inflammatory bowel disease (more often Crohn's disease than ulcerative colitis), cholecystitis (more common among children with predisposing conditions such as hemolytic anemia or cystic fibrosis or among older adolescents), pancreatitis, dietary protein allergy (typically in neonates and infants), malabsorption, and intraabdominal abscesses (most commonly observed in children with perforated appendicitis).

Incarcerated inguinal hernia is an extraabdominal cause of abdominal pain that can be life threatening. A careful genitourinary examination should be performed in all children with abdominal pain. Myocarditis and pericarditis are rare extraabdominal causes of abdominal pain. Systemic life-threatening conditions that can be associated with abdominal pain include diabetic ketoacidosis and hemolytic uremic syndrome. Other extraabdominal conditions in which abdominal pain is often present include the following: Henoch-Schönlein purpura (usually with a distinctive purpuric rash over the lower extremities and buttock), vasoocclusive crisis with sickle cell syndromes,

TABLE 49.2

LIFE-THREATENING CAUSES OF ACUTE ABDOMINAL PAIN

<2 yr	2–5 yr	6–12 yr	>12 yr
Abdominal			
Malrotation/volvulus	Trauma	Trauma	Trauma
Intussusception	Intussusception	Appendicitis	Ectopic pregnancy
Trauma (possible child abuse)	Appendicitis	Megacolon (from inflammatory bowel disease)	Appendicitis
Severe gastroenteritis	Incarcerated hernia	Peptic ulcer disease (with perforation)	Intraabdominal abscess secondary to pelvic inflammatory disease, cholecystitis, appendicitis, inflammatory bowel disease
Incarcerated hernia	Meckel's diverticulum	Peritonitis (primary or secondary)	Peptic ulcer disease—bleeding or perforation
Hirschsprung's disease	Obstruction secondary to prior abdominal surgery	Aortic aneurysm	Pancreatitis
Appendicitis	Peritonitis (i.e., primary, nephrosis)	Acute, fulminant hepatitis	Megacolon (from inflammatory bowel disease)
Tumors (e.g., Wilms' tumor)			Aortic aneurysm
			Acute fulminant hepatitis
Nonabdominal			
Heart disease, especially myocarditis, pericarditis	Toxic overdose[a]	Toxic overdose[a]	Collagen vascular disease
	Hemolytic uremic syndrome		
Metabolic acidosis due to inborn errors of metabolism	Diabetic ketoacidosis	Sepsis	Diabetes mellitus (infection or ketoacidosis)
	Sepsis		
Toxic overdose	Myocarditis, pericarditis	Diabetic ketoacidosis	Drug abuse/overdose
Sepsis		Collagen vascular disease	
Hemolytic uremic syndrome			

[a]Alcohol, amphetamines, aspirin, insecticide, iron, lead, phencyclidine, plants, etc.

testicular torsion, urolithiasis (typically with colicky pain and flank tenderness), and toxic ingestions (such as lead or iron).

The syndrome of functional abdominal pain should be considered among children with recurrent abdominal pain but should be a diagnosis of exclusion. The pain rarely occurs during sleep and has no particular associations with eating, exercise, or other activities. There may be a positive family history of GI symptoms or migraine. The child has normal growth and development, and the abdominal examination is unremarkable; occasionally, mild mid-abdominal tenderness, without involuntary guarding, is elicited.

Among postmenarchal females, life-threatening conditions within the reproductive tract that can cause abdominal pain include pelvic inflammatory disease (PID) with tuboovarian abscess and ruptured ectopic pregnancy. Although intrauterine pregnancy may be associated with lower abdominal pain, ectopic pregnancy should always be considered.

EVALUATION AND DECISION

The first priority is the stabilization of the seriously ill or injured child. Attention to airway, breathing, and circulation is critical because cardiorespiratory disease and shock may present with abdominal pain as the major complaint and abdominal emergencies left untreated or with deterioration can lead to cardiorespiratory failure. The next priority is to identify the child who requires immediate or potential surgical intervention, whether for a traumatic injury, appendicitis, intussusception, or other congenital or acquired lesions. Third, an effort is directed to diagnose any of the medical illnesses from among a large group of acute and chronic abdominal and extraabdominal inflammatory disorders that require emergency nonoperative management. Table 49.2 lists life-threatening causes of abdominal pain by age groups. Finally, the physician finds a host of self-limiting or nonspecific causes of abdominal pain, including nonorganic etiologies that must be dealt with effectively with the patient and family in the ED. The algorithm presented in this chapter for the approach to abdominal pain is shown in Figure 49.1.

Abdominal Pain in the Setting of Trauma

In the setting of major trauma, the physician should perform a rapid physical examination to distinguish superficial injury (e.g., soft-tissue or muscle contusion) from significant intraabdominal trauma (e.g., splenic hematoma or rupture, liver injury, or hollow viscus perforation). First, the *primary survey* should be performed, with the assessment of airway abnormalities,

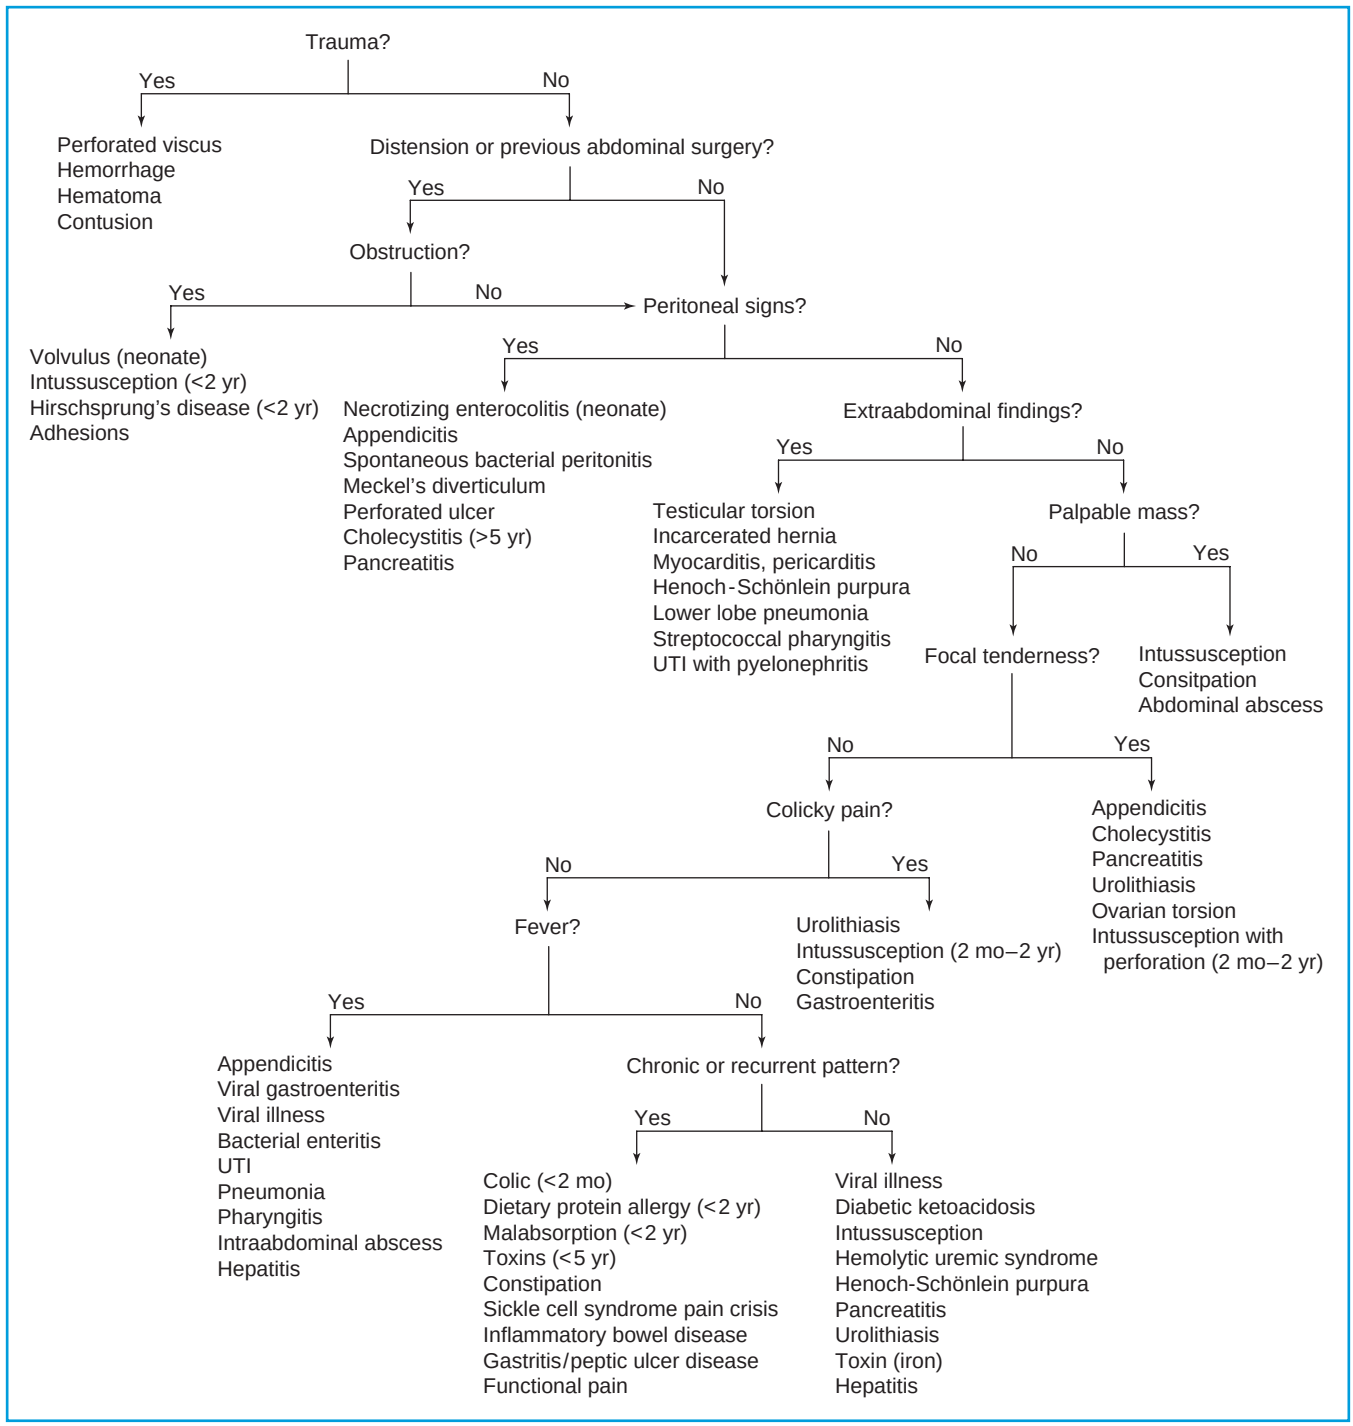

FIGURE 49.1 Acute abdominal pain (males and premenarchal females). UTI, urinary tract infection.

breathing pattern, and cardiovascular status (vital signs and clinical peripheral perfusion). As part of a complete *secondary survey*, a thorough physical examination is performed, with particular attention to neurologic status and observation for visible injuries. In children who are unstable at presentation and have obvious serious or multiple injuries or a high-risk mechanism of injury (penetrating injury, severe blunt trauma, fall from higher than 20 ft, ejection from a vehicle, impact velocity more than 35 miles per hour), a rapid, aggressive multidisciplinary workup is indicated in partnership with the surgical team.

A nasogastric tube should be placed if gastric distension is present. Children with localized and/or acute pain after blunt trauma may appear surprisingly well yet have significant solid organ or hollow viscus trauma. When significant intraabdominal injury is suspected in a stable patient, an urgent computed

tomography (CT) scan should be obtained to evaluate for solid organ injury. Lacerations of the liver and spleen are the most common intraabdominal injuries seen in children. Bedside ultrasound [*f*ocused *a*ssessment with *s*onography in *t*rauma (FAST)] may be used to evaluate for hemoperitoneum. The sensitivity of ultrasound for the detection of solid organ injury is low, and a significant proportion of children with liver and splenic lacerations have minimal intraabdominal fluid.

Considerations Among Children with Abdominal Distension or Prior Abdominal Surgery

A child who has had prior abdominal surgery and who presents with abdominal pain and vomiting should have abdominal radiographs, including flat and upright views, obtained to evaluate for obstruction. Bowel obstruction is most likely the result of adhesions in this population. Ileus, manifesting clinically with distension and absent bowel sounds, often accompanies surgical conditions, such as volvulus and intussusception, but may also be observed among children with sepsis, infectious enterocolitis, or pneumonia. Obstruction may present with isolated vomiting. A low-grade fever suggests an inflammatory process, including peritonitis.

A patient with episodic colicky pain with interposed quiet intervals, even in the absence of a "currant jelly" stool, makes one suspicious of intussusception or midgut volvulus. With intussusception, on plain radiographs, a paucity of bowel gas may be appreciated in the right lower abdomen and a mass may be visualized in the right mid to upper abdomen. The absence of these findings does not exclude the possibility of intussusception and, thus, in a patient with concerning history or physical examination findings, an ultrasound or contrast enema should be obtained. Although ultrasound has very good sensitivity in the diagnosis of intussusception, the test characteristics of the examination are operator dependant. A contrast enema can be used both to confirm the diagnosis and for therapeutic reduction.

An incarcerated hernia is a common cause of bowel obstruction in infants and young children. Inguinal hernias may incidentally incarcerate during acute illnesses in young, crying infants and may be a cause of abdominal obstruction. Signs of partial or complete obstruction with peritonitis indicate a perforated viscus from intussusception, volvulus, or, occasionally, appendicitis or Hirschsprung's disease. An upper GI radiographic series should be performed if malrotation is suspected.

Abdominal Pain Associated with Peritoneal Signs

Rebound tenderness (including tenderness to percussion) or guarding suggests peritoneal inflammation. Children with peritonitis will often avoid motion and keep their hips flexed to relieve tension on the abdominal musculature. The abdomen may be distended, with decreased or absent bowel sounds. In neonates and young infants, abdominal tenderness, which is associated with peritoneal findings or abdominal distension with or without emesis, should raise suspicion for necrotizing enterocolitis. Systemic signs such as temperature instability, apnea, and lethargy may be present. The presentation of a child with appendicitis may vary widely, and the clinical signs and symptoms depend upon the stage of disease. Early in the course of illness children will most often complain of diffuse, nonspecific, periumbilical abdominal pain, nausea, and anorexia. As disease progresses, vomiting, fever, and migration of pain to the right lower abdomen are common findings. Ultrasound can be used to confirm the diagnosis of appendicitis, but the diagnosis cannot be excluded if the appendix is not well visualized. CT imaging has excellent test characteristics in the diagnosis of appendicitis; however, the risk of radiation must be considered. Decision rules such as the Pediatric Appendicitis Score, which utilize various historical factors, physical examination findings, and laboratory results such as peripheral white blood cell count, may be used to assess the need for imaging and/or hospitalization.

Peritonitis in a child with nephrotic syndrome may be due to spontaneous bacterial peritonitis. Pain localized to the epigastrium can be due to gastritis; however, the presence of peritonitis should raise suspicion for a perforated ulcer. Cholecystitis and pancreatitis may also produce peritonitis, with abdominal pain localized to the epigastrium or right upper abdomen. A child with Meckel's diverticulum will usually present with painless rectal bleeding; however, abdominal pain may occur because of mucosal ulceration from ectopic gastric mucosa.

Extraabdominal Conditions Associated with Acute Abdominal Pain

A thorough physical examination is required to exclude extraabdominal conditions that can be associated with abdominal pain. On auscultation of the chest, localized, decreased, or tubular breath sounds or adventitious sounds (i.e., crackles) suggest pneumonia, not an uncommon cause of abdominal pain in the febrile infant. Children with "occult pneumonia" may have a normal respiratory rate and no detectable ausculatory findings on physical examination. Urinary symptoms may occur with pyelonephritis, and polydipsia with polyuria may herald the onset of diabetes mellitus with abdominal pain from ketoacidosis.

In males, a complete genitourinary examination should be performed, as testicular torsion and an incarcerated inguinal hernia will often produce pain referred to the abdomen. Infectious mononucleosis and streptococcal pharyngitis may be associated with diffuse abdominal pain. The presence of tachycardia, a friction rub or gallop, or hepatosplenomegaly may suggest a cardiac etiology such as pericarditis or myocarditis. The diagnosis of Henoch-Schönlein purpura can be made if abdominal pain is associated with arthritis, along with a classic petechial or purpural rash of the lower extremities.

Palpable Mass

A palpable mass on the left side of the abdomen may be appreciated in a child with constipation. The diagnosis of constipation should be made on clinical grounds, and radiography should be reserved for children in whom there is concern for

obstruction or if the diagnosis is in doubt. A detailed history should include questions regarding the frequency of bowel movements, associated straining, and whether the stool is hard. In suspected constipation, a rectal examination may be helpful to confirm the presence of stool in the rectal vault. A sausage-shaped mass in the right mid-abdomen is sometimes appreciated in children with intussusception. Less commonly, an abdominal abscess or neoplasm (commonly of renal origin) may be palpated.

Focal Tenderness

A child with a history of periumbilical pain that radiates to the right lower abdomen, fever, and vomiting should have high suspicion for the diagnosis of appendicitis. Typically, the child with appendicitis will have focal tenderness in the right lower quadrant; however, diffuse tenderness with involuntary guarding may be seen later in the course. In younger children, it is critical to assess for an atypical presentation of appendicitis. The diagnosis of ovarian torsion should be considered in females with acute onset of lower abdominal pain and vomiting. Epigastric tenderness may be observed in children with gastritis or pancreatitis. Right upper quadrant tenderness may be appreciated among children with hepatitis or cholecystitis. Jaundice or scleral icterus may be present. Pain or limitation of inspiration during palpation of the right upper quadrant (Murphy's sign) may be elicited in patients with acute cholecystitis. Focal tenderness in the flank region suggests pyelonephritis or urolithiasis.

Colicky Pain

Intussusception should be considered in a child with colicky abdominal pain, particularly if younger than 2 years. On examination, a sausage-shaped mass may be palpated in the right upper abdomen with ileocolic intussusception. Usually a "lead" point for an intussusception is seen in older children (e.g., mesenteric adenitis, lymphoma, polyp, cystic fibrosis, anaphylactoid purpura). Abdominal radiographs may be useful in confirming obstruction or the presence of a mass; a contrast enema is indicated urgently if there is a high suspicion for intussusception. In low or moderate probability settings, an ultrasound may yield preliminary findings that rule out the need for a therapeutic study for intussusception. Flank tenderness and/or gross or microscopic hematuria may suggest urolithiasis. Gastroenteritis and constipation can be associated with colicky abdominal pain, but these diagnoses should be made after more serious conditions have been excluded.

Fever

Although most children with appendicitis will have peritoneal signs or focal tenderness, this diagnosis must be considered in any child with fever and abdominal pain. Children with gastroenteritis may have crampy abdominal pain and diarrhea. Although viral pathogens such as rotavirus or adenovirus commonly cause gastroenteritis, the presence of fever, bloody stool, or severe abdominal pain may point to a bacterial etiology. A thorough physical examination should be performed to assess for extraabdominal conditions such as pharyngitis, UTI, and pneumonia. Other conditions associated with abdominal pain and fever are shown in Fig. 49.1

Chronic or Recurrent Pattern

Chronic abdominal pain may occur as a result of many of the conditions listed in Table 49.1. When abdominal pain is recurrent or chronic in infants younger than 3 months and is not accompanied by other findings or symptoms, the physician often makes a diagnosis of "colic" (see Chapter 16) or, based on history, of gastroesophageal reflux. However, several causes of recurrent abdominal pain in infants must be considered. These include recurrent intussusception; malrotation with intermittent volvulus; milk allergy syndrome; and various malabsorptive diseases such as cystic fibrosis, celiac disease, and lactase deficiency.

Abdominal pain and pallor can occur rarely in neoplasia, as with bleeding into an abdominal Wilms' tumor, hepatoma, or neuroblastoma. The presence of pallor and pain also raises the possibility of sickling hemoglobinopathies, with the development of a vasoocclusive crisis, a splenic sequestration, or even an aplastic crisis. Jaundice may be observed in the child with hemolysis or with hepatitis. At times, an intraabdominal vasculitis that causes pain may precede the rash of Henoch-Schönlein purpura or be a prominent finding with Kawasaki disease.

Chronic abdominal pain in the adolescents may be due to inflammatory bowel disease. In these children, inflammatory markers such as erythrocyte sedimentation rate and C-reactive protein levels are commonly elevated. In postpubertal females, dysmenorrhea, endometriosis, chronic PID, chronic UTI, or gallbladder disease can be associated with chronic or recurrent abdominal pain. It is particularly difficult to establish the cause of chronic pain when dealing with adolescents on an episodic basis, making appropriate referral essential.

Functional abdominal pain may be considered only after exclusion of other conditions. Patients will most often have a long-standing history of episodes of abdominal pain and will have no or minimal tenderness on abdominal examination. The presence of focal tenderness, rebound, guarding, or fever should prompt consideration of alternative diagnoses. The emergency physician's task is to allay any fears of serious organic disease during the acute episode. Because the long-term solution to a functional complaint is generally not in the realm of the ED, the physician should explain all the organic illnesses that the pain is *not* believed to be, and suggest a nonorganic cause of the pain. The emergency physician should provide an avenue for continued supportive follow-up through referral to the primary physician.

Additional Considerations in the Postpubertal Female with Acute Abdominal Pain

Among postpubertal females, pregnancy and complications of pregnancy must be considered (Fig. 49.2). A menstrual history and ascertainment of sexual activity are essential, and a urine β-hCG sample should be obtained in all females in whom pregnancy is a possibility.

