of recurrent aphthous ulcers is often present and the highest incidence of ulcers is recorded in siblings in whom both parents have recurrent aphthous ulcers. A hormonal disturbance may play a part, as in some female patients there is a relationship between the ulcers and the menstrual period; the onset of ulceration may coincide with puberty, or the ulcers may develop only after the menopause and the ulcers often disappear during pregnancy. The part that autoimmunity may play in the pathogenesis of this disease has not been fully elucidated. However, oral epithelial cells share common antigens with the 65 kDa heat

shock protein that is found in Gram-positive organisms. A specific peptide of 15 amino acid residues (91–105), derived from the sequence of the 65 kDa heat shock protein has recently been found to stimulate lymphocytes from patients with recurrent oral ulcers. The role of this peptide in the pathogenesis of oral ulceration is under investigation.

Pathology

An early intense lymphomonocytic infiltration, especially with a perivascular distribution, is a constant histological finding suggesting a delayed hypersensitivity reaction. This is followed by a polymorphonuclear infiltration. Immunohistological investigations suggest an enhanced immune response, with a significant increase in the number of CD4 and CD8 subsets of T cells, Langerhans cells, and macrophages and the expression of HLA DR in the epithelial cells.

Clinical features (Fig. 6)

Minor aphthous ulcers

About 80 per cent of recurrent oral ulcers are of this type; they are very common, especially in the 10 to 40 year age group, and they are found more frequently in females than males.

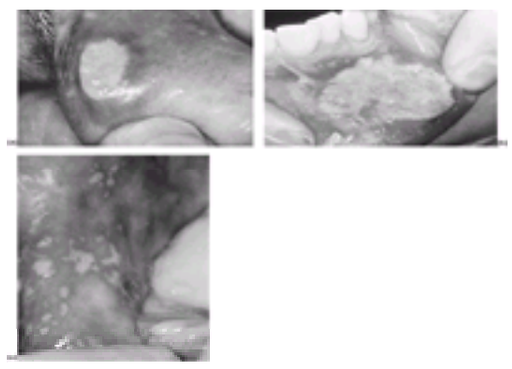

Fig. 6 The three types of recurrent oral ulcer: (a) minor aphthous ulcer; (b) major aphthous ulcer; (c) herpetiform ulcer.

A prodromal phase is recognized by most patients 1 to 2 days before the onset of ulceration, as a soreness or burning sensation. With the breakdown of epithelium and associated inflammatory reaction the pain increases in severity, particularly on eating. The ulcers are round or oval, up to five in number, and enlarge in size, although they remain well under 1 cm. They have a yellow floor with a slightly raised margin and often marked surrounding erythema and oedema. The most common sites of involvement are the mucosa of the lips and cheeks and margin of the tongue, and the ulcers last for 4 to 14 days. The rate of recurrence varies from 1 to 4 months and is usually irregular, though in some females ulcers may precede the menstrual period.

Major aphthous ulcers

These are severe variants of minor aphthous ulcer and fewer than 10 per cent of patients with recurrent oral ulcers have this type of ulcer. The pain that develops after the prodromal symptoms can be severe and persistent, so that patients find it difficult to eat and swallow food and often lose weight. Examination may reveal one to ten ulcers at a time and some of these may enlarge to about 3 cm. The ulcers are necrotic with a raised margin and inflammation of the adjacent tissue, so they occasionally mimic a carcinomatous ulcer. In addition to the lips, cheeks, and tongue, the soft palate and tonsillar region are commonly involved. There may be some regional lymph node enlargement. Healing of an ulcer may take 10 to 40 days and recurrences are so frequent that the patient suffers from continuous ulceration. Multiple small scars may result from large ulcers and these may assist in the diagnosis of major aphthous ulcers. The prevalence of major aphthous ulcers is raised in ulcerative colitis. A striking association has been found in smokers who give up the habit and develop recurrent aphthous ulcers.

Herpetiform ulcers

These are recurrent crops of up to a hundred minute ulcers, affecting any part of the mouth including the gum, palate, and dorsum of the tongue. They account for fewer than 10 per cent of recurrent oral ulcers and are much more common in females than males. Patients present with pain on eating and talking, and often with dysphagia; malaise and loss of weight can be prominent features. The lesions persist for 7 to 14 days and new ulcers commonly appear before the previous crop has healed, so that ulceration becomes continuous.

Diagnosis

The differential diagnosis of the three types of recurrent oral ulcer is given in Table 2. It is important to differentiate these ulcers from those found in patients with iron, folate, or vitamin B_{12} deficiency, who constitute fewer than 5 per cent of patients with recurrent oral ulcers. About 2 per cent may suffer from coeliac disease due to gluten enteropathy, and these ulcers respond readily to a gluten-free diet.

Agranulocytosis or neutropenia may manifest as shallow necrotic ulcers, predominantly affecting the oropharyngeal region. The ulcers tend to persist, unlike major aphthous ulcers which recur at different sites. However, cyclical neutropenia can mimic minor aphthous ulcers and the diagnosis depends on serial weekly white blood cell counts.

One of the most common diagnostic errors is to confuse the effects of denture trauma with aphthous ulcers, although the former are usually localized to the mucosa covering the mandibular and maxillary alveolus and the buccal and lingual sulci. The relation between denture trauma and ulceration is usually simple to find and requires the attention of a dentist.

The differential diagnosis from pemphigus, benign mucous membrane pemphigoid, and erythema multiforme is important and will be described below.

Not infrequently, patients with major aphthous ulcers are suspected of having a carcinoma, though a careful history will make it evident that these ulcers have recurred at different sites in the mouth. Although major aphthous ulcers may have a raised margin this is due to inflammation and not invasion, so that palpation fails to elicit the induration usually detected in carcinomatous ulcers. If in doubt biopsy of the ulcer is warranted.

Treatment

Topical corticosteroids are the best means to relieve aphthous ulcers. They are most effective if application is started during the prodromal phase when the mucosa has not yet ulcerated. If steroids are applied early ulceration may be prevented, but application at a later stage may still reduce the severity and duration of ulceration. The most useful preparations are triamcinolone in orabase, containing 0.1 mg triamcinolone per 100 g of an adhesive base, betamethasone, containing 0.5 mg steroid per tablet, or beclomethasone spray, up to six puffs daily. The tablets are kept in the mouth, or the ointment is applied to the ulcers, three to four times daily until the ulcer disappears. Systemic prednisolone has to be resorted to occasionally in patients with major aphthous ulcers when topical corticosteroids fail to control the ulcers.

Topical tetracycline is the drug of choice in suppressing herpetiform ulcers but is also useful in controlling some major aphthous ulcers, particularly when there is severe inflammation. Its mode of action is not clear and an effective preparation is to use capsules containing 250 mg tetracycline; the powder from a capsule is dissolved in 10 ml of water and kept in the mouth four times daily. Chlorhexidine solution (0.2 per cent) can be used as a mouthwash, which keeps the teeth free of

dental plaque, and may facilitate remission of ulceration.

Course and prognosis

Minor aphthous ulcers may recur from early childhood for many years, and these ulcers may often cause only transient discomfort to which the patient becomes accustomed. However, major aphthous and herpetiform ulcers usually cause a great deal of discomfort, difficulty in eating, and loss of weight. In children, major aphthous ulcers are particularly troublesome and need careful management. In the majority of patients with recurrent oral ulceration the disease burns itself out, but this may take many years. In a very small proportion of patients extraoral sites may become involved, of which the vulvovaginal region is most common, to form part of Behçet's syndrome. There is no way of predicting the development of Behçet's syndrome in patients with recurrent oral ulcers (see Chapter 18.10.5).

Bullous lesions

These are diseases that often affect the skin and mouth, but sometimes involve only the oral mucosa. Three conditions will be discussed in this section: pemphigus vulgaris, benign mucous membrane pemphigoid, and erythema multiforme (see Chapter 23.1).

Pemphigus vulgaris

Aetiology

This is a rare disease which in many instances presents in the mouth, although oral lesions are found at some stage of the disease in all patients. Autoimmunity plays a part in the pathogenesis of pemphigus vulgaris, with IgG antibodies targeted to normal epithelial membrane glycoproteins (66, 150, and 210 kDa). Autoantibodies may bind to keratinocytes and cause a loss of interepithelial adhesion. A significant association has been established with HLA DR4 and DRW6 in patients with pemphigus and either of these gene products may confer disease susceptibility.

Pathology

This shows loss of interepithelial adhesion, intraepithelial bullae, and acantholytic cells, with a diffuse leucocytic infiltration of the lamina propria.

Clinical features (Fig. 7)

The disease affects females two to three times as often as males, usually those over the age of 30 years. Painful, fluid-filled blisters or bullae may appear in any part of the mouth and burst within a few hours, resulting in shallow ulcers. These persist for weeks or months, but new lesions appear throughout the disease process. Oral manifestations of the disease may persist for many months, without overt ill health, but skin lesions, malaise, and loss of weight may occur at a later stage.

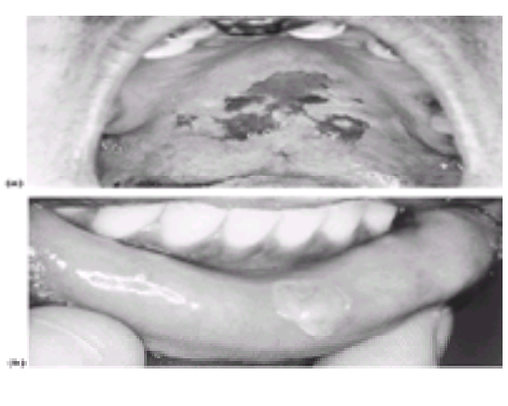

Fig. 7 (a) Bullae and erosions of pemphigus vulgaris affecting the palate. (b) Bullae and erosions of pemphigus vulgaris affecting the lower lip.

Differential diagnosis

Clinically the lesions are differentiated from recurrent aphthous ulcers by the presence of bullae, and when these ulcerate the edges lack the well-defined character of aphthous ulcers. Only occasionally is the Nikolsky sign helpful—rubbing the mucosa to induce a bulla. The most important diagnostic test is the presence of acantholytic cells on microscopic examination of direct scrapings from the lesion and a biopsy must always be taken. Antibodies to interepithelial antigens assist in the diagnosis. Pemphigus must be differentiated from pemphigoid and dermatitis herpetiformis (see below).

A less severe and rather rare variant of pemphigus vulgaris is pemphigus vegetans. Vegetation may be found on the oral mucosa and lips, and histological examination shows intraepithelial abscesses containing numerous eosinophils.

Treatment

Systemic corticosteroids such as prednisolone are given initially in doses of 40 to 60 mg/day and this is gradually reduced to the minimal dose that will prevent formation of new lesions. In order to keep the steroid dose to a minimum azathioprine can also be used, with a dose of 200 mg/day.

Course and prognosis

Treatment with corticosteroids must be maintained for life and has completely changed the prognosis of the disease. Patients rarely die now from the disease but they may develop the side-effects of steroid therapy.

Benign mucous membrane pemphigoid

Aetiology

This is a rare disease, affecting women twice as often as men, usually those over the age of 40 years. The aetiology is ill understood but there is some evidence that autoantibodies to the epithelial basement membrane may play a part in this disease.

Pathology

This shows subepithelial bullae, and the epithelium tends to detach itself from the underlying lamina propria. IgG, IgA, or IgM, with or without complement, are found in the basement membrane.

Clinical features

Bullous lesions involve the oral mucosa, conjunctiva, and the skin around the genitals, but in some patients only the mouth is involved. The bullae rupture within a day or two leaving erosions and ulcers. The gingiva is commonly involved, giving rise to persistent pain, bleeding, and a diffuse, raw, fiery red lesion. Other mucous membranes can be involved, such as the nose, larynx, pharynx, oesophagus, vulva, vagina, penis, and anus. The oral lesions usually heal without scarring unlike

those of the conjunctiva.

Differential diagnosis

Benign mucous membrane pemphigoid can be differentiated from pemphigus vulgaris on clinical grounds but only a biopsy examination will establish the diagnosis. There are no acantholytic cells and the bullae are subepithelial and not suprabasilar. Furthermore, autoantibodies can be detected, probably in fewer than half of patients, binding to the basement membrane of epithelium and not to the interepithelial substance. The disease should be differentiated from linear IgA disease, which shows linear deposition of IgA in the basement membrane, and dermatitis herpetiformis, in which IgA deposits are found in the papillae.

Treatment

If the disease is confined to the mouth topical corticosteroids are often adequate to control the lesions. However, when other sites are involved systemic corticosteroids are indicated, as in pemphigus.

Course and prognosis

This is a chronic disease which persists, often with exacerbations and remissions, over many years. The conjunctivitis may result in adhesions, corneal opacity, and blindness.

Erythema multiforme

Aetiology

Erythema multiforme may develop at any age but often occurs in young males. Many agents have been associated with this disease—drugs, such as sulphonamides and barbiturates, microbial infections, especially with herpes simplex virus—but a large proportion appears to be idiopathic.

Pathology

There is intracellular oedema with a zone of liquefaction degeneration of the upper layers of epithelium. Subepithelial bullae are often present and the lamina propria is infiltrated with lymphocytes, monocytes, neutrophils, and eosinophils.

Clinical features (Fig. 8)

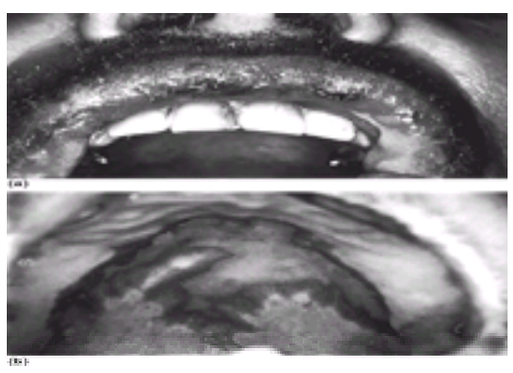

Fig. 8 Erythema multiforme: (a) haemorrhagic crusted upper lip; (b) diffuse erosion of the palate.

Oral manifestations may not be a significant feature. However, the mouth can be affected without skin involvement and the diagnosis is then more difficult. The patient develops painful, extensive erosions and ulcers with a predilection for the palate, tongue, and cheeks. The gum may show extensive erosions, which tend to bleed. Haemorrhagic crusting of the lips is often seen. A severe variant of erythema multiforme, which affects the eyes and genitalia in addition to the skin and mouth, is referred to as Stevens–Johnson syndrome.

Differential diagnosis

The diagnosis of oral lesions without the typical skin manifestations can be difficult. The clinical features to note are the extensive erosions affecting the palate, tongue, cheeks, and gingiva, and the haemorrhagic crusting of the lips. These features should avoid confusion with aphthous ulcers. An association with drugs or microbial infection is helpful in making the diagnosis. The age and sex prevalence differs from that in benign mucous membrane pemphigoid. A biopsy examination can formally exclude pemphigus and erosive lichen planus. The differential diagnosis of Stevens–Johnson syndrome from Behçet's syndrome has been discussed and the points noted about Reiter's syndrome also apply here (see Chapter 18.6).

Treatment

Whenever possible the offending drug or infection should be eliminated. The oral lesions often respond to topical tetracycline. Treatment with systemic corticosteroids may be indicated for extraoral manifestations.

Course and prognosis

If the causative agent is not found the lesions may recur over many years and cause a great deal of discomfort. In Stevens–Johnson syndrome, blindness may result from intercurrent bacterial infection.

Lichen planus

This is a disease that may affect the skin, the mouth, or both mucocutaneous surfaces (see Chapter 23.1).

Aetiology

Although the prevalence of oral lichen planus is not known it is surprisingly common in adults. Very little is known about its aetiology, but the condition can develop in graft versus host reaction after bone marrow transplantation. Several drugs are capable of inducing lichenoid changes in the mouth (for example penicillinase, colloidal gold). It seems to be associated with emotional or psychiatric stress. However, in most patients no cause can be determined.

Pathology

The pathological changes are hyperkeratosis, hyperplasia, and a characteristic liquefaction degeneration of the basal cell layers of the epithelium. The lamina propria shows a well-defined lymphomonocytic infiltration.

Clinical features (Fig. 9)

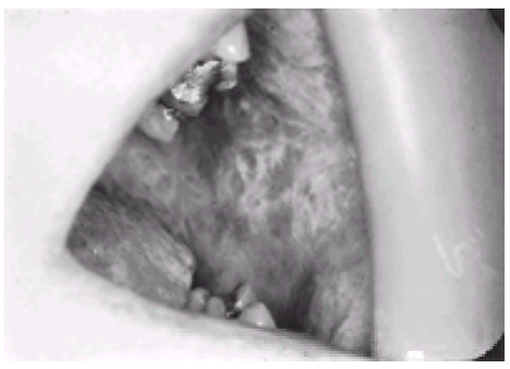

Fig. 9 Striae of lichen planus affecting the buccal mucosa and tongue.

In the mouth the lesions may remain symptomless for years and not infrequently they are first noticed by a dentist during routine examination. Some patients complain of a furry thickening of the mucosa and others of pain or bleeding from the gums on eating. There are three types of oral lichen planus: hypertrophic, erosive, and bullous. The hypertrophic variety is most common and is usually seen in all three types. There are white striae and minute papules, most commonly affecting the posterior part of the buccal mucosa, lips, and dorsum of tongue, though the palate, gum, and floor of the mouth are also involved. The striae crisscross giving rise to a fine lacy or fern-like pattern, and less commonly a honeycomb or annular patter. At times the striae may fuse together and result in a diffuse, somewhat smooth, shiny white plaque which may be difficult to differentiate from leucoplakia. Indeed, the dorsum of the tongue usually manifests diffuse white patches instead of the striated pattern.

In bullous lichen planus a bulla is rarely seen, presumably because it bursts to produce ulcers. Erosive lichen planus, however, is common, and patients complain of pain and discomfort on eating. There may be large shallow ulcers up to 3 cm in size surrounded by white striae and papules. The favoured sites are the same as in the hypertrophic variety, and whilst the latter may break down to result in erosive lichen planus, it is remarkable how often the hypertrophic variety remains unchanged. Except for discomfort, difficulties with eating, and occasionally loss of weight, there are no general manifestations and the regional lymph nodes are not enlarged, except with secondary infection. Not infrequently lichen planus may affect only the gum, inducing a diffuse, fiery red gingivitis and scattered erosions. This is a particularly troublesome type of lichen planus, referred to as desquamative gingivitis, with pain and bleeding, and tends to be resistant to treatment. It should be stressed that many patients with oral lichen planus do not have skin lesions.

A great deal of attention has been paid to the potential for carcinomatous transformation of lichen planus. Applying critical criteria, 1 to 2 per cent of oral lesions of lichen planus may transform to squamous cell carcinoma.

Differential diagnosis

The striae and papules of lichen planus are sufficiently distinctive features in the mouth to differentiate lichen planus from other lesions without the necessity for a biopsy examination. However, the diffuse hypertrophic variety can be confused with leucoplakia and then a biopsy is helpful. Erosive lichen planus may very occasionally lack the distinctive striae, and then erythema multiforme and benign mucous membrane pemphigoid should be excluded. Both systemic and discoid lupus erythematosus can present in the mouth as central erosions surrounded by a keratinized margin.

Treatment

In the absence of symptoms, hypertrophic lichen planus does not require any treatment. The patient, however, needs to be appraised as to the nature of the disease. Topical corticosteroids are usually effective in the treatment of erosive lichen planus but also suppress the striae and papules of the hypertrophic variety. Triamcinolone in orabase ointment applied three to four times a day is useful in localized lesions, but betamethasone (as sodium phosphate) is more effective and is usually used in the form of 0.5 mg tablets, kept in the mouth three times daily. An alternative is to use an aerosol inhaler containing beclomethasone, and applying four to six puffs daily. For these drugs to be helpful, they must be applied for one to several months. The lesions almost invariably recur, although the length of remissions varies greatly and corticosteroids may have to be applied with every remission.

Cleaning the teeth tends to be painful and the accumulation of a large amount of dental plaque aggravates the gingivitis. The patient should use a very soft toothbrush and needs to have the teeth scaled every 3 to 6 months. Chlorhexidine mouthwash can be helpful in controlling dental plaque.

Course and prognosis

The disease is chronic and tends to persist for years, with natural remissions and exacerbations. Topical corticosteroids prolong the remissions, and the erosions and discomfort are kept under control. Since carcinomatous transformation, especially of the erosive type of lichen planus, can take place in a small proportion of patients, they should be followed up regularly at a stomatological clinic.

Leucoplakia

White patches of the oral mucosa that cannot be removed by scraping are referred to as leucoplakia. By convention, lichen planus and lupus erythematosus are excluded from this group.

Aetiology

The prevalence of leucoplakia is not known, but it seems that during the past two decades it has become less frequent. There are many causes of leucoplakia and as these may have distinctive features they will be classified below. It should be noted, however, that in about half the leucoplakias a cause cannot be found. Syphilitic, candidal, and AIDS leucoplakias have been discussed, elsewhere. Causes include:

1. Physical and chemical agents: frictional keratosis, smoker's keratosis.
2. Microbial infection: chronic hyperplastic candidiasis, tertiary syphilis, and AIDS.
3. Congenital and hereditary leucokeratosis.
4. Idiopathic causes.

Pathology

The microscopic features of leucoplakia show a spectrum of changes; at the benign end is epithelial keratosis alone, followed by hyperplasia, and then epithelial atypia at the premalignant end. The lamina propria shows a parallel increase in mononuclear cells, especially plasma cells. Carcinoma *in situ* is the least common histological finding.

Clinical features

The white patches vary from a soft, slightly thickened mucosa, involving a small or large mucosal surface, to hard, irregular white plaques with intervening normal, erosive, or ulcerated sites. The latter is often referred to as speckled leucoplakia and must be recognized clinically because of its greater propensity to carcinomatous

transformation. Any part of the oral mucosa or gum may be involved but the cheeks and tongue are most often affected.

Frictional keratosis is usually found along the occlusal line of the buccal mucosa and presents as a linear white patch of even consistency.

Smoker's keratosis (Fig. 10) shows a characteristic distribution of the soft and adjacent hard palate, as keratinized papules with central red dots. The distribution is due to involvement of the palatal mucous glands and the red dots are the openings of the ducts. It is usually caused by pipe smoking, but cigarette smoking may also lead to keratosis of a diffuse type, most commonly affecting the cheeks.

Fig. 10 Smoker's keratosis of the palate.

Congenital and hereditary leucokeratosis can be distinguished by the presence of diffuse, soft, white plaques, often with a folded surface. The lesions tend to be symmetrical and affect the floor of the mouth. Other members of the family may have similar lesions.

Differential diagnosis

All leucoplakias should be biopsied, except smoker's keratosis of the palate, as even small white patches have at times proved to be early carcinomas (Fig. 11). It is also essential to find out the degree, if any, of epithelial atypia as this affects the prognosis of leucoplakia. Direct examination of scrapings can be helpful in the presence of candida hyphae; cultures should also be set up for candida. Serological tests can further aid in the diagnosis of candidiasis but are essential in the diagnosis of syphilitic leucoplakia.

Fig. 11 Leucoplakia of the tongue, which on biopsy examination showed a well differentiated squamous cell carcinoma.

Treatment

Smoker's keratosis is reversible in many instances if the patient gives up smoking. Frictional keratosis can also be cleared if some local cause of irritation is removed. Candida leucoplakia should be treated with topical antifungal drugs, though this rarely results in permanent clearance of the lesion. Syphilis should be managed by a course of penicillin and stringent follow-up, so as to detect any carcinomatous transformation early. Leucoplakia showing evidence of epithelial atypia should be excised and if the lesion is large a skin graft may be required. However, in many cases the lesion recurs, even after repeated excision. There is no satisfactory treatment for leucoplakia and the most important point is long-term follow-up so as to detect in time the development of an incipient carcinoma.

Course and prognosis

Leucoplakia may persist for life, without any discomfort or change. However, about 5 per cent of all leucoplakias may undergo malignant changes and this figure increases to about 30 per cent in leucoplakias showing histological evidence of epithelial atypia. It seems that epithelial atypia is more commonly associated with speckled leucoplakia, and the latter as well as syphilitic leucoplakia has a worse prognosis. In contrast, smoker's keratosis and frictional keratosis have a very good prognosis if the offending cause is removed. Congenital or hereditary leucokeratosis is thought to be free of malignant changes, although recently a few cases with carcinomatous transformation have been reported.

Benign neoplasms, cysts, and developmental and inflammatory lesions of the soft tissues

There are numerous benign neoplasms and soft tissue lesions of the mouth. This section will be restricted to some essential features of the following lesions: papilloma, fibroma, lipoma, neurofibroma, hamartoma, pigmented naevus, lymphangioma, denture granuloma, giant cell reparative granuloma, fibrous polyp, pregnancy tumour, mucous retention, and extravasation cysts.

Aetiology

The cause of benign neoplasms is unknown and the parts that physical or chemical irritation and microbial infection may play are ill understood. Mucous retention or extravasation cysts are caused by trauma or obstruction of the orifices of the ducts of the minor salivary glands. Whereas true benign neoplasms are rare, inflammatory lesions and cysts are commonly found in the mouth.

Clinical features

The soft tissue tumours present as painless, slow-growing swellings affecting any part of the mouth, but if they originate from the gum they are referred to as epulides. Fibrous polyps are the most common inflammatory lesions of the oral mucosa and result from trauma or irritation from rough edges of carious teeth. Most of the tumours are sessile, some are pedunculated as with some fibromas, and others are flat and pigmented as with the naevi. They are usually symptomless except for bleeding from hamartomas and giant cell reparative granulomas.

Differential diagnosis

There are some distinguishing clinical features, but the definitive diagnosis will depend on the histological examination of the excised specimen. A papilloma can be

recognized by its firm, small, keratinized, finger-like processes. Lymphangiomas are soft swellings which may cause considerable enlargement of the lip or tongue. Hamartomas are flat or nodular red lesions that may blanch when compressed; they are occasionally confused with pregnancy tumours, which are rather vascular granulomatous swellings of the gingiva found during pregnancy. Giant cell reparative granulomas are also very vascular, maroon-coloured lesions originating from the gingiva. Denture granulomas can be readily recognized from their relation to the flange of a denture; the lesion is often elongated, and can be indented or ulcerated by the denture. Mucous retention or extravasation cysts are small, often bluish, swellings affecting the lips or cheeks.

Treatment

Surgical excision, with a margin of normal tissue at the base of the lesion, is usually indicated. Pregnancy tumours, however, commonly regress spontaneously.

Course and prognosis

The soft tissue neoplasms will enlarge over the years and interfere with the normal functions of the mouth. Bleeding from any of the lesions is rarely profuse. Only the giant cell reparative granuloma has a tendency to recur after excision.

Oral carcinoma

Aetiology

Carcinoma of the mouth accounts for about 2 per cent of all cancers in Britain and the United States. The prevalence increases significantly after the age of 40 years and more than twice as many men as women are affected. The incidence of oral cancer, however, in India and Sri Lanka may account for about 40 per cent of all cancers. As in other carcinomas the cause is unknown, but smoking and alcohol have been implicated. There is some epidemiological evidence to support this, but unlike lung cancer it is pipe or cigar rather than cigarette smoking that have been associated with oral cancer. The association with chronic oral sepsis and irritation has not been critically examined. There is some evidence that microbial agents, particularly *Treponema pallidum*, *Candida albicans*, human papillomavirus, and HIV, may directly or indirectly influence the development of carcinoma.

Among the predisposing lesions, leucoplakia is the best-known; in 5 per cent of all patients and in about 30 per cent of those showing evidence of epithelial atypia the leucoplakia may undergo carcinomatous transformation (Fig. 12). Submucous fibrosis is another precancerous condition and is found predominantly in India and Sri Lanka. It seems to be related to eating chillis and possibly chewing betel nuts; it affects the palate, buccal mucosa, and tongue.

Fig. 12 Leucoplakia of the buccal mucosa, the lower edge of which is raised and on biopsy proved to be a well-differentiated squamous cell carcinoma.

Pathology

Squamous cell carcinoma in the mouth is usually a well-differentiated keratinizing neoplasm invading the surrounding tissue. Poorly differentiated, anaplastic oral carcinomas are much less frequent and are especially rare with carcinoma of the lip. Spread occurs by local invasion: lymph node metastasis is less common than is generally thought, and occurs at a late stage.

Clinical features

The presenting features of carcinoma vary with the site of involvement but there are two types, a lump or an ulcer. The patient complains of a swelling or ulcer that is resistant to healing and gradually enlarging in size. There may be little pain initially, but at a later stage discomfort and occasional bleeding may occur. Cancer of the tongue may give rise to local pain and earache. Whereas some patients complain of an excess of saliva, especially with the larger tumours, a dry mouth may be found during the early stages of malignant change and should be noted as another feature favouring malignancy. A small lump may enlarge to a hard swelling before the covering mucosa breaks down. A malignant ulcer shows a raised and often everted edge, and the most important feature is induration at the base of the lesion. Any part of the mouth can be involved but the lips (usually the lower lip) and tongue are most common, each accounting for about 25 per cent of oral carcinomas. The floor of the mouth, gingiva, cheek, hard and soft palate, and oropharynx may account for about 10 per cent of the carcinomas. In most patients there is only one lesion but some patients may have two or even multiple carcinomas. Metastasis may occur at a late stage to the submandibular or upper cervical lymph nodes, and occasionally to the submental nodes.

Differential diagnosis

Any long-standing or indurated lesion in the mouth, especially of elderly or middle-aged patients, should be queried for malignancy and biopsy examination is essential. A traumatic ulcer caused by a denture can be confused with a malignant ulcer, but it may lack induration, the offending part of the denture may fit into the ulcer, and removing the denture for about a week may bring about healing of the lesion. Major aphthous ulcers have been mentioned elsewhere (see above), but the salient differentiating features are a history of recurrent ulcers at different sites of the mouth over many years.

Adenocarcinoma of the small salivary glands may present as a lump of the soft palate, lips, or cheeks and only a biopsy will establish the diagnosis firmly. Carcinoma *in situ* is rare in the mouth, but it may present as a diffuse, erythematous, somewhat velvety lesion, affecting a part of the soft palate or cheek. Again a biopsy examination must be carried out for diagnosis.

Treatment

The principles of treatment of oral carcinomas are those applied to other carcinomas of the body. Surgical excision of the lesion and a margin of adjacent healthy tissue is the most common practice, and this may be extended if necessary to block dissection of the regional lymph nodes. Radiotherapy is an alternative approach and is commonly used in primary treatment of cancer of the lip, in inoperable cases, or with recurrent carcinoma following surgery. Chemotherapy is used less often in the management of cancer of the mouth and the results are variable. Management of oral cancer is a complex subject outside the scope of this section. It should be emphasized that oral hygiene is particularly important with any treatment so as to avoid ascending parotitis. A dry mouth usually follows radiotherapy and again meticulous oral hygiene should be advised, so as to prevent rampant caries and candida infection.

Course and prognosis

The 5-year survival rates differ considerably with the anatomical site of the cancer. Carcinoma of the lip has by far the best prognosis, irrespective of whether treatment is by surgery or radiotherapy, and the 5-year survival rate is about 80 per cent. In contrast the figures for carcinoma of the tongue range from 25 to 35 per cent, floor of the mouth 20 to 40 per cent, cheek 30 to 50 per cent, and oropharynx, palate, and gingiva at about 25 per cent. The prognosis is significantly better in

the absence of lymph node involvement.

Diseases of the salivary glands

Xerostomia

Xerostomia is a term describing dryness of the mouth and can be due to a variety of conditions.

Aetiology

Dry mouth is a common manifestation, especially in middle-aged women, and can be caused by anxiety and emotional and mental stress. Iatrogenic xerostomia is secondary to a number of drugs, the most common of which are antihistamines, tricyclic and other antidepressants, phenothiazine, hypotensive agents, diuretics, and preparations containing atropine. Another common cause is secondary to radiotherapy, but the salivary flow tends to recover although it may take many months. Some diseases affect the salivary glands directly and cause dryness of the mouth, for example Sjögren's syndrome and sialadenitis. Another large group of agents cause xerostomia by inducing changes in fluid balance; diabetes, anaemia, dehydration, and oedema are common examples.

Pathology

Diseases affecting the salivary glands cause a destruction of the secretory components by mononuclear cell infiltration and fibrosis of the salivary acini.

Clinical features

The patient complains of dryness of the mouth and sometimes the eyes, soreness of the mouth, especially the tongue and throat, and discomfort on swallowing of solids and at times difficulty in speaking. The most convincing clinical evidence of xerostomia is an atrophic, dry oral mucosa, often fiery red, due to infection by candida. Inspection of the duct orifices of the major salivary glands will fail to reveal salivary flow. Whole salivary flow rates are readily determined by collecting unstimulated (resting) or lemon juice stimulated saliva. Arbitrary levels of resting saliva of less than 0.1 ml/min and stimulated saliva of less than 0.5 ml/min are indicative of impaired salivary function. The patient may develop rampant caries or if he or she wears dentures there may be difficulties with retention.

Differential diagnosis

A thorough history may establish psychogenic or iatrogenic causes and diseases affecting fluid balance. Sialography and labial gland biopsy may be necessary in the diagnosis of Sjögren's syndrome, though a raised erythrocyte sedimentation rate, rheumatoid factor, antinuclear factor, autoantibodies, and HLA typing may assist in the diagnosis. Nevertheless there will be a large proportion of patients in whom a specific cause cannot be found.

Treatment

Management of the patient is clearly directed to elimination of the cause of xerostomia but this may be difficult or at times impossible to achieve. In such cases, palliative measures are helpful and these include frequent sips of water, meticulous oral hygiene, and early treatment or preferably prevention of candidiasis by topical nystatin or amphotericin B. Each patient responds differently; some prefer glycerin as a lubricant, others carboxymethylcellulose, and the latter can be taken as a solution or spray (Glandosane). A mucin preparation can also be helpful as a spray or as a lozenge (Saliva Orthana).

Sialadenitis

Bacterial or viral infections and rarely allergic reactions may cause inflammation of the salivary glands. These agents may give rise to acute, chronic, or allergic sialadenitis, and recurrent parotitis.

Aetiology

Ascending infection of the parotid gland used to be a common complication in elderly, postoperative patients who were predisposed by dehydration, reduced salivary flow, and lack of oral hygiene. Acute parotitis may also follow the use of drugs causing xerostomia. The most common micro-organisms involved are *Staphylococcus aureus*, *Streptococcus viridans*, and pneumococcus. The most common acute parotitis is mumps (see Section 7). The salivary glands are sometimes affected by HIV infection, with an enlargement of the parotid glands. Chronic sialadenitis is usually associated with duct obstruction and therefore affects the submandibular gland. Recurrent sialadenitis is a disease of unknown aetiology and may be associated with a decreased salivary flow causing retrograde infection. The disease may affect both adults and children.

Pathology

Acute sialadenitis shows an acute inflammatory reaction of the salivary tissue with a predominantly neutrophil infiltration, except in mumps in which there is an infiltration by mononuclear cells. In both chronic and recurrent sialadenitis there is a marked periductal and acinar infiltration by mononuclear cells, with some epithelial hyperplasia of the duct accompanied by acinar atrophy and fibrosis.

Clinical features

The presenting symptoms of acute sialadenitis are a painful swelling in one of the parotid glands of an elderly patient. Commonly the patient has a low-grade fever, oedema of the cheek, some trismus, and a purulent discharge may be expressed from the duct opening. In contrast, mumps affects healthy children and young adults.

In chronic sialadenitis there are usually clinical features of obstruction of the duct of one of the submandibular glands. There is pain and swelling in the submandibular or retromandibular region, with a reddened duct orifice discharging pus. Recurrent parotitis presents as an acute pain and swelling of one or both parotid glands, with erythema of the duct orifices and pus discharging from them. There may be an associated fever and malaise. Recurrences vary from weeks to months and after repeated attacks the affected gland may remain enlarged.

Differential diagnosis

There is little clinical difficulty in the differential diagnosis between acute sialadenitis of the parotid gland in the elderly patient due to ascending infection and mumps in the healthy young subject. Any discharging pus should be cultured for organisms and its antibiotic sensitivity should be determined. Recurrent parotitis, however, can cause difficulties; in addition to a history of recurrent painful swelling and discharging pus, sialography may show sialectasis and duct dilatation. In chronic sialadenitis there is usually clinical or radiological evidence of calculus and sialography may show duct dilatation.

Several granulomatous diseases may very occasionally affect the salivary glands, such as sarcoidosis, tuberculosis, syphilis, and actinomycosis. When there is bilateral salivary and lacrimal enlargement this is often referred to as Mikulicz's syndrome. Allergic sialadenitis is also rare and to determine the allergic agent can be difficult as drugs, foods, pollen, and other agents have been implicated.