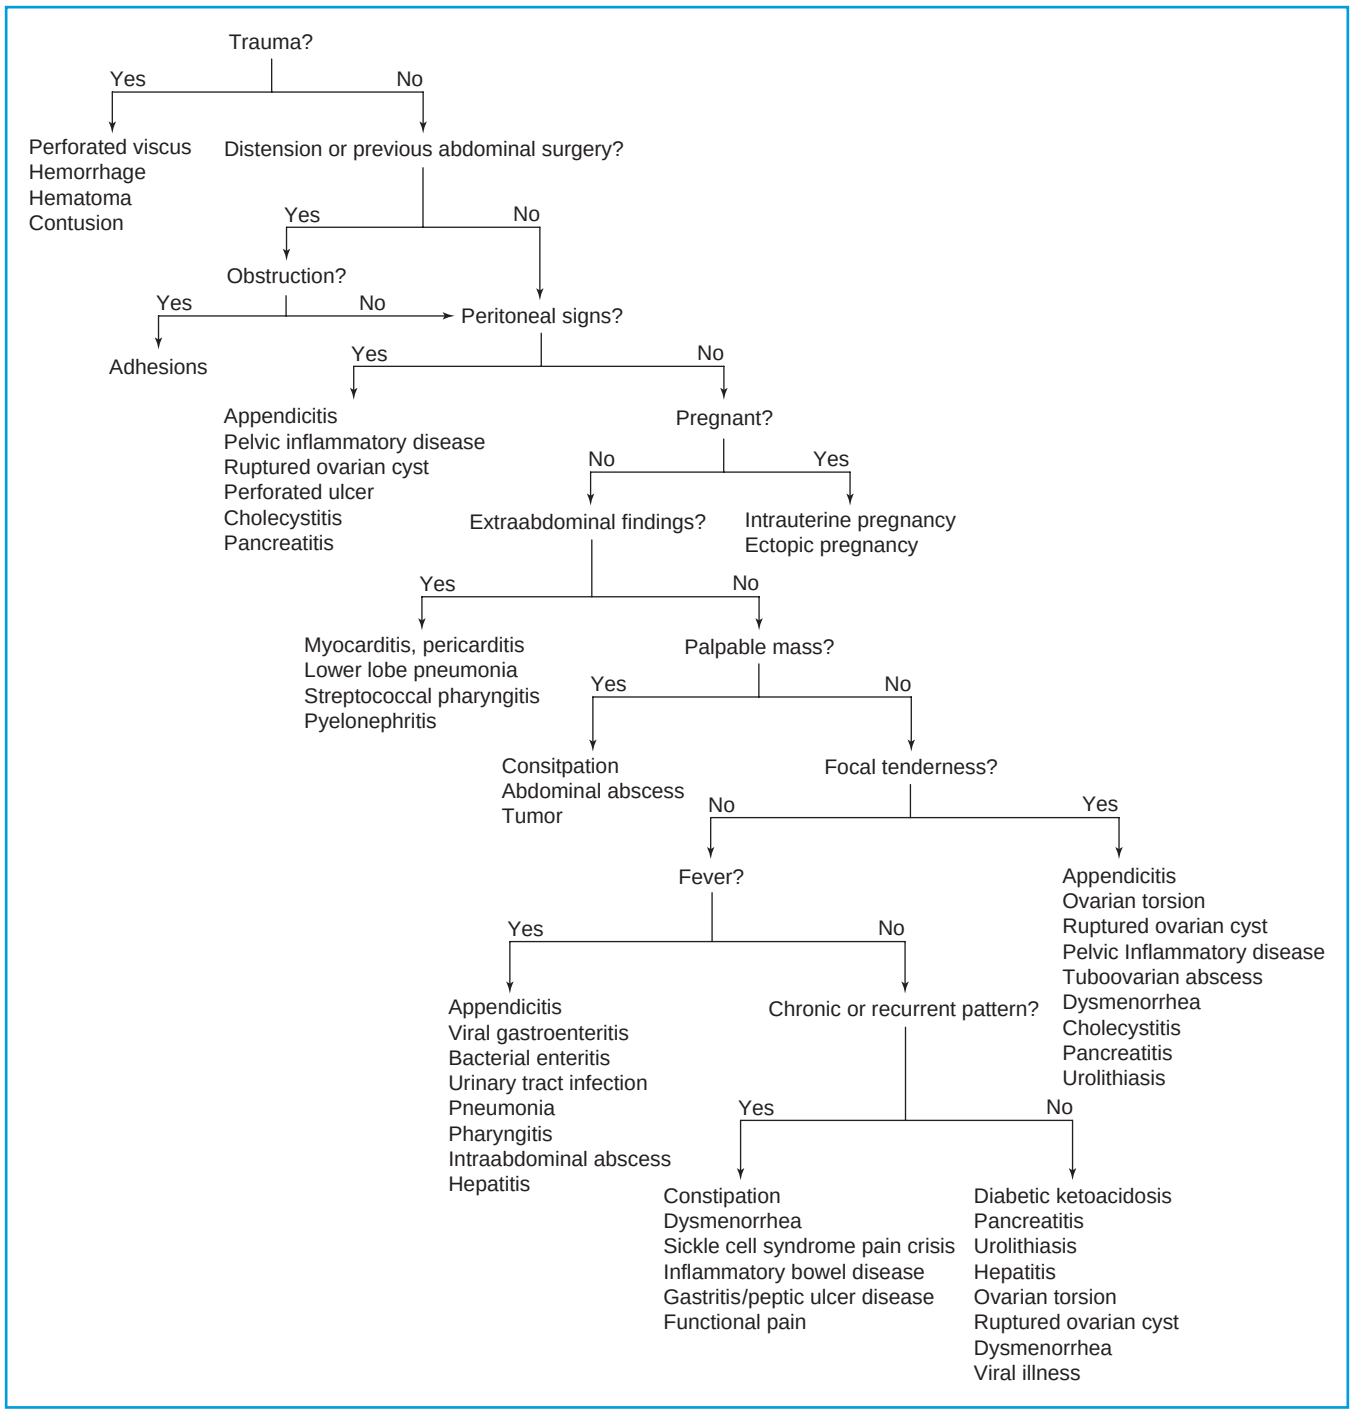

FIGURE 49.2 Acute abdominal pain (postmenarchal female).

The diagnosis of ectopic pregnancy must be considered among women with lower abdominal pain occurring within the first trimester of pregnancy (see Chapter 90). Vaginal bleeding occurs in most patients with ectopic pregnancy but is not always present. A transvaginal or transabdominal ultrasound should be obtained. The diagnosis of ectopic pregnancy is not usually confirmed by ultrasound; however, the presence of an intrauterine gestational sac is reassuring and argues against the diagnosis of ectopic pregnancy. A quantitative serum β-hCG sample should be obtained; it may need to be repeated within 48 to 72 hours if the diagnosis remains uncertain. In addition, RhoD immune globulin (RhoGAM) should be administered to Rh-negative women. Although the diagnosis of ectopic pregnancy should be considered in all pregnant women, crampy lower abdominal pain is commonly reported among women with intrauterine pregnancy.

Rupture of an ovarian cyst is the most common cause of lower abdominal pain in postpubertal women; however, the diagnosis can be made only after the exclusion of more serious conditions. An ultrasound should be obtained if focal right or left lower abdominal tenderness is present on physical examination to evaluate for ovarian torsion and tuboovarian abscess. A pelvic examination is required in any sexually active female with abdominal pain in whom a sexually transmitted disease cannot be excluded. Cervical discharge or tenderness suggests the diagnosis of PID. Appropriate cultures and microscopic examinations for sexually transmitted diseases are indicated and presumptive antimicrobial treatment should be initiated.

Other, nongynecologic etiologies of abdominal pain, including appendicitis, must also be considered. Chronic or recurrent abdominal pain may be due to dysmenorrhea or endometriosis. Laparoscopy may be required to confirm the diagnosis.

SUMMARY

Abdominal pain is one of the most common complaints of children who seek treatment in the ED. An algorithmic approach to the child with acute abdominal pain should be performed, with a focus on traumatic and surgical conditions. Generation of a differential diagnosis should take into consideration the age of the child.

When evaluating a child with abdominal pain, the first priority should be the stabilization of the seriously ill or injured child. The next priority is to identify the child who requires immediate or potential surgical intervention, whether for a traumatic injury, appendicitis, intussusception, or other congenital conditions. Finally, a thorough examination should be conducted to determine the etiology of abdominal pain. Laboratory evaluations and radiographic studies may be used selectively to support or refute specific differential diagnoses generated by the history and physical examination.

CHAPTER 50 ■ PAIN—BACK

HOWARD M. CORNELI, MD

Back pain has been found to be more common in children than was once thought, but few children see a physician for this complaint. Although back pain is seen less frequently in children than in adults, it is also more likely to signify pathology, especially before adolescence. The evaluation of back pain may be difficult because young children have less ability to describe their pain and even to localize it. Children are subject to conditions causing back pain that are seldom seen in adults, and the common adult causes are uncommon in children. Physicians usually do not see large numbers of children with back pain. Their evaluation, if sometimes challenging, is often important.

DIFFERENTIAL DIAGNOSIS

The causes of back pain are ubiquitous, but this does not mean that children with back pain cannot be diagnosed or that the evaluation is typically difficult or unrevealing. The more likely childhood causes can be divided into a few categories (Tables 50.1 and 50.2).

A history of trauma is important in evaluating back pain but may be misleading in young children whose frequent minor injuries may be seen by the parents as the trigger for a problem that is, in fact, nontraumatic. On the other hand, adolescents with overuse injuries may or may not identify trauma. High-force trauma (e.g., in a car crash) can cause severe back injuries, and careful evaluation for back pain and tenderness is critical in multiple trauma patients, who may have many more obvious injuries. Spinal trauma is covered in Chapter 116, and cervical spine injuries are covered in Chapter 115.

Less severe trauma is common in childhood. Typical falls can produce vertebral compression fractures, which are more common in children. Radicular pain may develop and may occasionally be severe. Contusion is common if bruising and tenderness accompany a history of a direct blow to the back. If this is not over the kidney or spine, simple contusion may be an appropriate diagnosis. Pain after lifting, work, or sports is also common. Although the signs of muscular back strain and lumbar disc herniation are similar to those seen in adults, these conditions occur less commonly in children. Spondylolysis, in contrast, is more common in young people, especially among adolescent athletes. This is a stress fracture or discontinuity of the pars interarticularis. When the vertebra slips forward on the one beneath, the resulting condition is called spondylolisthesis. Either condition can cause back pain, most often in the lower lumbar area or at the L5 to S1 level. These lesions often present during the adolescent growth spurt. The condition is believed to be associated with overuse, especially hyperflexion. Spondylolysis often presents with subacute or recurring pain, but pain may develop acutely in some cases. Lumbar flexion and extension may be limited and, especially in extension, painful. Another condition linked to overuse, Scheuermann's disease, is seen in adolescents as anterior wedging of several vertebrae, especially in the thoracic spine. This condition is painful in about half of those affected. Although disc herniation is much less common in childhood, it does develop in adolescents, especially with activities such as weight lifting. These activities can also cause posterior avulsion fractures of the vertebral apophysis, which displace into the spinal canal producing symptoms similar to disc herniation.

Rare but dangerous causes of back pain deserve special vigilance in children (Table 50.3). A spinal epidural hematoma may follow a fall or blow, sometimes presenting some days later, or it may arise spontaneously, especially in patients with bleeding disorders or those who are receiving anticoagulant therapy. Back pain may only briefly precede symptoms of spinal cord compression. Spinal epidural abscess can present with back pain, low-grade fever, and signs of spinal cord compression. Percussion usually elicits spinal tenderness. Transverse myelitis may be postinfectious, and back pain may precede weakness by as much as 1 to 2 days. These rare but severe conditions underscore the need for a careful neurologic examination in children with back pain. Appreciation of the signs of spinal cord compromise should lead to emergent imaging and neurosurgical consultation.

The infectious causes of back pain are many, yet infection in the back itself can be difficult to diagnose. The symptoms and signs of infection, as well as laboratory markers of inflammation, may be absent. Vertebral osteomyelitis and discitis may present with subtle symptoms in young children, in whom these are the most commonly seen symptoms. Parents may only note refusal to stand or sit. Back pain is often not obvious, and limp may point away from the back. It is advisable to palpate and percuss the back in any child with limp or apparent leg pain. Iliac osteomyelitis and sacroiliac joint infection are seen at times in childhood. Osteomyelitis of the ribs is rare.

Paraspinal or psoas abscess, and pyomyositis in the paraspinal or pelvic muscles, may present as back pain, which may sometimes be severe. Rare spinal infections include spinal tuberculosis (Pott's disease) and brucellosis, in which small vertebral abscesses may accompany lymphadenopathy and hepatosplenomegaly.

Common childhood infections associated with back pain include, of course, urinary tract infection (UTI), which may cause flank pain with or without upper tract involvement, and pneumonia or pleurisy, which present with back pain in some cases. Myalgias and generalized backache may be seen in influenza, mononucleosis, streptococcal pharyngitis, and other

TABLE 50.1

CAUSES OF BACK PAIN

I. *Traumatic, posttraumatic, or injury-related*
  A. Compression fracture

COMMON IMPORTANT CAUSES OF BACK PAIN IN CHILDREN

I. Traumatic
  A. Compression fracture
  B. Spondylolysis/spondylolisthesis
II. Infectious
  A. Discitis
  B. Vertebral osteomyelitis
  C. Urinary tract infection
  D. Pneumonia
III. Neoplastic
  A. Malignant tumors
  B. Benign tumors

generalized infections. Parents occasionally identify meningitis primarily as back pain, especially in an infant; the parent may note that it hurts the child to move the back. Because infections in young children sometimes lack the more obvious symptoms seen in older patients, associated back pain may be more prominent. The young child with a UTI often shows no urinary symptoms as such. Pneumonia may be clinically occult, with little cough and few findings on auscultation.

Abdominal conditions that may present with back pain or flank tenderness include pancreatitis, in which a steady, penetrating pain radiates prominently to the back; gallbladder disease, in which pain may radiate to the back; and appendicitis, especially in a retrocecal location. Ovarian pain, as with torsion or pelvic inflammatory disease, may at times radiate to the back, and intestinal pain, particularly that because of constipation, sometimes manifests as back pain. Kidney stones in children will usually cause typical renal colic and hematuria on urinalysis, but atypical cases with infection or obstruction may present a diagnostic challenge.

Collagen vascular diseases that cause back pain include ankylosing spondylitis and juvenile idiopathic (rheumatoid) arthritis with sacroiliitis. Both of these conditions more often affect boys older than 8 years. The back is notably stiff to flexion, especially in the lumbar region. Spondylitis may also be seen in association with reactive arthritis, regional enteritis, ulcerative colitis, and psoriasis.

TABLE 50.3

SERIOUS CAUSES OF BACK PAIN IN CHILDREN

I. Traumatic
  A. Spondylolisthesis
  B. Spinal epidural hematoma
II. Infectious
  A. Discitis
  B. Vertebral osteomyelitis
  C. Meningitis
  D. Transverse myelitis
  E. Spinal epidural abscess
III. Neoplastic
  A. Malignant tumors
  B. Benign tumors
  C. Leukemia/lymphoma

A host of neoplastic causes, both benign and malignant, may present with back pain (Table 50.1). These are not so rare that they can be ignored in an evaluation of back pain. Leukemia, and especially lymphoma, may present as back pain. Ewing sarcoma may mimic infection, with fever, leukocytosis, and rarefaction of bone on radiographs.

Sickle cell disease and other hemoglobinopathies may cause back pain. Children with sickle cell disease experience vasoocclusive crises in the spine and may be prone to vertebral osteomyelitis. Osteoporosis and osteopenia due to many causes, including chronic bed rest, paraplegia, and osteogenesis imperfecta, will make compression fractures possible after minor or minimal trauma. Dissecting aortic aneurysm has been reported rarely in children, usually with hypertension or with Marfan's syndrome and other connective tissue disorders.

Table 50.1 lists other miscellaneous causes of back pain. Several diagnoses for childhood back pain should be made cautiously or avoided altogether. Growing pains do not affect the back. Idiopathic scoliosis demonstrates back pain only in the most severe cases. Muscle strain is less common in children, especially before adolescence, and this diagnosis should be made only after other causes are excluded. An objective link between back pain and heavy school bags has not been demonstrated, although some children who perceive their loads as heavy may complain of pain. Chronic low back pain has been shown to have emotional and perceptual components in children, but psychogenic pain is less common in children than in adults and acute pain seldom merits this diagnosis. A psychological component may, of course, be suggested by chronic pain undiagnosed after thorough evaluation, a cheerful affect when describing symptoms, disproportional school absence, or unusual family dynamics. Even if suspicion of psychogenic pain exists, a careful initial investigation should be undertaken to exclude organic causes.

EVALUATION AND DECISION

Particular signs and symptoms may be suggestive. Pain at the end of the day, or worsened by exercise, is more likely to be musculoskeletal. Pain with prolonged standing or sitting may be due to vertebral causes, and pain with cough or sneeze can suggest disc disease or related lesions. Pain on arising may signify collagen vascular disease. Night pain may suggest tumor, and if relieved by nonsteroidal antiinflammatory drugs, suggest osteoid osteoma or osteoblastoma. Pain and tenderness over the spine are often skeletal, but such findings off the midline may be more likely muscular. Limp with back pain is worrisome. Relief with traction (as when a parent lifts the child under the arms) can suggest disc or vertebral pain, as in discitis, as can increased pain on spinal flexion or compression (e.g., during diaper changes).

Constitutional symptoms such as fever, diminished appetite, and weight loss suggest serious disease. Pain causing new or progressive kyphosis, scoliosis, or gait disturbance is almost always due to pathology. Sciatica, especially in the adolescent athlete or laborer, may signify disc herniation. Although chronic occasional pain that does not limit activity may turn out to be functional, pain that endures or recurs is often concerning, and worsening pain should be worrisome. Finally, be aware that parents may sometimes feel an infant or a toddler has back pain when adjoining areas are the true source (as in abdominal pain, hip pain, limb pain, or neck pain).

Age may be suggestive of cause. Discitis and osteomyelitis are most common in preschool children. Children older than 10 to 12 years are more prone to overuse injuries, such as spondylolysis.

Fever is likely, of course, to signify infection, but it can also be seen with neoplastic and collagen vascular diseases. Even more important, children with musculoskeletal infections can be afebrile at presentation in a significant proportion of cases.

The most important task in children with back pain is to rule out any sign of neurologic involvement (Fig. 50.1). Conditions that affect the spinal cord are seen often enough in children and their gravity should be borne in mind throughout the evaluation. The history should be reviewed for limb weakness or disuse or for a change in function of the bowel or bladder. Any suspicion of spinal cord involvement warrants prompt neurosurgical consultation.

Certain injury histories suggest specific diagnoses. Axial loading of the spine, as when a child lands in a seated position after a fall, is often associated with compression fractures of the vertebrae. The history of position in falls and collisions, however, is unreliable, and compression fracture is common in children who believe they landed supine.

A history should be sought of sports, lifting, or work-related exposures to back stress. Gymnasts, dancers, weight lifters, football players, and participants in similar sports often hyperextend their back. Unfortunately, not all children who develop stress injuries are engaged in easily identified activities. As excessive competition in sports is introduced to younger children, sports injuries may be seen earlier and more commonly in childhood. Concern also exists that trends to obesity and a sedentary lifestyle may increase back complaints in children.

A history may reveal an underlying disease, chronic inactivity (in the bedridden child), or drug therapy that may cause osteoporosis, which increases the risk of fracture. A review of systems, social history, and family history may reveal helpful clues. Change in posture or gait is important, as is any history of overuse. Headache might be worrisome, and weakness, numbness, or paresthesias would be critical. Family history may be positive in ankylosing spondylitis and related conditions. A family history of back pain can also be revealing in cases of functional pain. School performance and school absence can be relevant, as may social and family stress.

Chronic back pain may be seen in collagen vascular conditions, Scheuermann's disease, or a developmental defect in the spine, but tumors may also progress slowly with chronic back pain being the only noted symptom. On the other hand, the acute onset of pain or neurologic symptoms can be the first signs of a chronic (but expanding) mass lesion.

Physical examination must document spinal cord function in any child with back pain. This includes the evaluation of muscle bulk, tone, and strength; sensitivity to light pinprick as well as light touch; the deep tendon reflexes and Babinski reflex; and anal tone, the anal contracture reflex, and, in boys, the cremasteric reflex. If any neurologic compromise is suspected, additional sensory examination of proprioception, heat, and cold is warranted.

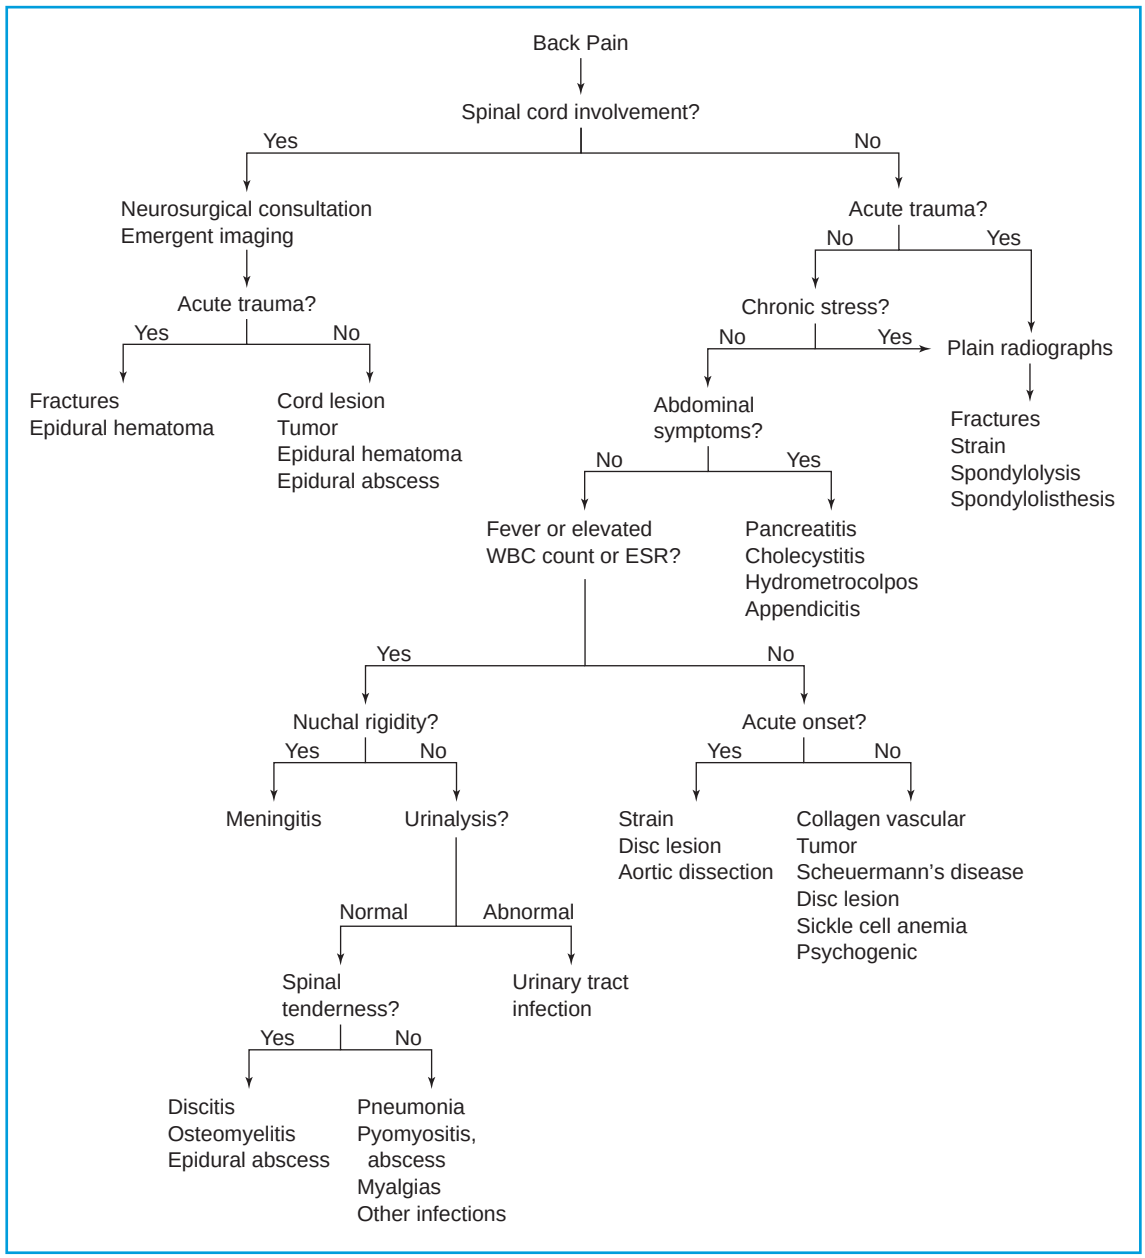

FIGURE 50.1 Approach to the diagnosis of back pain. WBC, white blood cell; ESR, erythrocyte sedimentation rate.

The physical examination should start with the appearance of the spine: unusual kyphosis, lordosis, or scoliosis should be noted. Excessive lumbar lordosis is associated with spondylolysis, spondylolisthesis, disc herniation, and muscular or ligamentous back pain. Pelvic tilt on single-leg standing suggests hip abductor dysfunction. After careful inspection of gait and posture, the examination should move on to palpation and percussion of the spine, flank, and ribs, sacroiliac and paraspinal regions; rotation of each hip; straight-leg raising and evaluation of hamstring tightness; and spinal mobility in rotation, flexion, and extension. Pain on flexion is more common with anterior lesions and pain on extension or hyperextension with posterior lesions. The examiner can provoke extension pain by providing slight resistance as the patient stands from toe touching, and hyperextension may be increased by gentle downward pressure on the shoulders as the patient slumps the shoulders back and the abdomen forward; this maneuver, repeated as the patient stands on one leg and then the other, is especially useful to detect spondylolysis. Spondylolysis should not produce spine tenderness or gait changes but spondylolisthesis may. Chest and abdominal examinations should also be performed, as should rectal and genital inspection. (Hydrometrocolpos has been reported as a cause of back pain, even in premenarchal girls.)

The cause of back pain may remain obscure even after a thorough history and physical examination. In children, it is often appropriate to seek consultation with a radiologist.

Imaging is more often revealing in children than in adults but still must be used selectively; ordering radiographs in all cases of back pain will have a low yield.

Midline pain, tenderness, or pain with motion should lead to radiographic studies, particularly after childhood trauma or falls. Exacerbation by activity, and persistence or progression of pain, also usually warrants imaging. Plain radiographs are almost always obtained first. Plain images are often sufficient to reveal compression fracture, bony tumor, Scheuermann's disease, and spondylolisthesis and may be revealing in spondylolysis and ongoing cases of discitis or osteomyelitis. Oblique views, although helpful when spondylolysis is suspected, may not be as sensitive as single photon emission computed tomography (SPECT). Bone scan has a clear role in finding discitis and vertebral osteomyelitis, and SPECT may enhance accuracy here as well.

Magnetic resonance imaging (MRI) is increasingly used in the evaluation of back pain. Besides other advantages, it defines almost all spine lesions. Note, though, that its most typical indication in adults, disc disease, is uncommon in children. The issues of both expense and sedation should limit its too-ready use. MRI is clearly indicated, however, if spinal cord pathology is suspected and is often useful when other imaging techniques prove inconclusive.

Computed tomography (CT) remains a useful method for emergent evaluation of trauma, in cases of avulsion fracture, or when lesions outside the spine, including kidney stones, are suspected. CT is limited, however, in its ability to delineate densities within the spinal canal and to study the alignment of structures in the vertical axis. MRI overcomes these limitations and provides highly detailed longitudinal images of the spine, the canal, the cord, and other tissues.

Plain chest radiography is indicated if pneumonia is considered. Radiolabeled white blood cell scans may detect soft-tissue infection or abscess. Ultrasound may outline ovarian lesions and abdominal tumors such as neuroblastoma.

Laboratory investigations may not be helpful in traumatic back pain and should be directed by the presentation otherwise. Urinalysis and urine culture will commonly be undertaken. A complete blood count (CBC), C-reactive protein, and sedimentation rate may help if infectious or inflammatory disease is suspected. Blood cultures sometimes give positive results in osteomyelitis and discitis. If a neoplasm is considered, obtaining a CBC, acute-phase reactants, uric acid, and lactate dehydrogenase levels may be helpful, along with urine catecholamine measurement if a neuroblastoma is possible. Sickle cell preparations or hemoglobin electrophoresis may be indicated. Pancreatic enzymes and biliary studies may rule out related pathology. Other evaluations may be used selectively.

The treatment of the varying causes of back pain is discussed in specific sections of this book. Negative results after appropriate diagnostic evaluation may warrant a trial of empiric therapy with nonsteroidal antiinflammatory medication, but close follow-up should be arranged.

In summary, because back pain is less common in children than in adults, and because it more often implies significant pathology, it deserves and must receive a careful evaluation.

CHAPTER 51 ■ PAIN—CHEST

ROBYN L. BYER, MD

The complaint of chest pain rarely represents a life-threatening emergency in children, in contrast to the same complaint in adults. Although heart disease is an uncommon source of chest pain in children, the fear of a cardiac origin for the pain may evoke anxiety in the child or in the parents. There are a wide variety of etiologies for chest pain including diseases of the respiratory, cardiac, gastrointestinal (GI), neurologic, psychiatric, and musculoskeletal systems; however, it is most commonly due to idiopathic noncardiac origins. Chest pain accounts for approximately 0.6% of all pediatric emergency department (ED) visits and affects boys and girls equally. Clinicians need to take a careful approach to the patient even in the pediatric setting. This chapter first briefly reviews the pathophysiology of chest pain, then outlines the differential diagnosis in children, and finally presents the evaluation, as appropriate in the ED.

PATHOPHYSIOLOGY

To understand the possible origins of chest pain or discomfort, it is important to review how this sensation is transmitted. Musculoskeletal pain is produced by irritation of these tissues and is transmitted through the sensory nerves. The stimulus is carried through the nerves in the dermatomal or intercostal distribution to the dorsal root ganglia, up the spinal afferents and into the central nervous system. This local, peripheral, sharp pain can also be produced by primary dorsal root irritation in the spine. Because of overlap of nerve distribution, pain may be sensed in locations distal to the irritation. For example, the third and fourth cervical nerves evoke pain as far caudally as the nipple line of the chest.

Tracheobronchial pain is transmitted by vagal afferents in the large bronchi and trachea to fibers in the cervical spinal column. Dull, aching, or sharp pain is felt in the anterior chest or neck. The irritation or sensation of cough is transmitted in a similar fashion. Pleural pain arises in the pain-sensitive parietal pleura and then travels through the intercostal nerves in the chest wall, giving rise to sharp, well-localized pain. The visceral pleura is insensitive to pain. The intercostal or phrenic nerves transmit diaphragmatic pain. Peripheral diaphragmatic irritation may cause local chest wall pain because of the intercostal innervation. Central diaphragmatic stimulation travels by the phrenic nerve, with the pain referred to the shoulder of the affected side.

The esophagus appears to be more pain-sensitive in its proximal portion. Pain is transmitted by afferents to corresponding spinal segments, with resultant anterior chest or neck pain. The pericardium is innervated by portions of the phrenic, vagal, and recurrent laryngeal nerves, as well as by the esophageal plexus. This appears to give rise to various sensations, including chest or abdominal pain, dull pressure, and even referred angina-like pain.

Other mediastinal structures, such as the aorta, have pain fibers in the adventitia of the vessel wall. They transmit pain through the thoracic sympathetic chain to the spinal dorsal roots, giving rise to sharp, and variably localized chest pain. Cardiac pain is likely transmitted by a number of routes, including the thoracic sympathetic chain and the cardiac nerves through the cervical and stellate ganglia. It has been proposed that pain arises from abnormal ventricular wall movement and stimulation of the pericardial pain fibers. These routes account for the sensation of cardiac chest pain as pressure or crushing pain substernally or as sharp pain in the shoulder, neck, or arm.

DIFFERENTIAL DIAGNOSIS

A differential diagnosis of chest pain in children is included in Table 51.1. In the case of trauma, cardiac or pulmonary compromise may arise from direct injury to the heart, great vessels, or lung (see Chapter 118). Most chest pain in the nontraumatized child is caused by acute respiratory disease, musculoskeletal injury, anxiety, or inflammation (Table 51.2). Often, the physician does not make a causative diagnosis of the chest pain and calls it nonspecific or idiopathic in origin. Occasionally, this idiopathic chest pain may be unrecognized organic disease, such as gastroesophageal reflux disease. Chest pain in children usually occurs without associated cardiorespiratory signs or symptoms, often as an acute or chronic problem. By the time of the ED visit, frequently, the pain has resolved. Although much less frequent, chest pain in association with cardiorespiratory distress demands immediate attention. Table 51.3 lists the life-threatening causes of chest pain by disease and mechanisms for decompensation. Chest pain in the dyspneic or cyanotic patient most often stems from a respiratory problem, such as pneumonia, asthma, pleurisy, or pneumothorax. Rarely does severe chest pain in an acutely ill child result from myocardial infarction (MI) due to aberrant coronary vessels, cocaine abuse, Kawasaki disease, hyperlipidemia, or other underlying cardiac diseases (aortic stenosis, an acute arrhythmia, or pericardial disease). Every individual evaluation must be started, however, with a broad differential diagnosis in mind to ensure proper diagnosis and management of the child with chest pain.

A cardiac cause for chest pain has been reported in up to 6% of pediatric patients, but this includes both those presenting to an emergency department and those evaluated in a cardiology clinic; the incidence in ED patients is likely to be lower.

TABLE 51.3

CAUSES OF CHEST PAIN

I. **Musculoskeletal/Neural**
- A. Muscle
  - Trauma—contusions, lacerations, strain
  - Infection—myositis
- B. Breast
  - Physiologic (fullness during menses or pregnancy)
  - Mastitis
  - Fibrocystic disease
  - Tumor (adenoma, other)
  - Gynecomastia
- C. Bone
  - Trauma—contusions, rib fractures
  - Osteitis, osteomyelitis
  - Costochondritis, Tietze syndrome
  - Tumor
  - Slipping rib syndrome
- D. Intercostal nerve
  - Neuritis—zoster, trauma
  - Toxin
- E. Dorsal root
  - Trauma
  - Radiculitis—viral, postviral
  - Spinal disease—scoliosis

II. **Tracheobronchial (Proximal Bronchi)**
- A. Foreign body
- B. Infection
  - Tracheitis
  - Bronchitis
  - Cystic fibrosis
- C. Asthma

III. **Pulmonary/Pleural/Diaphram**
- A. Trauma—penetrating and blunt
- B. Pleurisy/pleurodynia—viral, mycobacterial
- C. Pneumonia
- D. Cystic fibrosis
- E. Pneumothorax, hemothorax, chylothorax
- F. Empyema
- G. Pneumomediastinum
- H. Malignancy/mediastinal mass
- I. Postpericardiotomy syndrome
- J. Pulmonary embolus/infarction
- K. Vasoocclusive crisis (sickle cell disease)
- L. Tumor
- M. Subphrenic abscess/hepatic abscess
- N. Fitz-Hugh-Curtis syndrome

IV. **Gastrointestinal**
- A. Esophageal
  - Foreign body
  - Caustic ingestion
  - Gastroesophageal reflux/esophagitis
  - Esophageal spasms
  - Infection—*Candida*
  - Esophageal rupture/tear
- B. Hiatal hernia
- C. Gastritis/peptic ulcer disease
- D. Cholecystitis
- E. Pancreatitis

V. **Cardiac (angina, pericardial, aortic)**
- A. Angina—coronary insufficiency,[a] anomalous vessels, pulmonary hypertension
- B. Hypertrophic cardiomyopathy
- C. Aortic stenosis, pulmonary stenosis
- D. Asymmetric septal hypertrophy
- E. Pericardial defects and effusions, pericarditis
- F. Acute arrhythmias[a]
- G. Myocarditis[a]
- H. Aortic aneurysm—idiopathic, syphilitic, Marfan's syndrome
- I. Mitral valve prolapse

VI. **Central**
- A. Psychiatric—anxiety, hyperventilation, conversion reaction, depression, phobia
- B. Idiopathic—Texidor's twinge (precordial catch)
- C. Other—visceral pain–associated disability syndrome

[a]Associated drug induced (especially cocaine).

Major categories include arrhythmias, anatomic lesions, and acquired disorders. Myocardial ischemia is rare in pediatrics but can present with typical unrelenting substernal crushing chest pain with or without radiation to neck or arm, diaphoresis, nausea, dyspnea, and syncope. Patients are usually in distress and have physical examination abnormities, including pallor, diaphoresis, a gallop rhythm, a heart murmur, and decreased peripheral perfusion. Myocardial ischemia/infarction can occur as a result of a thrombosed coronary artery aneurysm. These aneurysms, which occur as a sequelae from Kawasaki disease, have both insufficient laminar flow and areas of stenosis that become obstructed via thrombosis, leading to decreased myocardial perfusion. Case reports of myocardial ischemia without risk factors in adolescents have been attributed to vasospasm. Cocaine exposure can result in palpitations and coronary vasospasm, leading to ischemia, MI, arrhythmias, or cardiomyopathy. Patients with cocaine toxicity are often anxious with confusion or combativeness and have significant tachycardia and hypertension. Other toxins have cardiac effects. The herbal medications aconite, ephedra, and licorice have also been implicated as the cause of chest pain, congestive heart failure, arrhythmias, and MIs.

Anomalous coronary arteries that originate from the opposite sinus and traverse between the great vessels usually presents with sudden death but can also cause chest pain with intense

TABLE 51.2

COMMON CAUSES OF CHEST PAIN

Functional (anxiety/psychosomatic)
Musculoskeletal contusion/strain
Costochondritis/myositis
Cough or respiratory infections (bronchitis, pneumonia, pleurisy, upper respiratory infections)
Asthma
Gastroesophageal reflux
Idiopathic

TABLE 51.3

LIFE-THREATENING CAUSES OF CHEST PAIN

Category	Disease/injury	Decompensation
Traumatic	Rib fracture	Tension pneumothorax or shock from hemothorax
	Cardiac contusion	Arrhythmia or myocardial infarction
	Laceration—heart or great vessel	Shock
	Contusion—great vessels	Dissecting aneurysm/shock
	Pulmonary contusion	Adult respiratory distress syndrome
Cardiac	Congenital heart disease	Arrhythmia, shock, pulmonary hypertension
	Myocardial infarction (anomalous coronary artery, Kawasaki disease, cocaine toxicity)	Arrhythmia, cardiogenic shock
	Myocarditis	Arrhythmia, cardiogenic shock
	Pericarditis	Tamponade
	Rheumatic heart disease	Arrhythmia, congestive heart failure
	Aortic aneurysm	Rupture-shock, dissection
	Obstructive cardiac disease	Acute hypertension
Pulmonary	Pneumothorax (asthma, cystic fibrosis, spontaneous)	Tension pneumothorax, pulmonary hypertension, shock
	Hemothorax	Shock, hypoxemia
	Pulmonary infection or empyema	Pulmonary hypertension, sepsis
	Aspiration—foreign body	Acute airway obstruction, progressive pulmonary hypertension
	Acute asthma	Tension pneumothorax, pulmonary hypertension
	Pulmonary embolus	Pulmonary infarction, hypertension, cardiovascular collapse
	Pulmonary venoocclusive disease	Pulmonary hypertension
	Tumor (chest wall, chest, or mediastinum)	Airway compromise, progression of tumor
Miscellaneous	Drug ingestion/overdose (especially cocaine)	Arrhythmia, cardiomyopathy, shock
	Sickle cell crisis	Pulmonary infarction or hypertension
	Cholecystitis	Sepsis, peritonitis

exercise. Pain is thought to be related to inadequate coronary perfusion via either compression of the great vessels, relative ostial stenosis, or both. The history is the key to this significant disease as the physical examination findings are usually normal.

Hypertrophic cardiomyopathy is the most common cardiac cause of sudden death, which is likely due to ventricular dysrhythmias, yet chest pain is not a common feature. This disease follows an autosomal dominant pattern of inheritance; however, spontaneous mutations may occur. Patients often have a systolic murmur that becomes more intense with standing or a Valsalva maneuver. Chest pain can also occur with severe obstruction from aortic stenosis, which is likely to be discovered by the pathological murmur on physical examination. The patient with chest pain that has onset with or worsening with exertion should be evaluated for these conditions.

Arrhythmias are not uncommon in children and usually present with chest pain and palpitations. Symptoms of heart pounding may occur with instantaneous initiation and termination whereas other children have been reported to abruptly stop an activity. Most are benign, such as premature atrial and ventricular contractions; however, children may present with signs of shock, congestive heart failure, or syncope secondary to supraventricular or ventricular tachycardia. Physical examination is often normal in the absence of active arrhythmias, but long-term effects can lead to cardiomyopathy. Dilated cardiomyopathy presents with chest discomfort, fatigue, exercise intolerance, palpitations, and physical examination findings, such as a gallop rhythm and a murmur secondary to mitral valve insufficiency.

Inflammatory conditions such as pericarditis and myocarditis can present with chest pain and systemic symptoms. Pericardial disease includes pericarditis, pericardial effusions, and cardiac tamponade. Pericarditis often presents with fever, a stabbing chest pain that improves with sitting up and leaning forward, respiratory distress, a friction rub, and distant heart sounds. Pericarditis and pericardial effusions can restrict outflow, leading to neck vein distension and, in severe cases of tamponade, pulsus paradoxus (see Chapter 84). The presentation of myocarditis can be subtler with mild chest pain and fatigue for several days, followed by the development of fever, dyspnea, and worsening chest pain. The examination often shows tachycardia (or bradycardia when severe), orthostatic changes not improved by fluid resuscitation, pulsus paradoxus, and a gallop rhythm. Both pericarditis and myocarditis are usually associated with a preceding viral illness. Endocarditis is most often seen in children with a history of congenital heart disease but can present in those with no known predisposing condition. Patients are often ill-appearing with a history of prolonged fever and may have signs of embolization. Other illnesses that can present with carditis include rheumatic heart disease and Kawasaki disease.

Chest pain associated with mitral valve prolapse is controversial. Studies have shown that mitral valve prolapse is not more common in those with chest pain than in the general population, and other etiologies of the chest pain (i.e., esophagitis) may exist in a patient with this condition. However, chest pain in patients with mitral valve prolapse may be secondary to papillary muscle or left ventricular endocardial

ischemia. A midsystolic click and late systolic murmur should be found on physical examination. Pain secondary to mitral valve prolapse should be considered only when no other etiology is found.

Patients with connective tissue disorders, such as Marfan syndrome, have the potential to develop aortic dilation, aortic dissection, and rupture. Symptoms of aortic dissection/rupture include generalized distress with unrelenting severe chest pain, decreased cardiac output, dyspnea, and, often, abdominal pain.

Children who present with chest pain days to months after cardiac surgery should be evaluated for signs of pericardial effusion known as *postpericardiotomy syndrome*. Patients with pulmonary hypertension may present with exercise intolerance, palpitations, and syncope. The resultant right ventricular dilatation may be found on physical examination as a narrowed second heart sound, hepatomegaly, and cyanosis if an atrial septal defect or ventricular septal defect is present. Eisenmenger syndrome is severe pulmonary hypertension from an uncorrected congenital heart disease, leading to cyanosis from right to left shunting of blood. Isolated anatomic abnormalities such as atrial septal defects have been known to present with chest pain and may or may not display the classic findings of a hyperactive precordium, widely split fixed second heart sounds, and both systolic and diastolic murmurs.

Unrecognized disease rarely causes isolated chest pain in a child who otherwise appears well, but the physician should consider drug exposure (e.g., cocaine; methamphetamine; nicotine; β-agonist abuse; the triptans; combination cold medications containing chlorpheniramine, dextromethorphan, and phenylpropanolamine; the herbal medications mentioned previously). Although cardiac conditions are infrequent, attention should be paid to diagnosing the rare patient with hypertrophic cardiomyopathy, angina, or early pericardial or myocardial inflammation (see Chapter 84).

Pulmonary diseases are common and account for approximately 12% to 21% of chest pain cases. A first episode of reactive airway disease should be suspected when an associated night cough, history of wheezing, or family history of atopy is present. There is a high incidence of exercise-induced asthma, which often presents with chest tightness, shortness of breath, and wheezing with exercise. These historical features are important, as the physical examination may be completely normal during the ED visit. Infectious diseases of the respiratory tract are associated with fever, malaise, cough, and coryza and may involve several family members simultaneously. Patients with pneumonia (see Chapter 92) often present with tachypnea and hypoxia in addition to fever and cough. Spontaneous (nontraumatic) pneumomediastinum and pneumothorax may occur in patients with reactive airway disease, cystic fibrosis, or as a result of barotrauma (i.e., Valsalva maneuver, forceful vomiting, or coughing). The pain of a pneumothorax is often unrelenting and pleuritic in nature. If the pneumothorax is moderate or large, patients present with significant respiratory distress and decreased breath sounds on the affected side. Spontaneous (nontraumatic) pneumomediastinum is most often reported in male adolescents without underlying lung disease and in those with asthma. It appears to occur with any activity that involves straining against a closed glottis. This is thought to cause a rise in intraalveolar pressure and subsequently a rupture of the alveoli releasing air into the interstitial space. Air then dissects along fascial planes of the hilum into the mediastinum and neck. Those with spontaneous pneumomediastinum present with substernal chest pain that frequently radiates to the neck and is worse with deep inspiration and position changes, subcutaneous crepitus, Hamman's sign (crunching heart sounds), dysphagia, and dysphonia. This diagnosis must be distinguished from pneumothorax, pericarditis, and esophageal perforation.

Pleural effusions can cause chest pain associated with decreased breath sounds and dullness to percussion on physical examination. Pleurodynia, often secondary to coxsackievirus B infection, causes sharp chest pain, fever, and a friction rub. Aspiration of a foreign body into the trachea or esophagus may occur without such history in a toddler or even in an older child, and approximately 50% of these children may complain of chest pain. Foreign bodies lodged in the airway often present with chest pain, cough, decreased breath sounds, and unilateral wheezing. However, auscultatory findings may be unimpressive despite a positive history.

Although pulmonary embolisms (see Chapter 98) are rare in children, they can present with pleuritic chest pain, cough, hypoxia, hemoptysis, dyspnea, respiratory distress, and the sense of impending doom. Usually, this condition is associated with risk factors such as obesity, oral contraceptive use, pregnancy, collagen vascular disease, nephrotic syndrome, cigarette smoking, recent surgery, immobility, trauma (particularly spinal injury), a positive family history, a hypercoagulable condition (known or unknown), or prior cardiorespiratory problems. Finally, children with sickle cell disease can develop a vasoocclusive crises resulting in acute chest syndrome.

GI diseases account for approximately 4% to 7% of pediatric patients with chest pain. Diseases include gastroesophageal reflux, esophagitis, gastritis, ulcer disease, and, rarely, esophageal rupture or spasm. History is important regarding symptom relationship to meals and body position. Pain of gastroesophageal reflux is typically described as burning, worse in the recumbent position, related to eating, and improved with antacid or H_2 antagonist therapy. The physical examination finding is usually normal or positive for epigastric tenderness. Foreign bodies in the GI tract can cause chest pain, drooling, dysphagia, and odynophagia. The history often uncovers this diagnosis, and radiography may be helpful. Spontaneous esophageal perforation (Boerhaave syndrome) is secondary to transmitted increased pressure against a closed glottis most often seen with vomiting and also with straining, coughing, defecation, seizure, childbirth, or forceful nose blowing. Presentation includes symptoms of chest pain, crepitus, pneumomediastinum, and hematemesis to hemorrhage and shock. Mackler triad includes vomiting, chest pain, and subcutaneous emphysema. There are case reports of adolescents diagnosed with diffuse esophageal spasm via motility testing after persistent chest pain. Intraabdominal processes such as cholecystitis can present with postprandial pain and pain in the right upper quadrant.

Musculoskeletal causes of chest pain are common accounting for 15% to 31% of cases and are typically overuse injuries (muscle strain and inflamed tissue). Chest pain often occurs after physical activity and is reproducible by palpation and contraction of the muscle group on physical examination. Direct trauma may produce a contusion or rib fracture. Costochondritis is an inflammatory condition of the costochondral junctions, which may be

preceded by a respiratory illness, and characteristically, has reproducible pain on examination. The pain is described as sharp and exaggerated by physical activity or deep inspiration. Tietze syndrome is a benign inflammatory condition of unknown cause, which results in isolated swelling of a costochondral junction. The inflamed area appears as a mass on the chest wall and results in chest pain that typically radiates to the shoulder or arm. This syndrome usually occurs in adults but has been reported in children and infants. When evaluating a chest wall mass, the differential diagnosis should include osteomyelitis and tumors.

Slipping rib syndrome is a pain syndrome caused by hypermobility of the anterior aspect of the 8th to 10th ribs, which do not directly attach to the sternum but instead are held together by fibrous tissue. It is thought that weakening of the fibrous tissue in the area allows the ribs to rub against the other, irritating the intercostal nerve and referring pain to the chest wall and abdomen. Patients describe a popping or clicking sensation followed by pain, which lasts several minutes. Pain is reproduced by hooking the lower ribs with the hand and pulling anteriorly.

A large group of children with chest pain will have no evidence of organic disease and no history of underlying cardiorespiratory disease or trauma. They may have a family history of chest pain and are able to identify a stressful situation that has precipitated the episode. Such children have psychogenic chest pain and represent approximately 5% to 17% of pediatric chest pain cases. Complaints of chest pain and other somatic aches often are chronic, and other symptoms of psychiatric illness or hyperventilation may be present. Nonorganic chest pain may appear to cause respiratory distress in the hyperventilating teenager, but close examination should distinguish this syndrome from serious problems (see Chapter 131).

Idiopathic etiology is the most common diagnosis of chest pain in pediatrics, representing 23% to 45% of cases. The term is used to describe chest pain when no organic etiology and no psychological factors are present to explain the pain. It is typically described as occasional short episodes of sharp chest pain with or without exercise and no other associated symptoms. Physical examination is completely normal and pain is not reproducible. Precordial catch syndrome, or "Texidor's twinge," is a relatively frequent cause of chest pain in healthy teenagers and young adults. It typically presents with an acute, sharp, well-localized pain (often in the left substernal region) that has a "split second" onset, is of short duration, worsened by deep inspiration, and usually occurs at rest or related to exercise. It is often relieved by position change (sitting up straight), which suggests that posture or ligamentous stretching of the supporting ligaments of the heart may have a role but the true etiology is unknown. The physical examination is normal without reproducible pain.

Other causes of chest pain include male adolescents with gynecomastia and female patients with fibrocystic breast disease. Rarely, chest pain, pressure, or shortness of breath, worse on supine position, will be associated with the presentation of a mediastinal mass.

EVALUATION AND DECISION

Child with Thoracic Trauma

The first step in evaluation of the child with chest pain is to perform a thorough history and physical examination. If the history is positive for a traumatic injury or if there is any evidence of trauma to the chest (see Chapter 118), the patient requires rapid evaluation and may need immediate resuscitation as well (Fig. 51.1A). Correction of cardiac or respiratory insufficiency may diagnose and treat the cause of chest pain.