Treatment

In acute, chronic, or recurrent sialadenitis the relevant antibiotics should be used to control the infection, but occasionally surgical drainage may also be necessary. Careful oral hygiene measures are important in all types of sialadenitis. In chronic sialadenitis the cause of obstruction, such as a calculus, should be removed. The treatment of recurrent parotitis is more difficult and if antibiotics do not control the disease, surgical intervention should be considered.

Course and prognosis

Acute sialadenitis will resolve with the aid of antibiotics and general management of the patient. Chronic sialadenitis may persist for many years and may lead to destruction of the gland unless the cause of duct obstruction is removed early. Recurrent parotitis in childhood may show spontaneous recovery after puberty.

Salivary duct obstruction due to calculus

Aetiology

The submandibular salivary ducts and, to a lesser extent, glands are the most common sites for the development of stones. Calcium phosphates and carbonates are deposited from the saliva round a nidus of desquamated cells or micro-organisms.

Clinical features

Salivary calculus is usually found in adults and the presenting symptoms are a sudden unilateral swelling and pain of the gland related to eating. The swelling may take minutes to appear and hours to subside. Examination reveals a soft swelling of the affected gland and careful digital palpation along the course of the salivary duct will localize the calculus. This may vary in size from a small grain to a concretion 10 to 20 mm in length. The presence and localization of a stone in a duct needs to be confirmed by radiographs, but the presence of calculi in the gland can be diagnosed only by radiography. Over 80 per cent of calculi are found in the submandibular duct or gland.

Differential diagnosis

Recurrent unilateral swelling associated with eating is characteristic of salivary gland obstruction but occasionally this may be caused by external agents. Trauma from a denture or sharp tooth may cause obstruction of the orifice of the parotid duct.

Treatment

If the calculus is near the orifice of the duct it can occasionally be teased out, otherwise surgical removal is indicated.

Course and prognosis

Single calculi do not tend to recur, but if treatment has been delayed numerous calculi may have formed inside the gland which may occasionally have to be excised.

Salivary gland tumours

A variety of epithelial tumours affect the major and minor salivary glands, of which the commonest is pleomorphic adenoma, or mixed salivary tumour (74 per cent), followed by adenocarcinoma (12 per cent), adenoma (8 per cent), mucoepidermoid tumour (3 per cent), and acinic cell tumour (2 per cent); the percentages give the prevalence in the parotid glands. Only pleomorphic adenoma will be considered in any detail and further reading should be consulted for other tumours.

Pleomorphic adenoma

Aetiology

The cause of this tumour is unknown, although salivary gland tumours can be produced in animals by carcinogenic hydrocarbons, polyomavirus, and other agents. The tumour originates from epithelial cells of the ducts, acini, or myoepithelial cells and these are thought to be capable of producing the stromal mucins of this tumour.

Pathology

The epithelial cells proliferate to form duct-like structures, sheets, and cords within a connective tissue stroma, which may show mucous, cartilaginous, or hyaline appearance. The tumour is encapsulated, although satellite tumours are often found outside the capsule.

Clinical features

The tumour is usually found in adults and the parotid salivary gland is most commonly affected, followed by the submandibular gland and rarely the sublingual gland. The minor salivary glands, however, are also affected, and the most frequent sites are the glands of the palate, lips, and cheeks. The tumour presents as a small, painless swelling, which may take years to enlarge and is not attached to the overlying skin or mucosa.

Differential diagnosis

As the tumour is slow growing it needs to be differentiated only from other tumours. Adenocarcinoma, mucoepidermoid carcinoma, and adenoid cystic carcinoma may mimic pleomorphic adenoma in its slow growth, but some may grow more rapidly, invade the adjacent skin or mucosa, and metastasize. These tumours can often be differentiated only on histopathological examination, and wherever possible an excision biopsy should be done.

Treatment

Surgical excision with a margin of normal tissue is the treatment of choice, as the tumour is radioresistant.

Course and prognosis

If left untreated the tumour may enlarge to a grotesque size. A small proportion of pleomorphic adenomas may undergo carcinomatous transformation. The tumour has a bad record for recurrences after excision and this is thought to be due to leaving behind satellite tumours outside the capsule.

Neoplasms, cysts, developmental lesions, and dystrophies of the bones and teeth

This section covers a very large number of lesions found in the jaws. Only essential features, especially of differential diagnosis, will be covered in the following disorders:

1. benign neoplasms: osteoma, chondroma, fibroma, ossifying fibroma, and giant cell tumour;
2. malignant neoplasms: osteosarcoma and chondrosarcoma;
3. cysts and tumours of dental origin: periodontal and dentigenous cysts, keratocysts, and ameloblastoma;
4. dental malformations or odontomes;
5. osteodystrophies: giant cell reparative granuloma, brown tumour of hyperparathyroidism, fibrous dysplasia, and Paget's disease.

Aetiology

The cause of the neoplasms and osteodystrophies is not known. Periodontal cysts, which are the most common lesions in this group, develop as a consequence of

chronic periapical infection.

Clinical features

The bony tumours and cysts are commonly symptomless unless they have reached a large size and the patient notices a swelling, or a denture ceases to fit. Pathological changes are often noticed by the dentist through movement of teeth or on routine radiographic examination of the teeth. Hyperparathyroidism should be excluded in cases when a giant cell granuloma is suspected. Cysts can be found at any age, but giant cell reparative granulomas, ossifying fibroma, and fibrous dysplasia are often seen in young people, unlike Paget's disease of bone which is seen only in the elderly. There is a predilection for the mandible to be involved more commonly with ossifying fibroma and giant cell reparative granuloma. Odontomes are developmental malformations of dental tissues that become calcified. This is a diverse group of disorders and varies from a simple enamel pearl, consisting of a nodule of ectopic enamel attached to a tooth, to a complex composite odontome, which is an irregular mass of calcified dental tissues. Ameloblastoma is a rare but important epithelial neoplasm of the jaws. Young adults are most often affected, the tumour is slow-growing, and affects the mandible more often than the maxilla. The neoplasm is locally invasive but does not metastasize. Osteosarcoma and chondrosarcoma are found in children or young adults but may develop in the elderly with Paget's disease. They present as fast-growing, painful, and firm swellings and they may metastasize to the lungs early.

Differential diagnosis

The diagnosis of bony lesions of the jaws is made on the basis of radiological appearances and the histological features of the biopsy. Periodontal cysts are very frequent and show a radiolucent rounded area with a sharply defined outline. If the crown of a tooth is enclosed within the cyst, it is referred to as a dentigerous cyst. The latter and keratocysts are usually found in the young, but with some keratocysts a tooth may be missing. Dental cysts must be differentiated from ameloblastomas, which tend to show multilocular and sometimes a honeycomb pattern on radiographs. These radiolucent lesions should also be differentiated from secondary carcinoma and myelomatosis. Giant cell reparative granuloma and tumour (osteoclastoma) show a radiolucent area, sometimes loculated, and the outline is not as well defined as a dental cyst. Hyperparathyroidism can be excluded by the radiographic appearance of other bones and by the calcium and phosphate levels in the blood. Ossifying fibromas are more common than fibromas and radiographs show a well-defined radiolucent area with speckled calcification. This can usually be distinguished from the 'ground glass' appearance, without a distinct border, found in fibrous dysplasia. In Paget's disease there is a distinctive 'cotton wool' appearance on radiographic examination and the alkaline phosphatase levels are high. Odontomes can be readily recognized on clinical examination, but those that are unerupted, particularly the compound and complex composite odontomes, show on radiographs a mass of overlapping denticles and an irregular radio-opaque mass respectively. Osteosarcoma and chondrosarcoma show patchy areas of bone resorption and deposition.

Treatment

The treatment of dental cysts is by enucleation of the cyst lining and usually extracting the involved tooth. The tumours and malformations are excised but some, such as giant cell reparative granuloma, can be curettaged. Brown tumours will recur unless the underlying hyperparathyroidism has been treated. Fibrous dysplasia may require removal of excessive tissue for cosmetic or functional reasons, but this should be delayed until normal bone growth has ceased. Bony changes in Paget's disease are best not interfered with, except when there are functional reasons such as inability to fit a denture. Composite odontomes should be removed surgically. The treatment of ameloblastoma is by local excision, with a generous margin of normal bone, or by hemimandibulectomy. Sarcoma of the jaw must be dealt with by early radical excision.

Course and prognosis

If the cysts or benign tumours are removed surgically they do not recur, except with keratocysts and the reparative granulomas. Ameloblastomas may recur after several excisions, without metastases, and this is why some surgeons prefer to do a hemimandibulectomy. The prognosis of the jaw sarcomas is very poor and the 5-year survival rate is between 25 and 40 per cent. Fibrous dysplasia tends to be self-limiting, but in Paget's disease there may be progressive enlargement, especially of the maxilla.

Miscellaneous disorders

In this section a brief discussion will be given on the following three topics: oral manifestations of blood disorders, halitosis, and disorders of the temporomandibular joint.

Oral manifestations of blood disorders

Mild anaemias or deficiencies of iron, folate, or vitamin B_{12} may manifest themselves as glossitis (Fig. 13) with a sore tongue or mouth, angular cheilitis, or recurrent ulceration (see Section 22). The tongue is commonly depapillated, the corners of the mouth may be inflamed and fissured, and occasionally there may be small shallow ulcers affecting the lips, tongue, and cheeks. The cause of any haematological deficiency should be investigated and, especially with folate deficiency, coeliac disease should be excluded. Replacement therapy usually deals with the clinical features effectively. It should, however, be emphasized that the complaint of a sore tongue can be associated with many other causes, such as erythema migrans, candidiasis, lichen planus, recurrent aphthous ulceration, and black hairy tongue.

Fig. 13 Smooth, depapillated, erythematous tongue in a patient with iron deficiency anaemia.

Erythema migrans (geographical tongue) is particularly common and is characterized by oval, depapillated areas with a well-defined edge affecting the dorsum of the tongue (Fig. 14). The lesions move from one site to another. The aetiology of erythema migrans is unknown and treatment is rather unsatisfactory. It is noteworthy that a sore tongue is a frequent complaint in middle-aged women, often without any demonstrable aetiological factor.

Fig. 14 Round or oval, depapillated lesions with a raised margin in a patient with erythema migrans of the tongue.

Acute leukaemia, particularly the myelomonocytic form, may occasionally present in the young in the form of sore, bleeding gums. This may vary from slight inflammation to that showing bulbous enlargement of the gingiva. There are usually inadequate local causes for such a gingivitis and anaemia may be evident; blood tests should be requested to exclude leukaemia.

Leucopenia and agranulocytosis, especially those due to drugs, may become clinically evident by ulceration of the throat or the mouth. Purpura may be associated with a deficiency of platelets, so that bleeding from the gum may also be a feature.

Many haemorrhagic disorders may become evident after extraction of a tooth, because bleeding does not stop. Less commonly, gingival bleeding may direct attention to the blood disorder.

Halitosis

Bad breath is usually a trivial complaint, though it is heightened by social pressures. There are four possible sources of halitosis: the mouth, nasopharynx, lungs, and the gastrointestinal tract. Altered blood round the gum may be the most important oral cause, and this may be associated with debris or pus from gingivitis and periodontal pockets. A characteristic halitosis is found in acute ulcerative gingivitis. It should be noted that bad taste and bad breath are subjective sensations which are often confused. Excessive bacterial plaque on the teeth is not a principal cause of halitosis; nevertheless, meticulous oral care should be advised.

Chronic tonsillitis may be responsible for halitosis but atrophic rhinitis causing ozaena is probably the most important cause to be excluded. Occasionally, respiratory tract infections may cause halitosis and a variety of gastrointestinal disorders have been associated with bad breath but there is little evidence to substantiate this. Frequently all these sources of halitosis may be excluded without finding a cause and these patients may have a fixation about bad breath related to emotional or sexual problems.

Temporomandibular joint disorders

The patient complains of pain, clicking, or limitation of movement. It is found in young women more often than men. Examination may reveal limitations in jaw movement, tenderness of the joint, and crepitus on movement, discovered by palpating the head of the condyle through the overlying skin. The cause is difficult to establish but malocclusion might be one of several factors. The condition may clear spontaneously but in some patients the occlusion should be checked and a bite-raising appliance is often helpful. Rheumatoid arthritis and osteoarthritis of this joint are occasionally seen clinically. Dislocation of the joint, which becomes fixed in the open position, may be caused by a blow on the jaw or during dental extractions under general anaesthesia. Ankylosis of the joint is nowadays extremely rare but in the past was caused by osteomyelitis.

14.6 Diseases of the oesophagus

John Dent and Richard H. Holloway

Introduction

Oesophageal function testing

Techniques are now available for the precise measurement of oesophageal function. The benefits of oesophageal function testing are most apparent when it is the only means for the accurate diagnosis of a treatable disorder. However, it is also valuable for the recognition of disorders for which there is no definitive therapy, since symptoms can be explained. Oesophageal function testing is relatively expensive and time-consuming and so should not be requested for the assessment of trivial symptoms or when the information gained will not aid management.

Barium radiology

The barium swallow is often undervalued for the diagnosis of structural abnormalities. Useful information can also be obtained about the motor function of the pharynx and oesophagus by videotaping the images and analysing, in slow-motion replay, repeated tests of standardized stimuli. The sensitivity of barium radiology is enhanced by the use of provocative solid boluses, such as bread, or barium tablets. Videofluroscopy is essential for the proper analysis of pharyngeal motor function, and complements other tests of oesophageal motor function such as manometry. Optimal results from radiology are achieved when there is a partnership between a clinician and a radiologist who have a special interest in oesophageal motor disorders; if the particular question(s) that are being pursued by the clinician are well communicated to the radiologist the examination technique can then be tailored accordingly.

Oesophageal manometry

Oesophageal manometry provides the most direct indication of patterns of oesophageal motor function. It is most helpful in the diagnosis of dysphagia, after exclusion of fixed, structural defects. Manometry plays only a minor role in the management of reflux disease; it assists if there is no oesophagitis and mild dysphagia is present, or if surgery is planned. Prolonged, ambulatory 24-h manometry, which requires sophisticated miniaturized equipment, may be useful in patients with dysphagia or non-cardiac chest pain.

24-h ambulatory oesophageal pH monitoring

The principal value of this procedure is to determine the association between symptoms and episodes of acid reflux. Investigation of this relationship is only of importance in a minority of patients in whom the origin of troublesome symptoms is unclear (Fig. 1).

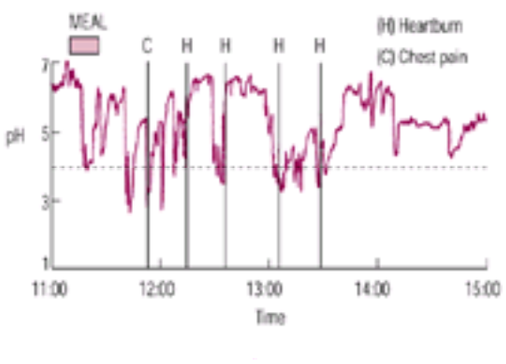

Fig. 1 Section of a 24-h oesophageal pH monitoring study showing the association of heartburn with episodes of acid reflux after a meal.

Radionuclide measurement of oesophageal transit

Computerized scintigraphic analysis of the movement of swallowed radiolabelled boluses can give quantitative information about the patterns of movement of material down the oesophagus. However, its poor spatial resolution makes it an inadequate method for the display of oesophageal anatomy. If structural abnormalities have been adequately excluded, slow or interrupted transit suggests abnormal motility, although patterns of transit are usually non-specific. If good barium radiology is available, radionuclide testing of oesophageal transit becomes redundant.

General management of oesophageal dysphagia

Symptomatic treatment of dysphagia is frequently necessary because of the limited options and efficacy of treatments for oesophageal disorders. Although these measures may appear obvious, this aspect of management is commonly neglected by both patient and physician.

Optimization of bolus consistency

Large particles of solid food may impact on strictures. Large boluses require greater propulsive force even in the absence of stricture, and may trigger oesophageal spasm. Boluses should therefore be small and, in some circumstances, reduced to semiliquid or liquid form. This can be achieved by the use of fluids in bolus preparation and avoidance of hard fibrous foods. Poor dentition should be treated. In some patients, defects of oesophageal function may be so severe that the diet should be pureed. Consultation with a dietitian will assist patients in identifying and preparing suitable food and in maintaining nutrition.

Assistance with oesophageal transit

Liquids assist transit by reducing the viscosity of food and providing a pressure head in the oesophagus. Gas generated within the oesophageal body from effervescent drinks can act as a piston which displaces oesophageal contents into the stomach in the erect position and may be sufficient to overcome an achalasic sphincter. The value of gravity in assisting transit should never be forgotten. Patients with severely impaired oesophageal transit should be advised to swallow medications in the upright position and with plenty of water so as to avoid injurious contact of the oesophagus with potentially corrosive tablets.

Alternative/supplementary approaches to feeding

Rarely, the above measures fail to maintain nutrition. Percutaneous endoscopic gastrostomy should then be used.

Gastro-oesophageal reflux disease

This is by far the most common oesophageal disorder. Reflux symptoms occurring at least once in 6 months are experienced in about one-third of people. Management should be tailored to the wide range of severity.

Definition

Gastro-oesophageal reflux occurs to some degree in everybody. It should only be considered a disease when it gives rise to significant symptoms or complications sufficient to impair the quality of life. The terms reflux or peptic oesophagitis should be reserved for circumstances when endoscopy shows that the oesophageal mucosa is clearly breached by the action of the refluxed gastric contents. Minor changes such as erythema, oedema, or friability have been shown to be very unreliable indicators of the presence of oesophagitis.

Aetiology

In most patients reflux disease arises from the excessive exposure of the distal oesophagus to refluxed acid, usually because of an abnormal frequency of reflux episodes. In a few patients, however, symptoms arise with relatively normal levels of acid exposure, presumably because of sensitization of the oesophageal mucosa.

In most patients reflux occurs as a result of defective neural control of the lower oesophageal sphincter. Severe reflux disease can also result from damage to the oesophagus as in scleroderma. Hiatus hernia is common in patients with reflux disease and causes displacement of the sphincter from the hiatus formed by the diaphragmatic crura. The hiatus provides important extrinsic support to the sphincter and helps to maintain gastro-oesophageal competence, particularly during straining. Hiatus hernia therefore impairs sphincter function and also acid clearance.

Most reflux occurs during the day, usually after food, but nocturnal reflux is also very important. Refluxed acid is cleared from the oesophagus by peristalsis and swallowed saliva. Slow clearance of oesophageal acidification contributes significantly to prolonged acid exposure in about 50 per cent of patients.

Consequences of excessive reflux

Symptoms

These are an important source of disability. Heartburn is most important and when it occurs on more than 2 days a week causes significant impairment of quality of life. However, presentation may be with the less specific pattern of dyspepsia, or with regurgitation, haematemesis, and dysphagia due to either stricture or motor dysfunction of the oesophageal body. Reflux may cause respiratory symptoms such as hoarseness, persistent cough, and asthma, which may predominate in some patients.

Oesophagitis

The chemical insult from excessive exposure of the mucosa to acid and pepsin leads to distal oesophageal erosion or ulceration in between 40 and 60 per cent of patients with troublesome reflux symptoms. The extent of ulceration varies greatly, from tiny patches of erosion to extensive circumferential ulceration in a small minority.

The risks of oesophagitis are not well defined. Peptic stricture and/or oesophageal columnar metaplasia (Barrett's oesophagus) are typically only associated with severe oesophagitis.

Stricturing causes dysphagia which may be debilitating and lead to malnutrition. Treatment with dilatation (bougienage) is a burden and is associated with a risk of perforation.

Columnar metaplasia (see below) is associated with the risk of developing oesophageal adenocarcinoma. It may also be associated with deep benign oesophageal ulceration within the columnar-lined segment. Occasionally such ulcers erode into mediastinal structures or the pleural space, sometimes with fatal consequences.

Bleeding from oesophagitis is relatively common, but is rarely life-threatening except when it occurs from a deep ulcer associated with columnar metaplasia..

Diagnosis and assessment of severity

History

The history is pivotal for diagnosis because of the extremely high prevalence of reflux-induced symptoms and the lack of a definitive, inexpensive diagnostic test for reflux disease. Fortunately, the specificity of patterns of symptoms of reflux disease is arguably the highest of any of the more common gastrointestinal diseases and

the majority of patients can be diagnosed confidently on the basis of their history. The strategic use of history and initial empirical therapy as a means to assess diagnosis and severity is summarized in Fig. 2, and discussed in detail in the section on treatment below.

Fig. 2 Principal decision paths for management of reflux disease.

Endoscopy

When investigation is needed, endoscopy is the first choice as it is the only test that can give sensitive recognition and grading of oesophagitis and reliable diagnosis of oesophageal columnar metaplasia. Endoscopy also allows for the effective identification of significant peptic strictures, other types of oesophagitis, and other upper gastrointestinal disorders such as peptic ulcer disease and oesophageal and gastric carcinoma. As discussed above, however, most patients with reflux disease do not have endoscopically visible mucosal damage, so a negative endoscopy does not exclude the diagnosis of reflux disease. The value of endoscopy as the initial investigation is greatly enhanced by the accurate diagnosis of endoscopic biopsy and, where indicated, cytology brushings.

Oesophageal function tests

The place of these is summarized in Fig. 2. Oesophageal manometry and ambulatory pH monitoring have a limited but important role in the diagnosis of reflux disease. Oesophageal pH monitoring is most useful in patients with troublesome symptoms but without endoscopic signs of oesophagitis in whom a trial of therapy has failed, and patients with atypical symptoms that cannot be clearly related to reflux. Patients with suspected reflux symptoms but with no endoscopic evidence of oesophagitis who are being considered for antireflux surgery should also undergo oesophageal pH monitoring.

Barium swallow and meal

This is an inappropriate primary diagnostic test; it is of no value for the detection of abnormal reflux, and is insensitive for the diagnosis of oesophagitis and cannot grade it. Other pathologies such as gastric ulcer and oesophageal stricture are demonstrated with reasonable sensitivity, but adequate evaluation of these findings requires endoscopic biopsy. In contrast, barium swallow has an important secondary role in the investigation of the mechanisms of troublesome dysphagia. Barium swallow is the best method for recognizing extrinsic oesophageal compression which may be producing symptoms that could be interpreted as being due to reflux, and in the assessment of anatomically complex hiatus hernia. The mere demonstration of hiatus hernia, however, does not necessarily indicate the presence of reflux disease.

Principles of management

New treatments have transformed management in recent years. The major aims of treatment are to provide adequate symptomatic relief and control of oesophagitis. Reduction of oesophagitis to minor patchy erosions is probably sufficient to prevent the complications of oesophagitis, although adequate symptomatic relief is usually achieved only when oesophagitis is completely healed. Management steps are easily confused, as endoscopy, assessment of symptoms, and treatment are used not only for diagnosis, but also assessment of severity and titration of therapy.

Cost-efficient, secure diagnosis

The steps needed for diagnosis are shown in Fig. 2. When the history is classical, the symptoms are only mild to moderate, and there are no alert symptoms, endoscopy is effectively redundant. Given the high proportion of patients who have no endoscopic abnormality, a negative endoscopy should not detract from the soundness of a diagnosis based on symptoms. When symptoms are indeterminate, or alert symptoms of dysphagia, haematemesis, or weight loss are present, endoscopy is the primary diagnostic approach. The place of endoscopy in patients with troublesome or severe but classical symptoms is becoming less relevant because of the advent of highly effective initial high-level medical therapy with proton pump inhibitors.

Assessment of severity

Morbidity arising from symptoms and the presence and severity of oesophagitis are the two most important measures of severity of reflux disease. However, they show only poor correlation. The response of symptoms to low- and medium-level therapy (see Table 1 and below) gives an indirect approximation of the severity of oesophagitis and helps to determine further action.

Tailoring and titration of therapy

Classification of therapies by level of efficacy regardless of their mechanism of action (Table 1) provides a framework for the tailoring and titration of long-term management. The lowest effective dose of any agent should be used in long-term therapy. Figure 2 and Table 2 summarize the logic of using endoscopic findings to choose an appropriate level of initial therapy. As the responsiveness of individual patients varies, therapy needs to be titrated upwards or downwards through levels of efficacy in order to find the lowest level that is effective, on the basis that this will minimize drug costs.

Most patients with reflux disease will have an initial trial of empirical therapy. There are two main options for this. Initial low- to medium-level therapy is the traditional model outlined in Fig. 2. This has the disadvantage of giving less crisp diagnostic information, and often gives only slow relief of symptoms, but will usually identify patients with severe oesophagitis since these will usually not respond adequately. Initial high-level medical therapy is now available. This is most likely to give crisp confirmation of the diagnosis and prompt relief of symptoms. For optimum cost-effectiveness, it should be followed by a step-down approach to long-term therapy as outlined in Fig. 2.

Options for treatment of oesophagitis and symptoms arising directly from reflux

Non-drug measures and antacids

The efficacy of these traditional approaches is often over-rated. The most useful measures are avoidance of large meals and provocative foods, drinks, and physical activities. The benefits to reflux disease of stopping smoking, weight loss, and elevation of the bedhead are uncertain. Antacids will not usually prevent symptoms, but may be effective in aborting episodes of heartburn. These low-cost measures are worth a trial in patients with mild intermittent symptoms (Table 1 and Table 2), and should be used as maintenance therapy if they prove effective, provided that their impact on lifestyle is acceptable to the patient. They are unlikely to succeed in people with troublesome reflux symptoms.

Acid suppression

Inhibition of secretion of gastric acid makes gastric juice less injurious but does not stop reflux. This has deservedly become the most widely used drug therapy because of its high efficacy and adjustability. The more severe the oesophagitis, the higher the level of acid suppression that is needed (Table 2). Proton pump inhibitors have a special role because of their effectiveness in reduction of food-stimulated acid secretion and their greater overall efficacy in control of acid secretion compared with histamine-2 receptor antagonists.

Long-term treatment with acid suppressants maintains patients free of symptoms and oesophagitis indefinitely but withdrawal is usually associated with prompt relapse. The maintenance dose appears to be the same as the lowest effective healing dose. There have been concerns about the safety of long-term acid suppression ever since the introduction of histamine-2 receptor antagonists. To date, follow-up of patients treated continuously for 10 or more years with acid suppression has shown no evidence of any effects of significance, but in the context of patients who may require treatment with these agents for decades, more extensive follow-up is still needed. Given these theoretical safety considerations and also drug cost, long-term treatment of reflux disease with these agents should use the lowest effective dose.

Motility stimulants

Only cisapride has been adequately researched. It has medium efficacy for both short- and long-term management. It appears unlikely that much is gained from an increase in dosage. The principal effect of cisapride appears to be on oesophageal acid clearance. Unfortunately, it has been recognized recently that cisapride has effects on cardiac conductance that may rarely lead to sudden death at peak serum levels encountered during therapy in some patients, especially when various drugs are coadministered. Because of the risk of cardiac effects, cisapride must be regarded as a second- or third-line therapy that needs to be used with special precautions.

Combination medical therapy

Use of cisapride and histamine-2 receptor antagonists in combination gives moderately improved results but is less effective than monotherapy with proton pump inhibitors. Given the safety concerns described above, and its relatively high cost, such combination therapy should be reserved for special cases.

Antireflux surgery

In skilled hands, antireflux surgery is a very effective long-term therapy. Negative factors are the dependence of the results on the expertise of the surgeon and the morbidity and small (approximately 0.5 per cent) mortality associated with the surgery itself. Laparoscopic antireflux surgery is a major advance, as it achieves good control of reflux with a major reduction in the morbidity inherent in the more traditional approach. More information is needed about long-term results.

Choice between therapies

Selection of a medical or surgical therapy should take account of the severity of disease and the risks of antireflux surgery specific to the patient. It should also take account of the patient's age, both from the point of view of operative risk and the time over which the patient will need treatment for reflux disease, the cost of effective medical therapy, and, naturally, the preferences of the patient. In the United States, good open antireflux surgery becomes cost-effective compared with medical therapy after about 10 years, although this assessment does not take into account the cost of mortality. The breakeven point is likely to be shorter with laparoscopic surgery and in countries where the costs of surgery are lower than in the United States. Cost comparisons also need to take into account the decreasing price of acid suppressing agents. The choice between medical therapies should be largely governed by the local cost of the alternatives that give the necessary level of treatment, as all of the first-line options are safe and well tolerated.

Management of complications of reflux disease

Peptic stricture

Dysphagia secondary to stricture (Fig. 3) needs to be distinguished from the more common dysphagia seen in patients with reflux disease which is due to defective triggering and control of oesophageal body peristalsis (see the section on non-specific oesophageal motor disorders below). Peptic stricture is managed by a combination of peroral dilatation and healing of oesophagitis by either medical or surgical means. Provided oesophagitis is healed, stricture is usually not an ongoing problem.

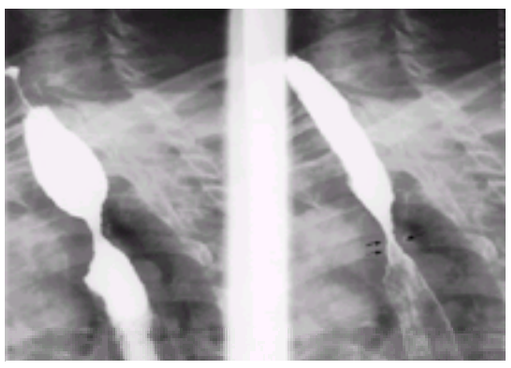

Fig. 3 Peptic stricture: asymmetrical circumferential narrowing with associated intramural diverticulosis suggests benign aetiology; the site suggests Barrett's mucosa, subsequently proven by endoscopy. (By courtesy of Dr H. Harley.)

Oesophageal columnar metaplasia (Barrett's oesophagus)

This increasingly recognized consequence of oesophagitis is dealt with in the section on oesophageal neoplasia. The association of columnar metaplasia with oesophageal adenocarcinoma contributes to the logic of vigorous treatment of severe oesophagitis.

Respiratory complications

Respiratory disease may occur as a result of either direct aspiration of refluxed gastric contents or from the reflex effects of gastro-oesophageal reflux. It is difficult to prove that reflux disease which coexists with respiratory disease is actually the cause of the respiratory problem. The best investigative approach is probably a trial of high-level acid inhibition with at least a double-dose of proton pump inhibitor for at least 2 months. Management of respiratory disease by antireflux surgery is a gamble that can only be supported primarily by clinical evaluation.

Regurgitation

Voluminous regurgitation is the main symptom in a small subgroup of patients with reflux disease. They may present complaining of vomiting, but a detailed history reveals that there is no prior nausea, and no effort involved in the appearance of the gastric content in the mouth. The determinants of high-volume reflux and regurgitation have not been defined. Treatment with proton pump inhibitors can have substantial benefits, but in more severe cases antireflux surgery is usually the only effective management.

Non-cardiac chest pain

Reflux is an important cause of non-cardiac chest pain (see below).

Primary oesophageal motor disorders

Idiopathic achalasia and achalasia-like states

Definition

These disorders are characterized by absent or incomplete relaxation of the lower oesophageal sphincter and impairment of peristalsis of the oesophageal body. Idiopathic achalasia, which was first described over 300 years ago, accounts for most cases and has an annual incidence of approximately 1 to 2 per 100 000. It affects all ages, but is diagnosed most often in early to mid adult life. The syndrome is also seen in Chagas disease and can sometimes accompany the intestinal pseudo-obstructive syndrome. Achalasia may be a manifestation of paraneoplastic neural dysfunction and may also be secondary to oesophageal amyloidosis.

Secondary or pseudoachalasia can arise from neoplastic infiltration of the gastro-oesophageal junction, and has been reported with carcinoma of the stomach, oesophagus, lung, pancreas, prostate, and with lymphoma.

Aetiology

Impairment of inhibitory neural control of the distal oesophagus is the universal abnormality. The syndrome can probably be produced by neural damage at several sites. The clearest evidence is degeneration of myenteric inhibitory neurones which, in the early stages, is associated with an inflammatory response.

Symptoms

Dysphagia with solids is almost universal. Regurgitation is also prominent. The regurgitated material tastes bland because it never enters the stomach. Cramping chest pain occurs in some patients during an early hypercontracting phase of the disorder. Weight loss is seen in patients with disabling dysphagia. The course of symptoms over time is variable. In some patients, symptoms remain static for many years but in others there is a progression with increasing problems with regurgitation over several years, as a result of development and increase of oesophageal dilatation. When this occurs, respiratory problems secondary to aspiration can become a major feature.

Diagnosis

Idiopathic achalasia is diagnosed on average 2 years after its first presentation, Delay is especially likely if oesophageal dilatation is absent. Dilatation varies in degree from a minor increase in oesophageal calibre to a grossly enlarged, colon-like oesophagus. Barium swallow shows oesophageal retention with a gastro-oesophageal junction that tapers smoothly to a closed sphincter, with occasional spurts of flow into the stomach (Fig. 4). In the absence of dilatation, a barium swallow is often reported as normal.

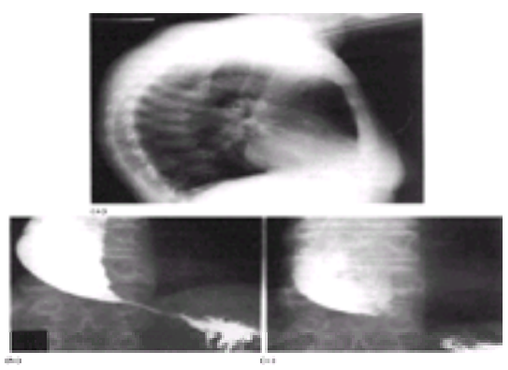

Fig. 4 Achalasia. (a) A lateral chest film shows the air–fluid level in the mid oesophagus just behind the air column of the trachea. (b) On a posteroanterior view this level is almost invisible. Barium-filled dilated oesophagus; intact mucosa in distal achalasia segment.

Oesophageal manometry is the only sensitive method for demonstration of the characteristic motor dysfunction. It is not unusual for manometry to be diagnostic of achalasia even though barium studies have been judged to be normal.

Idiopathic achalasia and achalasia-like states should be distinguished from constriction of the gastro-oesophageal junction by an infiltrating or encasing malignancy at the cardia. This diagnosis is often difficult to make. As a minimum, patients should be evaluated clinically for any symptoms or signs suggestive of malignancy, and upper gastrointestinal endoscopy should be done with mucosal biopsies. Computed tomography scanning is also of value.

Treatment

There are four potential approaches to treatment: drug therapy with agents that relax the lower oesophageal sphincter, mechanical disruption of the sphincter by either pneumatic dilatation or surgical myotomy, and pharmacological poisoning of the remaining excitatory nerves to the sphincter with botulinum toxin. The results of reduction of lower oesophageal sphincter pressure with drugs such as calcium antagonists and b-adrenergic agonists compare poorly with mechanical disruption of the sphincter, and by inference botulinum toxin.

Oesophagomyotomy, which is now being done increasingly as a laparoscopic or thoracoscopic procedure, is highly effective but is associated with a 5 to 10 per cent risk of troublesome gastro-oesophageal reflux. This risk can be minimized by the incorporation of an antireflux procedure.

Balloon dilatation is an attractive approach because of its simplicity and low cost, but it often needs to be repeated and in some hands fails in up to 40 per cent of patients, especially those who are young. It also carries a risk of perforation of about 5 per cent. With the development of minimally invasive surgery for oesophagomyotomy, balloon dilatation will probably be used most in older patients who have other medical problems that increase the risks of surgery.

Endoscopic injection of the sphincter with botulinum toxin is the most recent innovation. This toxin acts on residual excitatory nerves thereby lowering sphincter pressure. Short-term results are comparable to those of pneumatic dilatation but the procedure usually has to be repeated within 1 to 2 years. The toxin is also relatively expensive. It is a simple, low-risk procedure and most applicable to patients with significant coexisting morbidity which renders them unfit for dilatation or myotomy.

When oesophageal dilatation is present, prompt treatment is indicated to prevent its worsening, because of the morbidity and poor therapeutic outcome associated with gross oesophageal dilatation. Oesophageal emptying can be assisted by effervescent drinks (see above).

Prognosis

If effective treatment is applied before the development of major dilatation results are excellent, despite the persistence of major physiological abnormalities. Achalasia carries a very significantly increased risk for oesophageal carcinoma up to many years later which ranges from 2 to 7 per cent in authoritative reports. There is no apparent reduction of this risk with treatment. The average interval from diagnosis of achalasia to development of carcinoma has been estimated as 28

years. It is not usual practice to undertake surveillance for this risk, but some clinicians recommend periodic screening endoscopy.