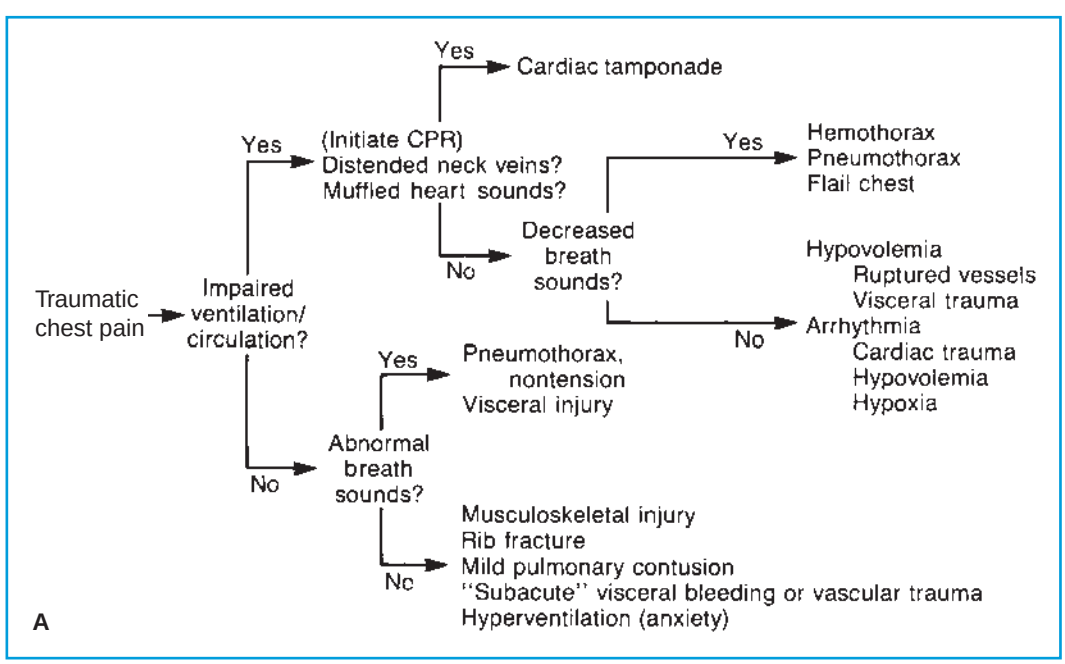

FIGURE 51.1 **A.** Diagnostic approach to traumatic chest pain. CPR, cardiopulmonary resuscitation. (*continued*)

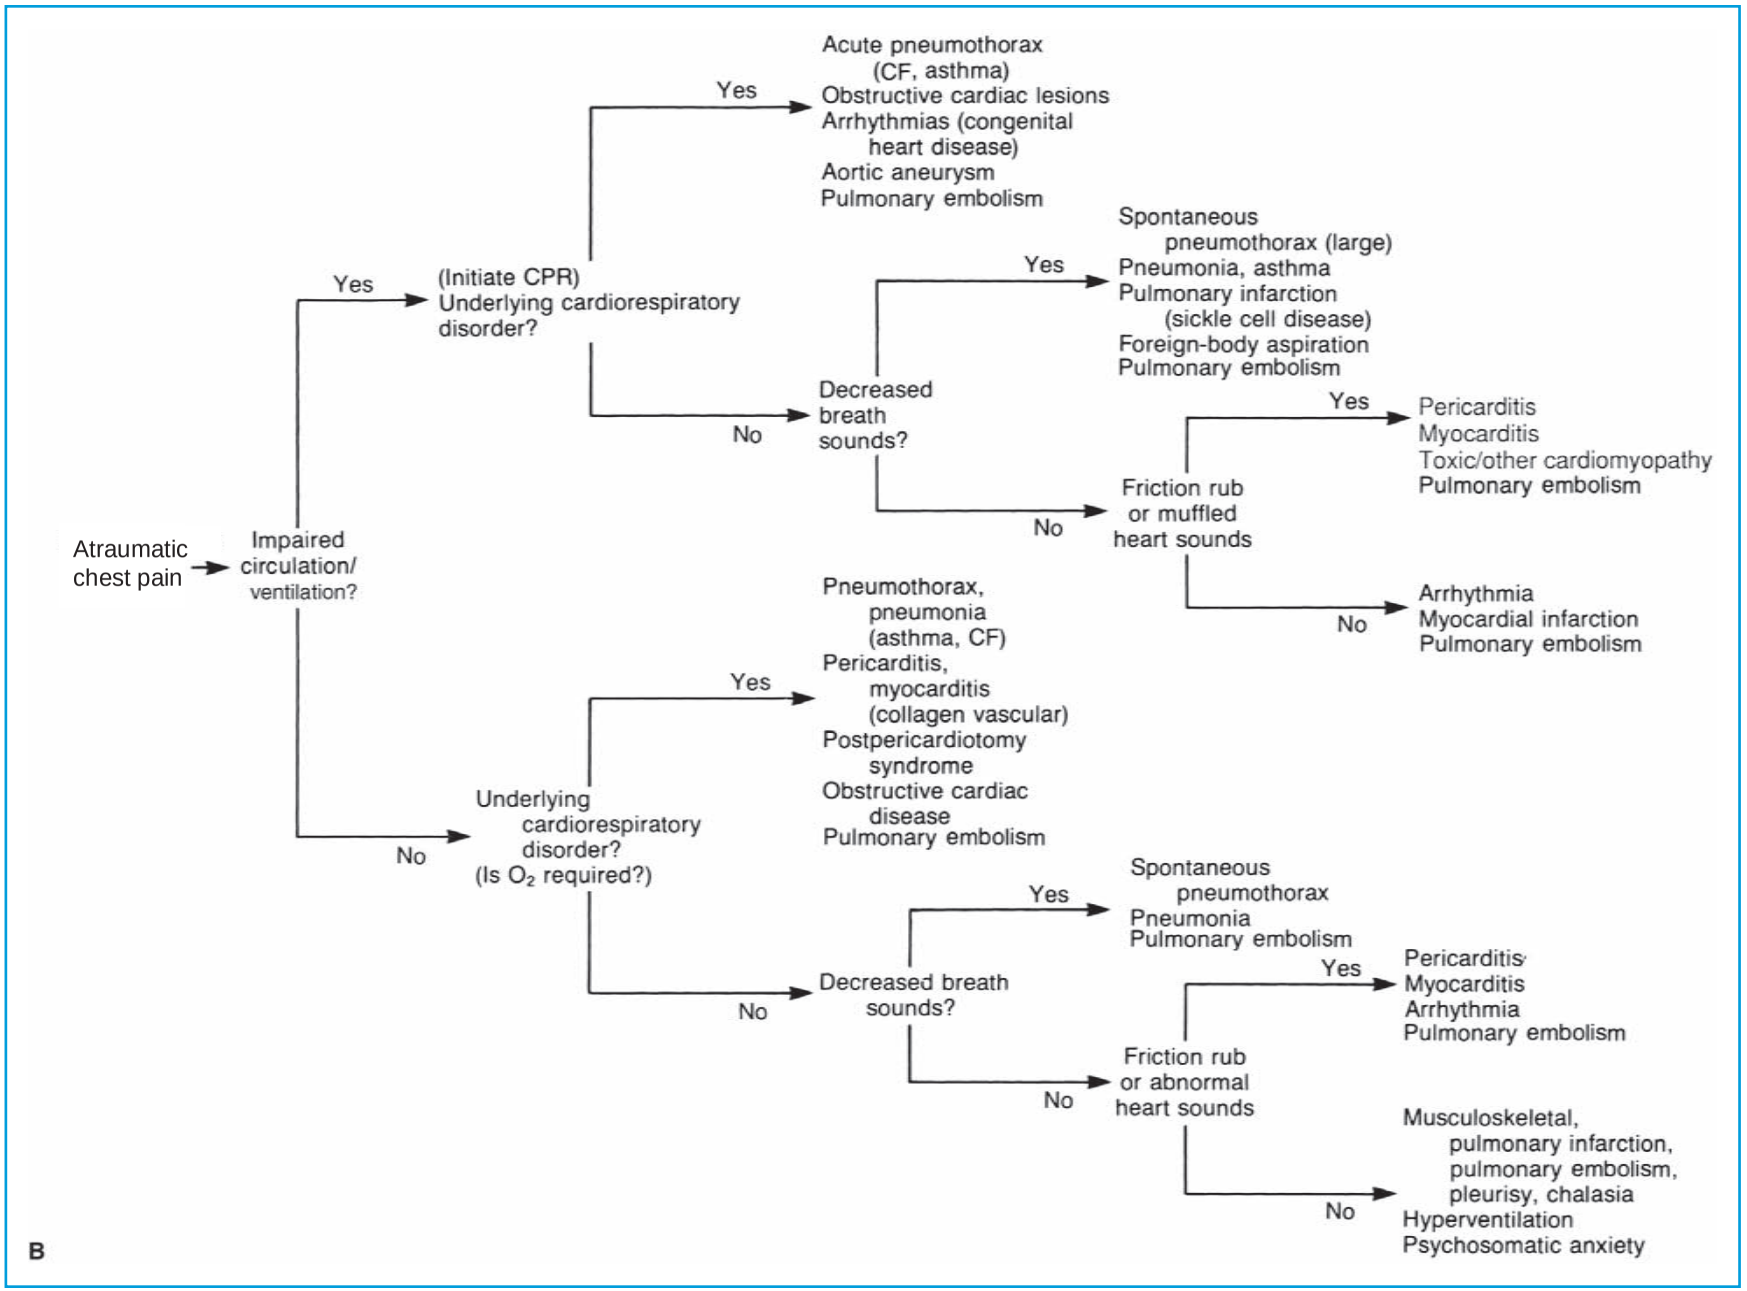

FIGURE 51.1 (*Continued*) **B.** Diagnostic approach to atraumatic chest pain. CPR, cardiopulmonary resuscitation; CF, cystic fibrosis.

Adequacy and symmetry of ventilation should be assessed to distinguish acute respiratory failure from hemothorax or pneumothorax. In children with chest trauma, tachycardia with hypotension is generally caused by hypovolemia secondary to a hemothorax, hemopneumothorax, or vascular injury. Reduced cardiac output and perfusion, however, may also be secondary to a rhythm disturbance (from a myocardial contusion or tension pneumothorax) or cardiac tamponade (which causes muffling of the heart sounds and pulsus paradoxus). A discrepancy of the pulse or blood pressure between the extremities points to aortic diseases, such as traumatic avulsion or aneurysm. Ruptured esophagus and tracheobronchial disruption may result from rapid deceleration injuries and may present with chest pain, subcutaneous emphysema, respiratory distress, and hypotension.

Many children with thoracic injuries but no respiratory distress also complain of chest pain. Although a careful examination is mandatory in an effort to exclude significant intrathoracic trauma, the cause of the pain usually resides in the chest wall: contusions of the soft tissues or rib fractures. A history of significant trauma even in the absence of cardiovascular abnormality dictates that radiographs and an electrocardiogram (EKG) be obtained. Injury to the heart, including myocardial contusions and acute rupture of cardiac structures, can occur during rapid deceleration and compression type injuries. Pulmonary injuries include contusions, pneumothoraces, and hemothoraces. These injuries may present with subtle physical examination findings. Patients have presented with chest pain following blunt trauma that was subsequently complicated by the development of posttraumatic ventricular septal defect and pseudoaneurysm.

Finally, the clinician should consider child abuse if rib fractures are seen in a young infant. In older children, a predisposing cause for fracture (i.e., bone cyst or tumor) should be sought.

Child without Thoracic Trauma

As above, the first step in evaluation of the child with chest pain is to perform a thorough history and physical examination assessing for cardiorespiratory instability (Fig. 51.1B). A thorough history including a complete review of symptoms, social history, and family history should be obtained. The description of chest pain should include quality, intensity, location, frequency, and duration as well as its relationship to exercise, food intake, position, or trauma. Chest pain relieved by leaning forward is consistent with pericarditis, while that which is worsened by reclining may represent gastroesophageal reflux or hiatal hernia. The review of symptoms should be broad, including systemic symptoms such as fever, fatigue, weight loss, diaphoresis, or intolerance to exercise; cardiac symptoms such as palpitations, heart racing, dizziness, or syncope; pulmonary symptoms such as dyspnea, cough, or wheezing; and GI symptoms such as vomiting, dysphagia, abnormal taste in the mouth, or abdominal pain. In general, chest pain that is acute in onset; is described as crushing sternal pain with or without radiation to left arm or neck; awakens a patient at night; or is associated with exertion, syncope, fever, fatigue, dyspnea, decreased exercise tolerance, or palpitations is concerning and demands a more extensive evaluation.

Next, the physician should inquire about a history suggestive of prior cardiorespiratory disease, such as asthma, cystic fibrosis, congenital or structural heart conditions, as well as a past medical history of collagen vascular disease, connective tissue disorders, hyperlipidemia, Kawasaki disease, or a prolonged febrile illness. It also is important to determine if there is a family history of sudden death, hypercholesterolemia, hypercoagulability disorders, or early cardiovascular disease.

Children with respiratory illnesses, such as asthma or cystic fibrosis are at risk for pneumothorax, acute respiratory failure from mucous plugging or pneumonitis, and acute pulmonary hypertension. In the child with a history of cardiac arrhythmias (see Chapter 84), congenital heart disease, cardiac surgery, or pericardial effusions, chest pain may signal an exacerbation of the underlying problem.

The social history should include recent stressors, and cigarette or drug use, including prescription medications such as oral contraceptives, stimulants such as cocaine, and herbal medications. In addition, it may be helpful to determine the patient's perception of the pain and how it is affecting his or her life. Research has shown that approximately one-third of children with chest pain have missed school secondary to their symptoms and approximately half of children with chest pain associate this pain as a problem with their heart.

In the absence of prior cardiopulmonary disease or trauma, the approach must be directed toward unmasking evidence for any of the serious cardiorespiratory illnesses listed in Table 51.3. A thorough examination usually uncovers evidence of the cardiac and respiratory causes of chest pain. The clinician must carefully assess the vital signs, looking for fever, tachycardia, bradycardia, tachypnea, bradypnea, hypertension, hypotension, and hypoxia. The patient may be well-appearing with no apparent distress or ill-appearing with significant distress. Concerning signs of the general appearance include cough, drooling, retractions, lethargy, pallor, or cyanosis. The physical examination in asthma shows a prolonged expiratory phase of respiration, variable degrees of chest hyperinflation, and wheezing accentuated by a forced expiratory effort. However, auscultatory findings, such as crackles or wheezing, may be minimal when obstructive pulmonary disease is moderately severe, and a history of foreign body aspiration should also be sought with new-onset wheezing. Fever, hypoxia, tachypnea, decreased breath sounds, and/or crackles suggests pneumonia, whereas dullness to percussion suggests effusion. Unilaterally absent or decreased breath sounds is concerning for pneumothorax, pneumonia, foreign body aspiration, or a pulmonary embolism. Crepitus of the neck or chest wall is indicative of pneumomediastinum and/or pneumothorax. Tracheal deviation may be seen in severe cases of tension pneumothorax where patients are in obvious distress.

If breath sounds are equal, yet there is an abnormal heart sound, a cardiac etiology is most likely. Pericardial disease can present with a friction rub, distant heart sounds, neck vein distension, hypotension, impaired circulation, pain with leaning forward, and pulsus paradoxus. Signs of myocarditis include persistent tachycardia and orthostasis, bradycardia, and a gallop rhythm. Physical examination findings such as dyspnea, crackles, wheezes, gallop rhythms, neck vein distension, and peripheral edema are seen in those with heart failure or cardiomyopathy. There is a wide range of clinical presentations of children with arrhythmias: They may be stable with irregular

heart rates and rhythm, or they can present in cardiovascular shock. Signs of MI include rate and rhythm disturbances, pallor, dyspnea, and diaphoresis, as well as signs of heart failure.

Patients with a pulmonary embolism may present with a variety of physical findings, depending on the degree of arterial obstruction and, thus, hemodynamic compromise (see Chapter 98). Findings may include tachypnea, tachycardia, decreased breath sounds, crackles, fever, a friction rub, an accentuated S2, unexplained cyanosis, pleural friction rub, and/or cardiovascular collapse.

In addition to the usual cardiac and pulmonary examination, one should search for "trigger points," where palpation of the chest wall reproduces the pain, suggesting musculoskeletal inflammation. Reproduction of the pain by a "hooking maneuver" performed over the lower anterior ribs implicates the "slipping rib syndrome." Pain following a dermatome unilaterally suggests intercostal neuritis; children with zoster (shingles) may have pain preceding the development of rash.

When focal, peripheral pain is found without a "trigger point," the physician should consider pain referred from areas of sensory nerve overlap. For instance, relationship of the pain to eating or swallowing suggests esophageal disease, and often, the physical examination may appear normal.

Extrathoracic abnormalities, such as a rash or arthritis, may provide clues to collagen disorders (see Chapter 101) or other systemic illness. Marfan syndrome should be suspected in the tall, thin patient whose upper-extremity span exceeds his or her height and with hyperextensible fingers.

During the examination, it is useful to relate normal findings to the child and family because this reassurance often serves as the major "treatment" of self-limited or functional problems. Some families and patients are simply looking for reassurance that the chest pain is not cardiac in origin. Concerning physical examination findings such as fever, persistent tachycardia, persistent hypertension, hypotension, pathological murmurs, a gallop rhythm, abnormal pulses, abnormal perfusion, hypoxia, and syncope warrant further investigation.

Laboratory studies may be indicated to help confirm a diagnosis and may relieve the anxiety of the child or family; such investigations should be directed toward causes suspected based on the initial evaluation rather than considered as "screening" tests. Pulse oximetry is a quick and inexpensive test that is helpful in determining the severity of any suspected pulmonary disease. Chest radiographs may reveal findings consistent with asthma, pneumonitis, pleurisy, spontaneous pneumothorax, or mass. Foreign bodies ingested and lodged in the esophagus can be visualized if radiopaque (e.g., coins). In the cervical esophagus, they will lie flat and be fully visible in the posteroanterior view of the chest. Airway foreign-body aspiration most frequently manifests, however, by hyperinflation or atelectasis on radiographs because most tracheobronchial foreign bodies are not radiopaque. Inspiratory and expiratory films or decubitus chest radiographs may demonstrate focal hyperinflation (i.e., the lobe with an obstructed bronchus remains inflated in expiration or when placed on the dependent side on a decubitus film). The wide mediastinum from an aortic aneurysm, abnormal cardiac silhouette related to a pericardial effusion or cardiomegaly, rib fractures or bone changes of metabolic bone derangements, and cysts all produce characteristic radiographic changes. A calcified ring may be visualized in approximately one-third of patients with a history of Kawasaki disease. The presence of atelectasis may suggest mucous plugging or may be subtle evidence of pulmonary infarction from an embolus or a vasoocclusive crisis of sickle cell disease. If found, the presence of a wedge-shaped pulmonary infiltrate with an ipsilateral elevated hemidiaphragm is suggestive of a pulmonary embolism.

An EKG should be performed if cardiac disease is suspected. For example, one would have an elevated level of suspicion for cardiac disease if the physical examination findings are suggestive of myocarditis or pericarditis or if the chest pain is thought to be anginal or exertional, or associated with syncope, dizziness, and/or palpitations. The EKG will be normal in almost all children with chest pain in which the physical examination is unremarkable. It may show signs of cardiac strain or ischemia with valvular heart disease, diseases of outflow obstruction, or ischemia. Acute cocaine exposure may present with classic signs of myocardial ischemia or myocardiopathy. A decreased QRS wave voltage and electrical alternans suggest the presence of a pericardial effusion in the child with muffled heart sounds. Decreased voltages, ST elevations, and T-wave abnormalities may also be seen in diseases such as myocarditis and pericarditis. Heart block and arrhythmias, such as atrial fibrillation and supraventricular tachycardia, can occur secondary to anatomic, ischemic, inflammatory, and drug-induced conditions. These electrical disturbances may be identified by careful evaluation of a rhythm strip. Finally, the S_1-Q_3-T_3 pattern may be seen on EKG evaluation in those with a pulmonary embolism.

Studies other than chest radiographs and EKGs are rarely necessary. An elevated leukocyte count with a shift to the left may point toward infection as the cause of pain. Examination of a peripheral smear and a hemoglobin electrophoresis are indicated in the child suspected of having sickle cell disease as the cause of chest pain. In children with sickle cell disease, a complete blood cell count, reticulocyte count, and blood culture are indicated to assist in ascertaining acute chest syndrome or pneumonia, as well as the presence of acute anemia and its cause. If an intraabdominal source for chest pain from diaphragmatic irritation is under consideration, further testing is appropriate. Serum amylase and lipase levels may be obtained in the workup of pancreatitis. The evaluation of a possible right-sided subdiaphragmatic abscess would include liver function tests and further delineation by ultrasound or computed tomography scan. Esophageal causes of chest pain may often be diagnosed clinically in the ED with a trial of antacid therapy followed by H_2-m receptor antagonist or proton pump inhibitors. To confirm the findings of a hiatal hernia, esophagitis, or a radiolucent foreign body, a barium study or endoscopy may be required. Findings of low PaO_2, EKG abnormalities, and a positive D-dimer are suggestive of pulmonary embolism. This suspected diagnosis requires the performance of a helical computed tomography scan for confirmation. The clinician may consider peak expiratory flow testing and/or therapeutic trial of bronchodilators when asthma is suspected as the cause of chest pain. Only rarely will it become necessary to obtain cardiac-specific creatine phosphokinase fractions and troponin for the evaluation of a possible MI. Toxicologic screens may be useful if the patient is considered at risk of drug abuse, particularly cocaine, or if the diagnosis remains unclear. Consultation with a pediatric

cardiologist may be necessary if the chest pain is concerning for a cardiac condition.

Not infrequently, a chest radiograph and an EKG are helpful in allaying parental fears of cardiac disease. However, the clinician should be aware that, in some cases, where a cardiac or respiratory condition is not suspected, ordering unnecessary tests may actually increase a patient's or parent's concern that true pathology exists. Definitive ongoing management requires referral to a primary care physician.

SUMMARY

Chest pain in children is a relatively infrequent sign of serious disease but often has great importance to the patient or family. Most cases can be diagnosed by the emergency physician from the history and physical examination alone, although, at times, a chest x-ray or an EKG is helpful. The physician should always consider drug-induced chest pain (especially associated with cocaine) and other life-threatening conditions. Patients with a history of exercise-induced chest pain and/or syncope, medical history of underlying cardiopulmonary condition, suspected Kawasaki disease, history of drug use, oral contraceptive and cigarette use, and older children with family history of early coronary artery disease or hypercholesterolemia appear to be at higher risk of cardiovascular disease. Psychogenic chest pain is a common occurrence and may be chronic or related to an acute stressful event. The possibility of cardiac disease needs to be addressed directly by the examining physician to alleviate fully the patient's (or family's) anxiety. The most common causes of organic chest pain are musculoskeletal (traumatic or inflammatory) and infectious disorders, usually self-limited or easily treated diseases. Occasionally, serious abdominal, pulmonary, or cardiac problems require immediate attention.

CHAPTER 52 ■ PAIN—DYSPHAGIA

RONALD A. FURNIVAL, MD, VAISHALI JHA, MD, AND GEORGE A. WOODWARD, MD, MBA

The primary function of swallowing is the ingestion, preparation, and transport of nutrients to the digestive tract. Secondary functions of swallowing are the control of secretions, clearance of respiratory contaminants, protection of the upper airway, and equalization of pressure across the tympanic membrane through the eustachian tube. Dysphagia is defined as any difficulty or abnormality of swallowing. Dysphagia is not a specific disease entity but is a symptom of other, often clinically occult, conditions and may be life-threatening if respiration or nutrition is compromised. Odynophagia (pain on swallowing) or sialorrhea (drooling) may also be present in the dysphagic pediatric patient. Globus pharyngeus refers to the feeling of a lump in the throat. This chapter briefly presents the normal anatomy and physiology of swallowing, the differential diagnosis of disturbances of this process, and the evaluation and treatment of the pediatric patient with dysphagia.

PATHOPHYSIOLOGY

Swallowing begins in utero as early as the 10th to 14th week of gestation, playing an important role in gastrointestinal development and regulation of amniotic fluid volume. By the 34th week of gestation, this complex process, involving 26 muscles, 6 cranial nerves (V, VII, IX, X, XI, and XII), and cervical nerves C1 to C3, is functional, although incompletely coordinated with breathing. In the first few days after birth, each infant develops an individual pattern of sucking, swallowing, and breathing, usually with a 1:1 or 1:2 ratio of breaths per suckle, to prevent aspiration of material into the larynx. This stage of suckling, or suckle feeding, is primarily under medullary control, with minimal input from the cerebral cortex. A transitional period begins at 6 months of age, as the cortex gradually exerts more control over the preesophageal phase of swallowing, allowing for the introduction of solid foods. The preesophageal region depends on normal sensorimotor function of cranial nerves V, VII, IX, and XII, which innervate voluntary skeletal muscles of the face, tongue, and neck, as well as the involuntary muscles of the posterior pharynx. Swallowing in the esophageal region remains an autonomic process, with vagal sensorimotor control coordinating peristalsis of the upper striated and lower smooth muscle of the esophagus. By 3 years of age, the swallowing pattern is mature, although the pediatric patient, unlike the adult, may regress to a less mature stage if normal swallowing is disrupted.

To facilitate suckle feeding and breathing, the infant oropharynx is anatomically different from the adult, with a relatively larger tongue, smaller oral cavity, and more anterior and superior epiglottis and larynx. As the face and mandible grow, the oropharynx enlarges, creating more room for the eventual voluntary use of the tongue and dentition, and the larynx descends, eventually allowing for mouth breathing. Although breathing continues to cease during swallows, the older child depends less on close coordination between eating and breathing.