Diffuse oesophageal spasm

Definition

Episodic chest pain and/or dysphagia resulting from spastic contractions of the distal half of the oesophageal body in the absence of any precipitating structural stenosis. There are no generally agreed criteria for diagnosis.

Aetiology

It is widely assumed that this is a dysfunction of neural control but there is a lack information that addresses this or other possibilities. What is known of the epidemiology is unhelpful with regard to aetiology. Stress is an unlikely primary precipitant but may exacerbate the problem. Good prevalence data are lacking. Diffuse spasm affects all ages and is much less common than achalasia.

Symptoms

Virtually all patients have episodic, crushing central retrosternal pain which can be excruciating; cardiac ischaemia is often the first diagnosis. Intermittent dysphagia occurs in about two-thirds of patients and leads to temporary abandonment of eating until symptoms abate—usually over about 30 min, but episodes of oesophageal obstruction can last for several hours. In most patients, symptomatic episodes occur less than once a month but in severe cases these may occur several times a week, or each time food intake is attempted.

Diagnosis

As with any intermittent fault, full-blown dysfunction is usually absent during investigation, but in a minority of patients there is asymptomatic motor dysfunction. Barium swallow then shows trapping of beads of contrast in the distal oesophagus—'the corkscrew oesophagus'—or sustained obliteration of the distal oesophageal lumen. Oesophageal manometry may show intermittent, simultaneous, prolonged, and vigorous oesophageal contractions interspersed with normal swallow-induced peristalsis. Relaxation of the lower oesophageal sphincter is normal. 24-h ambulatory manometry improves diagnostic accuracy by increasing the likelihood of capturing symptomatic episodes but is not necessary in all patients.

Most frequently the diagnosis is made on the basis of the history and the exclusion of other problems that may mimic diffuse oesophageal spasm. Most important amongst these is Schatski ring (see below). Achalasia is readily excluded by manometry. When appropriate, myocardial ischaemia should be excluded.

Treatment

There is no specific therapy. Smooth muscle relaxants such as nitrites, nitrates, and calcium antagonists may reduce symptoms but their use is often limited by side-effects. In many patients, reassurance is the most important management since the intensity and nature of symptoms gives rise to great concern. Opiate therapy is sometimes necessary. In the rare case of frequent, disabling spasm, long oesophagomyotomy can give good relief.

Prognosis

The major significance is impairment of quality of life and concern about life-threatening cardiac disease. There is no consistent progression over time. There are several reports of progression of diffuse oesophageal spasm to achalasia but in most of these it seems likely that early, spastic achalasia was initially misdiagnosed as diffuse oesophageal spasm.

Hypertensive peristalsis or nutcracker oesophagus

Definition

This is defined purely by the manometric criterion of primary peristaltic pressure waves in the oesophageal body that have peaks in excess of 250 mmHg (Fig. 5). There is preservation of the normal peristaltic pattern of a broad progression of the time of onset of the contraction wave in the oesophageal body.

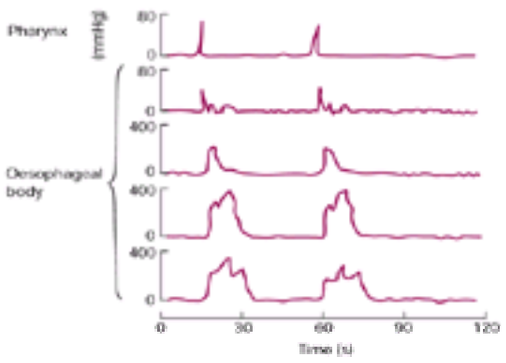

Fig. 5 Oesophageal manometric tracing made from points along the oesophagus in a patient with hypertensive peristalsis. The time of onset of the pressure waves shows a normal peristaltic gradient, but the contractions in the distal half of the oesophagus are very vigorous so that the peak pressures are abnormally high. The high-amplitude pressure waves are also somewhat prolonged and multipeaked.

Aetiology

This is not understood. It is not clear if it is a true motor disorder, and it may just represent the upper end of a continuum of peristaltic wave amplitudes. It has been shown to vary over time within individuals. There are indications that psychological factors can influence peristaltic amplitude. A minority of patients with hypertensive peristalsis also experience episodes of diffuse oesophageal spasm suggesting that the underlying dysfunction may be related to diffuse oesophageal spasm and is likely to involve neural control mechanisms.

Symptoms

The only clinical significance of hypertensive peristalsis is its relationship to non-cardiac chest pain. Hypertensive peristalsis alone does not produce dysphagia or derangement of oesophageal transit, because, by definition, peristalsis is preserved.

Treatment and prognosis

These are discussed in the section on non-cardiac chest pain.

Non-specific oesophageal motor disorders

Definition

This is a ragbag of manometrically defined oesophageal motor abnormalities which occur in isolation from other more clearly defined syndromes of oesophageal dysfunction, or in association with diseases such as gastro-oesophageal reflux disease, diffuse oesophageal spasm, and diabetic and other autonomic neuropathies. The pragmatic definition of these dysfunctions is that they are departures from normal patterns of oesophageal motor function which do not actually define specific diseases, but which are of clinical significance. Non-specific oesophageal motor disorder is the commonest single functional diagnosis made in most oesophageal manometric laboratories.

Aetiology

This is unknown, but it should not be assumed that only one mechanism is involved. Intermittent occurrence of dysfunctions suggests that they are due to defective neural control.

Symptoms

Multipeaked, swallow-induced distal oesophageal body contraction waves stand out from the other patterns not only functionally but also symptomatically. This pattern is loosely associated with the hypercontraction disorders of diffuse oesophageal spasm and hypertensive peristalsis, but sometimes does not appear to have any clinical significance.

Hypocontraction dysfunctions, recently termed 'ineffective' peristalsis, are associated with defective triggering and progression of both primary and secondary peristalsis. Failure to develop a propagated pressure wave of sufficient strength to maintain closure of the oesophageal lumen leads to deranged oesophageal transit. This probably explains the association of these disorders with mild intermittent dysphagia which occurs characteristically with solids. The non-obstructive dysphagia and slow oesophageal acid clearance seen in gastro-oesophageal reflux disease are due to such dysfunction. Secondary oesophageal body peristalsis has not yet been widely evaluated, but defects of this are probably an important cause of intermittent dysphagia, since, at least in patients with non-obstructive dysphagia and reflux disease, dysfunction of secondary peristalsis is substantially more common than primary peristaltic dysfunction. Oesophageal manometry with an adequate number of recording points in the oesophageal body is the only sensitive means for diagnosis.

Treatment

In most cases patients with symptoms found to be due to non-specific oesophageal motor disorders are in search of an explanation of the origin of their symptoms and reassurance rather than relief of symptoms. Cisapride may improve triggering and amplitude of peristaltic contractions and so theoretically transit. Usually, however, the symptoms arising from primary peristaltic dysfunction are not sufficiently severe to warrant continuous therapy. Secondary peristaltic dysfunction may be more troublesome, but there is no good information on the effect of prokinetic or other drugs on this.

Prognosis

These dysfunctions do not remit spontaneously. Patients are often helped by the measures outlined in the section on general management of oesophageal dysphagia, which minimize the demands on oesophageal transport mechanisms and provide propulsive forces that substitute for oesophageal contractions.

Non-cardiac chest pain

Definition

Implicit in this rather circuitous and negative label is the view that this pain has a cardiac-like quality, but there is no evidence for a cardiac origin. The oesophagus is the next most likely origin, but it is unlikely that all such pain arises from the oesophagus.

Aetiology

Long-term monitoring of oesophageal pH and motility has given us mixed messages. Evidence for triggering of pain by reflux or oesophageal motor dysfunction has been found in between one-fifth and one-half of patients evaluated. Oesophageal mucosal pain due to gastro-oesophageal reflux is the most common and rewarding positive diagnosis. Frank oesophageal spasm associated with achalasia and diffuse oesophageal spasm is an unusual but convincing cause of non-cardiac chest pain. In the majority of patients, most episodes of pain occur independently of reflux and any motor abnormality, although many of these patients have non-specific oesophageal motor disorders or hypertensive peristalsis (see above). Recently, sustained contraction of the longitudinal muscle has been identified by prolonged intraluminal ultrasonography in association with a high proportion of episodes of pain. Nevertheless, in many patients non-cardiac chest pain appears to be a primary oesophageal pain disorder and any motor disorder may be an epiphenomenon.

Symptoms

By definition, the pain resembles cardiac pain in its sensation and distribution. It can be very intense and distressing, can disturb sleep, and may be worse during periods of emotional stress. Postprandial occurrence, in association with heartburn, suggests that it may be caused by reflux. When pain is associated with dysphagia, vigorous achalasia or oesophageal spasm are very possible.

Diagnosis

Investigation is demanding and relatively unrewarding. Firstly, myocardial ischaemia should be assumed to be the cause until proven otherwise. Endoscopy should then follow. In patients who are having recurrent problems, monitoring of oesophageal pH and oesophageal motility studies are both indicated.

Treatment

If the pain is triggered by gastro-oesophageal reflux, high-level therapy should be tried (see section on gastro-oesophageal reflux disease). Achalasia and diffuse oesophageal spasm should be treated on their own merits. Half or more of patients will still have no clearcut diagnosis. In these, treatment with anxiolytics and antidepressants has been found to be moderately effective. Agents that reduce the strength of oesophageal contraction, such as calcium antagonists, appear ineffective in hypertensive peristalsis.

Prognosis

When the pain is clearly due to reflux disease, diffuse oesophageal spasm, and achalasia, the prognosis is as for these conditions. In patients in whom there is no such clear relationship, continuing anxiety about the origin of the symptoms and the fear that this might be cardiac tends to persist, with repeated admissions to hospital because of attacks of pain.

Oesophageal motor disorders secondary to systemic disease

Oesophageal motility may be affected by a number of systemic diseases (Table 3). These diseases may affect the striated or smooth muscle itself or the neural control mechanisms.

The division of the oesophageal musculature into striated and smooth muscle components is revealed clearly by the myopathic diseases that affect the oesophageal musculature. In patients with peripheral myopathy this would normally have been diagnosed. Weak or absent oesophageal contraction in the affected segment has the expected adverse impact on oesophageal transit, with a pattern of symptoms similar to the hypocontraction states of non-specific oesophageal motor disorders

(see above). The management of these dysfunctions is along general lines (see section on general management of oesophageal dysphagia).

Diseases of oesophageal smooth muscle

Scleroderma

Definition and aetiology

This eventually involves the smooth muscle of the oesophagus in at least three-quarters of patients. It may be part of the CREST (**C**alcinosis, **R**aynaud's syndrome. (o)**E**sophageal dysphagia, **S**clerodactyly, **T**elangiectasia) syndrome The time of onset of symptoms from oesophageal involvement is very variable in relation to other manifestations but is sometimes the presenting symptom. Muscle atrophy and fibrosis are the cardinal features, but neuropathic abnormalities may also contribute to dysfunction. Smooth muscle peristalsis is feeble or totally absent and the tone of the lower oesophageal sphincter subnormal or absent.

Symptoms

Troublesome reflux symptoms are the most common consequence of loss of function. The pattern of dysphagia resembles that seen in non-specific oesophageal motor disorder (see above). If dysphagia is severe, peptic stricture should be excluded, as complete loss of oesophageal smooth muscle peristalsis rarely leads to disabling dysphagia.

Treatment

Reflux disease is frequently severe and should be managed by high-level medical therapy in order to prevent complications such as stricture (see above). Antireflux surgery is relatively contraindicated because of the poor propulsive function of the oesophageal body.

Other disorders

A scleroderma-like picture of oesophageal dysfunction is sometimes seen in other connective tissue disorders such as mixed connective tissue disease. The smooth muscle segment is also involved in systemic myopathies including polymyositis–dermatomyositis and myotonic dystrophy.

Abnormal oesophageal motility is common in diabetes mellitus, and may be a feature of amyloidosis, chronic alcoholism, and the pseudo-obstructive syndrome. In these disorders, the disturbance is believed to be primarily due to dysfunction of neural control mechanisms.

Disorders of striated muscle

Involvement of the striated muscle segment of the oesophagus is rare and usually present with high dysphagia, often in association with oropharyngeal dysfunction (see Chapter 14.5). The inflammatory myopathies (dermatomyositis, polymyositis, and inclusion body myositis), the muscular dystrophies (myotonia dystrophica and oculopharyngeal dystrophy), and myasthenia gravis are the most common causes.

Abnormalities of oesophageal anatomy

Non-neoplastic abnormalities which distort oesophageal anatomy may interfere with normal function or may merely pose difficulties in the interpretation of findings.

Sliding hiatus hernia

Definition

Around 90 per cent of hiatus hernias are of this type in which the gastro-oesophageal junction is displaced upwards into the thorax, giving a simple shaped pouch of intrathoracic stomach.

Aetiology

The phreno-oesophageal ligament is effaced in sliding hiatus hernia, but it is not clear whether this is a primary defect of gastric anchorage.

Symptoms

Many patients with hiatus hernia are asymptomatic. Despite this, physiological studies indicate that herniation of the gastro-oesophageal junction impairs its function as an antireflux barrier by removing the normal diaphragmatic crural compression from the lower oesophageal sphincter. Thus, hiatus hernia can be taken as a risk factor for reflux disease, but not an abnormality that makes the diagnosis.

Treatment

Symptoms of gastro-oesophageal reflux are the only ones of major significance. These should be treated along conventional lines (see gastro-oesophageal reflux disease).

Prognosis

This is essentially that of any associated reflux disease.

Rolling or para-oesophageal hiatus hernia

Definition

A variable part of the stomach herniates through the hiatus alongside a normally situated gastro-oesophageal junction. This pattern of herniation may produce a gross disturbance of gastric anatomy, usually with a narrow exit from the herniated pouch into the main stomach cavity. Some rolling hernias are also associated with displacement of the gastro-oesophageal junction above the hiatus in which case these are known as mixed hernias.

Symptoms

Obstruction and distension of the pouch causes upper abdominal discomfort and can progress to strangulation. Gastric volvulus can occur because of the laxity of the gastric anchorage and may obstruct the gastro-oesophageal junction. Both of these problems have a very high mortality and demand urgent surgery. Elective surgery is normally recommended to reduce and anchor rolling hiatus hernias in order to remove these risks.

Prognosis

Unfortunately, there are no adequate data on the degree of risk associated with rolling hiatus hernia or on any anatomical factors that are especially hazardous.

Schatzki ring (B ring)

Definition

This is a characteristic short luminal stenosis which occurs at the gastro-oesophageal junction (Fig. 6). It is made up only of mucosa and submucosa, and may narrow the lumen to a few millimetres or cause a clinically insignificant minor indentation.

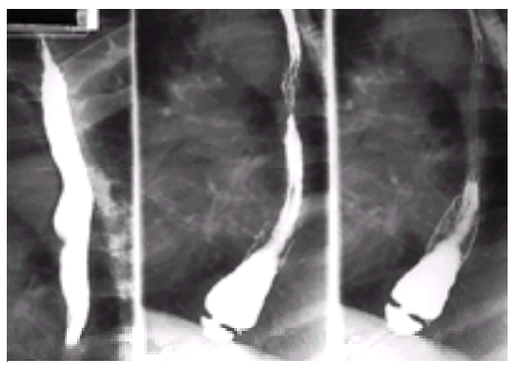

Fig. 6 Schatzki ring: a thin (2 to 4 mm in height), annular constriction at the gastro-oesophageal junction, best shown on prone-oblique views.

Aetiology

This is unknown. There is no firm evidence that reflux oesophagitis is the cause although this is sometimes assumed to be the case.

Symptoms

With mechanically significant rings, intermittent dysphagia occurs on eating solids. Meat is often the culprit, leading to the common term of 'steakhouse syndrome'. Episodes of bolus obstruction are not unusual, with associated chest pain caused by powerful oesophageal contractions. Failure to recognize a Schatzki ring frequently leads to the incorrect diagnosis of primary diffuse oesophageal spasm. Sensitive diagnosis is only achieved by an expert radiologist who has been asked to look for this abnormality. Adequate distal oesophageal distension during the barium swallow is essential for detection and this is best achieved by prone-oblique views. A less well-tailored barium examination and endoscopy frequently fail to show a symptomatic ring.

Treatment

Disruption of the ring by simple peroral dilatation or endoscopic diathermy or laser is very rewarding, as the dysphagia and chest pain are cured, sometimes after many years of symptoms. However, there is a significant incidence of recurrence and repeated dilatations at intervals are often needed.

Other rings and webs

Other short oesophageal stenoses may develop because of peptic stricture, muscular rings, and cervical webs with (Plummer–Vinson syndrome) or without iron-deficiency anaemia.

Oesophageal diverticula and pseudodiverticula

Wide-mouthed multiple diverticula are characteristic of scleroderma oesophagus. In the non-sclerodermatous oesophagus, diverticula occur in the mid and distal oesophagus, both types probably being 'blow-outs' secondary to hypercontraction motor disorders. These can become very large. It is rare for them to cause symptoms, but they may be associated with dysphagia and regurgitation of retained contents. Unless symptoms are disabling, they are best left undisturbed because leakage is common following surgical removal.

Multiple intramural outpouchings of barium are characteristic of intramural pseudodiverticulosis which appears to be due to dilatation of the ducts of submucosal glands by an unknown process.

Extrinsic oesophageal compression

This is a relatively common cause of dysphagia, and is most often a result of malignant mediastinal lymphadenopathy. Barium swallow or endoscopy usually show a relatively long constriction of the oesophageal lumen of variable calibre, associated with a normal mucosal appearance. Dilatation of such a compression is usually unrewarding because of its elastic recoil.

Mechanically significant extrinsic compression may also result from an enlarged heart, a dilated or unfolded aorta, or an aortic aneurysm. Kyphosis may accentuate the mechanical impact of these abnormalities. Congenital vascular abnormalities can also compress the oesophagus in adults, an aberrant right subclavian artery being by far the most common.

Mechanical, chemical, and radiation trauma

Mallory–Weiss tear

These mucosal tears extend across the gastro-oesophageal junction and are normally induced by vigorous straining associated with vomiting. Bleeding is the only consequence of significance. In 10 per cent of cases bleeding is severe enough to cause hypovolaemia. The history is usually quite characteristic, but definitive diagnosis requires endoscopy. Continued bleeding usually responds to endoscopic injection or electrocoagulation, vascular embolization, or vasopressin infusion. Very rarely, surgery is needed to underrun a persistently bleeding artery at the base of the tear.

Barogenic oesophageal rupture (Boerhaave's syndrome)

In this uncommon condition, straining and vomiting cause oesophageal rupture, most often in the left lower third of the oesophagus. High-volume spillage of the gastric contents into the pleural space causes shock and pain in the chest and upper abdomen with radiation to the back, left chest, or shoulder. The chest radiograph becomes abnormal only some hours after rupture. Surgical repair and drainage are usually necessary, and if this is delayed beyond 24 h, the mortality is very high. Unfortunately, diagnostic delay is not unusual.

Iatrogenic oesophageal perforation

Physicians encounter this problem most often as a result of their involvement in dilatation of oesophageal strictures, pneumatic bag dilatation for achalasia, or through problems with the management of oesophageal varices by balloon tamponade. Even with meticulous technique and appropriate equipment, oesophageal perforation can occur. Perforation is strongly suggested by development of chest or epigastric pain directly after instrumentation, sometimes with dyspnoea. Pneumothorax and surgical emphysema are diagnostic. Any suspicion of perforation should be acted upon by taking a chest radiograph which should be repeated in several hours if it is negative. Broad-spectrum antibiotics should be given on suspicion, as they are most effective in minimizing the risks of mediastinitis when given from the outset. Surgical consultation should occur promptly; the choice between conservative and surgical management needs to be individualized. Increasingly, instrumental perforation is being managed non-surgically with nasogastric suction, antibiotics, and intravenous nutrition with good results, primarily because instrumental injury

usually occurs when the stomach is empty.

Caustic ingestion

Definition and aetiology

Strong acids and alkalis are both very damaging to the oesophagus and are found in high concentrations in many agents commonly used in the household for cleaning and maintenance. Laryngeal and gastric injuries may overshadow oesophageal injury. Because of their relative lack of taste, alkaline solutions are more likely to be swallowed accidentally in large amounts. Alkaline injury is especially deep; acid tends to form a superficial coagulant, which limits penetration.

Symptoms

The severity and extent of injury are immensely variable and cannot be predicted accurately from estimates of the volume ingested. Around half of patients with a history of caustic ingestion have no significant injury. Oropharyngeal and laryngeal injury confirm caustic ingestion and can be a major threat to the airway, but do not predict the existence and severity of oesophageal injury which causes odynophagia, dysphagia, or haematemesis. Prompt fibreoptic panendoscopy appears to be safe. This may be normal or show only patchy mucosal oedema, erythema, and small haemorrhagic ulcers, indicative of superficial damage with a good prognosis. Extensive and circumferential ulceration, and grey or brown/black ulceration suggest transmural injury.

Treatment

Patients with severe injury must be observed closely for signs of perforation. Nasogastric suction should be used with the administration of broad-spectrum antibiotics as these appear to reduce the severity of infective complications. The use of steroids is controversial, the balance of evidence tending to oppose their use. Oesophageal stricture is to be expected with severe injury and appears not to be prevented by routine dilatation in the first 2 weeks after injury. A barium study should be done at 2 to 3 weeks to screen for stricturing, and then subsequently at about 3-monthly intervals thereafter for a year, so that the development of stricturing is recognized at a stage when dilatation may have some impact.

Prognosis

The main short- to medium-term risk is the development of stricture. Caustic strictures are difficult and hazardous to treat by peroral dilatation so that about half of patients require oesophageal resection. In the long term (average onset 40 years after injury) carcinoma of the oesophagus is a major hazard, the risk being 1000 to 3000 times the expected risk.

Medication-induced oesophagitis

Definition and aetiology

This entity was only recognized in 1970. The chemical properties of medications pose hazards to the oesophageal mucosa because of the relative susceptibility of this to injury through pH-dependent and other mechanisms. This susceptibility arises in part from the high local concentrations of medications that occur in the oesophageal lumen when a tablet gets 'hung up'. Pills move surprisingly slowly through the normal oesophagus. Defective oesophageal transport, poor pill design, increased mucosal susceptibility to injury, and poor pill-taking technique contribute to the problem. Medications known to have an especially high risk for oesophageal damage are listed in Table 4.

Symptoms

Symptoms are those for any form of oesophagitis with stricturing which can be very difficult to manage. Probably, much pill-induced injury goes unrecognized. Pill-induced injury is by far the most likely cause of oesophagitis and/or benign stricture at the level of the aortic arch, where pills can lodge for prolonged periods. Injury at the distal oesophagus, the other common site of hold-up, is probably usually misdiagnosed as being due to reflux disease.

Treatment and prognosis

Medications and formulations with a high risk of injury should be identified and avoided if possible, especially in elderly patients with reflux disease or abnormal oesophageal transit. Pill transit is facilitated if pills are taken in the erect position with plenty of water. Pharmaceutical companies need to pay more attention to the use of shapes, sizes, and coatings that can assist transit of pills through the oesophagus. Stricturing may require surgery.

Chemotherapy-induced oesophageal problems

Chemotherapy causes oesophageal problems in several ways. Therapy may impair mucosal defences by affecting cell turnover leading to 'mucositis'. This in turn may reduce resistance of the mucosa to damage from other agents, and increase susceptibility to infective oesophagitis from immune suppression. Oesophageal transit and acid clearance may be impaired through the neurotoxic effects of some agents. Fistulation or perforation may occur through cytotoxic effects on a malignancy in the oesophageal wall. The striking recent observation that combination chemotherapy is associated with the development of oesophageal columnar metaplasia in women being treated for breast cancer demands further investigation.

Oesophageal neoplasms

Cure is only possible in the small minority of patients whose disease presents early. Several approaches are possible for palliation and data are somewhat conflicting about the relative merits of each. Some approaches require considerable technical skill.

Squamous cell carcinoma

Definition

This is simply defined as a squamous carcinoma arising from the squamous oesophageal mucosa. It is by far the most common oesophageal neoplasm. In some parts of the world it is the most common of all cancers, but in the Western world it accounts for approximately 4 per cent of cancer deaths and has an annual incidence in the United States of 5 per 100 000 in Whites and 17 per 100 000 in Blacks.

Aetiology

The striking geographical variation in incidence suggests a major contribution from environmental factors. There are multiple proven or putative risk factors which include heavy alcohol use and intake of carcinogens from smoking, from soil and water, and from high rates of consumption of nitrosamines and aflatoxins. Other factors implicated are vitamin A deficiency, chronic candida infection, injury to the oesophageal mucosa due to ingestion of a corrosive substance years previously, and chronic irritation from oesophageal retention in achalasia. Some hereditary conditions such as tylosis predispose to squamous carcinoma. Invasive carcinoma is preceded by mucosal dysplasia and carcinoma *in situ*.

Symptoms

Dysplasia and carcinoma *in situ* are asymptomatic, and are only recognized by screening programmes set up in very high-risk areas, usually using blind cytological sampling methods. Inexorable progression of dysphagia over a few weeks is the almost universal presentation. Dysphagia usually only occurs when the tumour has become circumferential. Rarely, malignant mucosal ulceration presents with pain of the oesophageal mucosa due to malignant oesophageal ulceration. Substantial

weight loss has often occurred by the time of presentation.

Barium swallow typically reveals a stricture with an irregular, lobulated mucosal outline (Fig. 7), but occasionally the appearance mimics benign peptic stricture. The diagnosis is best proven by fibreoptic endoscopy, with mucosal biopsy and brush cytology. Occasionally, an asymptomatic oesophageal carcinoma is diagnosed when endoscopy is done for some other reason. Early lesions are often unimpressive, so that any minor mucosal irregularity should be sampled thoroughly by biopsy and cytology.

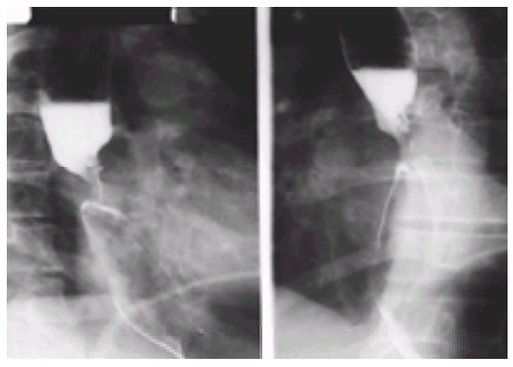

Fig. 7 Squamous carcinoma: a circumferential luminal narrowing which is asymmetrical and irregularly shouldered; the mucosal aspect is ulcerated.

Treatment

In very early, usually asymptomatic, carcinoma, resective surgery is the treatment of choice as it achieves high rates of cure. Curative resective surgery should only be attempted after careful staging of the tumour by clinical examination, chest radiograph, thoracic and abdominal computed tomography scanning, bronchoscopy, and liver function tests. Endoscopic oesophageal ultrasound is a much needed advance in the sensitivity of definition of the local extent of the tumour, but is not yet widely available. Palliation poses many challenges. There is a sorry lack of critical comparison of options. Resective surgery is unattractive, especially in elderly patients, because of its morbidity and mortality. Radiotherapy, with or without chemotherapy, is usually the best option for management of malignant obstruction. Repeated peroral dilatation, peroral placement of stenting tubes, laser photocoagulation, and injection of sclerosants are all options for the management of recurrent malignant strictures which have potential for improving the quality of life. Oesophagopulmonary fistula is a distressing development which usually causes pneumonia and persistent cough and which can sometimes be controlled by stenting.

Prognosis

This remains dismal except for regions where screening programmes identify early, asymptomatic cases. Only about one-quarter of patients are deemed to be potentially curable by surgery, and of these, about one-quarter will be alive and free of disease after 5 years. Thus, the overall 5-year survival rate is approximately 6 per cent. Such figures must be interpreted cautiously, because of differences between studies in the scope of presurgical staging, definitions of resectability, and criteria for exclusion of patients from consideration for surgery on the grounds of debility, old age, and other medical problems.

Adenocarcinoma and oesophageal columnar metaplasia (Barrett's oesophagus)

Definition

Between 80 and 90 per cent of adenocarcinomas arising in the oesophagus occur in association with oesophageal columnar metaplasia, or Barrett's oesophagus. In the minority of adenocarcinomas occurring in a squamous-lined oesophagus, the oesophageal mucus glands appear to be the source of malignant change.

Aetiology

Oesophageal columnar metaplasia (Barrett's oesophagus) develops as a result of the healing of severe reflux oesophagitis with metaplastic epithelium. This occurs from the gastro-oesophageal junction upwards over a distance that varies from 2 or 3 cm to the full length of the oesophagus. Oesophageal columnar metaplasia carries a 40-fold risk for development of oesophageal adenocarcinoma. Surveillance programmes in patients with oesophageal columnar metaplasia have shown a rate of development of adenocarcinoma that varies from 1 in 50 to 1 in 175 patient years. Occurrence of adenocarcinoma is very strongly associated with prior development of high-grade dysplasia in the metaplastic segment. The reasons for an apparently real increase in oesophageal adenocarcinoma are unknown. An increase in the prevalence of reflux oesophagitis, related to the reduced prevalence of *Helicobacter pylori* infection and a consequent increase in gastric acid secretion, is a plausible explanation.

Symptoms

The presentation of adenocarcinoma resembles that of squamous carcinoma (see above). Adenocarcinoma tends to be more fleshy and intraluminal but still presents at a very late stage. Metastatic disease is more common on presentation of adenocarcinoma than with squamous carcinoma.

Initial diagnosis and staging are along the same lines as for oesophageal squamous carcinoma.

Treatment of established adenocarcinoma

Careful staging is the cornerstone of appropriate management. Because of the usually distal site of occurrence of oesophageal adenocarcinoma, resection with oesophagogastrostomy is often best. Adenocarcinoma appears to respond less frequently to radiotherapy and chemotherapy than squamous carcinoma.

Management of the risk for adenocarcinoma in oesophageal columnar metaplasia

This is a very active field of research. Development of high-grade dysplasia in the columnar metaplastic segment precedes development of adenocarcinoma. This dysplasia can be recognized with sensitivity if at least four radially spaced biopsies are taken at every 2 cm of columnar-lined oesophagus. It is controversial whether such expensive surveillance methods are justified by the relatively low rate of recognition of early adenocarcinoma. There is also controversy about how a diagnosis of high-grade dysplasia should be acted upon. Some authorities recommend oesophageal resection on confirmation of this diagnosis, whilst others favour close surveillance with endoscopic ultrasound and repeated biopsies, with oesophageal resection being reserved for when there is clear evidence of disruption of the structure of the oesophageal wall, indicative of early invasive carcinoma. Others advocate perendoscopic ablation by laser or argon beam coagulation, or mucosal resection in the case of true intramucosal carcinoma. In large part, the approach to management of high-grade dysplasia is substantially moulded by the morbidity and risks of resective surgery and the availability of endoscopic ultrasound. In younger, fit patients, the balance is more strongly in favour of early resection than it is in older, less fit patients. Lack of detailed knowledge about the natural history of high-grade dysplasia makes the decision-making process especially difficult.

Failure to discuss the risk for adenocarcinoma and the option of endoscopic surveillance with a patient who has oesophageal columnar metaplasia could well be viewed as an indefensible lapse of practice, despite the uncertainties about cost-effectiveness.

Prognosis

For established symptomatic adenocarcinoma, prognosis is every bit as dismal as for squamous carcinoma. Post-mortem studies have shown that only a small proportion of patients with oesophageal columnar metaplasia are diagnosed as having this condition during life. Consequently, the impact of endoscopic surveillance

can at best only be limited. For those patients in whom screening is undertaken, it has been clearly established that high-quality screening leads to diagnosis of oesophageal adenocarcinoma at a stage when it may be cured by resection.

Other oesophageal tumours

Primary malignant tumours

Primary malignant tumours other than squamous carcinoma and adenocarcinoma are rare and all have a poor prognosis. These include malignant melanoma, lymphoma, carcinoid, leiomyosarcoma, neuroendocrine carcinoma (small cell carcinoma), adenoid cystic carcinoma, and pseudosarcoma. These tumours show a mixture of polypoid and infiltrating features and are usually only clearly distinguished from the more common malignancies by histology.

Benign oesophageal tumours

Leiomyoma is a relatively common oesophageal tumour which rarely causes symptoms. It is usually intramural but can become pedunculated. Around two-thirds of benign oesophageal tumours are leiomyomas. They usually only cause symptoms if they are very large, or on a long pedicle. Other benign intramural tumours of the oesophagus include lipomas and granular cell tumours. The main risk of these is that they are mistaken for malignant tumours and operated on inappropriately.

Squamous cell papillomas of the mucosa can mimic a polypoid squamous carcinoma and so should be removed endoscopically for histological diagnosis.

Infective oesophagitis and other non-neoplastic mucosal diseases

Most of these cause symptoms because of mucosal hypersensitivity. When the course is prolonged, interference with food intake may become a dominant problem in patient management. Viral oesophagitis can sometimes cause major haemorrhage. Some disorders damage the full thickness of the oesophageal wall and so lead to stricturing. Infective oesophagitis is by far the most important of these disorders, and has become more prevalent with the increased number of people who are immunosuppressed through HIV infection or chemotherapy.

Diagnosis is often aided by the setting in which the oesophageal problem occurs. Cutaneous or oral disease can suggest what is happening in the oesophagus, but barium swallow adds relatively little to the assessment of mucosal hypersensitivity. Endoscopy is the diagnostic method of choice. Mucosal appearance and the distribution of oesophageal lesions can be virtually diagnostic. In addition, biopsies and brushings allow for histological diagnosis and identification of infectious agents. Endoscopy has most to offer in patients with chronic symptoms, or those who are immunosuppressed.

Infective oesophagitis

The more important causes of infective oesophagitis are summarized in Table 5. Immune status is a major determinant of the pattern of infection. Though infective oesophagitis may be severe in immunocompetent patients it is characteristically self-limited and topical therapy is normally all that is needed (Table 5).

Immunocompromised patients usually need aggressive, systemic therapy, otherwise the infection does not resolve. The infection can be difficult to eradicate, tends to recur, and can cause major disability. Two or more infections are not unusual (Table 5).

Helicobacter pylori does not appear to be of any primary significance in the pathogenesis of oesophageal mucosal disease.

Other non-neoplastic mucosal diseases

Skin and systemic diseases associated with lesions of the oropharynx may also involve the oesophagus. These include epidermolysis bullosa, Behçet's disease, lichen planus, pemphigus vulgaris, bullous pemphigoid, benign mucous membrane (cicatrial) pemphigoid, and drug-induced disease (Steven's Johnson syndrome and toxic epidermal necrolysis).

Chronic, and less frequently acute, graft versus host disease may cause severe oesophageal problems through mucosal desquamation or mural damage. Resultant stricturing shows considerable variation in appearance.

Rarely, Crohn's disease can cause indolent, craggy ulceration and/or stricturing. Oesophageal sarcoidosis can mimic Crohn's disease.

14.7 Peptic ulcer diseases

*John Calam**

Introduction

Peptic ulcers are common: individuals in Western populations have a lifetime risk of 1 in 10 of developing an ulcer. They are a major cause of illness and death and are economically important. Research in the field of peptic ulcers initially focused on the elevated secretion of gastric acid in duodenal ulcer disease. Treatments to combat acid progressed from alkaline antacid preparations through histamine H_2-receptor antagonists, to proton pump inhibitors; maintenance therapy was required because ulcers recurred when the medication was stopped. Our understanding of peptic ulcer disease was radically changed in 1983 by the discovery of *Helicobacter pylori* and thereafter its role in gastric and duodenal ulcers. Most patients with ulcers are infected with *H. pylori*, and eradicating the infection permanently cures the ulcers (Fig. 1). Inhabitants of developing countries are also commonly infected with *H. pylori*, but the prevalence is lower and is falling in regions where better sanitation and hygiene limit transmission.

Fig. 1 Demonstration in 1988 by Marshall and colleagues that eradication *of H. pylori* greatly prolongs remission of duodenal ulcer disease. CLO+ and – refer to the diagnosis of infection after attempted eradication by the biopsy urease test, the CLO test, which Marshall also invented. (Reproduced from Marshall BJ *et al*. (1988). *Lancet* **ii**, 1437–42, with permission.)

As *Helicobacter* is controlled, another ulcerogenic factor has become important. Non-steroidal anti-inflammatory drugs (**NSAIDs**), often prescribed for musculoskeletal conditions which particularly affect the elderly, lead to ulcers in a population that is less well able to withstand the major complications of haemorrhage and perforation. The chance of dying as a result of a peptic ulcer is currently about a thousand times greater in the elderly than in the young, and peptic ulcers thus remain a challenge to modern medicine.