A normal swallow, using the suckling infant as an example, begins with rhythmic movement of the lips, tongue, and mandible. These parts function as a unit, creating negative intraoral pressure, while also compressing the nipple. The milk expressed from each suckle is stored in the posterior oral cavity until a larger fluid bolus is formed. As the tongue delivers the bolus to the pharynx, the nasopharynx is closed off by the posterior tongue and by elevation of the soft palate. The larynx elevates to a position under the tongue, closing the airway, as the epiglottis inclines to direct the bolus posterior. A pharyngeal wave of contraction sweeps the bolus toward the upper esophagus, where the cricopharyngeal sphincter relaxes, allowing passage into the esophagus. As the esophagus begins peristaltic contractions and the bolus moves past a relaxed lower esophageal sphincter into the stomach, the airway reopens, the cricopharyngeal sphincter constricts to close the upper esophagus, and respirations resume. Dysphagia can result from disruption of normal mechanisms at any stage of the swallowing process.

DIFFERENTIAL DIAGNOSIS

Acute dysphagia is one of the urgent symptoms needing immediate evaluation. While this may be an acute symptom in a healthy child, it may be a new or recurrent symptom in the increasing number of children surviving with chronic conditions. The differential diagnosis for dysphagia is extensive and is commonly divided into preesophageal or esophageal disorders (Table 52.1). Preesophageal causes of dysphagia are further subdivided into anatomic categories, including nasopharyngeal, oropharyngeal, laryngeal, and generalized problems. Infectious and inflammatory disorders of either anatomic region may disrupt swallowing, whereas neuromuscular problems tend to be predominantly preesophageal, given the autonomic function of the esophagus. However, the esophagus can be affected by motility disorders intrinsic to smooth muscle. Finally, the differential diagnosis includes several systemic conditions that may affect the normal swallowing process. In a large case series, Hartnick et al., described 568 pediatric patients who underwent fiberoptic evaluation of swallowing function and their underlying diagnoses. This group included 36% with structural abnormalities of the aerodigestive tract or

TABLE 52.1

DIFFERENTIAL DIAGNOSIS OF DYSPHAGIA

Preesophageal (Nasopharynx, Oropharynx, Larynx)
Mechanical/Anatomic
- General
- Congenital syndromes
  - Pierre-Robin
  - Treacher-Collins
  - Crouzon's
  - Goldenhar's
  - Cornelia de Lange
- Cysts (tongue, larynx, epiglottis)
- Tumors (neuroblastoma)
- Lymphangioma
- Foreign-body aspiration
- Traumatic (external, endotracheal intubation, endoscopy)

Nasopharyngeal
- Choanal stenosis/atresia
- Nasal septum deflections

Oropharyngeal
- Cleft palate/lip
- Submucosal cleft
- Macroglossia
  - Down syndrome (trisomy 21)
  - Beckwith-Wiedemann syndrome
- Micrognathia
- Lip/teeth defects
- Tongue/sublingual masses
  - Hemangioma
  - Lymphangioma
  - Lingual thyroid
  - Thyroglossal duct cyst
  - Branchial cleft cyst
- Hypopharyngeal stenosis
- Temporomandibular joint ankylosis
- Pharyngeal diverticula (congenital/traumatic)
- Adenoidal/tonsillar hypertrophy

Laryngeal
- Tracheostomy
- Tracheoesophageal fistula
- Cervical vertebral osteophytes
- Airway obstruction
- Laryngomalacia

Inflammatory/Infectious
- General
- Anaphylaxis
- Tetanus
- Rabies
- Botulism (especially infant botulism)
- Poliomyelitis
- Angioneurotic edema
- Sydenham's chorea
- Juvenile rheumatoid arthritis
- Stevens-Johnson syndrome

Nasopharyngeal
- Nasal septal abscess
- Sinusitis

Oropharyngeal
- Stomatitis (infectious, allergic)
- Pharyngitis/tonsillitis/uvulitis
- Retropharyngeal abscess
- Peritonsillar abscess
- Cervical adenitis

Laryngeal
- Epiglottitis
- Diphtheria
- Thyroiditis

Neuromuscular
- Prematurity
- Hypoxic injury
- Head trauma
- Neurologic impairment
- Cerebral palsy
- Developmental delay
- Meningitis
- Cerebral abscess
- Cerebral cortical atrophy/hypoplasia/agenesis
- Arnold-Chiari malformation
- Cerebrovascular disease

Cranial nerve palsies (V, VII, IX–XII)
- Palatal paralysis
- Laryngeal paralysis

Spinal cord impairment
- Syringomyelia
- Cricopharyngeal incoordination/spasm

Moebius syndrome
Myotonic muscular dystrophy
Guillain-Barré syndrome
Werdnig-Hoffman
Myasthenia gravis
Myotonic dystrophy
Dermatomyositis

Miscellaneous
- Ingestions (neuroleptic-induced dystonic reaction)
- Familial dysautonomia (Riley-Day syndrome)
- Prader-Willi syndrome
- Cerebrohepatorenal syndrome
- Vitamin deficiencies (pellagra, scurvy)
- Acrodynia
- Infantile Gaucher's disease
- Psychiatric
- Globus hystericus ("lump" in throat sensation)
- Pseudodysphagia
- Conversion reaction
- Hyperphagia
- Munchausen by proxy

Respiratory distress

Esophageal Causes of Dysphagia
Mechanical/Anatomic
- Tracheoesophageal fistula
- Esophageal atresia/stenosis
- Esophageal diverticula/duplication
- Esophageal strictures
  - Congenital (webs, fibromuscular, tracheobronchial remnants)
  - Acquired (corrosive ingestion, esophagitis, postoperative)
- Foreign-body ingestion
- Thermal injury (burn from hot food/drink)
- Esophageal tumors (hamartomas, leiomyoma, rhabdomyoma)
- Esophageal polyps
- External esophageal compression
- Cardiovascular anomalies (aberrant right subclavian artery, vascular rings, double aortic arch)
- Mediastinal tumors/infiltrations
- Atopic thyroid
- Diaphragmatic hernias
- Paraesophageal hernia
- Hiatal hernia

Altered esophageal motility
- Achalasia
- Gastroesophageal reflux
- Esophageal spasm

Inflammatory/Infectious
- Eosinophilic esophagitis
- Infectious esophagitis
- *Candida albicans*
- Herpes simplex
- Cytomegalovirus
- Human immunodeficiency virus

Reflux esophagitis
Allergic esophagitis
Radiation injury
Mediastinitis
Esophageal perforation
Crohn's disease
Chagas' disease (*Trypanosoma cruzi*, a South American parasite)

Miscellaneous
- Connective tissue disease
  - Scleroderma
  - Systemic lupus erythematosus
  - Polymyositis
  - Dermatomyositis
  - Sjögren's syndrome
  - Behçet's disease

Hyperkalemia, hypermagnesemia
Muscular hypertrophy of esophagus
Central nervous system tumors
Demyelinating diseases
Epidermolysis bullosa congenita
Lesch-Nyhan syndrome
Wilson's disease
Dyskeratosis congenita
Opitz-Frias syndrome
Lipidosis
Myxedema
Thyrotoxicosis
Alcoholism
Diabetes
Amyloidosis
Posttruncal vagotomy, antireflux surgery
Subcutaneous emphysema

TABLE 52.2

COMMON CAUSES OF DYSPHAGIA

Newborn/Infant
Prematurity
Tracheoesophageal fistula
Choanal stenosis/atresia
Birth trauma
Congenital abnormalities
Gastroesophageal reflux
Respiratory illness
Neurologic/neuromuscular disease
Infectious (botulism, candidiasis, herpetic esophagitis)
Inflammatory

Child
Foreign-body aspiration/ingestion
Caustic ingestion
Infectious
Ingestions (neuroleptic-induced dystonic reaction)
Neurologic impairment (cerebral palsy, mental retardation, head trauma)
Inflammatory

TABLE 52.3

LIFE-THREATENING CAUSES OF DYSPHAGIA

Foreign-body aspiration/ingestion
Anaphylaxis
Tracheoesophageal fistula
Upper airway obstruction
Traumatic esophageal perforation
Epiglottitis
Retropharyngeal abscess
Botulism
Tetanus
Polio
Diphtheria
Central nervous system infection/abscess
Stevens-Johnson syndrome
Corrosive ingestion
Laryngeal paralysis

airway, 26% with neurologic diagnoses, 12% with gastrointestinal disorders, 8% with genetic syndromes, 5% with prematurity, 3% with cardiovascular anomalies, and 2% with metabolic issues presenting with dysphagia.

In the adult patient, dysphagia most commonly results from a variety of neuromuscular disorders, whereas the pediatric patient more often has swallowing difficulty from congenital, infectious, inflammatory, or obstructive causes (Table 52.2). In the newborn or infant, swallowing may be disturbed as a result of prematurity, often associated with respiratory and neurologic disabilities. Gastroesophageal reflux is common in infants, although in a small percentage of patients, it may persist into childhood with reflux esophagitis. Eosinophilic esophagitis has recently been identified as an important cause of dysphagia, particularly in adolescents and young adults with environmental allergies, atopy, and food allergies. Ingestion or aspiration of a foreign body must always be considered in the toddler who has either the acute or chronic onset of dysphagia. Swallowing dysfunction is a common complication following pediatric head injury. In a review of 1,145 pediatric head injury patients, Morgan et al., found that 68% of those with severe injury and 15% of those suffering moderate injury subsequently had dysphagia requiring intervention. Postoperative dysphagia is also common after laryngotracheal reconstruction surgery or cardiovascular surgery. In a review of 2,255 children who had cardiovascular surgery, Jaquiss et al., found that 1.7% had vocal cord dysfunction associated with significant feeding problems and required prolonged gastrostomy feeding. These patients are predisposed to aspiration due to impaired airway protection.

Life-threatening causes of dysphagia may involve airway compromise, serious local or systemic infection, and inflammatory disease (Table 52.3). The newborn may have a congenital anatomic abnormality, such as tracheoesophageal fistula, with aspiration of swallowed fluid into the lungs, or may have traumatic injury to the upper airway and esophagus from iatrogenic instrumentation in the delivery room. The older child may have a foreign body in the airway or esophagus, with the possibility of complete airway obstruction (see Chapter 5). Anaphylaxis or other allergic and infectious processes may present with dysphagia and can threaten airway integrity. These include epiglottitis, retropharyngeal abscess, Stevens-Johnson syndrome, and central nervous system infections.

EVALUATION AND DECISION

The evaluation of dysphagia in the pediatric patient begins with a detailed history, including pregnancy and delivery, family history, feeding history, growth and development, and a history of other illness (Table 52.4). An accurate and complete history should suggest the diagnosis in approximately 80% of patients. Prenatal polyhydramnios, maternal infection, maternal drug or medication use, bleeding disorders, thyroid dysfunction, toxemia, or irradiation may lead to or indicate swallowing problems in the newborn or infant. Association between decreased rate of fetal suckling and digestive tract obstruction or neurologic damage is well known. Maternal myasthenia gravis may also cause temporary feeding problems in the newborn.

A history of traumatic delivery may result in neurologic injury or laryngeal paralysis. Newborn intubation may be associated with trauma to the trachea, larynx, or esophagus, as well as hypoxic brain injury. A history of prematurity, developmental delay, failure to thrive, hypotonia, or associated congenital abnormalities may indicate a neuromuscular cause for dysphagia. The feeding history should include acute or chronic onset of symptoms, age at onset, weight loss, failure to thrive, and type and amount of food the child eats. Presence of fever, pain, respiratory symptoms, facial color, stridor, liquid or solid food intolerance, vomiting, regurgitation, drooling, voice change, position during feeding, and the timing of symptoms in relation to feedings should also be documented. For example, the infant with an upper airway obstruction may become fatigued or begin coughing and choking shortly after beginning to eat. Choking during feeding in an infant may be due to an underlying anatomic abnormality of the trachea, esophagus or larynx. Congenital vascular lesions causing extrinsic compression of the esophagus may remain silent until

TABLE 52.4

IMPORTANT HISTORICAL FEATURES FOR DYSPHAGIA

General
Age of onset
Acute/gradual onset
Weight gain
Growth and development
Constant, progressive, or intermittent
Pain (location/quality)
Fever
Ingestion history (neuroleptics, foreign bodies, or caustics)
Difficulty chewing
Difficulty swallowing
Change in voice quality
Altered swallowing sensation (lump, sticking, or foreign body)
Drooling/salivation
Solid/liquid intolerance
Cough/choking while feeding
Respiratory symptoms after feeding (stridor, wheezing, or apnea)
Vomiting (gastric contents) vs. regurgitation (food without gastric contents, esophageal disorders)
Nasopharyngeal regurgitation
Gastroesophageal reflux
Peptic ulcer disease
Tobacco or alcohol usage
Recent esophageal or airway instrumentation
Arthritis, degenerative joint disease
Antibiotic use
Chemotherapy
Underlying illness, immunodeficiency

Newborn/Infant
Prematurity
Pregnancy history
- Infections
- Medications (especially antihypertensives)
- Bleeding
- Toxemia
- Thyroid dysfunction
- Polyhydramnios
- Fetal irradiation
- Food allergy

Birth history
- Birth trauma
- Hypoxia
- Endotracheal intubation or resuscitation

Cough/gag/cyanosis/fatigue/stridor/irritability with feeding
Feeding times greater than 30 min
Respiratory distress associated with feeding
Vomiting or regurgitation
Level of alertness
Weight gain or failure to thrive
Nasal regurgitation
Refusal to eat age-appropriate foods
Recurrent pneumonias
Family history of neuromuscular disease

the introduction of solid food, or may rarely manifest as dysphagia later in adulthood. Gastroesophageal reflux in infants may manifest as vomiting shortly after feeding or with a history of nighttime cough or emesis. Intrinsic lesions, from inflammation, tumor, or foreign body, may create problems with solid food but cause no difficulty with liquids. Infants with previously unrecognized neuromuscular disorders commonly present initially with dysphagia, particularly for liquids; drooling; prolonged feeding time; weak suckle; or nasal reflux of swallowed material. A history of fever may indicate aspiration pneumonia or other infectious or inflammatory causes of dysphagia. Determining whether symptoms are progressive or intermittent/nonprogressive can also be helpful.

The child with dysphagia should undergo a thorough general physical examination, initially focusing on the patient's cardiopulmonary status. Evidence of respiratory distress or cardiovascular compromise should be treated promptly in the appropriate manner, as outlined elsewhere in this text (see Chapters 1, 2, and 5). Assurance of a secure and stable airway should precede attempts to examine the oropharynx or to remove a foreign body (see Chapter 28).

In the stable dysphagic patient, evaluation of head size and shape, facial structure, mandibular development, tongue disproportion, and ear configuration may provide evidence of an underlying congenital abnormality, such as Pierre-Robin, Treacher-Collins, Crouzon's, and Goldenhar's syndromes. Evaluation of nasal airway patency in the infant can be determined by gently passing an 8F catheter through the nares into the stomach. If the catheter fails to pass easily, choanal stenosis, atresia, or esophageal obstruction must be considered. Inspection of the oral cavity, pharynx, and neck may reveal a cyst, mass, localized infection, or inflammatory cause for dysphagia. Cervical auscultation over the thyroid cartilage during feeding may note evidence of aspiration if upper airway breath sounds are abnormal or if the timing of breathing and swallowing is uncoordinated. The pulmonary examination may also detect signs of aspiration or respiratory compromise, including elevated respiratory rate, increased respiratory effort, stridor, stertor, rales, rhonchi, wheezing, or change in voice quality. Neurologic examination may reveal an altered level of arousal from an underlying brain injury or depressed sensorium from drugs or infection that may limit effective swallowing. Examination of the cranial nerves, particularly V, VII, IX, X, and XII, may reveal abnormalities from traumatic or surgical injury, tumor, or congenital disorder. Evaluation of muscle tone, strength, and reflexes in consideration of other neuromuscular causes of dysphagia completes the general physical examination.

Provided oral intake is not contraindicated by an expected procedure or intervention, observation of a typical feeding, given by a parent or primary caregiver, may help elucidate the cause of dysphagia. The manner of presentation of food to the patient, the consistency and amount given, patient position, duration of feeding, regurgitation (oral or nasal), agitation or behavior change, or the development of respiratory symptoms may further guide the diagnostic evaluation. Patients with upper airway obstruction may have an exacerbation of symptoms when attempting to drink. Patients with lesions such as tracheoesophageal fistula, vascular rings, or esophageal obstruction may begin coughing and choking soon after drinking without any initial difficulty. However, esophageal disorders such as extrinsic compression, strictures, tumors, or altered motility commonly are clinically silent and typically require use of radiographic or direct visual techniques for diagnosis.

Evaluation of the stable dysphagic patient may proceed on the basis of age and acute versus chronic onset of symptom development (Fig. 52.1). The neonate and young infant will require evaluation techniques and consideration of the age-related differential diagnoses outlined in Table 52.2, whereas the older child with an acute onset of dysphagia generally requires a more urgent approach. Witnessed or suspected foreign bodies, either ingested or aspirated, should be investigated with plain radiographs (or contrast studies if a radiolucent object is considered) and, if identified, emergently removed (see Chapter 28). A history of neck trauma or caustic ingestion should lead to the suspicion of aerodigestive tract abnormalities. These patients may present dramatically with neck pain, drooling, and evidence of facial or other trauma, but they may also have a subacute presentation (see Chapters 102, 110, and 115). Presence of fever or signs of systemic illness may result

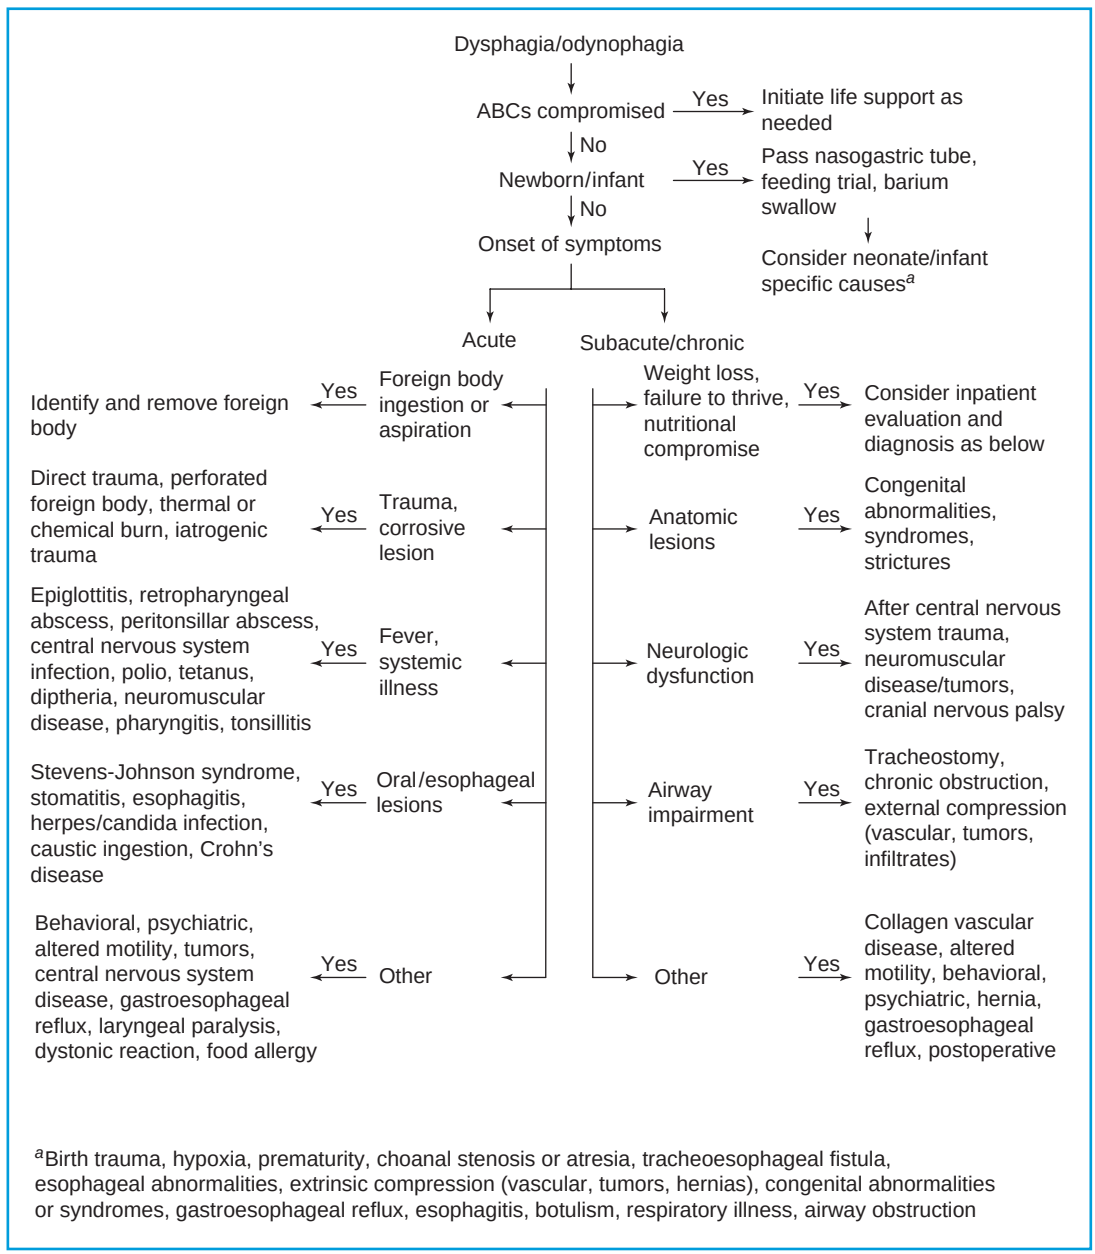

FIGURE 52.1 Evaluation scheme for the child with dysphagia or odynophagia. *Radiographic and assessment options:* neck, chest, abdomen, inspiratory/expiratory films, lateral decubitus films, fluoroscopy (including videofluoroscopy), contrast studies, ultrasonography, echocardiography, angiography, computed tomography, magnetic resonance imaging, esophageal manometry, laryngopharyngeal sensory testing, electromyography, endoscopy. *Laboratory options:* complete blood cell count, blood gas, cultures, toxin identifications, nutritional and electrolyte profile. *Consultant options:* pediatrics, general surgery, otolaryngology, gastroenterology, neurology, infectious disease, cardiology, pulmonology, rheumatology, oncology, nutrition, speech therapy, speech-language pathologist, occupational therapy. ABCs, airway, breathing, circulation.

from potentially life-threatening infectious or inflammatory conditions (Table 52.3). Less severe problems (gingivostomatitis or thrush) may present with mouth lesions and can be managed on an outpatient basis after careful assessment of hydration status. Severe problems, including Stevens-Johnson syndrome, herpetic esophagitis, and diphtheria, may be discovered on a detailed examination and may require inpatient management.

Patients with a nonacute history of swallowing difficulty can be evaluated and treated as shown in Figure 52.1. The initial emphasis with these patients lies more in determination of nutritional status and development issues than in acute emergency department intervention, although prolonged feeding difficulty can develop into a life-threatening problem. Evaluation of these patients often involves a multidisciplinary approach. The child with obvious anatomic abnormalities, neurologic impairment, specific syndromes, or a tracheostomy may need referral to appropriate subspecialists after initial evaluation. The child without obvious anatomic or neurologic abnormality who has weight loss or failure to thrive may be evaluated as an outpatient.

Radiographic evaluation of the stable dysphagic patient usually begins with an examination of the airway and soft tissues of the neck, looking for evidence of a foreign body, mass, airway impingement, or other abnormality. A chest radiograph may suggest aspiration pneumonia, congenital heart disease, or mediastinal abnormality or, as in the patient with achalasia, demonstrate fluid levels within an enlarged esophagus. Helical computed tomography scan, echocardiography, or angiography may further identify problems suspected from initial studies.

A videofluoroscopic swallowing study [VFSS or modified barium swallow (BS)] is currently the gold standard for evaluating preesophageal disorders. The patient is fed a typical solid or liquid diet (mixed with contrast material) by his or her parent or caregiver, while the radiologist records the preesophageal and esophageal swallowing phases on videotape. With a swallowing specialist present, such as a speech-language pathologist, the feeding presentation and position, consistency, amount, and type of foods can be varied, both to diagnose problems resulting in dysphagia or aspiration and to evaluate possible therapeutic interventions. This dynamic study may reveal evidence of aspiration, nasopharyngeal reflux, motility disorders, obstructions, masses, cricopharyngeal dysfunction, fistulas, inflammatory processes, or other causes of dysphagia. VFSS differs from the standard BS or upper gastrointestinal (UGI) series in that it does not use pure contrast, but instead uses food mixed with contrast in an attempt to simulate the normal feeding pattern as closely as possible. Several studies suggest multiple swallows should be observed because patients with pathology may not demonstrate those abnormalities on the first few swallows. VFSS is less effective than a UGI series or BS at diagnosing gastroesophageal reflux or lower esophageal, gastric outlet, and small bowel abnormalities (Fig. 52.2), but it is superior in identifying preesophageal causes of dysphagia.