Definition

A gastrointestinal ulcer is defined as a breach in the epithelium that penetrates the muscularis mucosae. If the muscularis is not breached it is called an erosion. Duodenal ulcers and gastric ulcers are often considered together as peptic ulcers but differ considerably with regard to epidemiology, pathogenesis, presentation, and

management: they are discussed separately. This chapter will also address acute erosive gastritis and non-ulcer dyspepsia. Oesophageal ulcers are discussed with erosive oesophagitis in Chapter 14.6. The Zollinger–Ellison syndrome is discussed in Chapter 12.10 and Chapter 14.8.

The major causes of peptic ulcers are *H. pylori* infection and NSAIDs.

Helicobacter pylori

Spiral bacteria were observed by European investigators in the stomachs of animals in the nineteenth century and in humans at the beginning of the twentieth century; but interest waned when a prominent American investigator reported no such bacteria in gastric biopsies from 1000 patients. In 1981 a British study showed that duodenal ulcers remain healed for longer after administration of the antibacterial bismuth than after the H_2-antagonist drug cimetidine. In 1983, the Australians Warren and Marshall succeeded in culturing *H. pylori* (originally known as *Campylobacter pyloridis*) from human gastric biopsies. They were assisted by new selective culture media, and serendipity—growth was achieved when the culture plates were incubated for longer than planned during a holiday. Warren and Marshall soon noticed the association between *H. pylori* infection and gastritis, that almost all patients with duodenal ulcers are infected, and that eradication of infection largely prevents recurrence of ulcers.

The epidemiology of *H. pylori*

Population surveys reveal two patterns of *H. pylori* infection. In developing counties about 80 per cent of the population are infected by the time they are adults and remain infected. In the West, the prevalence rises gradually throughout life to about 60 per cent in old age (Fig. 2). But this is due to a cohort effect rather than gradual acquisition of infection throughout life. The infection is usually acquired before the age of 5 years. Older Westerners were children when infection was much more prevalent than it is now. An exception is that adults frequently acquire infection during wartime: the prevalence of *H. pylori* in the West is distinctly lower in those born after the Second World War. It remains high in the poor and in immigrants from developing countries.

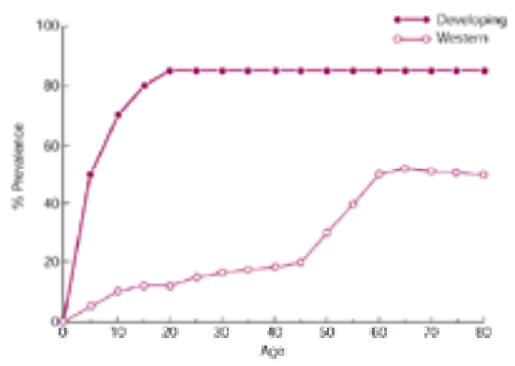

Fig. 2 *H. pylori* prevalence in Westernized versus developing countries. (Adapted from Marshall BJ (1994). *American Journal of Gastroenterology* **89**, S116–118, with permission.)

Bacteriology and transmission of *H. pylori*

Helicobacter pylori is a Gram-negative microaerophilic bacillus (Fig. 3). It uses its spiral shape and four to six flagellae, located at one end, and to move through the gastric mucus layer. It is well adapted to the gastric environment; for example its abundant urease generates alkali by splitting urea into two NH_4^+ ions and one HCO_3^- ion. Indeed *H. pylori* can only survive on gastric-type mucosa, perhaps because its adhesins bind specifically to certain motifs on gastric cells. It is readily cultured from gastric biopsies on selective media, but transport to the laboratory must be rapid. Transmission is from person to person, often within families. It is unclear whether spread is usually oral–oral or faecal–oral. Infection via drinking water occurs in developing countries. There is no significant animal reservoir. The genomes of several *H. pylori* strains have been sequenced and vary considerably. Different strains contain different lengths of 'cag pathogenicity island'. This is a cassette of genes involved in pathogenicity, plus the gene *cagA*. The presence of antibodies to cagA protein in a patient reflects the presence of the island, and is associated with ulcers and cancer. Variations in the gene *vacA* that encodes the *H. pylori* vacuolating toxin also appear to influence the likelihood of these consequences of infection.

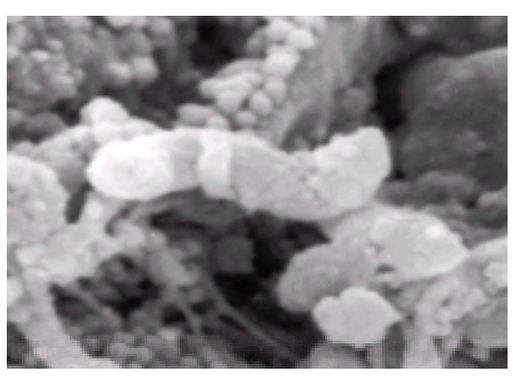

Fig. 3 Electron micrograph of *H. pylori*.

Diagnosis of *H. pylori* infection

Three methods can be used to detect *H. pylori* in gastric biopsies:

1. The biopsy urease test depends on the the ability of the bacterium to generate alkali.
2. *H. pylori* bacteria are readily detected histiologically using special stains.
3. Bacterial culture allows the antibiotic sensitivity of the patient's strain to be determined.

Two tests allow *H. pylori* to be diagnosed without endoscopy:

1. Serology is accurate and convenient but remains positive for several months after successful eradication, and is not useful for determining whether eradication has been successful.
2. The urea breath test. The patient drinks a solution of urea containing carbon atoms labelled with ^{13}C or ^{14}C. Labelled CO_2, generated by bacterial urease, can be detected in the breath by mass spectroscopy or radioactive counting if the infection is present (Fig. 4). This test is ideal for testing the success of eradication, if this is required (see below).

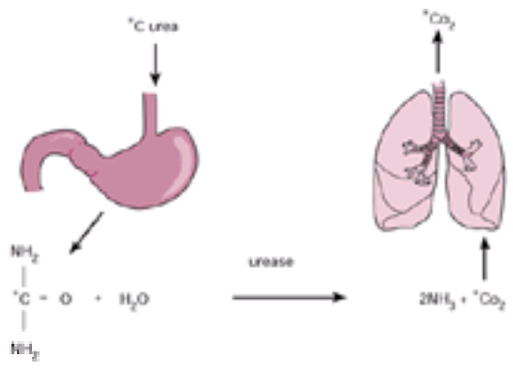

Fig. 4 Urea breath test. The patient drinks a solution of urea containing ^{13}C or ^{14}C carbon. If *H. pylori* is present then the carbon isotope appears in exhaled carbon dioxide.

Factors that determine the accuracy of the diagnostic tests

These tests are all quite accurate but can give incorrect results under certain circumstances: all except serology can give false negative results if the patient has received antibiotics during the past month. Also, the bacterium tends to move from the antrum to the proximal stomach when proton pump inhibitors are given. Biopsies should then be taken from the proximal gastric mucosa as well as the antrum. Proton pump inhibitors can inhibit *H. pylori*'s urease, which can affect results based on this enzyme. Serological tests remain positive for up to a year after the infection has been eradicated.

Disease associations of *H. pylori* infection

Gastritis

This was noted to occur in subjects who were accidentally or experimentally infected with the bacterium. A first infection is followed by a period of low or absent acid secretion, which lasts for weeks or months and which was called 'epidemic achlorhydria' before the cause was discovered. Before *H. pylori* was identified, it was well known that patients with duodenal ulcers have antral gastritis, whilst those with gastric ulcers and gastric cancer have pangastritis. *H. pylori* clearly contributes to the gastritis associated with these diseases because the inflammation resolves when the infection is eradicated. *H. pylori* gastritis is typically 'chronic superficial', meaning that lymphocytes and macrophages are located superficially. Infiltration with neutrophils ('activity') is variable. Prolonged infection predisposes to mucosal atrophy in which the number of chief and parietal cells in the gastric mucosa falls. Atrophy may then proceed to intestinal metaplasia in which the gastric epithelium is replaced with one resembling small or large intestine. The inflammatory response may diminish or even eradicate the infection by reducing acid secretion and the number of gastric cells to which *H. pylori* can adhere. Inflammatory mechanisms in *H. pylori* gastritis have been studied in detail because of their role in the pathogenesis of ulcers and cancer and their relevance to vaccine development. This topic is beyond the scope of this chapter. Briefly, *H. pylori* bacteria remain extracellular but induce gastric epithelial cells to express class molecules and chemokines such as IL-8. These recruit and activate inflammatory cells that express diverse inflammatory mediators including tumour necrosis factor-a, and products such as reactive oxygen species. *H. pylori* gastritis cannot be diagnosed on the basis of endoscopic appearance alone because the mucosa usually either looks normal or mildly reddened.

Duodenitis

Some individuals develop patches of metaplastic gastric mucosa in their proximal duodenum. This change depends on the rate of gastric acid secretion, being abundant in the Zollinger–Ellison syndrome and absent in pernicious anaemia. Gastric metaplasia is important because it allows *H. pylori* to colonize the duodenum leading to duodenitis. This can be erosive and increases the risk of chronic duodenal ulceration.

Gastric cancer

The World Health Organization has classified *H. pylori* as a gastric carcinogen. Infection is associated with an approximately eightfold increased risk of gastric cancer. Eradication of *H. pylori* from Japanese patents with early gastric cancer greatly diminished the risk of recurrent cancer after endoscopic resection. Gastric cancer is beyond the scope of this chapter but bears on the question of whether to eradicate *H. pylori* from individuals without ulcers—an issue which is currently unresolved.

Gastric MALT lymphoma (see Chapter 14.9.4)

Tumours of gastric mucosa-associated lymphoid tissue (**MALT**) are much more prevalent in *H. pylori* infection. This is as expected because uninfected gastric mucosa contains hardly any lymphocytes. Lymphomas restricted to the gastric mucosa usually disappear when *H. pylori* is eradicated because *H. pylori*-specific T cells provide contact-dependent help for growth of malignant B cells. The abnormal B-cell clone often remains detectable by gene rearrangement studies, and tumours reappear if the patient is reinfected. These lesions are less likely to respond to *H. pylori* eradication alone if they extend beyond the gastric mucosa. Chemotherapy or surgical excision may then be indicated, and therefore these tumours are generally best managed in a specialist centre.

Likelihood of disease following *H. Pylori* infection

Most individuals who are infected with *H. pylori* do not develop clinical disease. The likelihood of disease depends on the nature of the infecting strain, which is highly variable. The genome of more aggressive strains contains a pathogenicity island with genes encoding proteins that stimulate cytokine production. Infection with such strains can be identified by the presence of antibodies to cagA protein which is highly antigenic. Variations in *vacA* also affect the likelihood of serious clinical outcomes of the infection. However, people from parts of the world where heavy infection is frequent often harbour infection with more than one strain of *H. pylori,* which complicates this relationship.

Treatment of *H. pylori* infection

At the time of writing the following 1-week triple therapies are recommended in the British National Formulary because they provide the best combination of efficacy and convenience:

- Proton pump inhibitor twice daily plus amoxicillin 1000 mg twice daily plus clarithromycin 500 mg twice daily.
- Proton pump inhibitor twice daily plus metronidazole 400 mg thrice daily plus clarithromycin 500 mg twice daily.

The proton pump inhibitor can be either omeprazole 20 mg twice daily, or lansoprazole 30 mg twice daily. An H_2 antagonist, such as cimetidine, or an antibacterial agent such as bismuth citrate 400 mg twice daily can be used instead of the proton pump inhibitor.

The choice between these regimens depends on the local rate of metronidazole resistance. This is increased in inner-city areas because of immigration from developing countries where metronidazole is widely used, but is lower elsewhere in the United Kingdom. Resistance to clarithromycin is currently about 5 per cent in the United Kingdom but higher in the rest of Europe. Resistance to amoxicillin is exceedingly rare. It is important to encourage each patient to comply accurately, because about 60 per cent of strains will become resistant to metronidazole or clarithromycin if they are exposed to these without being eradicated. This lessens the chance that further attempts at eradication will succeed. An effective regimen for such cases is a proton pump inhibitor given twice daily, tripotassium dicitratobismuthate (TDB, DeNol) 120 mg four times daily 30 min before meals and at night, tetracycline 500 mg four times daily, and metronidazole 400 mg thrice daily all given for 2 weeks. *H. pylori* eradication regimens are subject to continued modification and it is thus recommended that current British National Formulary or local guidelines be consulted.

Whether eradication therapy has been successful or not can be determined by the urea breath test, but this must be performed at least 4 weeks after the end of the

eradication regimen to avoid false negative results. Patients must be retested if persistent infection would be hazardous, for example after haemorrhage of an ulcer, but this is unnecessary if symptoms from an uncomplicated ulcer have disappeared.

The role of non-steroidal anti-inflammatory drugs in peptic ulceration

Ingestion of NSAIDs (including aspirin) is the main cause of gastric and duodenal ulcers that are not associated with *H. pylori* infection. The ratio of *H. pylori*- to NSAID-associated ulcers is about 95:5 in the duodenum and 80:20 in the stomach because NSAIDs affect the stomach more than the duodenum. The ratio also depends on local *H. pylori* prevalence and NSAID use. In prosperous areas with low *H. pylori* prevalence and many elderly persons taking NSAIDs, the latter is now the main culprit. This is important because the elderly are less able to withstand the ulcer-related complications of haemorrhage and perforation. Use of NSAIDs greatly increases the risk of admission to hospital with an ulcer, and the chance of ulcer haemorrhage during ingestion of NSAIDs increases with the dose and duration of therapy. It also varies from drug to drug. NSAIDs act by inhibiting the enzyme cyclo-oxygenase which converts arachidonic acid to prostaglandins which normally protect gastrointestinal epithelia by increasing blood flow and secretion of mucus and bicarbonate. The isoenzymes cyclo-oxygenase-1 and cyclo-oxygenase-2 are largely responsible for the mucosal protective and anti-inflammatory effects respectively of NSAIDs (Fig. 5). Therefore newer NSAIDs, such as celecoxib and rofecoxib, that are highly selective for cyclo-oxygenase-2, control inflammation with less risk of causing ulcers.

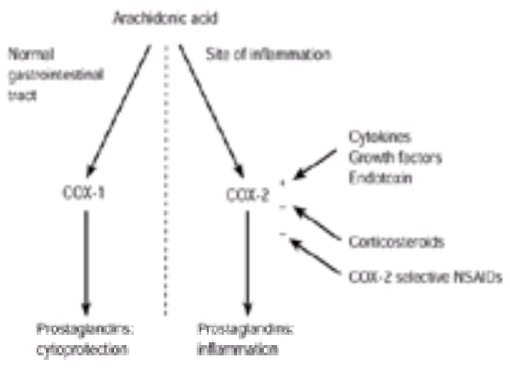

Fig. 5 The different roles of cyclo-oxygenase-1 and -2. Most existing NSAIDs inhibit both cyclo-oxygenase-1 and cyclo-oxygenase-2.

Ingestion of NSAIDs leads to a 'chemical' gastritis that is a milder form of the gastritis produced by reflux of bile into the stomach. The mucosa shows foveolar hyperplasia, oedema, vasodilatation and congestion, and few inflammatory cells. Ingestion of NSAIDs very often causes acute erosive gastritis that typically goes unnoticed unless it causes frank bleeding. Erosions tend to heal by the process of mucosal adaptation when NSAIDs are taken for more than about a week. Chronic ulcers develop with more prolonged ingestion of NSAIDs.

Prevention and control

The use of alternative medications such as paracetamol is the best way to prevent NSAID-associated ulcers. NSAIDs are now generally avoided in non-inflammatory conditions such as osteoarthritis. When NSAIDs are required a cyclo-oxygenase-2-selective drug is preferred. If an ulcerogenic NSAID has to be continued in a patient at risk then ulcer prophylaxis is indicated. Proton pump inhibitors and misoprostol are both effective in healing and preventing NSAID-associated ulcers. The former are generally preferred because they have fewer side-effects: misoprostol in particular tends to cause diarrhoea (see below).

Other factors which increase the risk of peptic ulceration

Cigarette smoking strongly predisposes to peptic ulceration. This may be because nicotine stimulates acid secretion and reduces mucosal blood flow, but eradication of *H. pylori* prevents the ulcerogenic effect. A moderate alcohol intake is not harmful and might even decrease the risk of duodenal ulceration. Duodenal ulceration is considerably more common in patients with cirrhosis or chronic pancreatitis, presumably because bile and pancreatic juice normally neutralize gastric acid when it enters the duodenum. It is usual to recommend a 'bland' diet in ulcer disease but no particular food is known to increase the risk of duodenal ulcer disease. Indeed the traditional Japanese diet, high in salt, pickles, and raw fish, may contribute to the low prevalence in Japan of duodenal ulcer disease and the high prevalence of gastric ulcers and cancer by causing corpus gastritis, which diminishes acid secretion. Hyperparathyroidism increases the prevalence of duodenal ulcer disease. Elevated circulating calcium concentrations stimulate gastrin release, and parathyroid tumours are associated with gastrinomas in the multiple endocrine neoplasia-1 syndrome (see Chapter 12.10).

The epidemiology of peptic ulcers

Ulcers of the stomach and duodenum led to 4111 deaths in England and Wales in 1996. This remains a cause for concern, but most peptic ulcers do not produce life-threatening illness.

Duodenal ulcer epidemiology

Duodenal ulcers are often asymptomatic so their prevalence can only be established by investigating apparently healthy people. Such a study in Finland showed that 1.4 per cent of the entire population had a duodenal ulcer at any time. The lifetime prevalence was 10 per cent in males and 4 per cent in females. In the United Kingdom duodenal ulcers are more common in the north of the country and in urban rather than rural regions. The incidence of duodenal ulcers gradually increases with age but peaks at about 60 years of age. In most parts of the world duodenal ulcers are about three times as common as gastric ulcers, but gastric ulcers are more common in some places including Japan, Sri Lanka, and the Andean region. The epidemiology of peptic ulcers is changing quite rapidly: in late nineteenth-century England, gastric ulcers occurred in young women and were much more common than duodenal ulcers. From the turn of that century until about 1960 the incidence of duodenal ulceration rose several times to become more common than gastric ulceration, which is now uncommon under the age of 40 years. Factors that might have contributed include cigarette smoking and the spread of *H. pylori* during the Depression and wartime. Also the integrity of the acid-secreting mucosa might have improved as the increasing use of refrigeration diminished the salt content of the diet and fresh fruit and vegetables provided antioxidants. Since 1960, the incidence of duodenal ulceration has stopped rising and may even have declined. The declining prevalence of *H. pylori* and early treatment of it has further changed the situation so that it is now becoming unusual for a gastroenterologist to see active duodenal ulcer disease in some prosperous regions in the west.

Gastric ulcer epidemiology

In most parts of the world chronic gastric ulcers are less common than duodenal ulcers, but gastric ulcers are still quite common. The most accurate epidemiological studies are from Finland. At any time about 0.3 per cent of that population has a gastric ulcer. The lifetime prevalence of gastric ulceration is 4 per cent in males and 3 per cent in females and the prevalence of *H. pylori* infection is similar in males and females. Gastric ulcers are rare in people under the age of 40 years and tend to occur in the lower socio-economic groups.

Duodenal ulcers

Duodenal ulcer is a common illness with serious complications. Over 90 per cent of these ulcers are due to *H. pylori* infection and can be permanently cured by its eradication (Fig. 1) but it is not possible to achieve this worldwide. Duodenal ulceration in the absence of *H. pylori* infection is the exception and is usually due to NSAIDs, Crohn's disease, or the Zollinger–Ellison syndrome.

Pathogenesis

Duodenal ulcer disease is associated with antrum-predominant *H. pylori* gastritis: the proximal stomach that secretes acid is relatively spared. *H. pylori* antritis

suppresses expression of the inhibitory peptide somatostatin and increases release of the acid-stimulating hormone gastrin. Gastrin elevates acid secretion both immediately and through the trophic effects of gastrin on the oxyntic mucosa. Eradication of *H. pylori* reverses these effects on gastric physiology. The increase in acid secretion directly damages the duodenal mucosa. Acid hypersecretion also produces gastric metaplasia in the proximal duodenum (Fig. 6). This allows *H. pylori* bacteria to colonize the duodenum and produce duodenitis that further impairs mucosal integrity and diminishes duodenal bicarbonate secretion. These changes result in duodenal ulcers.

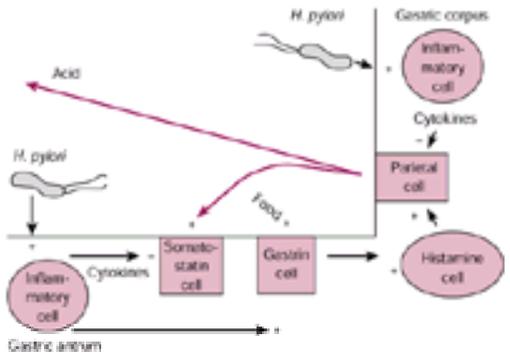

Fig. 6 Pathophysiology of *H. pylori* infection. Food stimulates gastrin cells in the gastric antrum to release gastrin. Circulating gastrin stimulates enterochromaffin-like cells in the gastric corpus to release histamine that stimulates adjacent parietal cells to secrete acid. Normally acid stimulates secretion of somatostatin that inhibits further gastrin release. Cytokines released in *H. pylori* antral gastritis suppress antral somatostatin-cells, leading to hypersecretion of gastrin and acid. But cytokines released in *H. pylori* gastritis of the gastric corpus tend to suppress parietal cells leading to diminished acid secretion.

Clinical presentation

Duodenal ulcers typically present with pain that is dull and located in the epigastrium or to the right of it over the duodenum itself. It is characteristically relieved by eating, then gets worse when the stomach empties. The pain usually wakes the patient from sleep in the middle of the night and is relieved by eating food, drinking milk, or taking an alkali preparation (antacid). Night pain is due to high nocturnal acid secretion without the buffering effect of food. The pain is also episodic with exacerbations lasting a few weeks separated by pain-free periods. These last for several weeks or months and probably reflect spontaneous healing of the ulcer. Pain radiating to the back suggests a posterior penetrating ulcer. Note that many ulcers do not cause pain and present with bleeding. This is particularly likely in the elderly, or if the patient is taking NSAIDs. Patients with duodenal ulcer often have other symptoms such as retrosternal burning and acid regurgitation. Nausea and vomiting are unusual and appetite is preserved. Persistent vomiting suggests pyloric stenosis. Symptoms resulting from other complications are described below.

Differential diagnosis

Gastro-oesophageal reflux disease also causes pain when the patient is in bed but patients usually notice an acid taste in the mouth or burning in the chest. Pancreatic pain typically radiates to the back, is exacerbated by eating, and is relieved by leaning forwards. Gallstone pain tends to be colicky and is exacerbated by eating fat. Pain due to the irritable bowel syndrome can occur in the epigastrium and be affected by eating but it usually extends to the lower abdomen and is typically affected by defaecation. Duodenal ulceration seen at endoscopy is usually due to *H. pylori* but NSAIDs, Crohn's disease, and the Zollinger–Ellison syndrome need to be considered, particularly if *H. pylori* is absent or if ulceration persists after it is eradicated.

Pathology

In duodenal ulcer disease the duodenum contains patches of gastric metaplasia colonized by *H. pylori* bacteria leading to infiltration with lymphocytes and neutrophil polymorphs. The ulcer itself consists of a breach in the epithelium with ulcer slough, inflammatory cells, and varying amounts of collagen scar in the base.

Diagnosis of duodenal ulceration

Duodenal ulcers are diagnosed most accurately by endoscopy. Antral biopsies can be tested for *H. pylori* and local treatment can be applied if the ulcer is bleeding (see below). Between episodes of ulceration the duodenum may show scarring or deformity. The presence of duodenitis also provides a clue to the diagnosis. High-quality double-contrast barium radiology is only slightly inferior. If an ulcer is seen, the likelihood of *H. pylori* infection is about 90 per cent—which is sufficient to justify treatment.

Treatment

Healing of duodenal ulcers can be accelerated by a number of acid-suppressing or mucosal protective drugs, but *H. pylori* eradication is now the mainstay of treatment (see above). Of the acid suppressors, proton pump inhibitors are more effective that histamine H_2-receptor antagonists, but the difference is not great in duodenal ulcer disease. *H. pylori* eradication should be commenced immediately. It is usually unnecessary to continue acid suppression after eradication therapy because eradication heals duodenal ulcers rapidly. However, it is sensible to continue acid suppression for about 8 weeks if the ulcer was complicated by bleeding or pyloric stenosis. *H. pylori* occasionally proves impossible to eradicate: healing may then be achieved and maintained by acid suppression. Alternatively prolonged remissions can be induced by courses of tripotassium dicitratobismuthate (DeNol).

Prognosis

Recurrence of *H. pylori*-related duodenal ulceration is uncommon after successful eradication. The rate of reinfection with *H. pylori* is about 0.7 per cent per annum in Western adults. Higher rates of reinfection have been reported in developing countries but this is not universal and the reinfection rate is 1 per cent per annum in China. Apparent reinfection in the West is often actually persistence of the initial infection. Recurrent ulceration in the absence of *H. pylori* may be due to NSAIDs, Crohn's disease, or the Zollinger–Ellison syndrome. In some patients recurrent ulceration after eradication of *H. pylori* is associated with persistent high acid output in the absence of a gastrinoma.

Gastric ulcers and erosions

Breaches in the gastric epithelium take two forms. Chronic benign gastric ulcers are relatively large and usually single. Acute erosive gastritis produces many small ulcers or erosions.

Chronic benign gastric ulcer

Gastric ulcers are important because they cause ill health, bleed and occasionally perforate, and because they are sometimes difficult to distinguish from gastric cancers. Most are associated with *H. pylori* infection and eradicating the bacterium greatly diminishes recurrence of ulcers, which demonstrates the causative role of the bacterium. Most other chronic gastric ulcers are associated with ingestion of NSAIDs. At the beginning of the twentieth century gastric ulcers were more common in the United Kingdom than duodenal ulcers and often occurred in young women. Now they are less prevalent than duodenal ulcers and typically occur in older people with low incomes. In some countries, including Japan, gastric ulcers are still more common than duodenal ulcers.

Pathogenesis

Ulceration occurs when luminal aggressive factors overcome mucosal defence. Suppression of acid accelerates healing of gastric ulcers so acid clearly contributes, but rates of acid secretion are normal or slightly below normal in these patients so acid cannot be regarded as the main cause. The duodenogastric reflux is increased

in patients with gastric ulcers, and the refluxed fluid weakens the mucosal barrier. *H. pylori* might cause ulceration directly by releasing a toxin such as its vacuolating toxin. Alternatively products of the inflammatory cells that it attracts, such as oxygen radicals or proteolytic enzymes, might compromise mucosal integrity (Fig. 7). The hydrophobic barrier of the mucosa is impaired in *H. pylori* infection. Non-steroidal anti-inflammatory drugs cause ulceration largely through inhibiting the production by cyclo-oxygenase-1 of protective prostaglandins in the gastrointestinal tract. In future this can be avoided by using highly selective inhibitors of cyclo-oxygenase-2, such as celecoxib and refecoxib. This is the isoenzyme that is involved in the inflammatory diseases for which these drugs are used (see above).

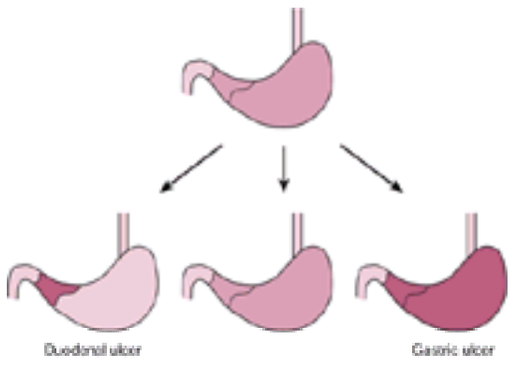

Fig. 7 Relationship between the distribution of *H. pylori* gastritis and the clinical outcome of the infection. Initially the infection affects the entire stomach. Most patients then develop a mild pangastritis and no clinical disease. Patients with duodenal ulcer have antrum-predominant gastritis, a healthy corpus and high acid secretion. Marked pangastritis is associated with low acid secretion and an increased risk of gastric cancer.

Clinical features

Patients with chronic gastric ulcers tend to be over 40 years old and from lower socio-economic groups. Epigastric pain is the most frequent symptom. It occasionally radiates to the back if the ulcer is located posteriorly. Food or antacids usually relieve it. It typically occurs in exacerbations lasting for several weeks with symptom-free periods in between. Night pain occurs in a minority of patients with gastric ulcer compared with most of those with duodenal ulcers. Gastric ulcers quite often produce nausea, anorexia, or weight loss suggestive of gastric cancer. Some patients vomit, but many ulcers have no symptoms until the patient presents with haemorrhage, and in practice one cannot reliably distinguish between these diseases on the basis of symptoms. Most patients with epigastric pain have non-ulcer dyspepsia or gastro-oesophageal reflux disease, rather than gastric or duodenal ulcers: gallstones can also cause epigastric pain but this tends to be colicky, at the right costal margin, and is exacerbated by fatty food. Pancreatic pain tends to be more constant, radiates to the back, and may be relieved by leaning forward. The differential diagnosis of gastric ulceration includes gastric cancer, lymphoma, Crohn's disease, syphilis, tuberculosis, and sarcoidosis. Importantly, gastric cancers occasionally produce ulcers that resemble simple peptic ulcers and these can heal when acid secretion is suppressed; further confusion may arise because biopsies from the ulcer edge do not always contain malignant cells.

Pathology

Histological examination of a chronic gastric ulcer shows a breach in the gastric mucosa that penetrates the muscularis mucosae. The base is composed of chronic inflammatory cells, and slough and fibrous tissue in varying proportions. The edge of the ulcer shows evidence of increased proliferation. The surrounding gastric epithelium may show *H. pylori* gastritis or chemical gastritis caused by NSAIDs or bile reflux.

Laboratory diagnosis

Cancer is excluded by examining multiple biopsies from the edge of the ulcer. *H. pylori* is sought as described above, but biopsy-based methods are prone to give false negative results because the stomachs of these patients typically contain areas of atrophy or intestinal metaplasia which are not colonized by the bacterium.

Treatment

Treatment of chronic gastric ulcers is by removing the cause if possible and giving ulcer healing agents if necessary. *H. pylori* is eradicated as described above. NSAIDs are discontinued if possible. In addition, administration of a proton pump inhibitor such as omeprazole accelerates healing of the ulcer. Until the ulcer heals, the patient should have an endoscopic examination every 4 to 6 weeks and multiple biopsies should be taken from the ulcer edge to exclude cancer. If NSAIDs have to be continued, the stomach can be protected against further ulceration by a proton pump inhibitor or misoprostol.

Prognosis

The immediate dangers are from complications and undiagnosed malignancy. Gastric ulcers are very likely to recur if they are healed by acid suppression alone. However, they unlikely to reappear if the cause is removed or adequate prophylaxis is given.

Acute erosive or haemorrhagic gastritis

Introduction

Acute gastric erosions are breaches in the gastric epithelium that are often multiple and small ({lt} 3 mm), reflecting an acute diffuse response to the gastric insult. If they do breach the muscularis mucosae they are called acute gastric ulcers. Cushing and Curling ulcers are historical terms used to describe ulcers in patients with head injury and burns respectively, but most acute gastric ulcers are now associated with severe illness or ingestion of NSAIDs or alcohol.

Acute gastric erosions in severe illnesses

These are common—80 per cent of patients receiving respiratory support from mechanical ventilators studied after 3 days in a British intensive care unit had erosions:

a. Acute gastric ulcers in patients with injury to the central nervous system were described by Cushing. Ulcers that frequently bleed occur in 50 to 70 per cent of patients with head injuries. They also occur after spinal injuries and after surgery to the central nervous system. The injury might cause the ulcers by increasing the release of gastrin because these patients have elevated acid secretion and plasma gastrin levels.
b. Curling described acute duodenal ulcers in patients with severe burns; however, acute gastric ulcers are even more common, and were present in 86 per cent of such patients in one recent study.
c. Acute gastric ulcers occur in patients suffering from many severe illnesses, including severe trauma, sepsis, shock, and major organ failure, presumably because these diminish gastric perfusion and compromise the metabolic integrity of the gastric mucosa.

Acute gastric ulcers due to ingested substances

Non-steroidal anti-inflammatory drugs including aspirin produce acute gastric ulcers by inhibiting synthesis of protective prostaglandins by cyclo-oxygenase-1. These impair mucosal protection by diminishing mucosal blood flow and the secretion of mucus and bicarbonate. Ulceration is most extensive shortly after the start of therapy: the stomach then adapts and ulceration subsides.

Alcohol induces acute gastric ulceration by a direct toxic effect. Studies in experimental animals suggest that vascular thrombosis also contributes to alcohol-induced ulceration.

Clinical features

The patient may complain of epigastric pain, nausea, anorexia, or vomiting but symptoms are usually absent until haemorrhage occurs The bleeding may be occult, show itself as small amounts of blood or 'coffee grounds' in gastric aspirates, or occur suddenly as a substantial haemorrhage.

Diagnosis

Acute gastric ulcers and erosions are readily seen with an endoscope, but the appearance varies from multiple erosions to submucosal haemorrhages to one or more points of active bleeding. During healing the ulcer may be elevated by surrounding oedema. Endoscopy is the principal diagnostic procedure and angiography is rarely needed.

Treatment and prevention

This disease is both treated and prevented by minimizing injurious factors. This involves correction of shock, sepsis, and respiratory and renal failure and avoidance of NSAIDs and alcohol. It is also important to correct coagulopathy that is frequently present in sick patients. Suppression of acid secretion is protective. This may be achieved with a histamine H_2-receptor antagonist or a proton pump inhibitor. However, it is recognized that acid suppression allows overgrowth of bacteria in the stomach lumen. This increases the risk of sepsis, particularly through aspiration in patients with impaired consciousness or cough reflex; hence prophylaxis with the antipepsin agent sucralfate, is generally preferred in patients undergoing intensive care.

The management of patients with established acute gastric ulceration involves blood transfusion, correction of coagulopathy, and suppression of acid secretion. The benefit from acid suppression is slight once haemorrhage has occurred. Endoscopic intervention and surgery are not usually appropriate because the condition is diffuse. If an operation is required it may need to be radical to control the haemorrhage (for example total gastrectomy).

Complications of ulcer disease

Haemorrhage

Haemorrhage remains a challenging problem and is the main cause of death from peptic ulcers. Blood loss may be slow and present as unexplained anaemia but more typically presents acutely with haematemesis or melaena or both with varying degrees of hypovolaemic shock. Such cases should be managed jointly by physicians and surgeons from the outset. Older patients need particular attention because they are much more vulnerable to the effects of hypovolaemia. Immediate action should be directed to the correction of circulatory shock by blood transfusion. Further transfusion may be required to keep the patient's haemoglobin level above 10 g/dl. Disorders of coagulation, pre-existing or due to transfusion, should also be corrected. Endoscopy is performed, preferably after the patient's condition has stabilized, to define the source of bleeding and to apply endoscopic treatments. Ulcers which are actively bleeding or show stigmata, such as adherent clot or a visible vessel, which make further bleeding likely can be treated with lasers, heater probes, or local injection of adrenaline. Rebleeding is an indication for surgery. After the acute episode, it is important to attend to the cause of the ulcer. Eradication of *H. pylori*, if it is present, greatly diminishes the frequency of further episodes of bleeding in future, but this is a measure that is frequently overlooked. Non-invasive tests can be used to diagnose the infection if biopsies were not taken at the time of endoscopy during the acute bleeding. NSAIDs are contraindicated after haemorrhage from NSAID ulcers. It is generally unnecessary to give long-term prophylaxis if the cause of ulceration has been removed, but this may be advisable if the patient is elderly, frail, or does not have rapid access to hospital.

Perforation

Ulcer perforation typically presents with a sudden onset or worsening of pain with considerable abdominal tenderness followed by the onset of peritonitis with board-like rigidity, rebound tenderness, and loss of bowel sounds. Gas in the peritoneum may lead to loss of liver dullness to percussion, and is usually visible beneath the diaphragm on erect chest radiograph. The patient is unwell with tachycardia, leucocytosis, and sometimes fever. The differential diagnosis includes acute pancreatitis, acute cholecystitis, and other causes of an acute abdomen such as gut infarction or perforation of other organs (see Chapter 14.3.1). The patient is resuscitated with intravenous fluids and antibiotics before transfer to theatre for repair of the perforation. Note that perforation, like other abdominal emergencies, may have a less specific presentation in the elderly, who may collapse or suffer confusion rather than the characteristic pain. Again, once the acute event has been dealt with, it is important to identify and treat the cause of the ulcer.