Fiberoptic endoscopic evaluation of swallowing (FEES) is a newly described diagnostic and clinical tool for the pediatric dysphagia patient. With a nasopharyngeal approach under local anesthesia, FEES allows direct visualization of the swallowing process with the ability to document aspiration and functional

FIGURE 52.2 Upper gastrointestinal series (UGI) of a 14-year-old girl presenting with dysphagia. The UGI demonstrates a significantly dilated upper esophagus, with a functional spasmodic obstruction of the lower esophagus, characteristic of achalasia.

pharyngeal or upper esophageal disorders. FEES may also be indicated for the suspected mass lesion, stricture, caustic ingestion, inflammatory lesion, or foreign body. Advantages of this endoscopic evaluation include no radiation exposure, ready availability, the use of regular positioning and diet (i.e., breastfeeding) without contrast material, and the ability to test sensation in the larynx and pharynx. Disadvantages of FEES primarily result from the lack of visualization of the oral or lower esophageal phases of swallowing and potential intolerance of the endoscope in an awake infant or child. FEES has been successfully used to initially screen dysphagia patients and to reevaluate swallowing function after feeding interventions to diet, position, presentation, and so on.

Other tests, such as a complete blood cell count and appropriate cultures in the febrile patient, or arterial blood gas for the patient with respiratory distress, may also be indicated. Cervical ultrasonography has been used to identify abnormalities with the tissues and function of the palate, tongue, and floor of the mouth; however, it is less useful than contrast studies for assessing airway problems and aspiration. Manometry may be useful in the dysphagic patient with an esophageal motility disorder, but it is better tolerated and more typically used in adults. Esophageal pH testing or radionuclide scintigraphy (milk scans) may document previously unsuspected gastroesophageal reflux. Bronchoscopy with bronchoalveolar lavage is occasionally used to assess recurrent small-volume aspiration. If lavage contains a high percentage of lipid-laden macrophages, aspiration is more likely. However, this technique has low sensitivity and specificity

for aspiration. Additional neurologic testing may include studies of brainstem-evoked responses, peripheral nerve conduction, or electromyography. More recent functional magnetic resonance mapping of the swallowing centers in the brain promises improved insight into dysphagia from a central etiology.

Treatment of dysphagia is dictated by the underlying diagnosis. Disorders with the potential to become life-threatening should be treated in the hospital under the care of appropriate specialists. Chronic dysphagia with actual or potential aspiration should be identified. If nutrition has been severely compromised from chronic dysphagia, one should consider nasogastric, nasojejunal, or gastrostomy tube feedings. Many pediatric facilities have developed multidisciplinary feeding/swallowing teams to provide subspecialty expertise, while maintaining continuity and coordination of patient care. Such pediatric teams may include developmental or general pediatricians, speech-language pathologists, pulmonologists, otolaryngologists, gastroenterologists, neurologists, nutritionists, psychologists, occupational or physical therapists, and social service workers. If such a specialty service is not available, involvement of appropriate individual specialists for the management of the patient with dysphagia is imperative as mentioned in Figure 52.1. However, therapy for many disorders can be initiated on an outpatient basis. Gastroesophageal reflux and resultant esophagitis can often be successfully managed with small-volume thickened feeds, positioning, and elevation of the head of the bed. Medical therapy consists of liquid antacids, metoclopramide (should not be used long term due to risk of permanent dystonias), H_2-blockers, or proton pump inhibitors. Children who have failed reflux therapy may be candidates for an evaluation for eosinophilic esophagitis. Treatment of eosinophilic esophagitis includes topical or oral steroids along with proton pump inhibitors. Mycostatin will be helpful in candidal esophagitis, whereas herpetic esophagitis often is self-limiting.

Pediatric dysphagia is an uncommon complaint in the pediatric emergency department but may be the presenting symptom for a wide variety of underlying clinical problems. The history and physical examination first must focus on potentially life-threatening causes and will often lead to a specific diagnosis. Causes of dysphagia not identified from the initial evaluation may require radiographic or subspecialty referral for further diagnostic and therapeutic management.

CHAPTER 53 ■ PAIN—DYSURIA

JACQUELINE BRYNGIL CORBOY, MD

Many conditions of the genitourinary tract produce symptoms of pain or burning associated with urination, or *dysuria*. The sensation is produced by the muscular contraction of the bladder and the peristaltic activity of the urethra, both of which stimulate the pain fibers in the edematous and inflamed mucosa. Young children may complain of painful urination when they are instead experiencing related symptoms, such as pruritus. When a child is too young to verbalize his or her symptoms, parents may interpret various nonspecific statements or behaviors by their child as indicative of painful urination.

Dysuria is a commonly reported symptom associated with a number of infectious and noninfectious causes (Table 53.1), but it usually stems from one of several common disorders of childhood and adolescence (Table 53.2). Most children with dysuria as a chief complaint will have primary disorders of the genitourinary tract, and although patients with urethritis secondary to systemic illnesses may have dysuria as one of their many symptoms, it is only occasionally the principal reason for a visit to an emergency department (ED).

Most diseases causing dysuria are self-limited or easily treated; however, the rarely seen systemic causes of urethritis or the spread of some bacterial pathogens beyond the genitourinary tract may be life-threatening (Table 53.3)

DIFFERENTIAL DIAGNOSIS

Systemic Conditions

Stevens-Johnson syndrome is a severe manifestation of erythema multiforme, which may affect the mucous membranes throughout the body, producing conjunctivitis, oral ulceration, and urethritis. The rash that occurs in most patients often has the appearance of target lesions. Although usually self-limited, in some cases, pulmonary involvement leads to death (see Chapter 85).

Skin conditions such as psoriasis, epidermolysis bullosa, and lichen sclerosis et atrophicus can involve the anogenital region, often producing pruritis, pain, and dysuria.

Reiter's syndrome, in the family of juvenile spondyloarthropathies, is characterized by conjunctivitis, arthritis, and urethritis. Rarely diagnosed, it is more common in the male population. Crohn's disease can have genitourinary complications in up to 30% of patients and may present as dysuria, often in the setting of a urinary tract infection, and may be complicated by fistula formation.

Also rare, Behçet's syndrome is another multisystem disease characterized by recurrent oral ulcerations, ocular panuveitis, vasculitis and, less commonly, genital ulcerations that may produce dysuria.

Localized Conditions

Infectious Causes

Infections of the genitourinary tract are the predominant cause of dysuria. In nonsexually active children and adolescents, pyelonephritis is the most serious of these disorders. It usually manifests with fever, often above 39°C (102.2°F), and flank pain or tenderness (older children and adolescents). Patients with cystitis, or lower urinary tract infection (UTI), often present with suprapubic pain or tenderness but may or may not have fever, which, if present, is usually low grade.

Urethritis is a more localized infection that often produces a discharge. Bulbar urethritis is a urologic problem affecting male adolescents, which presents with dysuria and microscopic hematuria, presumably of viral origin. Also in adolescents, *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are the most common bacterial pathogens responsible for urethritis. Asymptomatic infections with these pathogens may lead to the development of pelvic inflammatory disease, which can have serious consequences if left untreated. Non–gonococcal urethritis secondary to *Mycoplasma hominis* and *Ureaplasma urealyticum* infection has been described in male adolescents and to a lesser extent in female adolescents. When herpes simplex causes urethritis, vesicles are usually apparent on examination. Younger children may develop a nonspecific bacterial urethritis with involvement of the glans penis (balanitis) or both the glans and the prepuce (balanoposthitis). In the setting of an urban ED, infectious urethritis and/or cervicitis may be the source of isolated dysuria in up to 30% of adolescent girls, and often goes undiagnosed if urine is sent solely for urinalysis and culture. The development of nucleic acid amplification tests (NAATs), which use ligase chain reaction (LCR) or polymerase chain reaction (PCR) technologies, allows first-catch urine (*not* clean-catch) to be tested for the presence of *C. trachomatis* and *N. gonorrhea* in a noninvasive manner. Where available, these can provide an accurate screening tool for the testing of sexually transmitted diseases (STDs) without performing a cervical or male urethral swab culture. An alternative method of sample collection for NAAT in the female patient is that of the self-collected vaginal swab, which has been shown to be accurate when compared with provider-obtained cervical specimens as well.

Candidal and streptococcal vulvitis and vulvovaginitis, or diaper dermatitis in the non–toilet-trained toddler, may present with a chief complaint of dysuria. Physical examination usually reveals erythema, a cheeselike or mucoid discharge, and, in the case of *C. albicans*, erythematous "satellite" lesions (Chapters 90, 92).

TABLE 53.1

CAUSES OF DYSURIA

I. Systemic Conditions
  A. Stevens-Johnson syndrome
  B. Dermatologic disease (psoriasis, epidermolysis bullosa, lichen sclerosis)
  C. Crohn's disease
  D. Reiter's syndrome
  E. Behçet's syndrome
II. Localized Conditions
  A. Infection
    1. Pyelonephritis
    2. Cystitis
      a. Viral (adenovirus)
      b. Bacterial (*Escherichia coli* and other organisms)
    3. Urethritis/balanitis
      a. *Neisseria gonorrhoeae*
      b. *Chlamydia* species
      c. Herpes simplex
      d. *Mycoplasma* and *Ureaplasma*
    4. Vaginosis
      a. Group A streptococcus
      b. *C. albicans*
  B. Chemical irritation
    1. Detergents
    2. Fabric softeners
    3. Perfumed soaps
    4. Bubble baths (unconfirmed)
    5. Medication
  C. Trauma
    1. Local injury
    2. Masturbation
  D. Miscellaneous
    1. Hypercalciuria/uricosuria/urinary stones
    2. Labial adhesions
    3. Urethral stricture
    4. Dysfunctional voiding
    5. Psychogenic dysuria
III. Complaints Misinterpreted As Dysuria
  A. Pinworms
  B. Sexual abuse

Noninfectious Conditions

In young children, certain drugs taken systemically and topical exposures to a variety of chemicals have been reported to irritate the urethral mucosa; however, these findings have not been well documented. Potential local irritants include detergents, fabric softeners, perfumed soaps, and possibly bubble baths. These patients may have either no physical findings or only mild erythema, but they do not have discharge.

Minor injury is another relatively common cause of urethral irritation. In older children and adolescents, normal self-exploratory sexual play, masturbation, voluntary sexual activity, or sexual abuse may be the source of the trauma. As for patients with chemical urethritis, the examination is generally unremarkable.

Urinary stones in children develop in the setting of anatomic abnormalities and/or recurrent infection, and their passage may be associated with complaint of dysuria along with flank pain and hematuria. Children with idiopathic hypercalciuria and idiopathic hyperuricosuria, rare conditions that predispose these patients to produce renal calculi, may complain of dysuria even in the absence of an observable stone (Chapter 100).

Foreign bodies inserted into the urethra should always be considered in the young child. While not common, they can present with urinary symptoms months or years after their original insertion and often require surgical removal.

Urethral strictures, both congenital and acquired, may present with signs of obstruction such as urinary retention, as well as dysuria.

Labial adhesions occur relatively often in young girls. Although they are most often asymptomatic, micro tears may cause dysuria on occasion.

Dysfunctional voiding is a condition that may mimic UTI or urethritis and is responsible for approximately 40% of childhood visits to an urologist. This syndrome is multifactorial in origin and may be initially precipitated by a history of UTI. Behavioral modification or use of anticholinergic medications may be necessary to resolve this condition.

Throughout childhood and into adolescence, a complaint of dysuria may be psychogenic in origin, occurring in the absence of inflammation in the genitourinary tract.

Complaints Misinterpreted As Dysuria

Enterobius vermicularis (pinworms) normally infests the perianal area but occasionally spreads to the vagina in young girls. The pruritus that accompanies this infestation may be expressed as dysuria.

Young children who have experienced sexual abuse may present to the ED with a complaint of dysuria because they experience pain in their genital area or may exhibit behaviors that are interpreted by adult observers as indicative of genital pain.

TABLE 53.2

DIFFERENTIAL DIAGNOSIS OF COMMON CAUSES FOR DYSURIA

Disorder	Cause	Age	Fever	Tenderness
Pyelonephritis	*E. coli*/other bacteria	All	Common, ≥38.5°C	Flank
Cystitis	Viruses/*E. coli*/other bacteria	All	Occasional, ≤38.5°C	Suprapubic
Infectious urethritis	*N. gonorrhoeae*/*C. trachomatis*/*Mycoplasma*/*Ureaplasma*	Adolescents	None	Prostatic/pelvic (occasional)
Vaginitis/dermatitis	*C. albicans*/Group A streptococci	All	None	Local or none
Chemical/traumatic urethritis	Physical insult	Children	None	None

TABLE 53.3

LIFE-THREATENING CAUSES OF DYSURIA

Stevens-Johnson syndrome
Gonococcal urethritis/vaginitis (when complicated by pelvic inflammatory disease or systemic spread)

EVALUATION AND DECISION

The approach to the child with dysuria must be broad, and history will help determine the direction of the workup. A thorough investigation of possible causes should be conducted, including questions about trauma (both accidental and nonaccidental), exposure to chemicals such as detergents, fabric softeners, perfumed soaps, bubble baths, and medications that have been reported to irritate the mucosal lining of the urethra or bladder. A negative history for injury may not be accurate, however, because most traumas are not recalled by young patients or, in the case of masturbation or abuse, may be denied. The detection of STDs, a common cause of dysuria in adolescents, may in turn be facilitated by obtaining a history about the nature and extent of sexual activity or hampered due to denial by the patient for fear of parental consequences (Fig. 53.1).

The most important tasks for the emergency physician are to recognize the rare but serious systemic syndromes and to diagnose or exclude infections. When dysuria is associated with a constellation of other symptoms, systemic conditions must be ruled out. For example, if the patient also complains of joint pains and conjunctivitis, Reiter's syndrome should be considered. In a female patient with dysuria and abdominal pain, pelvic inflammatory disease must be excluded.

Historical findings may be further supported by physical examination, and special attention should be directed to the abdomen and genitourinary tract. Careful palpation for the presence of masses in the abdomen or suprapubic region should be performed. The presence of discharge, rashes, and other lesions may identify the source of the problem right away, negating the need for extensive workup. In both pubertal and prepubertal patients, the finding of vesicles suggests an infection caused by herpes simplex. Ulcerations without vesicles, however, may be indicative of systemic disorders such as Behçet's or Stevens-Johnson syndrome. Labial adhesions are

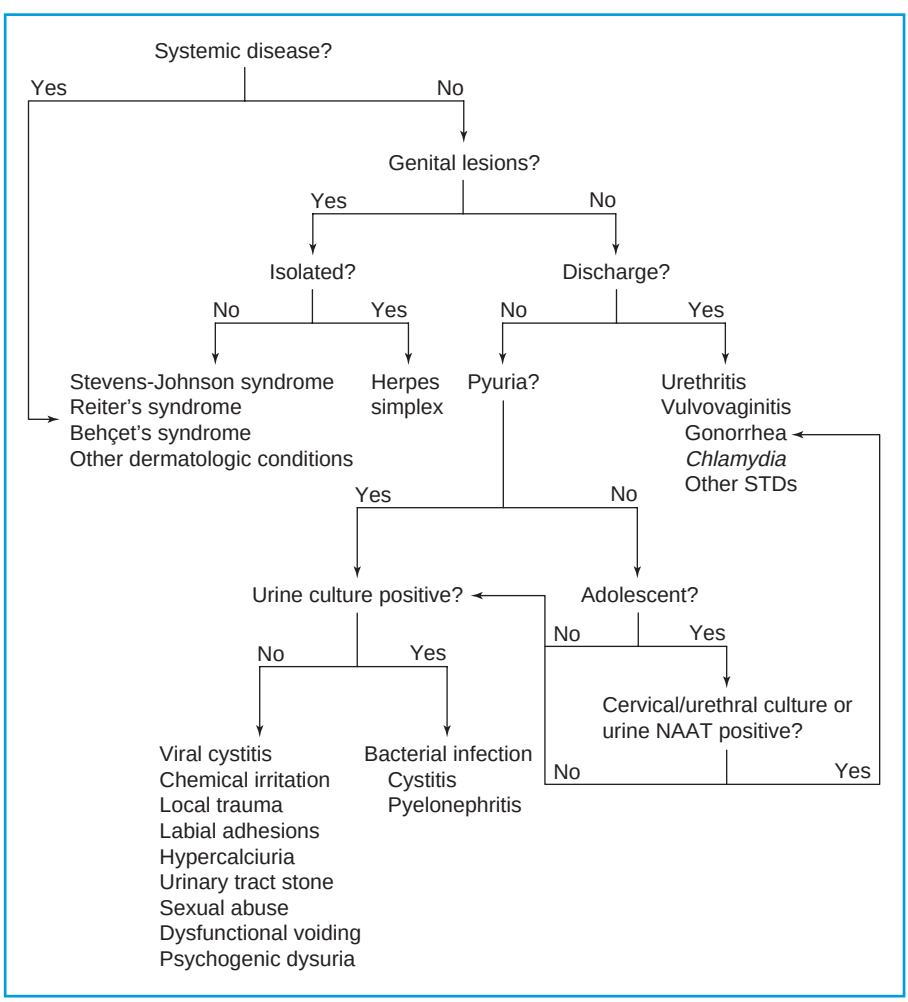

FIGURE 53.1 Approach to the diagnosis of dysuria. STDs, sexually transmitted diseases; NAAT, nucleic acid amplification test.

easily recognized on inspection in young girls. A urethral or vaginal discharge suggests an infection of the genitalia: urethritis in the boy and urethritis or vulvovaginitis in the girl. *N. gonorrhoeae* is an organism that commonly causes disease in this area. A Gram stain can be a helpful adjunct in determining the nature of the discharge. In prepubertal girls or boys of any age, the finding of gram-negative intracellular diplococci points to the diagnosis of gonorrhea. However, because nonpathogenic organisms that colonize the vagina after puberty have the same appearance as *N. gonorrhoeae* on Gram stain, this method is an unreliable tool in teenage girls. Urine NAATs, which use LCR or PCR technologies, allow urine to be tested for the presence of *C. trachomatis* and *N. gonorrhea*. These tests, however, are more expensive than traditional swabs but, where available, they can provide a reasonably accurate screening tool for the testing of STDs without performing a cervical or male urethral swab culture. A urethral or vaginal culture should also be obtained on all positive samples for confirmation and susceptibility testing. Postpubertal patients may be treated in the ED, but treatment in young children should await the results of cultures because of medical-legal implications.

If no discharge is seen, the physician should obtain a urinalysis and urine culture. Urinalysis and culture should be performed on specimens obtained by catheter or suprapubic aspiration on female children younger than 2 years and male children younger than 6 months. Clean-catch specimens may be analyzed outside those age groups. A positive result on testing by dipstick (leukocyte esterase and/or nitrites, with the former being more sensitive and the latter more specific) or the finding of pyuria on microscopic analysis increases the likelihood of bacterial infection (urethritis, cystitis, or pyelonephritis) but does not prove the diagnosis and must be confirmed by culture. Inflammatory conditions, such as chemical urethritis, and nonbacterial infections may also evoke a leukocyte response. Thus, the physician may choose to allow the results of cultures to guide the management of children with pyuria, rather than immediately beginning antibiotic therapy, unless clinical suspicion of infection is very high (e.g., prior history of UTI, or presence of fever and flank pain suggesting pyelonephritis).

In the young child with dysuria in the absence of pyuria, local trauma and chemical irritation are the most likely causes for the pain. Because a few children with UTIs do not have either a positive result on testing by dipstick or pyuria, most physicians obtain a urine sample for culture, particularly from febrile patients. However, some experts would argue that the likelihood of infection is low enough in the absence of positive indicators on urine analysis that no further testing is needed. Adolescents require either urine or swab cultures of the genital tract to diagnose mild gonococcal or chlamydial infections.

When no other cause for dysuria is found in a prepubertal girl who has adhesions of her labia minora, these adhesions may be responsible for the painful urination. Most girls with labial adhesions, however, are asymptomatic. Thus, infection or another cause for dysuria should be excluded in girls with this finding.

A few patients with a normal examination and negative cultures may complain persistently of dysuria. In this setting, dysfunctional voiding and idiopathic hypercalciuria represent potential diagnoses. If suspected, the diagnosis of hypercalciuria/uricosuria can be confirmed by measurement of calcium excretion in the urine. Another possible explanation in a female is that the patient is experiencing vaginal pruritus secondary to pinworms. Confirmation of this diagnosis requires either identification of the larvae or ova, or a response to a trial of mebendazole.

Last, the physician should give consideration to both sexual abuse and psychogenic dysuria. In most of these cases, further evaluation outside of the ED will be needed.

SYMPTOMATIC MANAGEMENT

When a specific diagnosis has not been established and the physician is awaiting the results of cultures, therapy directed at the symptom of dysuria can provide some relief. Generally, dilute urine causes less irritation than concentrated urine, so a generous fluid intake should be recommended. Warm water sitz baths may be helpful in the child with urethritis or vulvovaginitis. For the child older than 6 years, phenazopyridine (Pyridium®) at a dosage of 12mg/kg/day divided into three doses (daily maximum 600 mg/day), administered for up to two days, may be helpful as a urinary tract anesthetic.

CHAPTER 54 ■ PAIN—EARACHE

AMY M. ARNETT, MD

Ear pain or otalgia is a common symptom of many different conditions in or around the ear (Tables 54.1 to 54.3). Preverbal children may present with fussiness, crying, or waking intermittently at night. Children may have difficulty differentiating tinnitus from ear pain. Ear pain may be primary/otogenic or referred/nonotogenic in origin. A complete history and physical examination is necessary, focusing not only on the ear but also on adjacent areas and those regions innervated by nerves that also innervate the ear. Areas that might be a source of referred pain include the oral cavity, larynx, pharynx, and cervical spine; rarely, referred pain may be from a site below the clavicles. Patients with accompanying central nervous system symptoms, vertigo, or cranial nerve deficits need more extensive evaluation.

DIFFERENTIAL DIAGNOSIS

Otogenic Causes

Trauma is usually evident by physical examination. Hematomas of the pinna or auricle resulting from blunt trauma may occur over the cartilaginous portion or upper half of the ear between the perichondrium and the underlying cartilage. The hematoma may appear as a boggy, purple swelling. Sterile aspiration and a molded pressure dressing are necessary to avoid pressure necrosis of the underlying cartilage and a resulting distorted "boxer's" or "cauliflower" ear.

Body piercing has increased significantly in more recent years, with earlobes and ear cartilage being the most frequent sites. Common complications include infection, allergic reaction, keloid formation, and traumatic tearing. Another complication of piercing is an embedded earring, which often requires local anesthesia and removal. Superimposed infection is the most common complication of ear piercing with local symptoms, including redness, swelling, warmth, pain, and drainage. Earlobe infection is most commonly secondary to *Staphylococcus aureus* and responds well to local treatment and topical or oral antistaphylococcal antibiotics. Complications of ear piercing that involve auricular cartilage such as the helix include chondritis, perichondritis, or perichondrial auricular abscess from *Pseudomonas aeruginosa*. These patients may also present with systemic symptoms, including fever, chills, or nausea. Presentation may be 3 to 4 weeks after piercing and may require incision and drainage, debridement, and fluoroquinolone antibiotics to treat *Staphylococcus* and *Pseudomonas* and *Streptococcus pyogenes*. Nickel earrings may cause earlobe dermatitis. These earrings should be replaced with gold or stainless steel earrings, and topical corticosteroids should be applied as an antiinflammatory agent. Insect or spider bites may cause a local allergic reaction or secondary cellulitis of the ear. Swelling and erythema may occur with either; so, signs of infection such as pain, fever, and tenderness may help determine treatment by antihistamine versus antibiotic. Keloid formation may be pruritic or painful. These patients may be referred for definitive treatment. Tearing of the ear from a piercing may be repaired as any laceration; consider a location involving cartilage may require a layered repair by a facial trauma specialist.

Preauricular pits are asymptomatic until they become infected. Physical examination reveals a warm, erythematous, tender area anterior to the tragus. Treatment includes oral antibiotics to cover skin flora, occasional incision and drainage, and referral for eventual resection.

Frostbite of the auricle is painful. The ear usually appears pallid secondary to vasoconstriction. With thawing, it becomes hyperemic and edematous, and vesicles may appear. It is treated by rapid rewarming with application of moist gauze or cloths soaked in 40°C (104°F) water and continued through reperfusion pain. There is some literature to support aspiration of clear blisters, but hemorrhagic vesicles should be left intact. Consult your burn specialist for their current recommendations. Analgesics should be given for pain control. No debridement of damaged tissue is performed until full demarcation of tissue loss is determined, usually weeks later.

Furunculosis is a gram-positive, usually staphylococcal infection of a hair follicle at the external auditory meatus that causes marked pain and occasional otorrhea. This generally occurs in the cartilaginous portion of the canal and may cause cervical adenopathy. Treatment consists of warm compresses to encourage spontaneous drainage. Topical or oral antistaphylococcal antibiotics are rarely indicated. If spontaneous drainage does not occur, incision and drainage may be necessary. Coalescence of furuncles produces a carbuncle or abscess, which often requires drainage. In the era of colonization with methicillin-resistant *Staphylococcus aureus* (MRSA), culture and antibiotic coverage should be considered.

Herpes zoster oticus is a painful viral infection characterized by vesicles on the auricle, the external auditory meatus, and occasionally, the tympanic membrane (TM). It is caused by a residual *Varicella zoster* viral infection of the seventh and eighth cranial nerves. Complications include facial paralysis as in Ramsay Hunt syndrome, hearing loss, and vertigo. Other cranial nerves may be affected. Although this normally presents in adults, it may occur at any age. Patients in the early stages may be treated with an antiviral agent and/or systemic steroids; otherwise, treatment is mainly symptomatic.

Otitis externa (OE) usually presents in warm, humid weather. Because swimming can predispose the canal to this condition, it is often called "swimmer's ear." The initial presenting symptom may be pruritus. Scratching the canal may

TABLE 54.1

CAUSES OF EARACHE

Otogenic
External
- Trauma
- Ear piercing—infection/dermatoses
- Preauricular pit infection
- Frostbite
- Furunculosis
- Herpes zoster oticus (Ramsay Hunt syndrome)
- Insect/spider bites

Canal
- Otitis externa—swimmer's ear
- Otomycosis
- Foreign body (FB)
- Dermatoses—seborrhea or psoriasis
- Contact dermatitis
- Impacted cerumen
- Trauma

Tympanic Membrane/Middle Ear
- Acute otitis media
- Otitis media with effusion/serous otitis media
- Traumatic perforation
- Myringitis
- Hemotympanum
- Aerotitis or acute barotitis
- Cholesteatoma

Inner Ear/Periauricular Structures
- Labyrinthitis
- Subperiosteal abscess/acute mastoid osteitis
- Intracranial infections
- Facial nerve palsy

Nonotogenic—Referred Pain
Trigeminal Nerve (V)
- Oral cavity: stomatitis, gingivitis, trauma
- Dental: impacted teeth, trauma, caries, abscess
- Temporomandibular joint dysfunction
- Sinusitis
- Mastoiditis
- Parotitis

Facial Nerve (VII)
- Bell's palsy
- Herpes zoster infection—Ramsay Hunt syndrome

Glossopharyngeal Nerve (IX)
- Oropharynx: tonsillitis, posttonsillectomy, retropharyngeal abscess
- Nasopharynx

Vagus Nerve (X)
- Larynx: trauma, FB
- Esophagus: FB, burn

C2/C3
- Lymphadenitis
- Branchial cleft cysts
- Cervical spine: trauma, infection

Psychogenic

Drug Ingestions (Causing Tinnitus)
- Quinine, quinidine, ethacrynic acid, salicylates, nicotine, aminoglycosides

damage the skin and predispose the area to secondary bacterial infection. Ear pain, itching, and discharge are the primary complaints. Examination reveals pain with movement of the auricle or tragus, an erythematous canal with edema, and sometimes foul-smelling, yellow, brown, white, or gray discharge. *P. aeruginosa* and *S. aureus* are the most common causative organisms. Treatment includes cleaning and acidifying the ear canal, controlling pain, and possible antibiotic coverage. An otic suspension combining an acidic medium with an antiinflammatory and/or antibiotic is the usual treatment. Topical polymyxin/neomycin, ciprofloxacin, and ofloxacin all provide good bacterial coverage for *P. aeruginosa* and *S. aureus*. The fluoroquinolones are less ototoxic if middle ear entry is a concern. A wick may be inserted into the canal if it is too edematous to allow the drops to enter. If there is any accompanying cellulitis, oral antibiotics may be added. Ear plugs for swimmers and acidifying drops after swimming are good preventive measures. Typical pain may be treated with ibuprofen or acetaminophen but may require oral narcotics.

A serious complication of OE is malignant or necrotizing external otitis, which is a fulminant bacterial OE, usually with *P. aeruginosa*. This may extend beyond the limits of the external auditory canal, producing cellulitis, chondritis, osteitis, osteomyelitis, facial nerve paralysis, or septic thromboembolism. These patients require further radiographic evaluation for bony or sinus involvement, otorhinolaryngology (ORL)

TABLE 54.2

COMMON CAUSES OF EARACHE

Otogenic	Nonotogenic
Acute otitis media	Dental caries or abscess
Otitis externa	Pharyngitis
Foreign body	Sinusitis
	Cervical adenopathy

TABLE 54.3

SERIOUS CAUSES OF EARACHE

Hemotympanum secondary to basilar skull fracture
Local spread of acute otitis media to:
- Mastoid cavity—subperiosteal abscess with acute mastoid osteitis
- Vascular structures—lateral sinus thrombosis
- Intracranial region—meningitis, extradural abscess, subdural empyema, focal encephalitis, brain abscess
- Temporal bone—facial nerve paralysis
- Inner ear—labyrinthitis

Ingestions

consultation, and probable admission for combination intravenous antibiotics.

Impacted cerumen in the canal is a common cause of ear pain or discomfort. Normally, asymptomatic cerumen accumulation need not be removed; however, earwax removal is often necessary to complete an ear examination. Careful immobilization is essential. Removal under direct visualization through an otoscope is ideal. An ear curette or small cotton swab may be used. Removal of hard cerumen adherent to the canal may cause bleeding. The wax may be softened with a ceruminolytic agent, such as mineral oil, hydrogen peroxide, or docusate sodium, and then irrigated with warm water. A plastic syringe attached to the plastic tubing end cut from a butterfly needle may be used. A water jet device may also be used, but it must be set on low pressure to prevent damage to the TM. A perforated TM is a contraindication to ceruminolytics or irrigation. An antibiotic/antiinflammatory otic suspension is sometimes recommended as prophylaxis to prevent OE after canal irritation or irrigation.

Foreign bodies (FBs) may be painless, or they can cause trauma or an inflammatory reaction that may elicit pain. Physical examination visually confirms an FB. Successful extraction is dependent on good immobilization, visualization, and availability of equipment. Removal is accomplished by instrumentation with an ear curette or alligator forceps, irrigation with warm water, or suctioning depending on the type of FB. Inflamed canals may be treated with topical antibiotic/hydrocortisone otic drops. Long-standing or hazardous FBs such as button batteries can cause erosion and may require further evaluation and treatment after removal. Referral to ORL should be arranged if FB removal is unsuccessful.

Otomycosis is a fungal infection of the external canal. It may be acute or chronic, primary or secondary to bacterial infection and prolonged use of antibiotic drops. *Aspergillus niger* and *Candida* are the most common causative pathogens. The primary complaint may be pruritus. On physical examination, the canal is erythematous and edematous with grayish, whitish, or blackish debris that resembles dirty cotton. Treatment consists of cleaning and acidifying the ear canal with drops. Topical or systemic antifungals such as nystatin or clotrimazole may be necessary.

Dermatoses of the ear can also cause ear discomfort. Seborrheic dermatitis and psoriasis can affect the external auditory canal and produce scaling or drainage. The primary complaint may be itching. Usually, other areas are also affected, including the retroauricular region and scalp. Removal of crusts can be helpful. Treatment consists of topical corticosteroids.

Contact dermatitis may occur from topical medicines and should be considered in patients with persistent edema and erythema of the canal and auricle, despite appropriate OE treatment. Treatment of the contact dermatitis includes removing the causative agent, cleaning the ear, and applying acidic solutions or topical steroids to decrease the inflammation.

Acute otitis media (AOM) is the most common illness resulting in office visits to physicians who care for children (see Chapter 92). Ear pain is the most reliable symptom on presentation for AOM. In 2000, a review of office visits in the United States showed that approximately 16 million were related to AOM, resulting in 13 million prescriptions. Children in the first 2 years of life have more infections due to eustachian tube dysfunction with its more horizontal position and shorter length as compared with that of the adult; immature or impaired immunity; and increased frequency of upper respiratory infections with day care center exposure. History often includes recent viral upper respiratory infection, followed by deep-seated otalgia, fever, and decreased hearing in older patients.

In 2004, the American Academy of Pediatrics (AAP) and the American Academy of Family Physicians (AAFP) published Clinical Practice Guidelines for AOM. The definition of AOM includes acute onset of symptoms within 48 hours, presence of middle ear effusion, and signs of middle ear inflammation. Physical examination parameters used to evaluate the TM for AOM are position/bulging, color/translucency, and mobility. AOM may show a hyperemic, opaque, bulging TM with poor mobility and serous fluid or yellow pus filling the middle ear space. The auricle is usually normal. A conductive hearing loss may result from accumulation of fluid in the middle ear and impairment of the drum motion. Treatment options vary depending on the severity of infection, with a severe infection defined as the patient having a fever [temperature, more than 39°C (102.2°F)] and severe pain with AOM.

The pathogenesis of AOM often involves coinfection with viral and bacterial pathogens. The three major bacterial pathogens are *Streptococcus pneumoniae* (pneumococcus), nontypeable *Haemophilus influenzae*, and *Moraxella catarrhalis*. *Streptococcus pyogenes, S. aureus, Mycoplasma pneumoniae*, and gram-negative enteric bacilli are sometimes the causes. Children now receive routine heptavalent pneumococcal conjugate vaccine (PCV7) that should reduce pneumococcal otitis media. Amoxicillin (80 to 90 mg per kg per day divided in two doses) remains the first-line drug for nonsevere episodes of AOM because of its antibacterial coverage, safety, low cost, good taste, and narrow microbiologic spectrum (see Chapter 92). Amoxicillin-clavulanate (90 mg amoxicillin per kg per day divided in two doses), with better coverage for β-lactamase–producing bacteria should be considered as first-line treatment for patients with severe AOM, child care exposure, treatment with amoxicillin for less than 30 days prior, or age less than 2 years. Treatment is usually for 10 days, although shorter courses of 5 to 7 days may be considered in the patient at least 6 years old with uncomplicated disease. If symptoms do not improve in 48 to 72 hours, the patient should be examined and considered for second-line therapy to cover resistant strains of *Haemophilus, Moraxella,* or pneumococcus. Those antibiotics include amoxicillin-clavulanate for patients on amoxicillin, or intramuscular ceftriaxone for 3 days for patients on amoxicillin-clavulanate. Other oral cephalosporins or azithromycin may be considered, especially for penicillin-allergic patients. Although AOM has not always been well defined in previous studies, up to 80% of patients diagnosed with AOM improved within 72 hours without treatment. Therefore observation therapy or watchful waiting is now a consideration for treatment. The AAP guidelines suggest considering this for uncertain diagnosis of AOM in children older than 6 months and for routine AOM in children older than 24 months. Subsequent studies support delay in antibiotic treatment only in children older than 2 years. Children aged 2 to 12 years are treated for 48 to 72 hours with pain management; antibiotics are started only if symptoms persist or worsen. Many children have sterile effusions, which are presumed to be viral or unresolved effusions from previously treated infections and are not acutely infected. Pain may be

treated with oral analgesics, such as acetaminophen and ibuprofen, or topical anesthetic drops for temporary relief if there is no perforation. Oral decongestants, antihistamines, and intranasal decongestants have not proven to be effective. For those AOM patients with tympanic perforation and purulent drainage, a topical antibiotic drop such as ofloxacin otic or antibiotic/hydrocortisone otic suspension is sometimes given to treat the inflammatory reaction in the ear canal. Perforated TMs usually heal spontaneously, but they may lead to more chronic unhealed perforations, cholesteatoma, or tympanosclerosis. Children with significant recurrent infections may require further evaluation for immunologic problems and/or an ORL consultation for tympanostomy tube placement.

For a child with tympanostomy tubes, discharge from the ear canal is the most common symptom of a middle ear infection. Although most otorrhea is secondary to a viral illness, for persistent drainage, an ototopical therapy such as fluoroquinolone drops for 3 to 5 days is recommended as the first-line treatment. These patients may also be treated initially with oral pain medication.

Although rare, dangerous complications of AOM include local spread to the mastoid cavity, soft-tissue and vascular structures of the neck, intracranial region and temporal bone, or inner ear. On examination for subperiosteal abscess with acute mastoid osteitis, the pinna may be displaced inferiorly and anteriorly, with obliteration of the postauricular crease as a result of swelling. The eardrum may appear gray, not bulging or perforated. This most commonly occurs in infants due to immature immune systems. Treatment includes intravenous antimicrobials such as vancomycin and ceftriaxone, or ampicillin/sulbactam, and in some cases, surgical drainage.

Facial or abducens nerve paralysis is rarely associated with AOM and is treated with antibiotics and possible surgical nerve decompression. The middle ear and mastoid air cells are adjacent to the posterior and middle cranial fossa and sigmoid venous sinus of the brain. Local infection may spread to these adjacent structures leading to intracranial complications that are rare in developed countries, such as meningitis, extradural abscess, subdural empyema, focal encephalitis, brain abscess, lateral sinus thrombosis, and otitic hydrocephalus. All patients with facial or abducens nerve palsy, vertigo, or central nervous system signs require further radiographic evaluation, such as a computed tomography (CT) scan.

Otitis media with effusion (OME) or serous otitis media is defined as inflammation of the middle ear in which a collection of mucoid or serous liquid is present in the middle ear space without signs or symptoms of acute infection. Approximately 2.2 million cases are diagnosed annually, representing 25% to 35% of all otitis cases. The fluid may occur spontaneously due to eustachian tube dysfunction or as an inflammatory response after AOM. In 2004, the AAP published their Clinical Practice Guideline for OME, developed in conjunction with the AAFP and American Academy of Otolaryngology-Head and Neck Surgery. Although most effusions resolve spontaneously, the length of time for resolution is variable, and there is significant concern regarding conductive hearing loss during early speech and language development. Physical examination should include pneumatic otoscopy to test TM mobility. Tympanometry or acoustic reflectometry may be used to confirm an effusion. For healthy children with no craniofacial or neurologic abnormalities or sensory deficits, the effusion may be managed with observation for up to 3 months, with the more complicated patients receiving closer follow-up. Bacterial pathogens are identified in many children having tympanostomy tube placement for OME; however, studies have shown that antibiotics provide only temporary resolution of fluid and are not routinely recommended. Steroids, antihistamines, and decongestants are not recommended. Chronic effusions may require tympanostomy tube placement for drainage by ORL.

TM perforation may be caused by pressure from fluid behind the membrane or by external trauma. Trauma often occurs with compressive injuries such as a slap with an open hand or injuries from instruments such as cotton-tipped applicators being placed into the ear canal. Pain may be severe immediately after the injury, but it becomes duller with time. Most perforations heal spontaneously. If prophylactic antibiotic eardrops are considered, avoid ototoxic agents. Oral antibiotics are reserved for injuries from contaminated objects or those in a location believed to be infectious. If the perforation involves more than 20% of the drum, a referral for possible repair is needed. Acute hearing loss, facial paralysis, and severe vertigo associated with the perforation require ORL evaluation because of possible ossicle damage or direct injury to the facial nerve or labyrinth.

Bullous myringitis is a painful, usually viral, but possibly bacterial or mycoplasma infection of the TM, characterized by serous or hemorrhagic vesicles or bullae. The course is usually self-limited with treatment consisting of analgesics.

Hemotympanum secondary to a basilar skull fracture may be a serious finding on examination of the ear. The TM may appear dark red or purple secondary to the blood behind it. These patients may have other findings consistent with basilar skull fractures such as Battle's sign—ecchymoses behind the ear, raccoon eyes—periorbital ecchymoses, or cerebrospinal fluid drainage from the nose or ears. The most common complications include facial nerve paralysis, hearing loss, and vertigo. A CT scan is indicated to determine the extent of the injuries. If no significant intracranial injury is found, usually no acute treatment is needed. Antibiotic prophylaxis to prevent meningitis is not routinely recommended.

Aerotitis, or acute barotitis, is a special type of AOM, caused by middle ear barotrauma. A sudden change in altitude in an airplane or the pressure exerted during deep-sea diving can cause eustachian tube closure and produce a severe and painful pressure change in the middle ear with extravasation of blood into the middle ear space. The drum may appear edematous, bloody, or blue because of bleeding behind it. The patient has severe pain and hearing loss. Physical examination reveals a hemorrhagic TM and tenderness over the eustachian tubes. The process is self-limited, lasting 2 to 3 days and resolving spontaneously. Treatment consists of analgesics for pain and decongestants to encourage opening of the eustachian tube. Myringotomy is performed only for severe pain or persistent fluid. Vertigo or sensorineural hearing loss requires ORL referral.

Cholesteatomas may be visualized in the middle ear. These cyst-like structures, which consist of epithelial cells and cholesterol, may be congenital or acquired, often secondary to previous perforation with residual TM epithelial cells in the middle ear. Enzymes formed within the sac may cause erosion of adjacent bones. Although rare, abnormal growths in the canal or middle ear must be evaluated for possible neoplasm and should be referred for evaluation by ORL.

Nonotogenic Causes

Inflammation, infection, neoplasm, or trauma along the course of any nerves innervating the auricle or the external auditory canal, including cranial nerves V, VII, IX, and X and cervical nerves C2 and C3, can produce pain that the patient may interpret as originating from the region of the ear. Therefore, a full head and neck examination, as well as radiographic examinations may be necessary to disclose the cause of ear pain if the ear examination results are normal.

The trigeminal nerve (V) supplies some of the most common areas of referred ear pain, including those of dental origin, such as erupting teeth or abscesses and oral mucosal ulcerations from aphthous ulcers or viral stomatitis. Sinusitis, sialadenitis, or lymphadenitis in these regions may also cause pain. Early mumps may present as ear pain before obvious parotid swelling.

Facial nerve (VII) pain may be a precursor of Bell's palsy or herpes zoster oticus.

The glossopharyngeal nerve (IX) supplies the oropharynx, nasopharynx, and posterior third of the tongue. Inflammation of these areas from pharyngitis or tonsillitis is another common cause of referred earache. Peritonsillar abscess or cellulitis may produce unilateral pain. Earache may also occur after adenotonsillectomy. Nasopharyngeal or oropharyngeal tumors, such as lymphoma or rhabdomyosarcoma, although rare in children, may be associated with ear pain.

The vagus nerve (X) supplies the base of the tongue, larynx, and trachea. Inflammatory or mass lesions in these areas may refer pain to the ear.

Cervical nerves C2 and C3 supply the mastoid and posterior pinna; therefore, ear pain may result from cervical spine injuries, arthritis, or disc disease, as well as any generalized neck disorder.

When otologic examination is normal and no pathology is found in the distribution of the cranial or cervical nerves, the pain may be psychogenic, especially in a person with anxiety or depression. Also, children may not be able to describe tinnitus and refer to it as pain. Certain drug ingestions, such as quinine, quinidine, salicylates, nicotine, ethacrynic acid, and aminoglycosides, are possible causes.

EVALUATION AND DECISION

A history is always important in determining the cause of pain or discomfort and should include questions about other ear symptoms, including tinnitus, hearing loss, vertigo, drainage, and itching, as well as systemic symptoms, such as fussiness, crying when lying down, upper respiratory infection, fever, and alteration in oral intake. Children may have difficulty describing pain. Parents may attribute pulling on ears or fussiness to ear pain. Studies disagree on the relevance of ear pulling; it may not be significant when presenting alone but may be with other signs or symptoms. Preverbal children being evaluated for suspected ear pain need careful evaluation for other causes of their fussiness.

Physical examination should always be complete, especially in children who are not old enough to verbalize that their fussiness is ear pain. Most children do not like to be immobilized for evaluation of the ears and throat; so, otoscopy and visualization of the pharynx should be the last part of the examination. Initial examination of the ear includes gross examination of the auricle, otoscopy of the external auditory canal and TM, and then pneumatic otoscopy to examine the middle ear. Important aids to the examination include positioning of the child and removal of cerumen. The child may be positioned on the parent's lap or shoulder or placed supine on the examination table. Cerumen removal may be accomplished with the use of a small, cotton-tipped applicator, wire loop, or plastic cerumen curette; application of ceruminolytics; irrigation with warm water; or suctioning (see Chapter 135).

Particularly important components of the examination include the external ear, the auditory canal, the TM, the surrounding structures of the head and neck, and the neurologic evaluation (Fig. 54.1).

EXTERNAL EAR EXAMINATION

External problems are usually obvious on initial examination. Trauma, erythema, or vesicles on the auricle may be easily seen. Palpation of the area around the ear may reveal swelling or tenderness either from nodes, mastoiditis, parotitis, or preauricular pit infection.

Abnormal Otoscopy

Otogenic causes are usually diagnosed by visualization with otoscopy (Fig. 92.7). Inflammation in the canal or middle ear, FBs, abnormal lesions, perforations, or cholesteatomas may be seen. Evaluation of the TM for signs of infection includes describing position, color/translucency, and mobility. Despite teaching that redness of the TM is not helpful since it may occur with increased blood flow from fever or crying, recent studies show that distinct erythema of the TM is a predictor of AOM. Mobility is evaluated by applying pressure to the rubber bulb attached to the otoscope with a good seal in the canal and looking for inward movement with positive pressure and outward movement with negative pressure. Purulent discharge in the canal may be wicked out with cotton to better visualize the TM for possible perforation or FBs. Any patient with accompanying vertigo, facial nerve palsy, hemotympanum, or central nervous system symptoms requires further evaluation with a CT scan.

Normal Otoscopy

A normal otoscopic evaluation should prompt a search for referred pain. Evaluation of the cervical spine, oropharynx, and neck should reveal possible sources of inflammation from shared sensory nerves. Radiographs to evaluate dental sources are usually not required emergently. A history of possible drug ingestions should be obtained. If there is a clinical suspicion of disease in the nasopharynx or larynx, an examination with a nasopharyngoscope may be needed. A patient with a completely normal examination and no other accompanying complaints

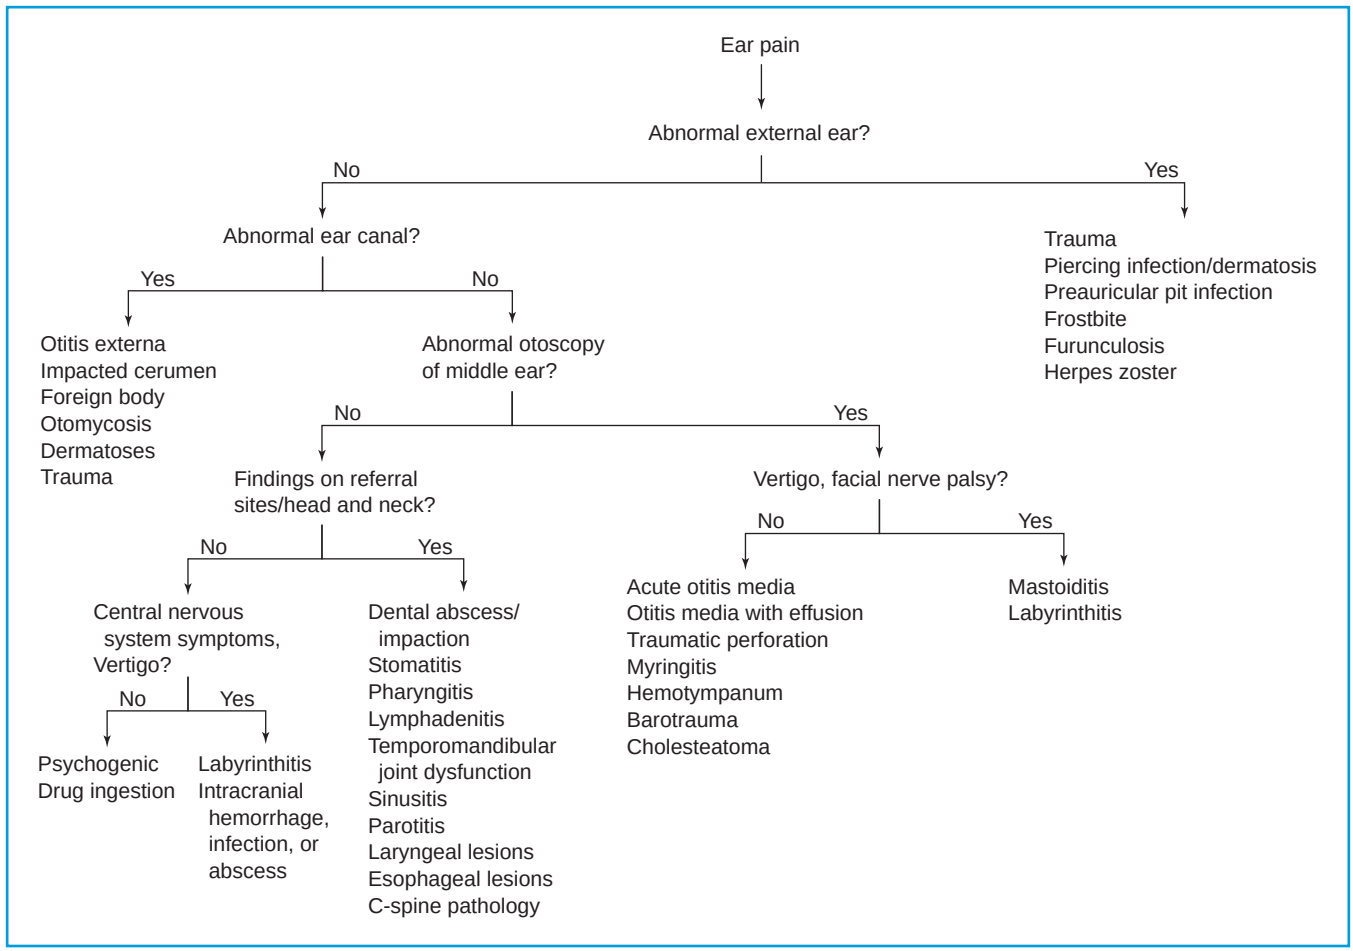

FIGURE 54.1 Approach to the diagnosis of earache. C-spine, cervical spine.

should be referred back to his or her physician for follow-up before a psychogenic cause is given.