Pyloric stenosis

Repeated duodenal ulceration sometimes leads to stenosis of the pyloric canal or proximal duodenum. The narrowing is due to oedema as well as fibrosis so it can resolve without the need for surgery. The main symptom is vomiting which may contain food eaten the previous day. Typical symptoms of duodenal ulceration may or may not precede the onset of vomiting. Patients rapidly become dehydrated and develop hypokalaemia with a metabolic acidosis, they may also be malnourished. A succussion splash, which is normally present up to 4 h after a meal, is present at other times. Barium radiology or upper endoscopy show a distended stomach containing retained food and secretions and with a narrowed pyloric canal. The differential diagnosis includes cancer of the distal stomach. Most of these patients settle without the need for further intervention if treated by gastric aspiration, acid suppression, and intravenous fluids for a few days. If not, the stenotic region can be dilated using a balloon passed via an endoscope. A few patients require an operation, but again the cause of ulceration must be identified and appropriately treated.

Gastrinoma

The Zollinger–Ellison syndrome comprises an association of pancreatic tumour, gastric hypersecretion, and intractable ulceration. The tumour causes the syndrome by releasing gastrin so it is called a gastrinoma. This disease is discussed in Chapter 12.10.

Non-ulcer dyspepsia

Dyspepsia is upper abdominal or lower chest discomfort or pain, related to eating, which may be accompanied by other gastrointestinal symptoms such as nausea, vomiting, anorexia, or distension. Non-ulcer dyspepsia refers to cases of dyspepsia where no ulcer or other cause such as gallstones or gastro-oesophageal reflux disease is found. Historically, it was the introduction of modern investigative techniques, particularly endoscopy, which allowed these patients to be identified.

Advances in clinical investigation allow some patients considered to have non-ulcer dyspepsia to be diagnosed and treated appropriately. For instance oesophageal pH studies might change the diagnosis to endoscopy-negative gastro-oesophageal reflux disease (GORD) (see Chapter 14.6). Some patients may therefore elude diagnosis because in effect they are not fully investigated. The diagnosis of non-ulcer dyspepsia is not intellectually satisfying but it is important to make. First the patient benefits from the reassurance of knowing that he or she has a recognized medical condition; secondly insight will be gained ultimately into the causes of non-ulcer dyspepsia and how it behaves in response to different treatments.

Epidemiology

Non-ulcer dyspepsia is exceedingly common. In one survey in southwest England, 38 per cent of the entire adult population had had dyspepsia during a 6-month period and a further 25 per cent gave a past history of dyspeptic symptoms. Many or even most of these individuals have non-ulcer dyspepsia.

Symptoms and their pathogenesis

Patients report a variety of symptoms. Research reveals a series of abnormalities of physiological function. Symptoms and the corresponding pathophysiology are described together below; in practice the relationship between symptoms and disorders of function remains ill defined and many patients have more than one symptom. A common theme is that irritation, mild injury, or anxiety diminish thresholds for perception of pain and discomfort in the gastrointestinal tract.

Burning

Many patients with dyspepsia report burning in the epigastrium or chest, or other symptoms suggesting gastro-oesophageal reflux. Irritation of the oesophagus, for example by alcohol or previous reflux episodes, diminishes the threshold for oesophageal pain, so that very mild reflux then causes symptoms. If studies of oesophgeal pH and manometry show definite reflux, the patient can be reclassified as having endsocopy-negative gastro-oesophgeal reflux disease. In busy clinical practice this distinction may be considered unnecessary because the treatment of the two conditions is similar and usually empirical.

Distension

A frequent complaint is that the abdomen feels distended, a symptom that also occurs in irritable bowel syndrome, but if the distension is largely felt in the upper abdomen and after meals, it is considered to be typical of non-ulcer dyspepsia. In addition, there is frequently a sensation of early statiety after meals and a proportion of non-ulcer dyspeptics show delayed gastric emptying on scintigraphy, the cause of which is unknown, although anxiety may contribute. Reflux of duodenal contents into the stomach also occurs more frequently in non-ulcer dyspeptics. The differential diagnosis includes ascites and obesity. Some patients create a bizarre appearance of distension by contracting their diaphragms and increasing their lumbar lordosis.

Pain

Pain is a frequent symptom in non-ulcer dyspepsia, although its origin is usually difficult to establish. It may be due to muscular spasm. The differential diagnosis includes diffuse oesophageal spasm and achalasia as well as other painful conditions including pancreatitis and gallstone disease.

Nausea, vomiting, and satiety

If nausea and vomiting persist in the absence of an organic lesion it is important to exclude other causes such as drugs, metabolic disease, and disorders of the inner ear or central nervous system. Otherwise it is important to consider bulimia, anorexia nervosa, and psychogenic vomiting.

Diagnosis

The physical examination is unremarkable apart from the upper abdomen which is often tender. Investigation aims to exclude other diseases. This is partly to direct treatment and partly so that the patient can be reassured. The condition is so prevalent that it is unnecessary and impractical to investigate all patients fully. Clinical judgement is required. Upper endoscopy is indicated if the picture suggests organic disease or if symptoms persist. Upper abdominal ultrasound scanning is indicated if gallstones are suspected. Whether to test all dyspeptics for *H. pylori* remains controversial (see below). The infection has proved to be no more prevalent in patients with non-ulcer dyspepsia than in the general population.

Treatment

Explanation of the diagnosis with reassurance may relieve anxiety and thus diminish symptoms. Remaining symptoms can then usually be managed with antacids without the need for further medical attention. If treatment is prescribed proton pump inhibitors are most effective but also most expensive (Fig. 8). Alkalis, histamine H_2-receptor antagonists, and prokinetics are often helpful and less expensive. Most large randomized double-blind studies show that eradication of *H. pylori* does not improve symptoms in non-ulcer dyspepsia.

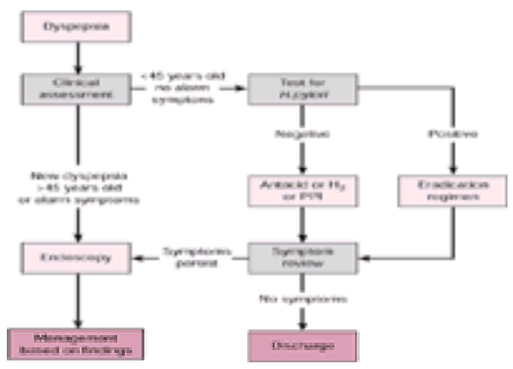

Fig. 8 Flow chart for the management of a patient presenting with dyspepsia of unknown cause that has failed to respond to lifestyle measures and antacids: H_2 = histamine H_2-receptor antagonist; PPI = proton pump inhibitor.

Prognosis and areas of uncertainty

Non-ulcer dyspepsia is a benign condition with no complications and a good prognosis. Only a minority of patients require long-term maintenance therapy. The problem is that some of the many dyspeptics in the community will develop serious organic disease. In a recent study, Swedes who reported symptoms of reflux were eight times more likely than healthy control subjects to develop adenocarcinoma of the gastro-oesophageal junction. Refluxed acid causes Barrett's oesophagus where these cancers originate (see Chapter 14.6). Therefore we need to learn how to manage this risk in the population of patients with dyspepsia. The second area of controversy is whether to eradicate *H. pylori* if it is found in a patient with non-ulcer dyspepsia.

Strategies for management of peptic ulcers and dyspepsia: the role of tests for *H. pylori*

The investigation and treatment of these conditions consume considerable healthcare resources (Fig. 9). Appreciation of the pathogenic role of *H. pylori* has prompted debate over how dyspepsia can be managed more efficiently. All agree that patients with recent onset of dyspepsia over the age of 45 years should be endoscoped promptly to exclude early gastric cancer. Three strategies have emerged for the management of younger patients:

1. 'Treat symptomatically and endoscope those with persisting symptoms'. This is the traditional approach. Initial treatment is with alkalis and less expensive acid-suppressing drugs. Those with persisting or troublesome symptoms are referred for endoscopy. Diagnoses such as ulcer, oesophagitis, and non-ulcer dyspepsia and the *H. pylori* status can then be made precisely, and management organized accordingly. The argument against this policy is that it does not make intelligent use of testing for *H. pylori* to rationalize demand for endoscopy.
2. 'Test and investigate'. The rationale is as follows: Research shows that patients under 45 years of age who are serologically negative for *H. pylori* and not taking NSAIDs are very unlikely to have peptic ulcers or gastric cancer. Therefore if these individuals are not normally endoscoped, endoscopy waiting lists and the number of negative examinations can be reduced. Negative *Helicobacter* serology allows the patient to be reassured that they have no serious disease and can be treated symptomatically with alkalis and acid-suppressing drugs. In practice, the main issue is whether the absence of *H. pylori* is sufficiently reassuring to relieve anxiety and the pressure for further investigations.
3. 'Test and treat'. Eradication of *H. pylori* heals and prevents gastric and duodenal ulcers. The World Health Organization has declared that *H. pylori* is a class 1 carcinogen. Therefore it is proposed to test all patients under 45 years of age with dyspeptic symptoms for *H. pylori*, and treat those who are infected. Endoscopy is reserved for patients whose symptoms persist after *H. pylori* eradication and those with new dyspepsia over the age of 45 years. The issue here is whether it is desirable to eradicate *H. pylori* from patients without ulcers. Most dyspeptics under 45 years of age do not have ulcers, even if they are infected with *H. pylori*. Overall this policy appears seems sensible. The main arguments against it are that antibiotic use will increase and that there is some controversial evidence that *H. pylori* protects against oesophageal disease. Overall, policies based on testing for *H. pylori* are less efficient in populations where the prevalence of the infection is very low, such as prosperous parts of North America, or very high, as in developing countries or in recent immigrants from them. Furthermore, in parts of the world with inadequate sanitation, reinfection rates can be as high as 30 per cent per annum, which diminishes the value of eradication.

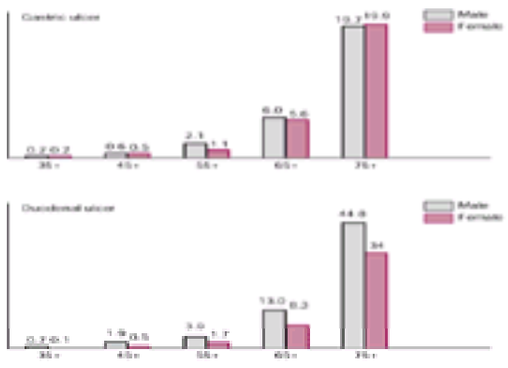

Fig. 9 (a) and (b) Age-specific death rates from peptic ulcer for England and Wales as rates per 100 000 per annum in 1998.

Treatments for peptic ulcer disease and non-ulcer dyspepsia

Antacids

Alkalis provide temporary symptomatic relief of pain in peptic ulcer disease but do not accelerate healing compared with placebo unless very large quantities are given. They are more useful in GORD and non-ulcer dyspepsia than in peptic ulcer disease. They usually contain the alkaline salts or hydroxides of magnesium or aluminium. Those based on magnesium are laxative and those based on aluminium tend to cause constipation. Some preparations contain mixtures of magnesium and aluminium to overcome this. Some preparations contain alginate which forms a flocculent raft on the gastric contents to reduce the effects of bile and acid reflux and protect the oesophageal mucosa.

Bismuth preparations

Tripotassium dicitratobismuthate (bismuth chelate, DeNol)

This bismuth complex acts mainly by suppressing *H. pylori* infection. It also has a protective effect on the mucosa, probably by stimulation of the synthesis of mucosal prostaglandins. Tripotassium dicitratobismuthate heals gastric and duodenal ulcers about as effectively as histamine H_2-receptor antagonists. It produces longer remissions of duodenal ulcer disease than do H_2 antagonists. This is probably because of its effect against *H. pylori* and because it remains in the gastric mucosa for several weeks after treatment. Currently tripotassium dicitratobismuthate is chiefly used as a component of second-line *Helicobacter* eradication regimens (see above). Bismuth preparations cause black stools—not to be confused with melaena. The bismuth content of tripotassium dicitratobismuthate is quite low. In the past 'epidemics' of bismuth encephalopathy occurred in Europe after patients ingested large amounts of other preparations containing unchelated bismuth. Tripotassium dicitratobismuthate only causes this complication if patients with impaired renal function take excessive doses for long periods.

Ranitidine bismuth citrate

This complex contains bismuth and the histamine H_2-receptor antagonist ranitidine. It can be used to treat duodenal ulceration associated with *H. pylori* infection. However, its main role is as a component of some highly effective *H. pylori*-eradication regimens (see above). It is contraindicated in moderate to severe renal failure and is not used for maintenance therapy since it may cause bismuth encephalopathy. It darkens the stools and can cause a black tongue.

Sucralfate

Sucralfate is a complex of aluminium hydroxide and sulphated sucrose, the properties of which include protection of the mucosa and ulcer healing. It is a weak antacid and may act by stimulating the synthesis of mucosal prostaglandins. It also binds bile salts. It is about as effective as histamine H_2-receptor antagonists at healing gastric and duodenal ulcers, but this role has now largely been taken over by proton pump inhibitors and *H. pylori* eradication. Currently sucralfate is mainly used in the prophylaxis of acute erosive gastritis in severely ill patients (see above). Side-effects are few but include mild constipation. It is to be avoided in patients with renal failure who occasionally develop aluminium toxicity.

Misoprostol

Misoprostol is a synthetic prostaglandin that increases the resistance of the stomach and duodenum to damage. Mechanisms include increased blood flow and secretion of mucus and bicarbonate. Misoprostol also mildly inhibits acid secretion. It accelerates healing of gastric and duodenal ulcers but this role has largely been taken over by proton pump inhibitors which are more effective, and by *H. pylori* eradication. The main use of misoprostol is in the prevention of gastroduodenal damage by NSAIDs, when these have to be given. The idea of replacing prostaglandins, the production of which is blocked by inhibitors of cyclo-oxygenase, is elegant, but this role has largely been taken over by proton pump inhibitors that are more effective and are about equally priced. The main side-effect of misoprostol is diarrhoea. This can be severe but is less likely if single doses do not exceed 200 µg. This is taken two to four times daily for prophylaxis. Note that misoprostol can induce abortion, so it should be avoided in women of childbearing age.

Histamine H_2-receptor antagonists

Secretion of gastric acid is normally stimulated by histamine, released from enterchromaffin-like cells in the gastric mucosa and acting on histamine H_2 receptors on parietal cells. Histamine H_2-receptor antagonists inhibit acid secretion by blocking this receptor. Sir James Black was awarded the Nobel prize for discovering this class of drug (as well as b-adrenergic antagonists). During the 1980s these drugs provided optimal treatment of peptic ulcer disease before being superceded by proton pump inhibitors and *H. pylori* eradication in the 1990s. However, they remain useful and are currently much less expensive. They are of use in non-ulcer dyspepsia and milder cases of gastro-oesophageal reflux disease (see Chapter 14.6). They protect the duodenum, but not the stomach, from ulceration due to NSAIDs. These drugs are not effective in haematemesis and melaena. Protection against acute erosive gastritis has not been shown consistently in trials. The four H_2 antagonists are cimetidine, ranitidine, nizatidine, and famotidine; but only the first two of these are widely used, largely due to the effects of marketing rather than to any differences in efficacy. Compared with ranitidine, cimetidine is less expensive, but it interacts with the metabolism of warfarin and anticonvulsants; it may cause mental confusion in the elderly.

Proton pump inhibitors

These drugs act by inhibiting the hydrogen/potassium adenosine triphosphatase enzyme system (H+/K+ATPase or 'proton pump') which pumps acid into the gastric lumen. They are prodrugs which are weak bases that are taken up into the acidic spaces in parietal cells, where the low pH creates a sulphenamide that is hydrophobic and therefore cannot diffuse away. The drug then forms disulphide bonds with cystine residues in the alpha chain of the proton pump, leading to its irreversible inactivation. Acid secretion is only restored when the cell synthesizes new proton pump protein. So these drugs are longer acting than H_2 antagonists even though they are cleared rapidly from the circulation. Once-daily dosing is satisfactory in most cases. Proton pump inhibitors are considerably more effective at preventing and healing gastro-oesophageal reflux disease than any other class of drug. In peptic ulcer disease their therapeutic advantage is smaller but significant. Their role in therapy is:

a. As a component of *H. pylori* eradication regimens. In this role they act by elevating the intragastric pH so that bacterial multiplication is encouraged and bacteriocidal antibiotics can act.
b. They accelerate healing of ulcers during and after *H. pylori* eradication. This is particularly relevant to chronic gastric ulcers that tend to be slow to heal because they are large.

c. They prevent NSAID-related ulcers if these agents have to be given. In this respect, proton pump inhibitors are more effective at protecting the stomach and duodenum than other classes of drug.
d. Omeprazole is the treatment of choice for the Zollinger–Ellison syndrome (see Chapter 14.8). Proton pump inhibitors are also highly effective in the treatment of non-ulcer dyspepsia, but most cases can be managed successfully with less expensive remedies.

They are currently the class of drug that is responsible for the greatest drug-expenditure in the United Kingdom and there is pressure to restrict their use. The main side-effects are diarrhoea and headache. The former may be less frequent with omeprazole than lansoprazole. Proton pump inhibitors can interact with the metabolism of other drugs including anticoagulants and anticonvulsants. Antacids and sucralfate impair absorption of lansoprazole.

Motility stimulants

Prokinetic drugs are not used to treat peptic ulcers, but are of use in non-ulcer dyspepsia as well as gastro-oesophageal reflux disease (see Chapter 14.6). Metoclopramide and domperidone are dopamine agonists that increase gastric emptying, small bowel transit, and the tone of the lower oesophageal sphincter. They can cause hyperprolactinaemia, leading to gynaecomastia, galactorrhoea, and diminished libido. Dystonias can occur, particularly in younger patients, and more often with metoclopramide than domperidone. Both are inexpensive. Cisapride is a motility stimulant that is believed to act by promoting release of acetylcholine in the gut wall. It has several side-effects and important drug interactions. In particular cisapride can cause serious arrhythmias and is contraindicated if the QT interval is prolonged. Concomitant medication with macrolide antibiotics increases the circulating concentrations of cisapride and the risk of arrhythmia.

Prevention and control

H. pylori infection will diminish worldwide if its transmission can be diminished by public health measures. Immunization has been shown to be effective in animal models but a human version is still some way off. Mass eradication is not a serious option due to the cost and the risk of generating antibiotic resistance. NSAID-associated ulceration is diminished by a policy of not using these drugs in non-inflammatory arthritis, and by using cyclo-oxygenase-2-selective drugs.

Special problems in pregnant women

Pregnancy decreases the frequency of peptic ulcers but gastro-oesophageal reflux is frequent. Treatment is largely with dietary and lifestyle changes, together with antacids or sucralfate. Persistent symptoms are treated with H_2-receptor antagonists. If symptoms continue and are severe despite these interventions, upper endoscopy and/or therapy with proton pump inhibitors may be considered during the second or third trimester. Misoprostol should be avoided because it can induce abortion.

Occupational, quality of life, and psychological aspects

Chronic peptic ulcer disease certainly impairs quality of life, but happily this can be improved either with acid-suppressing drugs or *H. pylori* eradication. There is no objective evidence to support the widespread belief that psychological stress predisposes to peptic ulcers. The myth is perpetuated by using the obsolete term 'stress ulcer' to describe acute erosive gastritis.

The need for further research

The main area of uncertainty is over how to apply our knowledge about *H. pylori* to the general population. It could be argued that whole populations should be tested and treated if found to be infected because the bacterium clearly plays a major causative role in important diseases including peptic ulcers and gastric cancer. Against this there is the cost, which would be considerable, and a significant risk of generating antibiotic-resistant strains of *H. pylori* and other bacteria. Some studies raise the possibility that *H. pylori* infection might protect against oesophageal diseases, but this is controversial and several studies do not support the idea. Long-term studies of the effects of eradication compared with no eradication in healthy infected patients would help to resolve this, but would be a major undertaking. At present no country is evaluating mass eradication, with the exception of Japan where *H. pylori* and gastric cancer are both unusually prevalent. Developing countries lack the resources to mount such a programme. General improvements in public health and hygiene in the west are diminishing the prevalence of *H. pylori* infection without the need for specific action against this bacterium. On the other hand it is quite usual to eradicate *H. pylori* from infected patients without ulcers, even though the overall conclusion from trials is that this does not improve symptoms. This may be irrational but it points to the difference between the science of medicine and its art. Informing the patient that a serious infection has been found and eradicated can have a very useful and reassuring effect and ultimately might even prevent late complications of persistent infection.

14.8 Hormones and the gastrointestinal tract

P. J. Hammond, S. R. Bloom, A. E. Bishop and J. M. Polak

Introduction

The discovery of secretin, the first recognized hormone, by Bayliss and Starling in 1902 marked the birth not only of gastrointestinal endocrinology, but of endocrinology itself. This was followed in 1905 by the identification of gastrin, but the technique of identifying hormones was, thereafter, more successfully applied to the study of secretions from the ductless glands, and gastrointestinal endocrinology languished for the next six decades. The determination of the amino acid structure of gastrin following its extraction from a solid tumour in 1964 marked a renewed interest in the field, and the introduction of techniques for large-scale chemical extraction and purification of gut peptides resulted in the discovery of further gut peptides. Most of the gut peptides, such as cholecystokinin and substance P, have been identified within the central and peripheral nervous systems, playing a neuromodulatory role in many organs. These neurocrine peptides are synthesized in nerve cells rather than endocrine cells in the gut and act locally as peptide neurotransmitters or neuromodulators.

The endocrine cells of the gastrointestinal tract are not grouped into anatomically distinct glands, like most endocrine cells, but are scattered through the length of the gastrointestinal tract. The principal role of gut peptides is in the integration of gastrointestinal function, and they regulate the actions of the epithelium, muscles, and nerves throughout the gastrointestinal tract. This local effect of peptides may be either autocrine, regulating the function of the cell secreting them, or paracrine, influencing the behaviour of neighbouring cells of different type. Thus somatostatin, originally identified as a hypothalamic inhibitor of growth hormone release, has been shown to have inhibitory effects in many different organ systems. It is locally released and its main mechanism of action is a direct one on neighbouring cells, for example to inhibit gastric acid and insulin secretion. In addition to altering gastrointestinal function many peptides, such as gastrin, secretin, and enteroglucagon, probably play an important paracrine role in controlling the growth and development of the gastrointestinal tract. In contrast, for most gut peptides there is little evidence that they act as true hormones in an endocrine fashion.

Two techniques have contributed to the increased understanding of gastrointestinal endocrinology. Molecular biology has helped identify members of peptide families by molecular cloning techniques, and has provided information about peptide processing, which has shown that different peptides may originate from a single common precursor. Sensitive peptide radioimmunoassay has allowed detection of gut peptides, which have very low concentrations in plasma and tissues. Furthermore, the specific peptide antibodies can be used for immunocytochemistry to demonstrate the cellular and neuronal localization of gut peptides (Fig. 1), and for immunoneutralization studies to elucidate the pathophysiological functions of gut peptides. Peptide localization is further defined by electron microscopy, which demonstrates specific peptide storage granules (Fig. 2), and *in situ* hybridization, which allows the sites of peptide synthesis to be identified. The most recent advance in gastrointestinal endocrinology has been the molecular characterization of hormone receptors by cloning techniques. This has demonstrated different receptors for the same ligand and provides an explanation for the diverse biological actions of many gut peptides in the same tissues. The development of agonists and antagonists to specific receptors will allow the physiological roles of the gut peptides to be fully characterized, and may be of therapeutic benefit in restoring normal gastrointestinal function in a disease.

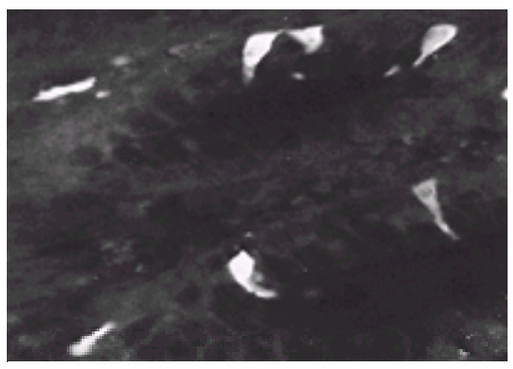

Fig. 1 Somatostatin cells, immunostained using the technique of indirect immunofluorescence, in the mucosa of human colon (×300).

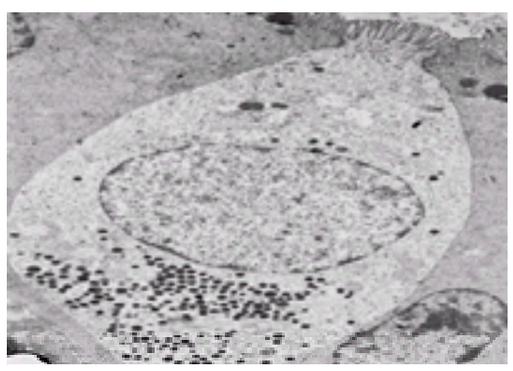

Fig. 2 Electron micrograph of a mucosal endocrine cell showing well-developed microvilli and secretory granules grouped at the basal membrane (×5500).

This section describes the gut peptide hormones and neurotransmitters, classifying them by common structure or precursor peptides, and then outlines abnormalities in gastrointestinal disease. The roles of gut peptides in the syndromes associated with gastroenteropancreatic tumours are considered in detail in Chapter 14.18.3.3, while the carcinoid syndrome is described at the end of this section.

Hormones and paracrine peptides

Gastrin–cholecystokinin family

Gastrin

Gastrin occurs in a variety of molecular forms but all the biological activity resides in the four carboxy-terminal amino acids. The major molecular forms contain 17 (G17; 2098 Da), 14 (G14; pentagastrin), and 34 (G34; big gastrin) amino acids. Larger molecular forms have been described but may be artefacts. In humans, gastrin is particularly localized to the gastric antrum, where G17 is the predominant form, but is also found in the upper small intestine, mainly as G34. These two are the predominant circulating forms. Gastrin is synthesized in G cells and electron microscopy shows gastrin granules to be large and electron lucent.

Gastrin release is particularly stimulated by protein ingestion and gastric distension. Its main physiological action is the stimulation of gastric acid secretion. Gastrin's other important physiological role appears to be its trophic effect on the gastric mucosa. Infusion of gastrin stimulates gastric motor activity and contraction of the lower oesophageal sphincter, but the physiological significance of this action is unclear.

Cholecystokinin

Cholecystokinin has an identical, five amino-acid, carboxy-terminal sequence to gastrin, but its specificity is conferred by the adjacent three amino acids, and this octapeptide confers its biological activity. It is found in the gut in 33, 39, or 58 amino-acid molecular forms predominantly, and is produced by the I cells of the duodenal and jejunal mucosa. The octapeptide cholecystokinin is a neurotransmitter in the central nervous system and a small amount is found in specific enteric neurones of the upper gastrointestinal tract.

Cholecystokinin secretion is stimulated by long-chain fatty acids and certain amino acids. The development of cholecystokinin antagonists specific for the two cholecystokinin receptor subtypes (cholecystokinin A, which is cholecystokinin specific, and cholecystokinin B, which appears to be also the only gastrin receptor) has allowed the important physiological roles of cholecystokinin to be characterized. The cholecystokinin A receptor appears to be involved in stimulation of gallbladder contraction and trophic effects on the duodenum and pancreas. The ability of cholecystokinin A receptor antagonists potently to inhibit meal-stimulated gallbladder contraction may be of therapeutic value in biliary colic.

The secretin family

The secretin family comprises a number of peptides with significant sequence homology. These include, in addition to secretin, glucose-dependent insulinotropic peptide, glucagon, enteroglucagon (see below), vasoactive intestinal peptide, peptide histidine methionine, and growth hormone-releasing factor. The last is released from the hypothalamus, mainly as a 44 amino-acid peptide, to stimulate release of growth hormone, but is also found in significant concentrations, mainly in a 40 amino-acid form, in the small intestinal mucosa, where its function is unknown.

Secretin

Secretin is a 27 amino-acid peptide (3056 Da), which appears to occur in only one molecular form, the whole molecule being needed for full biological activity. Circulating concentrations of secretin are lower than those of most other gut hormones. It is produced by S cells sparsely scattered throughout the duodenal and jejunal mucosa and is stored in characteristic secretory granules.

The main stimulus to secretin secretion is a duodenal pH of less than 4.5, although this occurs rarely. It is probably also secreted late after a meal, but the timing and quantities of this secretion are uncertain. The main physiological role of secretin is stimulating production of watery, alkaline pancreatic juices in response to acid in the duodenum. It may play an important part in the developing gastrointestinal tract, concentrations of secretin being particularly high in the early postnatal period.

Glucose-dependent insulinotropic peptide

Glucose-dependent insulinotropic peptide (**GIP**) is a 42 amino-acid peptide (5105 Da) with considerable sequence homology at the amino-terminal to secretin, glucagon, and vasoactive intestinal peptide. It is produced by K cells, predominantly in the upper small intestinal mucosa, but also in the gastric antrum and ileum, and is stored in large granules.

At pharmacological doses, GIP inhibits gastric secretions, and was originally named gastric inhibitory peptide. However, its physiological role appears to be as a component of the enteroinsular axis, being released in response to a mixed meal, particularly carbohydrates and long-chain fatty acids, and stimulating insulin release. This potentiation of insulin release in response to oral as opposed to intravenous glucose is the incretin effect. GIP has recently been implicated in the stimulation of cortisol release in two patients with ACTH-independent Cushing's syndrome whose serum cortisol rose postprandially.

Vasoactive intestinal peptide

Vasoactive intestinal peptide (**VIP**) is a 28 amino-acid peptide neurotransmitter (3326 Da) widely distributed through the central and peripheral nervous systems. The highest concentrations of VIP occur in the submucosa of the intestinal tract, where it is found in postganglionic intrinsic nerves (Fig. 3). VIP is a potent stimulator of small intestinal and colonic enterocyte secretion of water and electrolytes, acting via an elevation in cAMP. Other important actions include: smooth-muscle relaxation, both in the alimentary tract and in the systemic vasculature; stimulation of insulin release, counteracted by a direct glucagon-like effect of VIP in stimulating hepatic gluconeogenesis and glycogenolysis; stimulation of pancreatic bicarbonate secretion; and relaxation of the gallbladder, pyloric sphincter, and circular muscle of the small intestine with contraction of the longitudinal muscle. VIP inhibits release of gastric acid but not at physiological concentrations in humans.

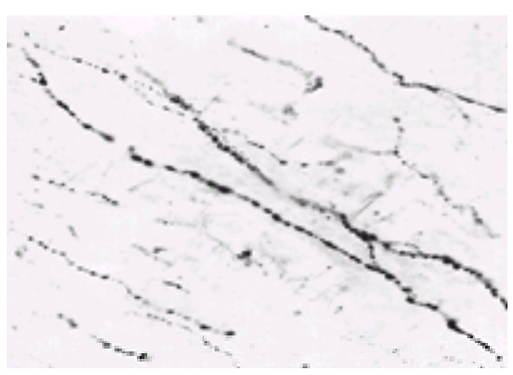

Fig. 3 Vasoactive intestinal polypeptide fibres, immunostained using the unlabelled antibody enzyme (PAP) method, in the submucosa of human colon (×500).

Peptide histidine methionine is a 27 amino-acid neuropeptide with considerable sequence homology to VIP and derived from the adjacent exon of the prepro-VIP gene. It mimics the actions of VIP, probably acting via the same receptor, but is less potent.

Pituitary adenylate cyclase-activating peptide is a recently identified peptide occurring in 27 and 38 amino-acid forms and with considerable sequence homology to VIP. It has a similar tissue distribution to VIP and shares the same receptor outside the central nervous system and pituitary gland. It has similar actions to VIP on intestinal secretion and motility.

Peptide products of preproglucagon

In the pancreas the major product of the preproglucagon molecule is pancreatic glucagon, but in the intestinal L cells preproglucagon is cleaved into enteroglucagon, a 69 amino-acid peptide containing the entire sequence of pancreatic glucagon, and the two glucagon-like peptides (GLP-1 $_{7–36}$ NH_2 and GLP-2; see below).

Enteroglucagon

Enteroglucagon (also termed glicentin) is found in high concentrations in the mucosa of the ileum, colon, and rectum. It is released after a mixed meal, particularly of carbohydrate and long-chain fatty acids. Pure enteroglucagon has not become available for infusion studies and so evidence for its physiological role remains circumstantial. The amount of enteroglucagon secreted is proportional to the amount of unabsorbed food entering the colon, and high enteroglucagon concentrations are found in conditions associated with loss of the small intestinal absorptive capacity. Thus it has been postulated that enteroglucagon has a trophic effect on the small intestinal mucosa and may be important in gut adaptation. Enteroglucagon is further cleaved by the L cells to produce oxyntomodulin, a 37 amino-acid peptide released into the circulation, which is a potent inhibitor of pentagastrin-stimulated gastric acid secretion.

Glucagon-like peptide 1

Glucagon-like peptide 1 (**GLP-1**) is a 36 amino-acid peptide, which is secreted in a cleaved form containing the 30 carboxy-terminal amino acids (GLP-1 $_{7–36}$ NH_2). It is a more potent stimulus to insulin secretion than GIP, and appears to be the most important incretin in humans. It also inhibits secretion of glucagon and potentiates release of somatostatin. Infusion of GLP-1$_{7–36}$ NH_2 greatly reduces insulin requirements following a meal in patients with type 1 or 2 diabetes, and this effect may have therapeutic potential.

Pancreatic polypeptide, neuropeptide Y, and peptide tyrosine tyrosine

Pancreatic polypeptide, neuropeptide Y, and peptide tyrosine tyrosine are peptides with structurally similar genes and propeptide molecules probably derived from a common ancestral gene.

Pancreatic polypeptide

Pancreatic polypeptide is a 36 amino-acid peptide (4226 Da) first isolated as a contaminant during the purification of insulin. It is produced by specific cells found at the periphery of the pancreatic islets, particularly those in the head of the pancreas, and scattered through the exocrine pancreas. Pancreatic polypeptide granules are small and electron dense.

Concentrations of pancreatic polypeptide rise dramatically after a meal, particularly one high in protein, and this is at least in part due to activation of cholinergic fibres from the vagus. At physiological plasma concentrations, this polypeptide inhibits pancreatic exocrine and biliary secretion, and these may represent its biological actions, although there are no obvious consequences of its deficiency or excess.

Neuropeptide Y

Neuropeptide Y is a 36 amino-acid peptide neurotransmitter, which is often colocalized with noradrenaline. It is found in both extrinsic adrenergic nerves to the myenteric plexus and in intrinsic nerves in the myenteric and submucosal plexi, and highest concentrations occur in the upper intestine and distal colon. It is a potent vasoconstrictor, inhibits intestinal secretion, and depresses colonic motility.

Peptide tyrosine tyrosine

Peptide tyrosine tyrosine (**PYY**) is a 36 amino-acid peptide found in endocrine cells of the ileum, colon, and rectum. It has a similar distribution to enteroglucagon, with which it is often colocalized. It is released after a meal, particularly one containing carbohydrates or long-chain fatty acids, and its main function appears to be to slow intestinal transit, allowing more time for absorption. Other actions include delaying gastric emptying, decreasing intestinal motility, and inhibiting gastric acid secretion.

Bombesin and the gastrin-releasing peptides

Bombesin is a 14 amino-acid peptide (1620 Da) initially isolated from amphibian skin. It was found to be a potent stimulator of gastrin, and hence of gastric acid secretion. Its mammalian counterparts have similar properties and so were named gastrin-releasing peptides. In humans, gastrin-releasing peptide is a 27 amino-acid peptide found in the gut in the intrinsic neurones of the myenteric and submucosal plexi, particularly in the stomach and pancreas. In addition to its effect on gastrin, it stimulates release of motilin and cholecystokinin, and pancreatic enzyme secretion. Gastrin-releasing peptide has been shown to be an autocrine growth factor for small-cell lung carcinomas, and probably has trophic effects on the developing gut.

Opioids

The opioid peptides leu- and met-enkephalin and dynorphin are widespread through the nerves of the myenteric and submucosal plexi of the gastrointestinal tract. Their principal actions appear to be inhibition of gastrointestinal secretion and increased smooth muscle contractility.

Tachykinins

Substance P is an 11 amino-acid peptide (1345 Da) whose existence was demonstrated in 1931 through its ability to cause smooth-muscle contraction and vasodilatation. A number of homologous peptides have now been characterized, and are collectively known as tachykinins, because of their rapid action. In humans there are two tachykinin genes, preprotachykinin A encoding substance P and neurokinin-a, and preprotachykinin B encoding neurokinin-b. These three tachykinins are localized to neurones in the myenteric and submucosal plexi throughout the gastrointestinal tract, with high concentrations in the duodenum and jejunum. Their principal effects are smooth-muscle contraction, vasodilatation, and inhibition of intestinal absorption.

Other gut peptides

Motilin

Motilin is a 22 amino-acid peptide (2700 Da) secreted by small intestinal M cells, whose density decreases from duodenum to ileum. The biological activity resides in the 9 amino-terminal amino acids. Peaks in motilin secretion coincide with initiation of the duodenal myoelectric complex, and so motilin appears to control the reflex motor activity of the small intestine, which occurs at approximately 2-hourly intervals in the fasted state, keeping the small intestine free of debris. Circulating amounts of motilin rise after a meal or drinking water and it may have a physiological role in accelerating gastric emptying and colonic transit. The macrolide antibiotics, such as erythromycin, are motilin-receptor agonists, hence their side-effects of diarrhoea and abdominal cramps.

Neurotensin

Neurotensin is a 13 amino-acid peptide (1673 Da) present throughout the central nervous system, and in enteric neurones and N cells of the ileal mucosa. It was originally isolated from bovine hypothalamus.

Plasma neurotensin concentrations rise after a meal, particularly those with a high fat content, and the rise is proportional to the size of the meal. At physiological doses, neurotensin inhibits gastric acid secretion and gastric emptying, and stimulates pancreatic exocrine and intestinal secretion. However, as with pancreatic polypeptide, there are no obvious consequences of neurotensin excess.

Somatostatin

Somatostatin was initially isolated from the hypothalamus as a 14 amino-acid peptide (1640 Da) that inhibited the release of growth hormone. It is widely distributed throughout the central and peripheral nervous system, and is found in a variety of endocrine tissues. In the gastrointestinal tract it occurs in 14 and 28 amino-acid forms. Somatostatin is secreted by specialized (D) cells distributed throughout the gut mucosa and on the inner rim of the pancreatic islets. D cells have all the characteristics of endocrine cells, but also possess axon-like basal elongations along which the peptide can be transported and secreted directly on to local cells. Five human somatostatin receptors have now been identified and cloned, the type 1 receptor predominating in the gastrointestinal tract. As gastrointestinal and other neuroendocrine tumours often possess high-density somatostatin receptors, scintigraphy with radiolabelled somatostatin analogues has been used for tumour localization (see Carcinoid syndrome below).

Somatostatin inhibits hormone release and blocks the response of the effector tissue, and inhibits a wide range of gastrointestinal functions (Table 1). Its acts principally as a paracrine factor or neurotransmitter, although small amounts of somatostatin are released into the plasma in response to physiological stimuli, including food ingestion, and so it may have an endocrine role.

Chromogranin-derived peptides

These structurally related, acidic proteins are present in the secretory granule matrix of neuroendocrine cells and are useful markers of normal and neoplastic neuroendocrine cells. To date, this family of proteins has been shown to consist of three molecules: chromogranin A, the first to be identified and also known as (parathyroid) secretory protein I; chromogranin B, or secretogranin I; and chromogranin C, or secretogranin II. It appears that the chromogranins have dual physiological roles: they may act in the processing of some regulatory peptides and prohormones. Their latter property was suspected when the primary structures of the three proteins were determined. All were found to contain multiple pairs of basic amino acids, forming sites for potential proteolytic cleavage. Chromogranin A gives rise to several peptides, including catestatin, chromostatin, vasostatin, and parastatin. Another derived peptide, pancreastatin was first characterized as a potent inhibitor of insulin release and later found in mucosal cells throughout the gut, where it is often co-stored with other peptides. It is released by gastrin from enterochromaffin-like cells of the gastric fundus, fitting with its action of enhancing meal-stimulated gastric acid secretion. The chromogranin B molecule yields, amongst other peptides, GAWK (from its first four amino acids: glycine, alanine, tryptophan, and lysine), a peptide distributed abundantly throughout the gut in both mucosal endocrine cells and intramural nerves. Chromogranins are proving to be of relevance to clinical medicine as plasma concentrations of chromogranins A and B can be used to determine the presence of a neuroendocrine tumour and as a means to monitor the efficacy of treatment.

Other peptide neurotransmitters

Calcitonin gene-related peptide is a 37 amino-acid peptide produced by alternative splicing of the calcitonin gene transcript. It is a widespread neurotransmitter and in the gut occurs in both extrinsic sensory nerves and intrinsic neurones. It inhibits gastric acid and pancreatic secretion, and causes relaxation of vascular smooth muscle.

Galanin is a 29 amino-acid peptide neurotransmitter isolated from porcine intestine. It is widely distributed in enteric nerve terminals and in nerves supplying the liver and pancreatic islets. Its main actions are inhibition of intestinal smooth-muscle contraction and inhibition of postprandial insulin release.

The potent vasoconstricting peptide endothelin has been demonstrated in the plexi of the gastrointestinal tract and in mucosal epithelial cells. However, its role in the regulation of gastrointestinal function is unknown.

Gut peptides in gastrointestinal disease

Gastric pathology

The most common cause of an elevated level of gastrin is achlorhydria, which may be the result of atrophic gastritis, pernicious anaemia or uraemia, or from iatrogenic causes such as the use of H_2-receptor antagonists or the proton-pump inhibitor omeprazole, or following vagotomy. The elevation in gastrin is a consequence of the loss of negative feedback on gastrin secretion by the low stomach pH. If the antrum is mistakenly retained after gastric surgery, this similarly removes the antral G cells from exposure to gastric acid and is associated with high gastrin concentrations. Achlorhydria-related hypergastrinaemia results in hyperplasia of the gastric histamine-producing enterochromaffin (**ECL**) cells. Atrophic gastritis in humans, and prolonged achlorhydria as a result of antisecretory therapy (for example, omeprazole) in rats, are associated with gastric carcinoid tumours, and these are thought to develop as a result of the direct trophic effect of gastrin on the ECL cells. Antisecretory therapy in humans has not been associated with the development of these tumours, but recommended therapeutic doses should not be exceeded and in patients on long-term therapy, hypergastrinaemia should be avoided.

Peptic ulcer disease is not usually associated with abnormalities in gut peptide secretion, although a decrease in somatostatin release in patients infected with *Helicobacter pylori* may influence the paracrine regulation of gastric function.

After gastrectomy or truncal vagotomy, patients may develop the dumping syndrome due to accelerated gastric emptying. In these individuals there is a marked increase in the postprandial rise of VIP, neurotensin, PYY, and enteroglucagon, and a decrease in the release of motilin. VIP and neurotensin may both contribute to the postprandial hypotension associated with dumping, but neurotensin may have a beneficial effect in slowing gastric transit. The long-acting somatostatin analogue octreotide, which inhibits release of these peptides and inhibits gastric emptying, is often a very effective treatment for this condition.

Malabsorption

Malabsorptive conditions are associated with a decrease in the amount of peptides produced in the affected region, and a compensatory elevation of other peptides, particularly those trophic peptides implicated in the bowel's adaptation to loss of absorptive surface, such as enteroglucagon.

Coeliac disease is an autoimmune disease resulting from dietary gluten sensitivity and it is associated with villous atrophy of the upper small intestine (see Chapter 14.9.3). The postprandial peptide response in patients with untreated coeliac disease shows greatly reduced secretion of GIP and secretin, which originate from the affected region of bowel. In contrast, there is marked elevation of enteroglucagon, neurotensin, and PYY (Fig. 4). The decrease in secretin and increase in PYY may be responsible for the reduced pancreatic exocrine and biliary secretion found in this condition. Enteroglucagon stimulates enterocyte turnover in the affected segment, despite the villous atrophy. It may have a trophic effect on the remaining small intestinal mucosa and delay gut transit time, and neurotensin may help to improve absorption by delaying gastric emptying. In tropical sprue, a postinfective malabsorptive state usually seen in travellers to Asia and Central and South America, a different profile of postprandial peptide release is seen. There is marked elevation in enteroglucagon and PYY, as in coeliac disease, but also in motilin secretion, whilst other peptides behave normally. After successful treatment of coeliac disease or tropical sprue, peptide responses return to normal.

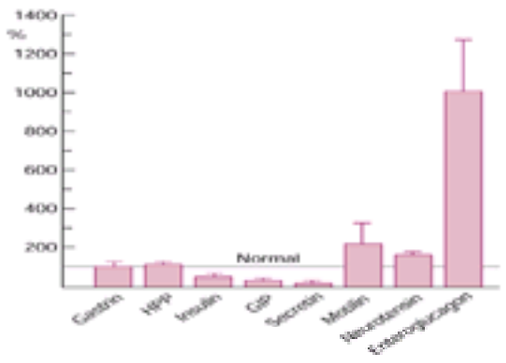

Fig. 4 The percentage incremental rise in gut hormones following a standard test breakfast in patients with coeliac disease compared with normal controls.

Chronic pancreatitis (see Chapter 14.18.3.2) results in varying degrees of pancreatic endocrine dysfunction in addition to the exocrine insufficiency. Thus patients often have insulin-dependent diabetes, and basal and arginine-stimulated glucagon concentrations may be reduced, although they are elevated in some individuals. Basal, and meal- and secretin-stimulated concentrations of pancreatic polypeptide are reduced if steatorrhoea is associated with chronic pancreatitis. The early loss of pancreatic polypeptide secretion in most individuals probably reflects the location of its secretory cells throughout the exocrine pancreas and on the periphery of the islets. However, secretion of pancreatic polypeptide is occasionally preserved and its concentration is not of diagnostic value in chronic pancreatitis.

Cystic fibrosis is often associated with diabetes mellitus and pancreatic exocrine insufficiency. Fasting and milk-stimulated concentrations of pancreatic polypeptide are usually suppressed. GIP concentrations fail to rise after a milk stimulus, implying a failure of the enteroinsular axis, and this may contribute to the associated glucose intolerance.

The malabsorption associated with pancreatic exocrine insufficiency of any cause leads to an excess of nutriments in the colon, and as a result the concentrations of enteroglucagon, PYY, and neurotensin are raised. The gut adaptation resulting from the effects of these peptides may contribute to the improvement in absorptive function with age in patients with cystic fibrosis.

Intestinal resection

Intestinal resection has profound effects on gut peptide concentrations. A jejunoileal bypass used to be constructed in patients with gross obesity. Peptide concentrations were normal preoperatively, but patients were hyperinsulinaemic and glucose intolerant. After the procedure there was an almost complete absence of the prandial GIP response and consequently a much reduced first-phase insulin response. The initial beneficial effects of the operation were ultimately negated by massive hypertrophy of the remaining bowel. The appearance of large volumes of undigested nutrients in the distal ileum is associated with a 16-fold increase in enteroglucagon responses and an eightfold increase in neurotensin secretion, and this may provide an explanation for the hypertrophy. After partial ileal resection, the concentrations of gastrin, enteroglucagon, pancreatic polypeptide, motilin, and PYY are elevated, but after colonic resection only gastrin and pancreatic polypeptide are raised, as there is a decrease in production of the other predominantly colonic peptides.

Diarrhoea

In acute infective diarrhoea, the concentrations of enteroglucagon, PYY, and motilin are increased, probably contributing to the altered gut motility and aiding mucosal repair. Patients with Crohn's disease have an elevated pancreatic polypeptide, GIP, motilin, and enteroglucagon, while in ulcerative colitis there is a modest elevation in pancreatic polypeptide, GIP, motilin, and gastrin, the last in response to the hypochlorhydria associated with the disease. Elevated levels of endothelin have been reported in ulcerative colitis and Crohn's disease and oral administration of an endothelin receptor antagonist in a model of colitis was found to ameliorate diarrhoea and tissue damage. No demonstrable abnormalities in gut peptides account for disordered motility in the irritable bowel syndrome.

Intestinal tumours

The trophic effects of gut peptides may contribute to proliferation of malignant gut tumours. In particular, colon carcinoma cells have receptors for a number of potentially mitogenic peptides, including gastrin, gastrin-releasing peptides, and VIP.

Neuropathic disease

In conditions associated with destruction of intrinsic enteric nerves there is loss of the neurocrine peptides found in the affected region. Chagas' disease (see Section 7) results from chronic infection with *Trypanosoma cruzi* and in the gastrointestinal tract can result in mega-oesophagus and megacolon. Concentrations of VIP and substance P and of their nerve fibres are greatly reduced in biopsies from affected segments. Similar changes are seen in the affected bowel from children with Hirschsprung's disease, which results from an aganglionic colonic segment. In contrast, neuropeptide Y-containing, mostly adrenergic, nerves are not reduced. Also, patients with the Shy–Drager syndrome, who have chronic autonomic failure with loss of preganglionic extrinsic nerves, have no abnormalities in neurocrine peptides or peptidergic nerve fibres on rectal biopsies (Fig. 5). Acquired immune deficiency disease is frequently accompanied by diarrhoea without evidence of secondary infection, and reduced immunostaining for substance P, VIP, and somatostatin in biopsies suggests a neuropathic process may be responsible. Alterations in neuroactive peptides have been observed in a number of inflammatory diseases. Increased density of VIP innervation has been reported in several gut diseases including reflux oesophagitis, radiation colitis, ulcerative colitis, and Crohn's disease. Calcitonin gene-related peptide has been shown to mediate the protective effect of sensory nerves in experimental colitis. It was recently reported that upregulation of the galanin-1 receptor is a mechanism for the increased colonic fluid secretion in infectious diarrhoea resulting from various pathogens.

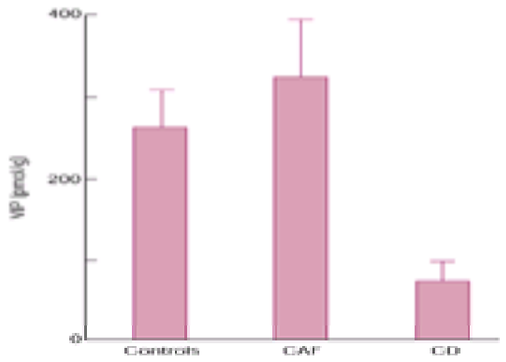

Fig. 5 Rectal vasoactive intestinal polypeptide concentrations (pmol/g wet tissue) in controls and patients with chronic autonomic failure (CAF) and Chagas' disease (CD) with gastrointestinal involvement. Reduced concentrations were seen in Chagas' specimens (reproduced from *Lancet*, 1980, **i**, 559, with permission).

Carcinoid syndrome

Introduction

The term *Karzinoide* was originally used by Obendorfer in 1907 to describe a carcinoma-like lesion without malignant qualities. It has now come to refer to tumours capable of producing serotonin (5-hydroxytryptamine; **5-HT**). However, several different cell types either synthesize or take up 5-HT and so the term carcinoid is

applied to a variety of malignant tumours with different biological behaviour grouped by their similar histological appearances. This section will focus primarily on those tumours associated with the classic carcinoid syndrome.

Primary gastrointestinal carcinoid tumours are derived from the embryonic foregut (thyroid, bronchus, stomach, common bile duct, and pancreas), midgut, or hindgut. The most common sites for carcinoid tumours are the appendix and rectum, but these tumours are often found incidentally on histological examinations of appendicectomy and rectal biopsy specimens. These tumours are almost always benign. Rectal neuroendocrine tumours generally produce glucagon-like peptides and PYY rather than 5-HT and are not usually associated with a clinical syndrome, even when they metastasize.

The carcinoid syndrome occurs in about 10 per cent of patients with carcinoid tumours. It does not develop when the tumour drains through a normal liver, and so midgut tumours have almost always metastasized, usually to the liver, before symptoms develop. The carcinoid syndrome is most commonly due to a metastatic midgut tumour, about 50 per cent of which metastasize to the liver. Primary carcinoid tumours are bronchial in origin in about 10 per cent of cases, and rarely occur in the ovary and testis. Tumours in these sites may be associated with the syndrome in the absence of metastases. The annual incidence of the carcinoid syndrome is about 1 in 500 000.

Clinical manifestations

The cardinal feature of the classic carcinoid syndrome is the flush. The carcinoid flush predominantly involves the head and upper thorax, and is usually associated with a tachycardia, hypotension, and increased skin temperature. Patients may have a sensation of intense heat and wheezing may occur. Rarely, flushing extends to the trunk and limbs, and may be associated with lacrimation, facial oedema, and great distress. Attacks are paroxysmal, and usually unprovoked, although precipitating factors include alcohol or food ingestion, stress, emotion, or exertion. Flushing initially lasts for only a few minutes, but as the disease progresses may become almost continuous, and such patients often develop a chronically reddened and cyanotic facial hue, with widespread telangiectasia, the leonine facies. This fixed flush is more commonly seen with bronchial carcinoids, which are often metabolically inactive, but when associated with flushing can cause severe attacks lasting for hours or days, occasionally with profound hypotension and even anuria. Gastric carcinoids are often associated with raised, localized, wheal-like areas of flushing, which are usually pruritic and may migrate.

The other characteristic feature of the syndrome is secretory diarrhoea, which may be profuse, with passage of several litres a day occasionally accompanied by electrolyte disturbance. It may be associated with cramping abdominal pain, nausea, and vomiting. Rarely these symptoms may result from small bowel obstruction from a large ileal carcinoid tumour, but the majority of primary tumours are small, usually being less than 1 per cent of total body tumour weight. Hepatic metastases may cause right hypochondrial pain, particularly if the liver capsule is involved or stretched, and acute exacerbations may occur if metastases become ischaemic and undergo autonecrosis. Weight loss and, in the later stages, cachexia are common as a result of poor dietary intake, malabsorption, and increased catabolism. Pellagra with dermatitis of sun-exposed areas may occur, the increased conversion of 5-hydroxytryptophan into 5-HT causing nicotinamide deficiency.

Cardiac valve abnormalities affect about 50 per cent of patients. They occur as a result of endocardial fibrosis, with plaques of smooth muscle in a collagenous stroma deposited on the valves. Lesions are almost always on the right-hand side, left-sided valve damage only occurring in association with bronchial carcinoids, which drain into the left atrium, or atrioseptal defects with right to left shunting. The most common lesions are tricuspid incompetence and pulmonary stenosis, and the usual clinical outcome is oedema and breathlessness due to right ventricular failure, which can be fatal. The other causes of breathlessness in association with the carcinoid syndrome are bronchospasm, which affects a small number of patients, often occurring with flushing attacks, and metastatic involvement of the lung and pleura. Arthritis occurs in a small number of patients, and sclerotic bone metastases may be seen, usually in association with foregut tumours.

Carcinoid tumours, in common with other gastroenteropancreatic tumours, have the potential to produce a variety of peptide products and may be associated with other syndromes, with or without the carcinoid syndrome. The most common of these associated syndromes is Cushing's, due to an ectopic ACTH-secreting, bronchial or pancreatic carcinoid. Carcinoid tumours may also be a feature of multiple endocrine neoplasia type 1 (see Chapter 12.10).

Biochemistry

The biologically active metabolite characteristically produced by metastatic carcinoid tumours is 5-HT, synthesized from the amino acid tryptophan (Fig. 6). 5-HT probably plays a part in the pathogenesis of some of the symptoms of the carcinoid syndrome, particularly the diarrhoea and bronchoconstriction. It is metabolized to 5-hydroxyindole acetic acid (**5-HIAA**), which accounts for 95 per cent of the urinary excretion of 5-HT.

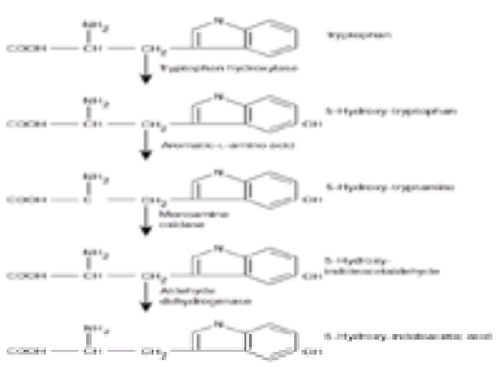

Fig. 6 Biochemical pathway for the synthesis and degradation of 5-hydroxytryptamine.

A variety of vasoactive substances may be secreted by carcinoid tumours and have been implicated in the pathogenesis of the flush. Flushing can be provoked by intravenous noradrenaline, which has been shown to activate kallikrein in the tumour, leading to synthesis and release of bradykinin. Other possible mediators of the flush include histamine, the tachykinins substance P and neurokinin A, and prostaglandins, although the flush is rarely affected by inhibitors of prostaglandin synthesis, such as indomethacin. Gastric carcinoids are derived from histamine-producing enterochromaffin cells and histamine is probably the cause of the characteristic wheal-like flush seen with gastric tumours.

Investigations

The diagnosis of carcinoid syndrome is made on the basis of elevated concentrations of 5-HIAA in a 24-h urine collection, and urinary 5-HIAA acts as a marker of disease progression. Various foods, including avocados, bananas, aubergines, pineapples, plums, and walnuts, should be avoided while collecting specimens to prevent false-positive results. A number of drugs and other substances interfere with the spectrophotometric assay: paracetamol, fluorouracil, methysergide, and caffeine give false-positive results, and ACTH, phenothiazines, methyldopa, monoamine oxidase inhibitors, and tricyclic antidepressants false-negatives. The other products of carcinoid tumours are not routinely assayed. Circulating markers of neuroendocrine tumours, such as pancreatic polypeptide and chromogranin, may corroborate the diagnosis, and other gut hormones are occasionally elevated in association with carcinoid tumours, most frequently gastrin.

Localization of carcinoid tumours is rarely a problem, as most have gross hepatic metastases, visible on computed tomographic (**CT**) scanning or abdominal ultrasonography, at the time of diagnosis. In those rare cases where the syndrome occurs in the absence of metastases, tumour localization may offer the prospect of cure. These tumours are unlikely to be in the gastrointestinal tract and so chest radiographs and CT scans of the chest and pelvis should be taken. The recently developed, indium-labelled, somatostatin analogue pentetreotide may prove valuable in localizing these tumours, although the resolution is only about 1 cm and bronchial carcinoids are frequently atypical and do not bear somatostatin receptors. An alternative method of isotopic localization is using 123- *m*-iodobenzylguanidine (MIBG) scanning, which may be equally effective. These scanning techniques can be useful in patients with metastatic disease to demonstrate the extent of spread (Fig. 7), particularly in those who are being considered for liver transplantation, which would be precluded by the presence of extrahepatic metastases. Angiography may be of value in assessing suitability for hepatic embolization. Carcinoid tumours have characteristic histological features being composed of regular polygonal cells arranged in nests. The capacity of 5-HT to reduce silver salts (so-called argentaffinity) led to the development of a diagnostic histochemical stain, but more

recently, immunostaining for serotonin has been used to identify the tumours.

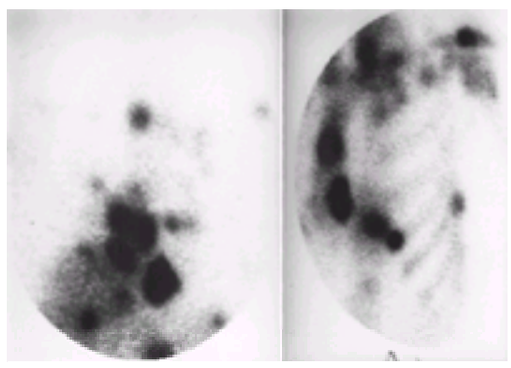

Fig. 7 Indium-111-labelled somatostatin analogue scan (left) in a patient with carcinoid syndrome showing metastases to liver, bone, and intrathoracic lymph nodes compared with a conventional base scan (right).

Treatment

The realistic aim of therapy in patients with the carcinoid syndrome is to relieve the symptoms. Simple treatments such as codeine phosphate, diphenoxylate, and loperamide may help to control the diarrhoea. Many of the symptoms can be controlled with the peripheral 5-HT antagonists: cyproheptadine, a 5-HT type 2 receptor blocker, often helps the diarrhoea; ketanserin may be effective in reducing flushing; and the 5-HT type 3 receptor antagonist ondansetron can alleviate nausea and anorexia. Parachlorphenylalanine, an inhibitor of tryptophan hydroxylase, and chlorpromazine block synthesis of 5-HT, but are rarely used. Histamine may mediate some of the features of the syndrome, especially in patients with gastric carcinoids, and in these cases H_1- and H_2-receptor blockade may be useful. With the exception of simple antidiarrhoeal agents, these treatments have been largely superseded by the long-acting, subcutaneously administered, somatostatin analogue octreotide. This inhibits the release of the mediators of the syndrome by the tumour and antagonizes their peripheral effects. Octreotide is effective in alleviating symptoms in over 90 per cent of patients. It is rarely associated with significant side-effects: the acidic solution can cause pain at the injection site; gallstones often develop, but are rarely of clinical significance; and a few patients develop steatorrhoea, which can be prevented by giving pancreatic enzyme supplements. Octreotide is now the first-line treatment for most patients and may be lifesaving in the carcinoid crisis, when symptoms become severe and continuous. In addition to octreotide, during crises patients usually need close monitoring of fluid and electrolytes, often by measurement of central venous pressure, and appropriate replacement therapy. Minor injury including overenthusiastic clinical examination of large carcinoid masses in the liver may induce a life-threatening state akin to the tumour lysis syndrome characterized by pain, fever, shock, and renal failure compounded by hyperuricaemia and hyperphosphataemia. Allopurinol, and the judicious use of infusions of sodium bicarbonate to make the urine more alkaline, as well as antimicrobials, may reduce the threat of renal failure in this condition. Corticosteroids may improve shock.

The principal disadvantage of octreotide is that patients develop resistance with time, and most become refractory to any form of treatment after about 4 years. Vitamin supplements containing nicotinamide are necessary when patients have pellagra, and these can be given prophylactically. The treatment of cardiac manifestations is the same as for valve disease and cardiac failure of other causes. Patients with painful bony metastases may benefit from palliative radiotherapy.

In patients who fail to respond or are intolerant to octreotide, tumour debulking may provide palliative relief. Surgery is rarely indicated, although enucleation of large metastases may give some benefit. Carcinoid tumours rarely respond to chemotherapy, either with streptozotocin and 5-fluorouracil, or with a variety of other agents, including cyclophosphamide and doxorubicin, although recent evidence suggests interferon-a may be of more benefit. The most effective means of debulking is hepatic embolization, which devascularizes the tumour while the blood supply to the normal liver is maintained by the portal vein. Octreotide should be given in high dose during this intervention, as the necrotic metastases release large quantities of vasoactive mediators that can cause a severe carcinoid crisis with profound hypotension, leading to acute renal failure (see tumour lysis syndrome above).

Prognosis

Carcinoid tumours behave like other gastroenteropancreatic tumours, with the majority following an indolent course. The median survival from the time of diagnosis is about 5 years, with a range of up to 20 years. Thus palliation is very worthwhile in these patients, allowing them to lead a normal life until the terminal stages of the disease.

Multiple endocrine neoplasia and non-diabetic pancreatic endocrine disorders are described in Chapter 12.10.

14.9.1 Differential diagnosis and investigation of malabsorption

Julian R. F. Walters

Malabsorption by the gastrointestinal tract results in excess loss of dietary nutrients in the faeces and, if dietary intake does not increase to compensate, nutritional deficiency in the body. The normal physiology of nutrient absorption is complex—specific molecular mechanisms have evolved for each of the various types of nutrient. Understanding the principles involved in normal absorption enables different causes of malabsorption to be appreciated, appropriate differential diagnoses to be made, and investigations planned accordingly.

Principles of normal absorption

Absorptive capacity

For each of the classes of nutrients, the overall efficiency of intestinal absorption varies. Some compounds, such as components of dietary fibre, are not absorbed even in health. Others are normally almost completely absorbed, but in disease, absorption is insufficient to cope with the load, giving symptoms of diarrhoea from excess faecal water, or steatorrhoea from excess faecal fat.

The principal determinants of the maximum absorptive capacity are the area of the intestinal mucosa, increased by surface folding, villi, and microvilli to about 200 m^2, and the function of the individual cellular transporting mechanisms. As part of the total absorptive process, the intestine also has to reabsorb endogenous secretions produced to aid digestion. Approximately 7 litres of digestive fluids from salivary, gastric, biliary, pancreatic, and intestinal sources add significantly to the absorptive requirements for water, electrolytes, protein, and fat. Secretory diarrhoea and protein-losing enteropathy are conditions where endogenous output exceeds the absorptive capacity of the bowel.

Sites of absorption

Gastrointestinal motility mixes food with digestive secretions and propels them from the mouth to the anus. During this passage, nutrients are exposed to specialized areas of the gut with specific digestive or absorptive functions. The duodenum and proximal jejunum are mostly involved with digestion and fluid secretion. However, the more acidic pH in this area means the solubility and hence the absorption of polyvalent cations such as iron and calcium is high. The bulk of nutrient absorption takes place in the more distal jejunum and ileum. The terminal ileum is specialized for cobalamin (vitamin B_{12}) and bile salt absorption. The colon salvages fluid and electrolytes not absorbed by the small intestine and absorbs short-chain fatty acids produced by colonic bacteria from poorly digested carbohydrates. Loss of specialized areas by surgical resection or disease activity can produce specific patterns of malabsorption.

The intestinal epithelial cells differentiate as they move from crypt to villus tip. The older villus-tip enterocytes perform most of the absorptive functions, though some digestive enzymes are found in less mature cells. Fluid secretion probably occurs from the crypts. Goblet cells secrete mucus, trapping an unstirred water layer which is a relative barrier to the diffusion of large molecules but allows the smaller products of digestion to reach the surface of the epithelium. Other epithelial cells secrete various hormones or have immunological functions.

Mechanisms of absorption

Absorption occurs by transcellular and paracellular pathways. The paracellular pathway is through the tight junctions which link the epithelial cells. By this pathway, passive absorption of small molecules occurs by diffusion down electrical and concentration gradients. Solvent drag is the term used to describe movement down concentration gradients, which are themselves created by the movement of water. Active transport takes place through the epithelial cell against these gradients and necessitates the expenditure of energy generated within the cell.

Three steps are involved in transcellular absorption: entry to the cell at the apical (brush-border) membrane, passage through the cytoplasm, and exit from the cell at the basolateral membrane. Polarization of the enterocyte produces differences in structure and function of the apical and basolateral membranes. Specific carrier molecules are present in one of these membranes but not the other; this asymmetry generates vectorial flow in a single direction through the cell. The molecular basis for absorption of most types of nutrients has now been defined.

Diagnosis of malabsorption

The diagnosis of malabsorption is often missed until it is obvious. Diseases of the small intestine, colon, pancreas, liver, and stomach can all produce malabsorption; these may be obvious (such as the result of previous surgery) or may not be suspected until malabsorption is diagnosed.

History

Delayed growth and development, loss of weight, lassitude, and weakness may be described, but can be due to many other conditions. Changes in the nature of the stool or frequency of bowel habit suggest gastrointestinal disease but are not invariable, as apparently normal stools or constipation can also be found. In describing their faeces, patients may indicate the features of steatorrhoea, rather than watery diarrhoea. Careful questioning is needed to differentiate descriptions of changes in stool frequency or volume, and the passage of gas, liquid, oil, or grease. Bloating, borborygmi, and abdominal discomfort are often reported and seepage of oil from the anus may be described.

A previous history of abdominal surgery, radiation, and alcohol or drug usage may immediately make obvious the likely cause of malabsorption. A family history of coeliac disease or dermatitis herpetiformis makes gluten sensitivity more likely. Malabsorption of nutrients such as iron, folate and vitamin B_{12}, calcium, or vitamin K can give specific histories of anaemia, bone disease, and fractures, or bleeding and bruising.

Examination

General nutritional status can be assessed by height, weight, body mass index, and by anthropomorphic measurements such as skin fold thickness. Anaemia, bruising, petechias, ascites, oedema, glossitis, mucosal changes, and neuromuscular irritability (including positive Trousseau's or Chvosteck's signs) may be found and indicate specific deficiencies. Pigmentation and clubbing can occur. Abdominal distension, scars from previous surgery, masses, or fistulas can suggest specific diagnoses. The nature of the stools must be examined.

Evidence from routine investigations

Commonly obtained haematological and biochemical investigations can show a reduced haemoglobin concentration, microcytosis or macrocytosis, raised red cell distribution width, thrombocytopenia, and low serum iron, transferrin saturation, B_{12}, and folate. The prothrombin time or international normalized ratio (INR) may be raised. Albumin, calcium, phosphate, 25-hydroxyvitamin D, zinc, and other nutrients may be reduced. Elevated alkaline phosphatase and parathyroid hormone can suggest metabolic bone disease secondary to malabsorption.

Differential diagnosis

When malabsorption is suspected, two parallel diagnostic pathways need to be followed: first, to define the extent of the nutritional deficiency, and second, to define the cause of the malabsorption.

Generalized or isolated nutrient malabsorption?

When an isolated nutritional deficiency, such as that of B_{12} or iron, is identified, it must be remembered that this may be due to a more generalized process and evidence for malabsorption of other nutrients may be found if looked for. However, abnormalities in specific transport pathways, either genetic or acquired, account for some common types of malabsorption (Table 1).

Malnutrition, maldigestion, or malabsorption?

Evidence of deficiency of a nutrient does not necessarily imply malabsorption. In many cases, nutritional intake is impaired, or insufficient to meet increased demands. Pregnancy places additional demands on iron, calcium, and many other nutrients. Menorrhagia requires extra iron intake. Excessive loss of protein, electrolytes, and water may require increased intake, and additional calories are required in catabolic states such as infection, surgery, and critical care. Assessment of intake and requirements may determine that poor nutrition is the principal factor and dietary supplementation is required.

Impaired digestion, usually from pancreatic insufficiency, will produce a clinical state similar to malabsorption resulting from intestinal disease. Absorption of simple nutrients, as in an elemental diet, will be normal, but complex foods, particularly fats, will not be hydrolysed to forms that can be absorbed. Evidence of pancreatic disease should be looked for with imaging and function tests.

Conditions that cause malabsorption are listed in Table 2. Some such as coeliac disease are common, others such as the short bowel syndrome in patients with extensive surgery may be obvious, but other diagnoses may not be made unless specifically sought.

Investigation of malabsorption

Function tests

Tests to investigate absorptive functions are described in Chapter 14.2.4. These may be necessary to define the extent of nutrient malabsorption, but in most cases are not needed in routine clinical practice, where the emphasis is usually on defining the precise pathological cause of the malabsorption. The Schilling test for B_{12} malabsorption is particularly useful in diagnosing functional ileal disease.

Faecal fat measurements are often necessary to confirm that malabsorption (or maldigestion) needs to be investigated. The absorption of fat depends on a large number of different steps and is a sensitive indicator of malabsorption. Faecal collections are made over several days on a defined fat intake. Despite the unpleasantness of these collections and assays, this may be the only way of confirming that fat malabsorption is in fact occurring. A number of other tests have been developed in attempts to circumvent these problems.

The pancreolauryl test (see Chapter 14.2.4) is a simple way to look for impaired lipid digestion, and is sufficiently sensitive to diagnose pancreatic insufficiency when it is severe enough to produce steatorrhoea. False positives can occur in a range of intestinal conditions.

Xylose absorption tests have been used traditionally to help differentiate pancreatic maldigestion (when they are usually normal) from intestinal malabsorption such as coeliac disease (when they are usually abnormal). This test may give many false-positive results and has largely been superseded by tests aimed at detecting specific pathologies. Testing stools or urine for laxative abuse may be necessary, and endocrine causes of diarrhoea and malabsorption, although rare, should not be forgotten.

Serological tests for coeliac disease

IgA-class endomysial antibody serology is a highly sensitive and specific test which has simplified screening for coeliac disease in patients with any suggestion of possible malabsorption. These antibodies are detected by immunofluorescence on sections of monkey oesophagus or umbilical cord, and are a subclass of the previously used reticulin antibodies. False-negative results in coeliac disease occur in the presence of selective IgA deficiency (approximately 1 in 50 of the population), but IgG-class endomysial antibodies are detected. With effective treatment of coeliac disease with a gluten-free diet, endomysial antibodies become negative. Gliadin antibodies have much lower specificity and are not valuable in screening.

The antigen recognized by endomysial antibodies is now known to be tissue transglutaminase. More easily performed tests with this antigen, such as enzyme-linked immunoassays (ELISAs), will replace immunofluorescent testing for endomysial antibodies when they are confirmed to be as reliable.

The availability of simple blood tests, with high positive and negative predictive values for coeliac disease, means that this condition can now be strongly suspected before intestinal biopsy is performed.

Endoscopy and small bowel histology

Endoscopy is widely available and enables tissue to be taken from the small intestine to make a histological diagnosis of the pathology causing malabsorption. Oesophagogastroduodenoscopy allows biopsies from the upper duodenum. At colonoscopy, biopsies can be taken from the terminal ileum. Enteroscopy allows much more of the small bowel to be inspected and biopsies taken. Fortunately, common intestinal diseases such as coeliac disease are diffuse and diagnosis can usually be made from duodenal biopsies taken at routine upper endoscopy. Multiple biopsies reduce the likelihood of sampling error.

Biopsy of the more distal parts of the jejunum and ileum may be performed using the Crosby capsule or other similar designs. The capsule attached to a fine tube is swallowed allowing biopsies to be taken under fluoroscopic control, after which the capsule is recovered. Systems for multiple biopsies have been developed. These capsules are generally safe, but are used infrequently now that coeliac disease is usually diagnosed by endoscopic duodenal biopsies. Unfortunately, none of these methods allows reliable targeting to specific areas of small intestine seen on radiology. Laparotomy (or laparoscopy) may be needed to take full-thickness biopsies from jejunal and ileal lesions.

Mucosal appearances at endoscopy may be abnormal, suggesting histological diagnoses. With modern endoscopes, the resolution and magnification is such that villi can be detected. A smooth mucosa, with reduced folds of Kerckring, scalloped valvulae conniventes, pallor, and a mosaic appearance suggest villous atrophy, as in coeliac disease. Small white spots can indicate areas of intestinal lymphangiectasia. In the terminal ileum, ulceration can indicate Crohn's disease. Biopsies can be

directed to abnormal areas.

Histology will be definitive in most small bowel diseases. Villous atrophy with crypt hyperplasia is most frequently caused by coeliac disease. Tropical sprue, allergy to cows' milk protein in children, and a range of other conditions occasionally cause a similar picture. Intestinal lymphangiectasia, lymphoma, eosinophilic enteritis, Whipple's disease, amyloid, and abetalipoproteinaemia have characteristic appearances. Parasites including *Giardia* sp. may be seen.

Radiology

Plain abdominal films may show calcification in chronic pancreatitis, faecal loading, or abnormal gas-filled loops of bowel.

Contrast studies of the small intestine will define abnormal anatomy. Small bowel enema (enteroclysis) is preferred for showing mucosal detail, although barium follow-through studies are more easily tolerated and can give better images of proximal duodenum and terminal ileum. Mass lesions or strictures from Crohn's disease, tuberculosis, lymphoma, other tumours, fibrosis, radiation, ischaemia, or drug-induced injury will be demonstrated. Enteric fistulas and diverticula are diagnosed. Post-surgical anatomy can be defined and the length of remaining intestine in the short bowel syndrome estimated.

Endoscopic retrograde cholangiopancreatography (ERCP), and increasingly magnetic resonance cholangiopancreatography (MRCP), will show pancreatic abnormalities that can cause pancreatic exocrine insufficiency. CT, ultrasound, and angiography have roles in further defining conditions associated with malabsorption.

Microbiology

Small bowel bacterial overgrowth is a common and frequently undiagnosed cause of malabsorption. Absolute bacterial counts in proximal small-intestinal fluid are hard to obtain without contamination, so diagnosis tends to be on clinical suspicion confirmed indirectly via glucose hydrogen breath testing (see Chapter 14.2.4).

Infestations causing malabsorption (including *Giardia* and *Strongyloides* spp.) will be diagnosed by demonstrating parasites in fresh stool, or duodenal aspirates.

Response to treatment

Confirmation of the diagnosis of malabsorption is often made by assessing the response to treatment. Symptomatic patients with typical villous atrophy and positive antibody tests, who respond clinically and serologically to a gluten-free diet, can be confirmed to have coeliac disease and do not routinely need further biopsies. In small intestinal bacterial overgrowth, the diagnosis is often only finally made by the response to broad-spectrum antibiotics, which will also correct the abnormal Schilling test in this condition. Pancreatic exocrine insufficiency can be confirmed with a satisfactory response to enzyme replacements.

14.9.2Small bowel bacterial overgrowth

P. P. Toskes

Introduction

The occurrence of malabsorption in a patient with overgrowth of bacteria in the small intestine is known as small bowel bacterial overgrowth (**SBBO**).

Until recently, SBBO was typically associated with patients in whom disordered motility or structural abnormalities of the gastrointestinal tract were identified (Table 1). It is now recognized that SBBO occurs in a range of conditions associated with abnormal motility including gastroparesis, irritable bowel syndrome, and chronic pancreatitis—three conditions that now account for most patients in whom bacterial overgrowth is documented. Thus SBBO should be suspected in patients with these conditions whose symptoms prove resistant to conventional treatment or in whom steatorrhoea, weight loss, or flatulence develop unexpectedly. SBBO is now also recognized as the most important cause of malabsorption in elderly subjects, in whom a structurally intact small intestine becomes inhabited by colonic flora. Establishing a diagnosis of suspected SBBO by rigorous investigation is of key importance to its proper treatment.

Indigenous bacterial populations of the normal gastrointestinal tract

An understanding of SBBO is based upon a thorough knowledge of the indigenous bacterial populations of the normal gastrointestinal tract (Table 2). The proximal small intestine is normally inhabited by a few bacteria. Qualitative and quantitative changes appear at the ileum and become quite striking in the colon. Table 3 indicates the endogenous factors that prevent SBBO in humans. Of the factors listed, by far the two most important are the normal intestinal motility and an appropriate amount of gastric acid secretion. When either or both of these mechanisms are inhibited, SBBO may ensue.

Thus the stomach and proximal small intestine normally contain relatively few bacteria, which are usually lactobacilli, entercocci, Gram-positive aerobes, or facultative anaerobes present in concentrations of up to 10^4 viable organisms per gram of jejunal contents. Coliforms are rarely found in the healthy proximal small intestine. Anaerobic *Bacteroides* are not found in the proximal small intestine of a healthy gastrointestinal tract. The ileum represents a zone of transition from the sparse populations of the proximal small intestine and the very dense bacterial populations of the colon. In the colon the bacterial population increases up to one million times and reaches 10^9 to 10^{12} bacteria per gram of colonic content. The quality of the bacteria also change remarkably in the colon. Here there are fastidious anaerobic bacteria such as *Bacteroides*, anaerobic lactobacilli, and clostridia. These anaerobes outnumber the aerobic bacteria by as much as 10 000 to 1. The complexity of the colonic flora is such that more than 400 different species may be present in the colon of a single individual.

Bacteria normally metabolize bile acids, androgens and oestrogens, exogenous and endogenous cholesterol, unabsorbed dietary lipids, proteins, and carbohydrates as well as fibre, protein and urea, and other substances. The by-products of this metabolism may be of benefit or harm to the normal host. An exaggeration of this metabolism occurs in the presence of SBBO. It is noteworthy that the normal bacterial flora also are important in the metabolism of some drugs and other xenobiotics. Drugs metabolized by intestinal bacteria are listed in Table 4. The importance of the excessive metabolism of medications that may occur in SBBO is yet to be defined. Perhaps the relatively frequent occurrence of SBBO in the elderly may lead to ineffective medication of this age group.

Clinical conditions associated with SBBO

Table 5 lists the recognized clinical conditions associated with SBBO. In the past when much more gastrointestinal surgery was performed, the common causes of clinically significant bacterial overgrowth were structural abnormalities (for example Billroth II, anastomosis, surgery for Crohn's disease). Stagnant loops of intestine resulting from fistulas or surgical enterostomies and leading to SBBO were also common. Duodenal and jejunal diverticula can lead to SBBO, particularly if there is an associated hypo- or achlorhydria. Figure 1 depicts multiple duodenal and jejunal diverticula in a patient with cobalamin (vitamin B_{12}) malabsorption and steatorrhoea secondary to SBBO. Obstruction of the small intestine caused by Crohn's disease, adhesions, radiation damage, lymphoma, or tuberculosis may cause SBBO. Devastating malabsorption may occur secondary to SBBO associated with a gastrocolic or gastrojejunocolic fistula with colonic contents passing into the stomach or upper small intestine. SBBO may result from the ileal anal pouch procedure used to treat ulcerative colitis and adenomatous polyposis. The dysmotility syndrome, especially if combined with hypo- or achlorhydria, may lead to SBBO. Such motility disturbances include scleroderma, intestinal pseudo-obstruction, and diabetic autonomic neuropathy. Figure 2 demonstrates a diffusely dilated small intestine in a patient with diarrhoea, steatorrhoea, and scleroderma associated with SBBO. Antibiotic therapy completely reversed the abnormalities. Subjects with an absent or disordered migrating motor complex may develop SBBO. Such patients have no radiographic abnormalities and present with unexplained malabsorption. Elderly patients may develop malabsorption secondary to SBBO, and indeed it has been suggested that bacterial overgrowth may be the most common cause of clinically important malabsorption in the elderly. The elderly often have motor disorders (often induced by previous gastrointestinal tract surgery) and decreased acid secretion. The importance of both normal intestinal motility and normal gastric acid secretion in the prevention of clinically significant SBBO cannot be overemphasized. For example, patients with scleroderma and reflux oesophagitis who are well while receiving H_2 receptor antagonists may develop marked malabsorption manifested by diarrhoea and steatorrhoea after introduction of a proton pump inhibitor.

Fig. 1 Multiple duodenal and jejunal diverticula in a patient with cobalamin malabsorption and deficiency and steatorrhoea associated with SBBO.

Fig. 2 An upper gastrointestinal and small bowel series in a woman with scleroderma who presented with severe weight loss, cobalamin (vitamin B_{12}) deficiency and marked steatorrhoea. These abnormalities were corrected by broad spectrum antibiotics. Note the marked dilatation of intestinal segment was seen throughout the entire small bowel.

Up to 40 per cent of patients with chronic pancreatitis may have concomitant SBBO. The management of such patients may be quite problematic unless the clinician recognizes the need to treat both the pancreatic insufficiency and the SBBO. These patients with chronic pancreatitis may develop SBBO because of a decrease in intestinal motility resulting from pain, use of narcotics, inflammatory changes or obstruction from the large inflamed pancreas, or previous pancreatic surgery.

Several other clinical entities are associated with SBBO, but the pathogenesis is ill understood. These include endstage renal disease, cirrhosis, myotonic muscular dystrophy, fibromyalgia, chronic fatigue syndrome, and various immunodeficiency syndromes such as chronic lymphocytic leukaemia, immunoglobulin deficiencies, and selected T-cell deficiency.

Clinical manifestations of SBBO

No matter what the clinical condition leading to SBBO may be, there are several typical features as listed in Table 1. In addition, non-specific symptoms of nausea, bloating, abdominal distention, and abdominal pain may be the presenting symptoms of SBBO.

In suspected cases, a thorough evaluation is warranted; many of these patients may have had small bowel diverticula for years before suddenly developing marked symptoms as a result of SBBO. It may be that such patients needed to have a significant reduction in their gastric acid secretion before the structural abnormality could contribute to the SBBO. It is important to realize that SBBO may be superimposed on several clinical conditions whose initial symptoms are exactly those of SBBO. Patients with Crohn's disease, radiation enteritis, short bowel syndrome, or lymphoma may have superimposed SBBO. To what extent the malabsorption is the result of the primary intestinal disease or the consequence of SBBO is often difficult to determine. Weight loss associated with clinically apparent steatorrhoea has been observed in about one-third of patients with SBBO severe enough to cause cobalamin deficiency. Osteomalacia, vitamin K deficiency, night blindness, and even hypocalcaemic tetany as well as the vitamin E deficiency syndromes (neuropathy, retinopathy, T-cell abnormalities) may result.

Mechanisms of the metabolic abnormalities associated with SBBO

The malabsorption of nutrients associated with SBBO can largely be attributed to the abnormal intraluminal effects of the overgrowth flora combined with enterocyte injury induced by the overgrowth flora. A patchy small-intestinal mucosal lesion has been identified in experimental animals with SBBO and in human subjects with the condition. Steatorrhoea associated with SBBO results from bacterial alteration or bile salts, which leads to an impairment of micelle formation. In addition, accumulation of toxic concentrations of free bile acids may also contribute to the steatorrhoea by inducing a patchy intestinal mucosal lesion, thereby impairing the transport of fat. The predominant cause of the anaemia associated with SBBO is cobalamin deficiency. The anaemia is megaloblastic and serum cobalamin levels are low. Neurological changes indistinguishable from those of pernicious anaemia may ensue. The anaemia can be corrected by physiological doses of cobalamin. Cobalamin malabsorption that cannot be corrected by exogenous intrinsic factor is a characteristic of clinically significant SBBO. Competitive uptake of cobalamin, particularly by Gram-negative anaerobes, appears to be the mechanism responsible for the cobalamin malabsorption in SBBO. Iron deficiency may also occur in association with SBBO due to blood loss through the gastrointestinal tract, perhaps resulting from patchy ulceration. These patients may have blood detected on examination of their stools together with a microcytic and hypochromic anaemia. In some patients there may be two populations of red blood cells, microcytic and macrocytic. Folate deficiency is not a common occurrence in SBBO because the overgrowth flora synthesize folate and it is available for the host to utilize; serum folate levels may be elevated.

Hypoproteinaemia is frequent is SBBO and is occasionally severe enough to lead to oedema. Its causes are multifactorial but include decreased uptake of amino acids by a damaged small intestine, intraluminal breakdown of protein and protein precursors by bacteria, and protein-losing enteropathy.

A decrease in urinary xylose excretion is frequently seen in patients with SBBO. The primary reason for the decreased urinary xylose excretion is intraluminal degradation of the sugar by the overgrowth flora. Diarrhoea has many potential causes: the overgrowth flora may produce organic acids that increase osmolarity of the small intestine and decrease intraluminal pH. Furthermore, bacterial metabolites such as free bile acids, hydroxy fatty acids, and organic acids stimulate secretion of water and electrolytes into the lumen.

General diagnostic approach to patients suspected of having SBBO

SBBO should be considered in the differential diagnosis of any patient who presents with diarrhoea, steatorrhoea, weight loss, or macrocytic anaemia, particularly if the patient is elderly and has had previous abdominal surgery. A history of previous surgery for small intestinal obstruction should raise the question of whether the obstruction was bypassed by an end-to-side anastomosis, leaving a blind pouch, or side-to-side anastomosis, resulting in recirculation of the contents of the small intestine. The presence of dysphagia in a patient with malabsorption should suggest the diagnosis of scleroderma, and repeated bouts of intestinal obstruction without obvious organic cause should suggest intestinal pseudo-obstruction. Figure 3 suggests an algorithm for the evaluation of patients with malasorption including those with SBBO. This algorithm emphasizes the use of non-invasive, inexpensive tests. It also focuses on the fact that, in most medical centres, clinically important malabsorption is more likely to be due to pancreatic insufficiency or SBBO then coeliac disease or tropical sprue. When the history suggests that SBBO may be contributing to the malabsorption, further evaluation is necessary for optimal management. The presence of steatorrhoea should be documented. If the patient has clinically significant bacterial overgrowth, cobalamin absorption is frequently impaired, even though the patient may not yet have developed low levels of serum cobalamin. Intrinsic factor will not improve cobalamin absorption in these patients. The urinary excretion of xylose may be decreased and the serum folate level may be increased in some, but not all, patients with SBBO.

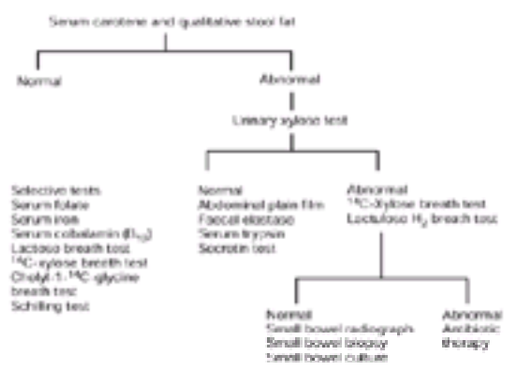

Fig. 3 Algorithm for evaluation of malabsorption. (From Toskes, 1992. Malabsorption. In: Wyngaarden JB, Smith LH, Bennett JC, eds. *Cecil's textbook of medicine*,

Specific diagnosis of SBBO

The definitive diagnosis of SBBO requires a properly collected and appropriately cultured aspirate from the proximal small intestine. The specimen should be obtained under anaerobic conditions, serially diluted, and cultured on several selected media. In patients with SBBO, the total concentration of bacteria generally exceeds 10^5 organisms per millilitre of jejunal secretions. *Bacteroides*, anaerobic lactobacilli, coliforms, and enterococci are all likely to be present in varying numbers. Although in most patients the intraluminal microbial proliferation can be documented in the proximal jejunum, it is important to recognize that pockets of overgrowth may be missed by a single culture and that bacterial overgrowth may occur in the more distal parts of the small intestine.

A properly collected and analysed intestinal culture requires intubation of the small intestine and it is both time-consuming and expensive. In many clinical practices today, small intestinal intubation for quantitative cultures to demonstrate SBBO is simply not performed. Consequently, a variety of surrogate tests for detecting SBBO have been devised based on the varied metabolic actions of the bacteria within the overgrowth flora. Table 6 lists these various tests and compares them in respect to sensitivity, specificity, and simplicity. Measurement of urinary excretion of indican, phenols, drug metabolites, and deconjugated para-amino benzoic acid suffer from a lack of sensitivity and specificity in distinguishing SBBO from other causes of malabsorption. The quantification of deconjugated bile acids and short-chain fatty acids in jejunal secretions requires an intubation of the intestine and thus is resisted by clinicians and patients for the same reasons that cultures of the intestine are not popular.

Another approach to diagnosing SBBO is the timed analysis of breath excretion of volitle metabolites produced by intraluminal bacteria. Both the measurement of expired, labelled carbon dioxide after oral administration of ^{14}C- or ^{13}C-labelled substrates, and breath hydrogen after administration of non-labelled fermentable substrate have been utilized.

The first breath test to be utilized clinically to detect SBBO was the bile acid or ^{14}C-cholyglycine breath test. This test, unfortunately, suffered from signfiicant false-negative and false-positive results. The bile acid breath test does not distinguish SBBO from ileal damage or resection with excessive breath $^{14}CO_2$ production resulting from bacterial deconjugation within the colon of the unabsorbed labelled bile salt. This was particularly problematic because SBBO may be superimposed on ileal damage in conditions such as Crohn's disease, lymphoma, and radiation enteritis. False-negative results have also been described with this test in 30 to 40 per cent of patients with culture-proven SBBO.

Studies in experimentally induced SBBO demonstrated that the overgrowth flora had the capacity to metabolize significant quantities of xylose and produce carbon dioxide. A 1-g ^{14}C-xylose breath test was developed and found to be sensitive and specific for detecting the presence of SBBO in patients with culture-proven SBBO. Xylose was chosen as a substrate because: (i) it is catabolized by Gram-negative aerobes which are always part of the overgrowth flora; (ii) it is predominantly absorbed in the proximal small intestine in contrast to the predominant ileal absorption of bile salts, leading to virtually 'no dumping' of xylose into the colon; and (iii) it is metabolized substantially less than other proximally absorbed substrates such as glucose. Elevated $^{14}CO_2$ levels appear in the breath of 85 per cent of patients with culture-proven SBBO within the first 60 min of the test, with the 30-min sample being the most reliable. Laboratories throughout the world have demonstrated the reliability of the ^{14}C-xylose breath test when compared with intestinal culture. In those studies that utilized intestinal culture as the gold standard and evaluated shorter sampling intervals, particularly the 30-min time point, the sensitivity and specificity approximated 90 per cent. Some recent studies have raised doubts as to the reliability of the ^{14}C-xylose breath test, but those studies evaluated patients with severe disorders of motility and it is quite possible that the xylose never left the stomach appropriately to come in contact with the overgrowth flora in the proximal small intestine. In addition, there must be an overgrowth of Gram-negative coliforms for the xylose test to be positive. In at least one of the recent studies failing to confirm the reliability of the ^{14}C-xylose breath test, the cultures also lacked Gram-negative coliforms. Others have suggested refinement of the ^{14}C-xylose breath test to include a transit marker for intestinal motility, which may enhance its specificity.

It is not recommended that ^{14}C-labelled xylose be used as a substrate in the diagnosis of SBBO in children or fertile women. Consequently, ^{13}C-labelled xylose has been developed and demonstrated to be an effective test in detecting SBBO. These ^{13}C-labelled substrates have been utilized in selected centres but are not yet in general use in clinical practice.

Breath hydrogen analysis allows a distinct separation of metabolic activities of the overgrowth flora from that of the human host because hydrogen is not produced to any significant extent in mammalian tissue. Excessive breath hydrogen production has been noted in patients with bacterial overgrowth after the administration of 50 to 80 g of glucose or 10 to 12 g of lactulose. A fasting elevation of breath hydrogen is an excellent test for detecting SBBO, but only about one-third of subjects with culture-proven SBBO will have elevated fasting levels of breath hydrogen.

There must be rigorous attention paid to methodological details when tilizing a hydrogen breath test. Certain foods that cause prolonged excretion of hydrogen must be avoided the night before the test, and 2 h must elapse after cigarette smoking or physical exercise sufficient to produce hyperventilation before taking the test. It is also recommended that a mouthwash be performed before testing to eliminate the possibility of an early hydrogen peak resulting from oral bacteria. Finally, strict interpretation criteria must be adopted. Even with careful attention to these details, the sensitivity and specificity of the hydrogen breath test is disappointing when used to detect SBBO. Recent studies have demonstrated that up to 27 per cent of normal subjects failed to show any rise in breath hydrogen following the administration of lactulose. The non-radioactive nature and the ease of performance of hydrogen breath tests make them quite attractive. However, many studies indicate that these tests have an unacceptable lack of sensitivity and specificity for clinical use and clinical laboratories do not pay attention to the critical details required for their proper conduct.

Therapeutic approach to the management of SBBO

The aim of therapy for SBBO is to correct when feasible the cause of the stasis, but surgery is often impractical (scleroderma, multiple diverticula, diabetes, intestinal pseudo-obstruction) and unacceptable to the patient. Thus, management of patients with SBBO is lifelong. Antibiotic therapy is the cornerstone of treatment and remarkable improvement in symptoms can be achieved in most patients. It is important to emphasize once again that SBBO may be a treatable component of the malabsorption seen in patients with conditions such as Crohn's disease, intestinal lymphoma, or radiation enteritis. The deterioration in absorption in such patients may not be caused by their primary disease process but by the associated overgrowth. Clinicians also must be aware that bacterial overgrowth may be present without causing any disease. Not all patients who have a pathological flora in the proximal small intestine develop clinically important symptoms. An abnormal breath test or a pathological culture must be put into perspective before therapeutic decisions are made.

It would seem attractive to select the appropriate antibiotic by evaluation of the sensitivity of the bacteria present in the small bowel lumen. However, this approach is very problematic because there are many different bacterial species present, often with very different antimicrobial sensitivities. Under such conditions, it may be extremely difficult to select the most appropriate agent on the basis of the sensitivity results. It is important to select an antibiotic that is effective against both aerobic and anaerobic enteric bacteria. Although most patients with clinically significant malabsorption secondary to SBBO have a flora that is largely overgrown with anaerobes, malabsorption associated predominantly with the overgrowth of Gram-negative aerobes also occurs.

Table 7 lists antimicrobial agents that have been effective in treating SBBO whether in controlled clinical trials or extensive clinical practice. Antibiotics whose activities are largely limited to anaerobes, such as metronidazole or clindamycin, are not usually effective as monotherapy. Antibiotics that are known to have poor activity against anaerobes should not be used in treating SBBO; such antibiotics include penicillin, ampicillin, the oral aminoglycosides, kanamycin, and neomycin. Historically, the treatment of first choice has been tetracycline, but recent experience in the United States suggests that up to 60 per cent of patients with SBBO do not respond to tetracycline largely because of *Bacteroides* resistance to this drug.

In most patients, a single course of therapy (7 to 10 days) markedly improves symptoms and the patient may remain symptom-free for months; in others, symptoms recur quickly and acceptable results can only be obtained with cyclic therapy (1 week out of every 4); and in still others, continuous therapy may be needed for 1 to 2 months. If the antimicrobial agent is effective there will be a resolution or marked diminution of symptoms within 1 week. Diarrhoea and steatorrhoea will decrease and cobalamin malabsorption will be corrected.

Prolonged antibiotic therapy poses potential clinical problems including diarrhoea, enterocolitis, patient intolerance, and bacterial resistance. A prokinetic agent that could help clear the small intestine of the overgrowth flora would be an attractive therapy. Experimental animal studies suggest that SBBO might be favorably influenced by prokinetic agents. There have been two small studies of these agents in patients with SBBO, one utilizing cisapride and one using octreotide. Both agents led to positive results in respect to SBBO following the prokinetic treatment. Another study utilizing octreotide and erythromycin in patients with scleroderma and SBBO attained positive responses following prokinetic therapy. Large controlled trials of prokinetic therapy in patients with SBBO have yet to be completed. Since the days of Metchkinoff, it has been thought that one could manipulate the intestinal flora by giving live 'probiotic' microbial supplements that would change the balance in the intestinal flora. Studies to date with probiotic therapy in subjects with SBBO have been disappointing. A recent placebo-controlled, randomized cross-over trial compared norfloxacin, amoxicillin–clavulanic acid, and *Saccharomyces boulardii* in 10 symptomatic patients with SBBO. Both antibiotic treatments led to significant decreases in symptoms and a substantial improvement in the results of hydrogen breath testing. The probiotic treatment with *S. boulardii* did not result in any improvement in these parameters.

Nutritional support is an important part of treatment of SBBO and may be needed despite attempts to control the bacterial overgrowth by antimicrobial agents because there may be irreversible damage to the enterocytes. Therefore, a lactose-free diet and substitution of a large proportion of dietary fat by medium-chain triglycerides may be necessary. Patients with cobalamin malabsorption should receive monthly injections of cobalamin (1000 µg). Deficiencies of other nutrients such as calcium and vitamin K should also be corrected.

Clinicians should have a low threshold for suspecting SBBO as a cause of malabsorption. The algorithm presented in Fig. 3 emphasizes the performance of simple, outpatient testing to pinpoint the cause of the malabsorption. Therefore, an appropriate attempt should be made to document whether SBBO is present or not. The consequences of SBBO can lead to serious malabsorption that results in clinically important deficiencies of several nutrients and, moreover, can be easily diagnosed and treated.

14.9.3Coeliac disease

D. P. Jewell

Definition

Coeliac disease is an inflammatory disorder of the small intestine induced by the prolamins of certain cereals, namely the gliadins of wheat, hordeins of barley, and secalins of rye. The inflammation is associated with loss of villous height and crypt hypertrophy and leads to malabsorption. The functional and histological abnormalities are reversed towards normal following exclusion of those cereals from the diet; they reappear on luminal challenge with the noxious prolamins.

History

Coeliac disease may well have been recognized in ancient times, as Aretaeus, the Cappadocian, wrote of the 'coeliac affection'. This was clearly a malabsorptive illness with steatorrhoea, affecting children and adults, but whether it represents a gluten-sensitive enteropathy is impossible to know. Samuel Gee of St Bartholomew's Hospital, London gave an excellent account of the disease in 1888 and concluded that 'if the patient is to be cured at all, it will be by means of a diet'. It was the Dutch paediatrician, W.K. Dicke, who finally recognized the role of wheat and his initial observations made in the 1930s were confirmed during the 'winter of starvation' in Holland in 1944. He noted that children with coeliac disease paradoxically improved as bread became virtually unobtainable. Using dietary challenge and faecal fat output as an indicator, Dicke together with J. H. van de Kamer and H. A. Weijers showed that it was gliadin, the alcohol-soluble component of gluten, that was the damaging substance. The demonstration of a flat intestinal mucosa by J. Paulley in 1954 and the development of a technique to take biopsies from the small intestine by Margot Shiner in 1956, who studied the histological findings with I. Doniach, as well as Rubin and colleagues in 1960, characterized the disease histologically and allowed easy and accurate diagnosis. The ability to follow the response of the mucosa to dietary manipulation by serial biopsy also allowed clinicians to demonstrate that coeliac disease in children was the same disease as idiopathic steatorrhoea in adults. Therefore, the disease is now referred to as coeliac disease or as a gluten-sensitive enteropathy.

Pathology

Coeliac disease affects the small intestine but the mucosal inflammation can vary in severity and in extent. Many patients have very mild proximal disease and the mucosal damage can be patchy. The characteristic, but not specific, feature is loss of villous height so that, under a dissecting microscope, the mucosa appears completely flat (Fig. 1). This is confirmed on histological examination (Fig. 2). The mucosa may be completely flat or there may be very short, broad villi—this appearance is often called subtotal villous atrophy. However, the total mucosal thickness (surface epithelium to muscularis mucosae) is usually normal or only slightly reduced because the crypts become elongated—usually referred to as crypt hypertrophy. The surface epithelial cells become flattened, the basal polarity of their nuclei is lost, and the microvilli of the brush border become short and irregular. This last change is revealed by electron microscopy.

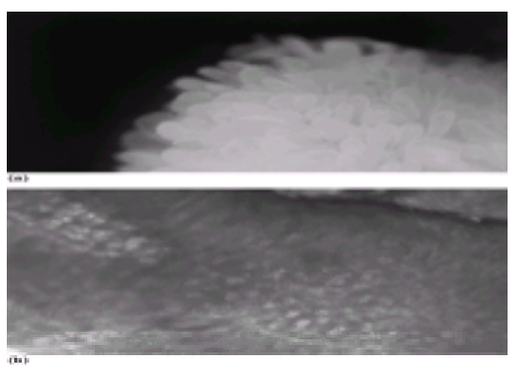

Fig. 1 (a) Dissecting microscopic appearance of a normal jejunal biopsy. (b) Dissecting microscopic appearance of coeliac disease.

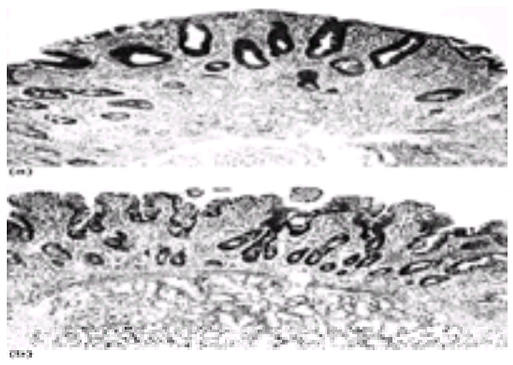

Fig. 2 Histological appearances of a distal duodenal biopsy in a patient with coeliac disease before (a) and after (b) a 3-month period on a gluten-free diet. Following treatment, there is much less inflammation and the villous pattern has begun to reappear.

Within the lamina propria, there is a marked infiltration of chronic inflammatory cells—plasma cells and lymphocytes. In addition, there is an increase in neutrophils, eosinophils, and mast cells. The proportion of intraepithelial lymphocytes is also increased in comparison with the number of enterocytes, although the absolute number is probably not increased.

Within the plasma cell population, there is an increase in the cells producing IgA, G, and M isotypes, although IgA cells still predominate. There is a marked increase in the proliferation rate of crypt cells, which, in a histological section, is shown by numerous mitoses at the base of the crypts. This increase in crypt cell proliferation is

thought to be mediated by cytokines released by the underlying lymphocytes and macrophages and leads to elongation of the crypts and loss of villous height.

It has been proposed that three stages in the development of coeliac disease are defined—infiltrative, hyperplastic, and destructive. These stages have been identified on the basis of challenge studies as well as biopsies of asymptomatic members of coeliac families. In the infiltrative stage, the epithelium becomes infiltrated with increased numbers of lymphocytes and this is the lesion frequently seen in patients with dermatitis herpetiformis. This stage leads on to the point where there is some inflammation of the lamina propria, with elongation of crypts. Both these stages are asymptomatic and can be regarded as latent coeliac disease. The destructive stage is the full lesion with loss of villi and a marked inflammatory infiltrate. Whether this classification is helpful, or indeed representative of what actually happens, is not yet clear.

As well as these characteristic changes in the small intestine, there may be a diffuse infiltration of other mucosal surfaces with lymphocytes and plasma cells. In particular, a proctitis has been recognized recently, but this is only detected if a rectal biopsy is taken and is virtually never severe enough to cause symptoms. This generalized mucosal infiltration presumably represents homing patterns of lymphocytes sensitized within the small-intestinal lamina propria.

Following a gluten-free diet, these histological changes return towards normal. For the majority of patients, a repeat biopsy after 3 months will show much less inflammation, the villous height will have increased, and the crypt elongation will have diminished. The mucosa usually returns to normal in children, but in adults, minor changes may persist with a crypt:villous ratio of 1:2 rather than the normal ratio of 1:4.

When patients in remission on a gluten-free diet are challenged with gluten, histological changes may be seen within a few days. In fact, electron microscopic changes may occur within a few hours of challenge and a fall in brush-border disaccharidase activity occurs in 24 h. However, some patients may take much longer to relapse and there have been some individuals who have virtually no histological change for up to a year.

Epidemiology

Coeliac disease is primarily a disease of Caucasians and, as it is closely associated with the extended haplotype HLA B8-DR3-DQ2, it is rare in those parts of the world where this haplotype is uncommon. Over 90 per cent of individuals with coeliac disease possess HLA DQ2, most of the remainder having HLA DQ8. The prevalence of coeliac disease in Europe and North America is about 1 in 300—much higher than was previously thought. This apparent increase has been due to more frequent diagnosis resulting from the accuracy of screening programmes that measure antiendomysial antibodies (see below).

There is little sex difference, although some studies have shown a preponderance of women. There is a familial incidence, with about 10 per cent of first-degree relatives being affected, and studies of monozygotic twins have shown a concordance of 70 per cent. These data indicate a strong genetic susceptibility.

Pathogenesis

There are two clear facts about the aetiopathogenesis of coeliac disease. The first is that fractions of gliadin, the alcohol-soluble component of gluten, are the toxic dietary constituent, together with similar fractions of rye and barley prolamins. The second is that there is a genetic susceptibility to gluten intolerance because of the close association with the HLA haplotype B8-DR3-DQ2 in northern Europeans and with B8-DR5/7-DQ2 in southern Europeans. This difference is due to the fact that the same DQ a–b heterodimer can be encoded on the same chromosome (*cis* position) in DR3 individuals or on opposite chromosomes (*trans* position) in DR5/DR7 individuals (see Section 5). This suggests that DQ molecules confer most of the susceptibility. What is not clear is how this particular haplotype interacts with gluten to produce mucosal inflammation in one person whereas the majority of people with this haplotype are able to ingest gluten with impunity. The other unsolved question is the exact nature of the toxic peptide.

An attractive hypothesis to explain why certain individuals lose oral tolerance to gluten is that it occurs as a result of an infection with adenovirus 12. This hypothesis was suggested by the observation that there was a dodecapeptide on the surface of a-gliadin which was similar to a peptide contained within an E1b protein of the virus. Many patients with coeliac disease demonstrate cellular and humoral immune responses to the virus, and so it is conceivable that the immune response to the virus cross-reacts with the gliadin peptide and thus induces intestinal inflammation. The gliadin dodecapeptide is now known to bind avidly to DQ2.

Some progress has been made in determining the toxic peptide, but in most studies toxicity has been assessed by *in vitro* methods rather than by direct feeding studies in patients. The amino acid sequences that seem to be shared by these toxic peptides are pro–ser–glu–glu or ser–pro–glu–glu. Two recent studies have identified an epitope (PQPQLPY) which appears to be dominant for the induction of a T-cell response. Furthermore, it requires the deamidation of a specific glutamine (at position 65) by tissue transglutaminase to elicit the response. B-cell responses also appear to depend on deamidation in this sequence. This is particularly interesting as tissue transglutaminase is now known to be the antigen to which the antiendomysial antibody is directed (see below).

The inflammatory lesion in the small intestine seems to result from an immunological reaction to the gluten peptides, with both cellular and humoral responses being involved. The mucosal abnormality is usually a proximal one and is presumably a reflection of luminal concentration of the relevant peptides. The release of cytokines and inflammatory mediators is thought to amplify the immune response and to influence epithelial stem-cell kinetics, with subsequent crypt elongation and loss of villous height. Malabsorption occurs because of loss of absorptive area and the presence of a population of immature surface epithelial cells whose absorptive and secretory function may be additionally impaired by cytokines and inflammatory mediators.

Clinical features

Coeliac disease in infants classically presents soon after weaning at the point that cereals are introduced. The babies usually fail to thrive, are miserable, refuse to eat, and lose weight. The abdomen becomes distended, there is muscle wasting, and they may have diarrhoea, which usually has the features of steatorrhoea. Abdominal pain and vomiting may be prominent symptoms and can mislead the clinician. Rectal prolapse may occur.

In older children, growth retardation is a common presentation and if the gastrointestinal symptoms are minimal, the diagnosis can be overlooked. Nutritional deficiencies can occur and may again be the reason for presentation, anaemia being the most common deficiency. Delayed puberty is another mode of presentation.

In adults, the most common presentations are anaemia and variable abdominal symptoms of discomfort, bloating, excess wind, and an altered bowel habit. Mouth ulcers are also frequent and can be the presenting symptom. The anaemia is most commonly due to iron deficiency and frequently occurs in the absence of intestinal symptoms; the macrocytic anaemias that sometimes occur in coeliac disease are described in Section 22. Many patients presenting with diarrhoea, wind, and abdominal pain are wrongly diagnosed as having an irritable bowel syndrome and there may then be a considerable delay before the true diagnosis is made. Patients suspected of having an irritable bowel syndrome should be specifically questioned about mouth ulcers and weight loss, either of which can be a pointer to organic disease. They should also be asked about feeding difficulties as a child, about growth milestones, and the age of achieving puberty. Less commonly, patients will present with a more typical history, with features of steatorrhoea, weight loss, bruising, and other symptoms of nutritional deficiencies resulting from malabsorption.

The classic findings in infants are those of an irritable child with stunted growth, muscle wasting, and a 'pot belly'. The infant usually has feeding difficulties and may show evidence of colic, and has a marked diarrhoea. However, in toddlers and older children who present with growth failure or anaemia, there may be few signs. Similarly, in adults, there may be no physical signs in those presenting with symptoms suggestive of an irritable bowel syndrome. Signs of iron deficiency may be present and there may be aphthous ulcers in the mouth, mild finger clubbing, and evidence of recent weight loss. It is very unusual, nowadays, for patients to show evidence of bleeding and osteomalacia (or rickets in children). Even less common are patients who are so malnourished that they have signs of ascites and hypoproteinaemic oedema.

Diagnosis

The crucial test to establish the diagnosis is a small-intestinal biopsy. This has traditionally been taken from the duodenal–jejunal junction (the ligament of Treitz) using a Crosby capsule. However, a distal duodenal biopsy taken at endoscopy is being used increasingly to make the diagnosis and comparative studies with a true jejunal biopsy have justified its use.

Several serological tests have been developed as screening tests which include antibodies to gliadin (IgA or IgG isotype), IgA antibodies to reticulin, and IgA antibodies to endomysium. The endomysial antibody has proved to be the most useful with a specificity and sensitivity of 90 to 95 per cent. The antibody is detected

by immunofluorescence using monkey oesophagus or human umbilical vein. The antibody is directed towards tissue transglutaminase and is increasingly being detected using enzyme-linked immunosorbent assay (ELISA) with transglutaminase-coated wells. The titre falls as the disease goes into remission on a gluten-free diet, but can take 3 to 12 months to become negative. Failure of the serum to become negative for the antibody, or reappearance of the antibody suggests non-compliance with the diet. Since it is an IgA antibody that is measured, a false-negative result may occur in the 5 per cent or so of patients with coeliac disease who have a coexistent IgA deficiency. The antiendomysial antibody is useful for screening high-risk populations, such as family members of patients with coeliac disease, diabetes, or osteoporosis.

Assessment of malabsorption

Careful documentation of nutritional deficiency as a result of malabsorption must be made and should include the following.

Full blood count

The haemoglobin level may be low, but the mean corpuscular volume may be low (iron deficiency), high (vitamin B_{12} or folate deficiency), or within the normal range. This can occur either because there is no significant deficiency of a haematinic or because there is a mixed deficiency, usually a combination of iron and folate. The red cell folate is a more reliable indicator of folate deficiency than the serum concentration and if it is low, there may be a pancytopenia. Vitamin B_{12} concentrations are only low in patients with extensive involvement of the small intestine and so are usually normal. Serum iron, total binding capacity, and ferritin concentrations should be measured to record the patient's iron status.

Biochemistry

Quantitative estimations of faecal fat excretion are becoming progressively more difficult to obtain despite their obvious value in assessing small-intestinal function. Qualitative assessment of excess fat by staining faecal smears with Sudan black or oil red O can be a reasonable alternative but merely records the presence or absence of a steatorrhoea. Fat malabsorption is inevitably accompanied by malabsorption of the fat-soluble vitamins A, D, E, and K. Serum concentrations of b-carotene, calcium, alkaline phosphatase, vitamin D, and the prothrombin time (INR—international normalized ratio) should therefore be assayed. Patients with diarrhoea may become hypokalaemic. Serum magnesium concentrations may also be low in severe coeliac disease and, with hypocalcaemia, can lead to tetany. Serum albumin is often low, as is the concentration of zinc.

Immunological tests

In addition to the titres of diagnostic antibodies discussed above, serum immunoglobulin concentrations should be measured. The most common pattern of abnormality is a raised IgA with a low IgM, but virtually any pattern may be seen. However, 5 per cent of patients with coeliac disease have an associated IgA deficiency, and loss of villous height and crypt hypertrophy frequently accompany common-variable acquired immunodeficiency.

Radiology

Barium radiology cannot give a positive diagnosis of coeliac disease and is not usually necessary unless it is required to exclude other small-intestinal diseases. In patients with mild disease the appearances may be normal, but if abnormalities are present, the appearances vary according to the radiological technique used. If a barium meal and follow-through is done, the small intestine may appear dilated and the barium often segments and flocculates. The proximal loops may appear smooth with a corresponding accentuation of the valvulae conniventes in the ileum—the so-called jejunization of the ileum. If a small-bowel enema is used (enteroclysis), the features are those of dilation and oedema of the valvulae conniventes.

Differential diagnosis

Few patients present with overt malabsorption, so the diagnosis of coeliac disease requires a high index of suspicion. However, once a biopsy is obtained that shows appearances compatible with coeliac disease, the differential diagnosis is limited.

For infants, the most common differential diagnosis is cow's milk allergy. An eosinophilia in the lamina propria as well as in peripheral blood is common, but this can also occur in coeliac disease. A soya milk allergy can also cause a flat small-intestinal mucosa. The precise diagnosis is usually dependent on a dietary history and the results of dietary exclusion.

In adults, infection with giardia, common-variable hypogammaglobulinaemia, lymphoma, Crohn's disease, and other small-intestinal diseases such as radiation enteritis, amyloid, and Whipple's disease may all show villous flattening and mucosal inflammation. Tropical sprue is usually associated with less marked changes—so-called partial villous atrophy—but has to be considered in patients who have spent time in endemic areas. Rarely, patients may be seen with a flat biopsy but with crypt hypoplasia—these do not respond to a gluten-free diet. Some patients with crypt hypoplasia also have a thickened band of subepithelial collagen, so-called collagenous sprue. Systemic diseases such as the vasculitides and systemic sclerosis may also be associated with an abnormal mucosal biopsy. Bacterial overgrowth of the small intestine may be associated with some mucosal inflammation and minor villous changes but they are rarely sufficiently severe to be confused with coeliac disease.

Dermatitis herpetiformis is commonly associated with an abnormal mucosal biopsy. The mucosal inflammation can be as severe as coeliac disease and responds to gluten withdrawal. The skin lesions also respond to a gluten-free diet, albeit slowly.

Non-specific infections of the small intestine may lead to a degree of malabsorption and mucosal inflammation. In only a small proportion can giardia be detected, and the precise aetiology of the majority is never determined. The illness is usually sudden in onset and gets better spontaneously over several weeks. It has been named 'temperate sprue'. Although this entity is uncommon, it can mislead clinicians. Most patients presenting in this way are started on a gluten-free diet as soon as the result of the biopsy is known and their improvement is regarded as a dietary response. Thus a patient presenting with a very short history of symptoms and whose mucosal biopsy suggests coeliac disease must be considered carefully. HLA typing and the presence of serum endomysial antibodies may be very helpful in making the correct diagnosis. If there is still doubt, the patient should be given a gluten-free diet but when the mucosa has recovered, a gluten challenge with subsequent biopsy should be undertaken.

Associated diseases

There is an increased prevalence of autoimmune diseases in patients with coeliac disease, especially those that are associated with the HLA B8-DR3 phenotype. These include diabetes, thyroid disease, and Addison's disease. Fibrosing alveolitis, systemic lupus erythematosus, and polyarteritis have also been reported. There may be an increase in epilepsy, especially temporal-lobe epilepsy, in patients with coeliac disease.

About 5 per cent of individuals with coeliac disease have an isolated IgA deficiency but the reason for and significance of this are not clear.

Treatment

Once the diagnosis is confirmed by a small-intestinal biopsy, patients should be started on a gluten-free diet. This diet should also exclude barley and rye, but with oats the need is less clear. As the evidence for oat toxicity is confused, many clinicians allow oats and only exclude them if the repeat biopsy does not show a good histological response. However, others exclude oats as the diet is begun and then consider reintroducing them once the disease has gone into histological remission.

All patients should be advised of the diet by a dietician and should be told to keep to it strictly. For children, the parents must be well briefed, including being told of the dangers of many sweets and 'fast foods'. For all patients, the diet is a lifelong necessity. Many children inevitably ingest small amounts of gluten during adolescence and many of them remain asymptomatic and develop normally. This has given rise to the highly erroneous view that children can 'grow out' of the disease. If the diagnosis was correct in the first place, then the patient has coeliac disease for life and if the diet is not strict, it may predispose them to complications in the future.

Patients should also be given details of the national coeliac society, if there is one. Most countries in which coeliac disease occurs have such a society. They provide a considerable amount of information about the disease and update patients about the gluten contents of new products appearing in the supermarkets. They also give invaluable advice about diet and foreign travel, as well as providing a social forum for patients and opportunities for fund raising to support research.

Nutritional supplements may be necessary at the start of treatment. If there are low serum concentrations of iron and folate, or biochemical evidence of osteomalacia, appropriate supplements are clearly required. However, once a gluten-free diet has begun, mucosal recovery occurs rapidly so that long-term supplementation is rarely necessary.

Patients with extensive mucosal damage are unable to digest lactose because of lactase deficiency. These patients may need a lactose-free as well as a gluten-free diet until there is histological recovery.

Once patients have been on the diet for 3 to 4 months, a further small-intestinal biopsy must be obtained to check for histological recovery. If the mucosa is still inflamed and villous height has not returned towards normal, a thorough review of the patient's diet is needed. Hidden sources of gluten (Communion wafers being a classic example) can often be found by a skilled dietician. If oats have not been excluded, then this is worth doing. In children, additional exclusion of soya products is occasionally needed.

Long-term follow-up, preferably in specialized clinics, is desirable but need only be on an annual basis once patients are stabilized on their diet. This allows patients to be seen by a dietician as well as their physician and reinforces the need to comply with a strict diet. Compliance should also be checked by measuring antiendomysial antibody—it should be negative if the disease is in remission.

Complications

The two major complications of coeliac disease are an ulcerative jejunoileitis and a T-cell lymphoma, and some investigators consider the jejunoileitis to be a manifestation of a lymphoma. They usually occur in middle age and usually present with weight loss, anaemia, abdominal pain, and diarrhoea. Thus any coeliac presenting with these symptoms having been previously well on a gluten-free diet must be carefully screened for these complications. Biopsies should be snap-frozen in liquid nitrogen to allow immunohistochemical analysis of T-cell markers and the detection of T-cell receptor rearrangements. The prognosis of a lymphoma complicating coeliac disease is poor.

In addition, there is a slight increase in the frequency of small-bowel carcinoma, although this is still very rare. There is also an increased incidence of other gastrointestinal cancers, especially oesophageal tumours, although the reasons for this increase are obscure.

There is some evidence suggesting that the patients who develop malignant disease, especially lymphoma, are those who have been poor compliers with the diet. Although this association is not absolutely proven, it provides the basis for continuing to advise a strict diet and to monitor compliance on a regular outpatient review.

Osteoporosis

Bone density scans have shown that most patients with coeliac disease have reduced bone density at diagnosis, but that this improves after a year or so of a strict gluten-free diet. The recommended intake of calcium for individuals with coeliac disease is 1500 mg daily, which is high, and requires skilled dietetic advice. For those patients with frank osteoporosis, treatment with calcium and vitamin D is required. For those with osteopenia, a follow-up scan should be done following a year on a gluten-free diet and calcium supplementation.

Prognosis

Provided that patients adhere to a strict diet, the prognosis is excellent and there are no data which suggest that there is an excess mortality in this group. Children develop normally and proceed into adolescence without delay. However, as mentioned above, compliance with the diet is often poor in adolescents and some clinicians still believe that many of them can have a more liberal diet if they are asymptomatic. It is this group that often present some years later with anaemia, mouth ulcers, or more serious evidence of malabsorption.

Unresponsive disease

A rare group of patients who are found to have a flat small-intestinal biopsy fail to respond to a gluten-free diet despite meticulous attention to avoid even minute amounts of gluten over many months. By definition these patients do not have coeliac disease, although they are often referred to as 'non-responsive coeliacs', a phrase that is misleading and should be avoided. Treatment of this group is difficult. Corticosteroids with or without azathioprine may help some, and more recent case reports suggest oral cyclosporin may also be of benefit. Excluding other dietary items such as soya can be tried, or an elemental diet that removes all dietary antigens. Some of these patients have a variety of central and peripheral neurological signs that do not fit classic vitamin-deficiency syndromes. The aetiology and pathology of these neurological lesions is unknown and the initial suggestions that they represented vitamin E deficiency have not been substantiated. The prognosis for these patients is poor because the neurological damage is slowly progressive and patients gradually lose weight despite full nutritional support.

It is always worth reviewing the intestinal biopsies in patients who do not respond to gluten withdrawal. Small-intestinal lymphoma, loss of villous height with crypt hypoplasia, and collagenous sprue are alternative diagnoses that may not have been recognized during the initial assessment.

14.9.4Gastrointestinal lymphoma

P. G. Isaacson

Introduction

Gastrointestinal lymphomas, the most common extranodal lymphomas, are almost exclusively of non-Hodgkin's type, primary gastrointestinal Hodgkin's disease being extremely rare. A primary gastrointestinal lymphoma is defined as a lymphoma that has presented with the main bulk of disease in the gastrointestinal tract, with or without involvement of contiguous lymph nodes, necessitating direction of treatment to that site. The stomach is the commonest site of primary gastrointestinal lymphoma followed by the small intestine. Oesophageal and colorectal lymphomas are rare. The lymphomas that may arise in the gastrointestinal tract are listed in Table 1. Two of these, namely B-cell lymphoma of mucosa-associated lymphoid tissue (**MALT**) and enteropathy-associated T-cell lymphoma (**EATL**), do not arise in peripheral lymph nodes and will be discussed in more detail in this section. Any of the lymphomas that normally arise in lymph nodes may present as a primary gastrointestinal tumour, the most frequent being diffuse large B-cell lymphoma and mantle-cell lymphoma, which usually manifests in the gut as lymphomatous polyposis. Burkitt's lymphoma, which is the commonest childhood gastrointestinal lymphoma, is an especially common primary small intestinal lymphoma in the Middle East. The increasingly important group of B-cell lymphoproliferative conditions associated with immunodeficiency commonly present in the gastrointestinal tract, but they are more properly considered in the context of immunodeficiency-related lymphoproliferative conditions as a whole.

MALT lymphomas

The term MALT-lymphoma is used to designate a group of low-grade B-cell lymphomas whose histology recapitulates the features of mucosa-associated lymphoid tissue (MALT) as exemplified by the Peyer's patch. Paradoxically, there is usually no lymphoid tissue in the sites where MALT lymphomas occur, but lymphoid tissue of MALT-type accumulates prior to the development of lymphoma. In the stomach this is usually the result of chronic inflammation in response to *Helicobacter pylori* infection and its associated autoimmune phenomena. Intestinal MALT lymphomas are less frequent but include the entity known as immunoproliferative small intestine disease (**IPSID**) that has interesting parallels with gastric MALT lymphoma.

Gastric MALT lymphoma

Clinical presentation

Gastric MALT lymphoma typically occurs in patients over 40 years of age but can occur at any age. The sex incidence is equal. The presenting symptoms are usually those of non-specific dyspepsia and more suggestive of gastritis or peptic ulcer than a neoplastic lesion. Likewise, endoscopy more often shows inflamed, sometimes eroded mucosa than a tumour mass.

Pathology

Most MALT lymphomas of the stomach arise in the antrum, and macroscopically are characterized by an ill-defined thickened inflamed and ulcerated mucosa. The histological features closely simulate those of MALT (Fig. 1). Reactive non-neoplastic follicles are surrounded by the lymphomatous infiltrate in the region corresponding to the Peyer's patch marginal zone. The infiltrate extends into the surrounding tissue and invades individual gastric glands to form characteristic lymphoepithelial lesions (Fig. 2). Although the term centrocyte-like is most commonly used to describe the cells of MALT lymphoma, their cytological characteristics are more variable and they may more closely resemble small lymphocytes or show the features of so-called monocytoid B-cells. Scattered transformed blasts are usually present and plasma-cell differentiation, characteristically maximal beneath the surface epithelium, is present in one-third of cases. The lymphoma cells may specifically colonize the reactive follicle centres in a way that may lead to an appearance closely resembling follicular lymphoma. Gastric MALT lymphoma is characteristically multifocal.

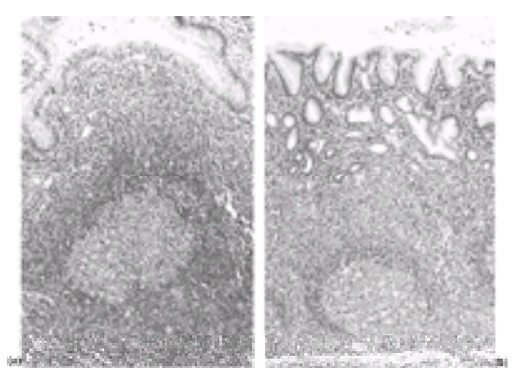

Fig. 1 (a) Peyer's patch comprising a B-cell follicle surrounded by a mantle zone external to which is the marginal zone. There are collections of small B lymphocytes within the dome epithelium. (b) Gastric MALT lymphoma. The tumour cells surround the reactive B-cell follicle in the marginal zone and invade gastric glands to form lymphoepithelial lesions. The overall structure is similar to the Peyer's patch.

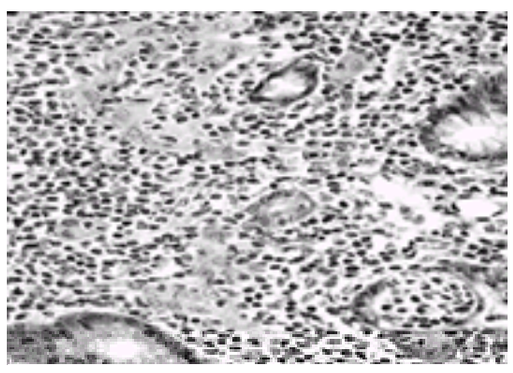

Fig. 2 Detail of the neoplastic infiltrate in a gastric MALT lymphoma showing 'centrocyte-like' cells invading gastric glands to form lymphoepithelial lesions (top left

and bottom right).

Biopsy appearances of gastric MALT lymphoma

There are many pitfalls in making the diagnosis of MALT lymphoma in small endoscopic biopsies. Amongst these are the retrieval of inadequate tissue, the presence of predominantly submucosal lymphoma, and the presence of cryptic foci of high-grade lymphoma or an associated adenocarcinoma. The differential diagnosis between MALT lymphoma and florid *H. pylori*-associated chronic gastritis (follicular gastritis) can be especially difficult. Molecular evidence of B-cell monoclonality is also helpful, but a diagnosis of lymphoma should never be made unless the histological criteria are fulfilled.

Dissemination to lymph nodes and other sites

Most gastric MALT lymphomas are at clinical stage 1_E at the time of diagnosis, but approximately 20 per ent have spread to the gastric lymph nodes or beyond. The more common distal sites include the small intestine, spleen, and bone marrow. In both lymph nodes and spleen the lymphomatous infiltrate tends to concentrate in the marginal zone.

The phenotype and genotype of gastric MALT lymphoma

The B-cells of MALT lymphoma express surface and, to a lesser extent, cytoplasmic immunoglobulin (usually IgM), which shows light-chain restriction. The cells express mature B-cell antigens including CD21 and CD35. They are CD5- and CD10-negative. This phenotype is homologous with that of marginal zone B cells, which are now acknowledged as the normal-cell counterpart. Various cytogenetic abnormalities have been described in MALT lymphomas, including trisomy 3, t(1;14) and t(11;18). The immunoglobulin (**Ig**) genes are mutated with ongoing mutations. Detection of monoclonal Ig gene rearrangement by Southern blotting or, more usually by the polymerase chain reaction (**PCR**), can assist in making the diagnosis of lymphoma in gastric biopsies, but caution is required since PCR evidence of monoclonality has been reported in biopsies from cases of florid *H. pylori*-associated gastritis.

High-grade transformation of gastric MALT lymphoma

Transformation of low- to high-grade MALT lymphoma is heralded by the emergence of increased numbers of transformed blast cells, which eventually form sheets or clusters (Fig. 3) and finally grow to confluence effacing any trace of the preceding low-grade tumour. This gives rise to difficulty both in grading some MALT lymphomas and in classifying large B-cell lymphomas of the stomach and other parts of the gastrointestinal tract. Those large-cell lymphomas in which no MALT component is evident are best classified as diffuse large B-cell lymphoma without reference to MALT.

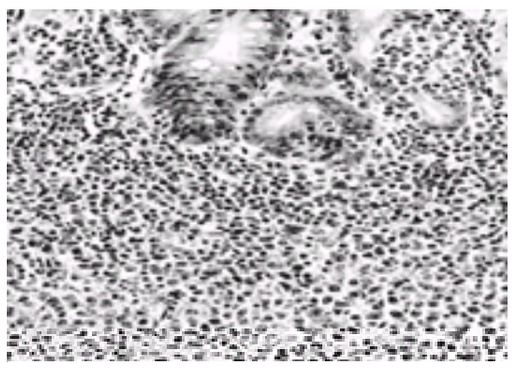

Fig. 3 MALT lymphoma showing transformation from low-grade (small cell) histology (upper half of figure) to high-grade (large cell) lymphoma (bottom half of figure).

The clinical behaviour of gastric MALT lymphoma

In comparison with nodal low-grade B-cell lymphomas, such as follicular lymphoma, which, at the time of diagnosis are characteristically at an advanced stage, MALT lymphoma is usually at stage I_E or II_E when diagnosed and is slow to disseminate. Hence low-grade MALT lymphomas respond favourably to therapy and there is an excellent overall survival approximating 90 per cent at 10 years. The survival for cases in which there is evidence of high-grade transformation is significantly worse, 45 per cent at 10 years.

Helicobacter pylori and gastric MALT lymphoma

There are several lines of evidence that implicate *H. pylori* in the pathogenesis of gastric MALT lymphoma. These include the fact that normal gastric mucosa is devoid of organized lymphoid tissue which, however, accumulates as a consequence of *H. pylori* infection, and the observation that the organism can be detected in most cases. The epidemiological study of Parsonnet *et al.*, which showed that there was a significantly higher frequency of preceding *H. pylori* infection in patients with gastric lymphoma compared to matched controls with non-gastric lymphoma, added further support to this association. The evidence became even more compelling following *in vitro* studies, which showed that the cells of low-grade gastric MALT lymphoma respond to *H. pylori* antigens via a T-cell mediated mechanism. The clinical significance of these findings was first shown by Wotherspoon *et al.* who described the regression of gastric MALT lymphoma in patients following eradication of *H. pylori* using appropriate antibiotics. Subsequent studies have shown that eradication of *H. pylori* may result in striking regression of the lymphoma in approximately 75 per cent of cases. Deeply invasive lymphomas, those in which there are foci of high-grade transformation, and cases with t(11;18) are unlikely to respond.

Immunoproliferative small intestinal disease (IPSID)

This condition is a subtype of MALT lymphoma, which occurs most commonly in the Middle East, although small numbers of cases have been reported from elsewhere. It is a disease of young adults and usually presents with severe malabsorption. The histology of IPSID is similar to that of gastric MALT lymphoma, except that plasma-cell differentiation is much more prominent both in the intestine and mesenteric lymph nodes. These plasma cells synthesize large amounts of alpha heavy chain without light chain, which can be detected in the serum. Hence the term 'alpha chain disease' which was first used for this condition. IPSID remains localized to the small intestine for prolonged periods and patients usually die from the severe malabsorption. High-grade transformation may also occur.

In its early stages, IPSID may be responsive to broad-spectrum antibiotics, which presumably eradicate bacterial spp. from the intestinal lumen. Thus, there is a remarkable parallel with the relationship between *H. pylori* and gastric lymphoma, although no specific organism has yet been implicated in IPSID.

Enteropathy-associated T-cell lymphoma (EATL)

An association between malabsorption and intestinal lymphoma has long been recognized, and at first it was thought that the lymphoma was in some way responsible for the malabsorption. It subsequently became clear that the reverse is true, and that intestinal lymphoma, in common with a variety of other tumours, was a complication of the malabsorption, which was most likely due to coeliac disease (gluten-sensitive enteropathy). In 1978, Isaacson and Wright characterized the lymphoma associated with malabsorption as a single entity, namely a variant of malignant histiocytosis. Later, Isaacson *et al*. showed that both the phenotype and genotype of this lymphoma were those of T cells rather than histiocytes, hence the term 'enteropathy-associated T-cell lymphoma' (EATL) was coined to describe the disease.

Clinical features

EATL is characteristically a disease with an equal sex incidence that occurs in the sixth and seventh decades of life, although sporadic cases have been described in younger patients. The commonest presentation is the sudden onset of abdominal symptoms, usually with the reappearance of steatorrhoea, after a short (months to years) history of successfully treated adult coeliac disease. Some of the patients may have first presented with dermatitis herpetiformis. In a minority of cases there is a well-documented history of childhood coeliac disease. The lymphoma may also present as an abdominal emergency with no history of malabsorption, the features of coeliac disease are found in the uninvolved portion of the resected small intestine. Abdominal pain, weight loss, fever, finger clubbing, and an ichthyotic rash are all common presenting symptoms and signs. The lymphoma usually results in intestinal perforation or haemorrhage rather than obstruction.

Jejunal biopsy in patients with EATL usually shows villous atrophy with crypt hyperplasia, but it may show only minor changes that, in some cases, may be limited to an increase in intraepithelial lymphocytes. It is unusual to obtain lymphoma tissue in the biopsy, although evidence of active or healed ulcers is sometimes present.

Most patients with EATL are subjected to a laparotomy. The lymphoma may involve any segment of the small intestine but is more common in the jejunum where is occurs as multiple nodules, ulcers, and strictures or, less frequently, as a large mass. The small intestine may appear normal, although there is usually considerable enlargement of mesenteric lymph nodes.

The clinical course of EATL is very unfavourable, except in a minority of cases where resection of a localized tumour has been followed by long remission. In most cases the lymphoma involves multiple segments of intestine rendering resection impossible, or has already disseminated beyond the mesenteric lymph nodes and out of the abdomen.

Pathology

EALT may involve any part of the small intestine and, rarely, other parts of the gastrointestinal tract including the colon and stomach, but most cases arise in the jejunum. The tumour is usually, but not always, multifocal and forms ulcerating nodules or large masses that may be accompanied by benign-appearing ulcers and strictures. The mesentery is often infiltrated and mesenteric lymph nodes are commonly involved. There is sometimes remarkably little macroscopic evidence of disease in the intestine in contrast to mesenteric lymphadenopathy.

The histological features of EATL show great variation both between cases and within any single case. The tumour cells may be only slightly larger than normal small lymphocytes or resemble immunoblasts but, more usually, are strikingly pleomorphic (Fig. 4). Intraepithelial tumour cells may be prominent. Interpretation of the histology is further complicated by the heavy inflammatory component, often containing many eosinophils, and extensive necrosis, which, together, may mask the neoplastic infiltrate (Fig. 5). Granulomas may be present and cause confusion with Crohn's disease. Non-specific 'benign' ulcers are frequently present in EATL and microscopically these show only chronic inflammation (see below).

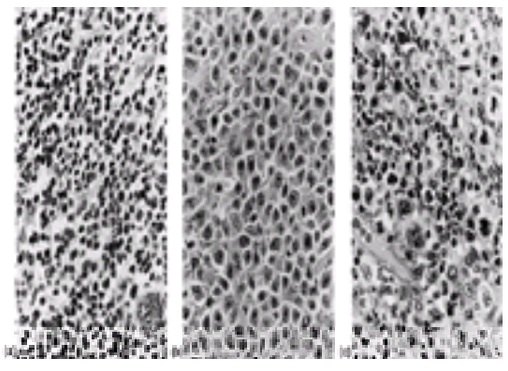

Fig. 4 Histological appearances of three different cases of EATL showing the cytological variability. In (a) the tumour is composed of small- to medium-sized lymphocytes; in (b) the tumour is composed of monomorphic, large immunoblasts; in (c) the tumour shows striking pleomorphism.

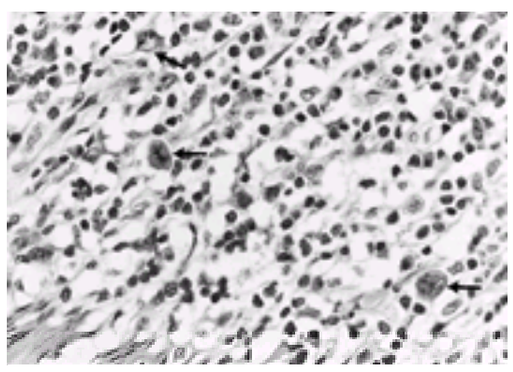

Fig. 5 A higher magnification of the ulcer base in which isolated malignant cells are evident (arrows).

The histology of the small intestine remote from the site of the tumour is an important consideration in the diagnosis of EATL. In most cases the changes are identical with those of coeliac disease with villous atrophy with crypt hyperplasia, plasmacytosis of the lamina propria, and an increase in intraepithelial lymphocytes. The degree of intraepithelial lymphocytosis may be spectacular and so extreme as to virtually obscure the epithelial cells (Fig. 6). The lymphocytes are small, without neoplastic features, and in these extreme cases spill into the lamina propria where they may merge with the lymphomatous infiltrate.

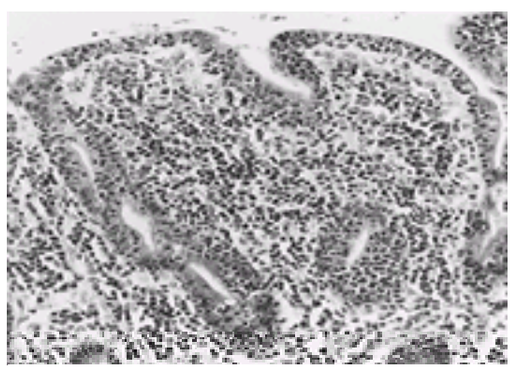

Fig. 6 Uninvolved mucosa from a case of EATL showing an extreme degree of intraepithelial lymphocytosis with spilling of lymphocytes into the lamina propria.

Episodes of ulceration followed by remission with healing may occur before the manifestation of EATL (so-called ulcerative jejunitis; see below). This can lead to a

confusing appearance of the mucosa with scarring and distortion of mucosal architecture, and the appearance of cells of the ulcer-associated cell lineage.

Lymph node involvement

The mesenteric lymph nodes are commonly involved, and almost always show accompanying hyperplasia that may mask the malignant cells which may be present in remarkably small numbers. Selective necrosis of lymph nodes, often involving entire nodes, remote from the main lesion is a feature of some cases. The cause of this necrosis is obscure.

Immunophenotype and genotype

In most cases the cells are CD3+, CD7+, CD4–, CD8-, CD56-, CD103+ and contain cytotoxic granules. Although the cells are CD4/8-negative they do not express the g/† T-cell receptor. Occasionally the lymphoma cells fail to express CD3 and may be CD8+; more rarely they are CD56+. These properties suggest that EATL arises from intraepithelial T cells. No characteristic genotypic features have been described.

EATL and coeliac disease

There is strong evidence that the enteropathy in EATL is a consequence of coeliac disease. Its histology and distribution are those of coeliac disease, and the HLA type of patients with EATL and coeliac disease are identical. Moreover, gluten sensitivity has been demonstrated in numerous EATL patients and a gluten-free diet has been shown to protect against the development of lymphoma. There remains the dilemma posed by those cases with minimal or even absent enteropathy. These patients are thought to suffer from the so-called latent coeliac disease, which can be confirmed by the finding of a positive endomysial antibody test diagnostic of coeliac disease.

Refractory coeliac disease, chronic ulcerative jejunitis, and EATL

Patients with established coeliac disease who become resistant to a gluten-free diet are said to have developed refractory coeliac disease (refractory sprue). Patients with this disorder may present with gluten-resistant malabsorption *de novo*, and in these cases the diagnosis can be substantiated by the finding of endomysial antibodies. A subgroup of patients with refractory coeliac disease develops multiple intestinal ulcers, and this syndrome has been termed chronic ulcerative jejunitis. Patients with refractory coeliac disease, particularly those with ulcerative jejunitis, may progress to develop EATL. It has recently been shown that the intraepithelial lymphocytes in patients with refractory coeliac disease and ulcerative jejunitis comprise a monoclonal population with an abnormal immunophenotype (cCD3+, CD4–, CD8–) similar to that of EATL. Moreover, when these patients develop EATL there is clonal identity between the intraepithelial lymphocytes and the subsequent lymphoma. Interestingly, the intraepithelial lymphocytes in the 'non-lymphomatous' small intestinal mucosa of EATL likewise share the abnormal phenotype and clonal identity of the lymphoma. Thus, patients with refractory coeliac disease can be said to be suffering from a clonal T-cell disorder that is directly linked to EATL. The optimum treatment for this condition remains to be clarified.

Management

The treatment of EATL is most satisfactory in those cases with a localized tumour, when surgical excision may be followed by long remission or even cure. Most cases are multifocal or have already disseminated at diagnosis and require treatment appropriate for a high-grade, non-Hodgkin's lymphoma, which may include bone marrow autografting. This form of therapy is particularly hazardous in EATL because of the danger of intestinal perforation. Some cases of ulcerative jejunitis, even when small foci of lymphoma are present, may respond to steroids.

14.9.5 Disaccharidase deficiency

T. M. Cox

Disaccharidases are specific glycosidases that are required for the complete assimilation of nearly all dietary carbohydrate apart from free glucose and fructose. The enzymes are found on the luminal surface of the small gut; their activity may be reduced by genetically determined deficiencies or acquired by generalized disease of the intestinal mucosa. Disaccharidase deficiency causes a characteristic syndrome of carbohydrate intolerance.

Physiology of carbohydrate digestion Fig. 1)

Free disaccharides occur in the diet or are derived from the luminal hydrolysis of starch and glycogen by salivary and pancreatic a-amylase. Because amylase cannot hydrolyse the a-1,6 branching linkages and has little specificity for a-1,4 bonds adjacent to these points, the initial products of starch digestion are branched oligosaccharides containing at least one a-1,6 bond. Maltase-glucoamylase is a mucosal a-glucosidase that removes glucose moieties sequentially from the non-reducing terminus of linear oligosaccharides. a-Dextrinase (isomaltase) continues the hydrolysis of branched carbohydrate polymers by cleaving the a-1,6 glycosidic bonds of the limit dextrins that remain. a-Dextrinase is a component of the bifunctional enzyme complex, sucrase–isomaltase, the sucrase moiety of which hydrolyses sucrose into fructose and glucose. The disaccharides sucrose, lactose, and trehalose, like the a-dextrins, are poorly absorbed: to be assimilated, they are also split into monosaccharides by glycosidases located on the brush-border membrane (sucrase, lactase, and trehalase). Mucosal disaccharidases are optimally active at pH 6.0 and are present principally in the duodenum and jejunum—activity also persists in the ileum but is absent in the colon.

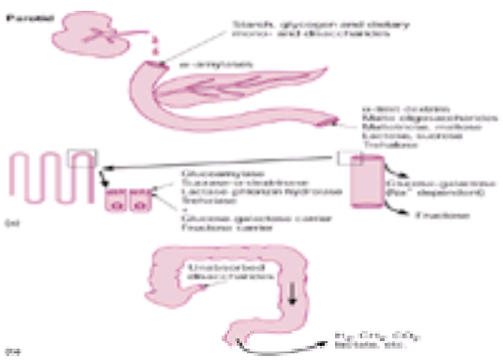

Fig. 1 Carbohydrate digestion and absorption.