CHAPTER 55 ■ HEADACHE

CHRISTOPHER KING, MD, FACEP

Headache is a common complaint of pediatric patients in the emergency department (ED). It is estimated that by the age of 15 years, up to 75% of children have experienced headaches, although most are cared for at home. Parents may seek medical care if the child has a new-onset headache that is particularly painful and does not respond to nonprescription medications, if the child complains of progressively more severe headaches, or if the child has headaches that are recurrent over days, weeks, or months. Children with known migraine headaches are normally seen by a physician only when their standard medication regimen is not effective. Headache as an isolated complaint is a relatively unusual presentation in pediatric patients; it is more often one of a number of symptoms, such as fever, lethargy, sore throat, neck pain, and vomiting.

Like other challenging presentations, headache is seen with regularity and is almost always benign, but in a small subset of patients, it can portend a potentially life-threatening illness. Just as it can be difficult to identify the one child with appendicitis from a succession of patients with viral gastroenteritis, so too the clinician's skill can be tested in distinguishing which child among the many with headache has a serious underlying process. Therefore, the primary responsibility of the emergency physician is to make this important discrimination between "bad" headaches and benign headaches.

Fortunately, this can almost always be done successfully after a thorough history and physical examination, and when necessary, laboratory and radiographic tests. One notable exception to this rule, however, is brain tumor. Although most serious illnesses that cause headache (e.g., meningitis, encephalitis, ruptured vascular anomaly) will be readily classified in the "bad" category, the presence of a brain tumor may not be. The history can be subtle, and the examination is commonly unrevealing, often leading to a delay in diagnosis. Therefore, characteristics of headaches caused by a brain tumor are described in detail in this chapter. Above all, the key to proper management of such patients is ensuring appropriate follow-up care.

PATHOPHYSIOLOGY

For a headache to occur, there must obviously be some noxious stimulus that affects one or more pain-sensitive structures. Injury to an area that is insensitive to pain, as occurs with most types of nonhemorrhagic stroke, may cause significant morbidity but will not manifest as headache. It is therefore useful to consider the sensory innervation of the head and neck. All extracranial structures are sensitive to pain. Thus, processes that affect the sinuses, oropharynx, scalp, neck musculature, and so on often cause patients to complain of headache. In contrast, certain intracranial structures are sensitive to pain and others are not. For example, the brain, ependymal lining, choroid plexus, and much of the dura and pia-arachnoid over the hemispheres are insensitive to pain. Pathologic processes affecting these areas can cause headache, but only by impinging on adjacent pain-sensitive structures. The most pain-sensitive intracranial structures are the proximal portions of the large cerebral arteries at the base of the brain, the venous sinuses, and the large cerebral veins.

Various physiologic mechanisms come into play in causing headache. Painful stimuli can be broadly categorized as resulting from vascular effects, muscle contraction, inflammation, and traction/compression (Table 55.1). Examples of each of these types of headache etiology are described in the following discussion of differential diagnosis. It should be noted that visual problems are an unlikely cause of significant headaches in children. A child with persistent headaches that have previously been attributed to "eye strain" may, therefore, deserve a more careful evaluation.

Attempting to predict the neuroanatomic location of a pathologic process using only the site of headache described by a child is unreliable. In part, this is attributable to the unpredictable displacement of structures caused by a mass lesion. In addition, the extremely complex relationships of the various nerves involved in pain sensation of the head and neck lead to unexpected patterns of referred pain. Thus, a posterior fossa lesion can cause frontal or orbital pain, and supratentorial lesions may result in pain localized to the occiput or the back of the neck.

DIFFERENTIAL DIAGNOSIS

A comprehensive discussion of the various causes of headache in pediatric patients is beyond the scope of this chapter. The conditions described here are those most likely to be seen in acute- and emergency-care settings (Table 55.2) and those with the greatest potential for imminent morbidity or mortality (Table 55.3).

Vascular

Headaches associated with vascular changes are believed to be caused primarily by vasodilation, although the exact mechanism has yet to be fully described. One common example of this type of headache is migraine. Migraine headaches are typically chronic and remitting, with a characteristic pattern that is easily described by the patient or parents (see Chapter 96). Often, a strong family history of migraines is present. For the emergency physician, the main issue with migraine patients is

TABLE 55.1

  F. Arterial dissection
V. Others
  A. Posttraumatic/postconcussive
  B. Psychogenic

generally pain control, because the diagnosis is already known. However, a significant change in the quality, severity, or timing of headaches in these patients may represent a separate and potentially more serious problem. In such cases, the clinician should not be dissuaded by the existing diagnosis from pursuing an appropriate workup as indicated.

Headaches accompanying fever are also believed to be mediated by vascular effects. Because fever is such a common symptom, this is probably the most common cause of headaches in pediatric patients seen in the ED. Hypertension is another possible cause of vascular headaches in children. Hypertension causes not only global changes in cerebral vasculature, but also possibly a component of increased intracranial pressure (ICP) that leads to headache.

Finally, hypoxia is a potent stimulus for cerebral vasodilation and can produce headaches on that basis. Therefore, children who experience a hypoxic insult (e.g., carbon monoxide poisoning) or those with disease states that predispose to hypoxia (e.g., cystic fibrosis, cyanotic heart disease) may present with headaches resulting from an acute process or an exacerbation of an underlying illness.

Traction/Compression
Brain tumor
Intracranial hemorrhage
Hydrocephalus
Cerebral edema
Brain abscess
Arterial dissection

Muscle Contraction

Headaches can be caused by contraction of the scalp or neck muscles. This is the classic "tension" headache that so often plagues adults. These headaches usually occur when a patient has experienced prolonged periods of mental or emotional stress. This leads to recurrent episodes of muscle tension and/or spasm, which cause muscle soreness. The patient can often localize a specific site where the pain is felt, and the involved muscles may be tender to palpation. Although muscle contraction is an unlikely cause of headache in younger children, the stress of life during adolescence will often produce this type of headache. Onset is typically at the end of the day. A headache that is present on arising in the morning or that awakens a patient from sleep would be an unusual manifestation of muscle contraction.

Inflammation

A wide variety of inflammatory conditions can result in headache, ranging from benign to potentially life-threatening entities. Children with bacterial meningitis or encephalitis may present with headache, although this is usually only one of a constellation of symptoms, such as fever, lethargy, neck pain, confusion, or coma. Headache is unlikely to be the sole complaint in these patients. However, an older child or adolescent

who has viral meningitis can present with a severe headache, minimal or mild neck discomfort, and no other signs of significant illness. Fortunately, viral meningitis is generally a benign process. Rare causes of inflammatory headache include retroorbital cellulitis or abscess and brain abscess. Focal findings on neurologic and/or ocular examination will normally provide clues to these unusual diagnoses.

Headaches can also be caused by inflammatory processes affecting other structures of the head and neck. For example, pediatric patients with pharyngitis caused by group A streptococcus will often complain of headaches. Indeed, the classic presentation for streptococcal pharyngitis in children is sore throat, fever, headache, and abdominal pain. In a child who has difficulty localizing pain, otitis media and otitis externa can also present as headache. Pediatric patients with sinusitis will sometimes complain of facial or periorbital pain, although younger children may simply have a persistent nasal discharge. Dental abscess can be overlooked as a cause of headache-type pain because it is a relatively uncommon finding in children. Therefore, a careful examination of the teeth and gingiva should be performed for all pediatric patients with unexplained headaches. Finally, inflammation of the temporomandibular joint (TMJ) is a rare cause of unilateral headaches in children (TMJ syndrome). These patients typically report increased pain while chewing and have point tenderness over the mandibular condyle.

Traction/Compression

Headaches can be caused by mass effect from a pathologic lesion that produces traction and/or compression involving pain-sensitive structures of the head and neck. For the emergency physician, the most important conditions in this category are intracranial hemorrhage and brain tumor. An intracranial hemorrhage produces displacement of surrounding tissues and, in cases of more significant bleeding, increased ICP. In the pediatric population, this is most often the result of a severe head injury (see Chapter 116). However, in rare instances, a child can have a nontraumatic intracranial hemorrhage from a ruptured vascular anomaly (e.g., an arteriovenous malformation), which leads to bleeding into the brain parenchyma and ventricles. As with other vascular events, this type of hemorrhage is characterized by the abrupt onset of severe pain. In contrast, headaches resulting from a brain tumor typically have a more insidious onset. The child will often complain of progressively worsening headaches for several weeks or even months. Additional symptoms, such as persistent vomiting or gait abnormalities, may also be present. Unfortunately, the physical examination can be normal during the early phase of the illness, and as mentioned previously, this commonly leads to a delayed diagnosis. Other processes that cause headache as a result of traction and compression include idiopathic intracranial hypertension (pseudotumor cerebri), brain abscess, hydrocephalus, and persistent spinal fluid leak after lumbar puncture.

An unusual cause of headache in pediatric patients that deserves mention because of its potentially life-threatening nature is arterial dissection. Patients may have a headache for hours or days before developing neurologic deficits caused by worsening vascular insufficiency and ultimately stroke. The classic presentation of vertebral artery dissection is neck pain and a severe occipital headache that occurs after minor (even trivial) trauma to the neck, followed by the onset of symptoms such as ataxia, nystagmus, and unilateral weakness. Although, as noted previously, nonhemorrhagic cerebral infarcts are not typically associated with headache, this is one important situation in which headache and ischemic stroke can coexist.

Psychogenic

Although less common than in adults, headaches of psychogenic origin are also seen in children. Possible causes include school avoidance behavior, malingering with secondary gain issues, and a true conversion disorder. These patients often have a history of chronic headaches that have been unresponsive to various treatment methods, and they may have undergone a battery of tests without receiving a diagnosis. Parents of these children are usually worried and frustrated. Their reasoning in coming to the ED after an extensive prior workup is often simply "to get another opinion." For the emergency physician, establishing definitively that a child's persistent headaches are the result of a psychogenic cause is generally impossible. Obviously, this should be considered a diagnosis of exclusion. However, if the history and physical examination do not suggest a more serious cause of headaches, the best management approach is to communicate genuine concern about the patient, attempt to allay some of the parental fears, and plan appropriate outpatient follow-up.

EVALUATION AND DECISION

As stated previously, the diagnosis for pediatric patients presenting with headache will be evident in all but a small minority of cases after a thorough history and physical examination. Laboratory tests and imaging modalities are rarely needed. Even if a definitive diagnosis cannot be established immediately, the identification of a potentially life-threatening cause of headaches will almost always be possible before the child leaves the ED. Concern about the possibility of a more serious cause warrants aggressive use of whatever diagnostic or therapeutic interventions are indicated, such as a computed tomography (CT) scan of the head, lumbar puncture, or intravenous antibiotics. Occasionally, a child with a suspected brain tumor will be appropriately discharged from the ED without undergoing any diagnostic tests. Such a disposition assumes that proper follow-up for such patients can be arranged and that magnetic resonance imaging (MRI) of the head will be performed within 24 to 48 hours. An approach to the diagnostic evaluation of a child with headaches is outlined in Fig. 55.1.

Clinical Assessment

History

Before proceeding to specific questions about headache symptoms, the clinician should inquire about the general health of the patient, particularly during the hours leading up to the current presentation. For example, the presence of a high fever, decreased activity, and poor oral intake is suggestive of a serious inflammatory cause such as meningitis. A patient with

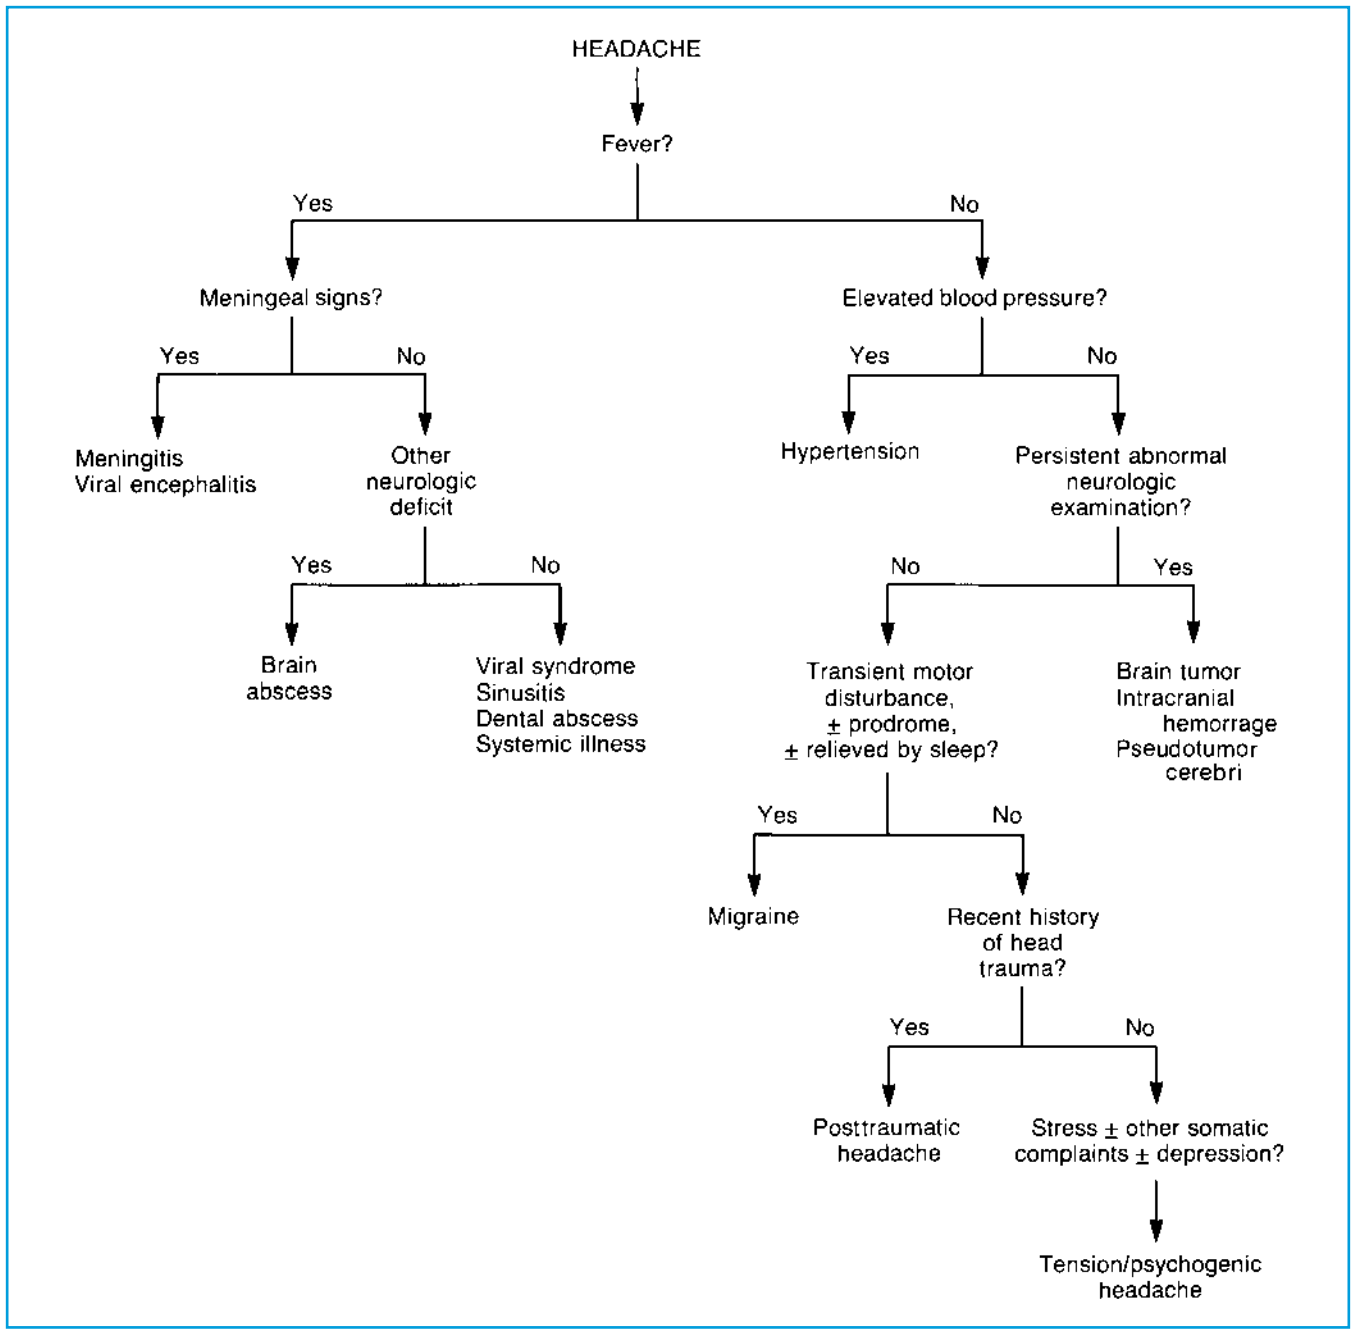

FIGURE 55.1 Approach to the diagnosis of headache.

these same symptoms who also has an abrupt change in mental status may have encephalitis. If a child has been relatively well but has complained of headache associated with persistent nasal discharge (especially if it is purulent), this may be caused by a sinusitis. A child with tooth pain, ear pain, or sore throat may also have a readily apparent reason for headaches.

After general health issues are covered, the clinician should then obtain a complete history regarding the headache itself. As with many illnesses, the cause of headaches can usually be diagnosed with a high degree of accuracy solely based on history; the physical examination is often merely confirmatory. One of the more important points to investigate is the mode of onset. A headache that starts abruptly and causes extreme pain may represent a vascular event such as a ruptured arteriovenous malformation, whereas a headache with a more gradual onset would be inconsistent with this diagnosis. It is sometimes useful to question the patient about the severity of the pain, although in younger children, this history may not always be reliable. A youngster who is smiling and playing with toys may nod "yes" in response to the question, "Is the pain very, very bad?" In such cases, the description of the severity of pain must obviously be correlated with the child's clinical appearance. Questions about the quality of pain (e.g., boring, throbbing) are often less useful in children for similar reasons.

The frequency and duration of headaches can also provide valuable clues about the origin of the pain. A child who complains of a constant headache for several days without respite (i.e., goes to sleep with it, wakes up with it) usually has a tension headache or, perhaps more likely, a psychogenic headache. In general, headaches that become progressively more frequent or prolonged should raise suspicion for a more serious underlying condition. Similarly, a child with headaches that have steadily worsened in severity over time warrants careful evaluation, again given the limitations of a child's description of pain. Parents can often help clarify such situations. For example, they may report that the child previously complained of headaches while continuing to play, but now the headaches cause the child to stop any activity, lie down, and start crying.

An important exception to the generally benign nature of headaches that are described as constant over prolonged periods is the rare patient who presents to the ED with undiagnosed pseudotumor cerebri. Classically an overweight female adolescent or young adult, these patients will often complain of severe, unrelenting headache that may gradually worsen over a period of several days. This description is especially significant if the patient also reports newly impaired vision, because this may be a sign of excessive pressure on the optic nerves, which, if untreated, can result in permanent blindness.

The time and circumstances of occurrence are also important historical points to ascertain. For example, headaches that are present when a child arises each morning or that awaken a child at night should raise suspicion about a possible brain tumor. In contrast, headaches that occur only later in the day are typically related to stress and result from muscle contraction. Vascular headaches are typically worsened by exertion. In addition, any precipitating events that consistently cause or exacerbate a headache should be identified. If an older child has a headache that is significantly worse when leaning down (e.g., to pick up something off the floor), this is most likely to be caused by sinusitis, although in rare cases, this history may be present in a child with a brain tumor.

Any relevant details about the patient's medical history and family history should routinely be obtained. As mentioned previously, children with cystic fibrosis or congenital heart disease may have headaches caused by worsening hypoxia. Likewise, a patient with renal disease may develop headaches in response to an elevated blood pressure. For the child with a stable pattern of chronic, remitting headaches, the most important question regarding family history is whether anyone has had migraine headaches. It should be remembered, however, that many people use the term *migraine* rather broadly to refer to any type of severe headache. Therefore, the clinician may find it useful to describe typical migraine symptoms before questioning parents about this aspect of the history. Abrupt onset of headache and nausea in several members of one household (or headache and syncope in a child) may be the result of carbon monoxide poisoning.

Before leaving this subject, it is worth reemphasizing the importance of a thorough history in developing an appropriate clinical suspicion of a possible brain tumor. A variable period of time exists when a child with a brain tumor will experience headaches before any abnormal physical findings are apparent. Making a presumptive diagnosis of brain tumor as a likely cause of headaches during this early stage of the illness will, therefore, depend entirely on the history. In their classic article,

TABLE 55.4

CHARACTERISTIC HISTORICAL FINDINGS OF BRAIN TUMOR HEADACHES IN CHILDREN

Nocturnal headache or pain on arising in the morning
Worsening over time (severity, frequency, and/or duration)
Associated with vomiting (although may also occur with migraine), especially if vomiting gets progressively worse
Behavioral changes
Polydipsia/polyuria (craniopharyngioma)
History of probable neurologic deficits (e.g., ataxia/incoordination/"clumsiness," blurred vision, or diplopia)

From Honig PJ, Charney EB. Children with brain tumor headaches: distinguishing features. *Am J Dis Child* 1982;136:121–141, with permission.

Honig and Charney described several historical points that are characteristic of children with brain tumor headaches (Table 55.4). Although no single pathognomonic response on history unerringly establishes the diagnosis, eliciting one or more of these findings should certainly raise the level of concern that a child's headaches may be caused by a brain tumor.

Physical Examination

Finding an abnormality on the physical examination of a child with headaches will be a relatively rare event. Nevertheless, a thorough head-to-toe examination should be performed in every case because identification of even a subtle finding (e.g., early papilledema) can significantly alter the course of evaluation and treatment. As with all children seen in the ED, the first step of the examination is to assess the patient's appearance. Does the child look sick or well? Does the child appear to be in severe pain, mild pain, or no pain at all? A child who appears ill may have a more serious underlying condition, such as meningitis or an intracranial hemorrhage, requiring a rapid examination and prompt initiation of treatment.

The vital signs should also be assessed, particularly the temperature and blood pressure. Although omitting the blood pressure reading for younger children is a tendency, this is never acceptable for a patient who has headaches. Significant hypertension, usually resulting from undiagnosed renal disease, is a rare but potentially dangerous cause of headaches that can affect children of any age. Consequently, if a blood pressure is not taken initially by triage personnel, this must be performed as part of the child's evaluation in the ED. For any patient with headache who complains of associated visual impairment, formal (age-appropriate) visual acuity testing should be performed. Measuring basic growth parameters for a pediatric patient with headaches can also provide valuable information. Macrocephaly may be the result of hydrocephalus, and short stature can be associated with a craniopharyngioma that causes impaired pituitary function.

The head and neck examination will sometimes reveal an obvious source of headache in a child. The scalp should be examined for evidence of head injury. Even when no history of trauma exists, the child may have had an unwitnessed event, or the history may be intentionally misleading with a victim of child abuse. Tenderness of the scalp or neck muscles is often present with headaches resulting from stress and muscle contraction.

Cranial auscultation may reveal a bruit in patients with arteriovenous malformation. The eyes should be examined to detect any abnormalities in pupillary responses or extraocular movements. A sluggish pupil may be caused by an expanding mass lesion that is compressing the third cranial nerve, and pain with extraocular movements may be elicited with a retroorbital cellulitis or abscess. The eyegrounds should also be carefully examined for signs of papilledema, which would suggest an elevated ICP. If necessary, a short-acting dilating eye drop such as tropicamide (Mydriacyl) can be administered to facilitate the examination. The clinician may find an otitis media or otitis externa when the ears are examined. Streptococcal pharyngitis as a cause of headaches may be evident as swelling, erythema, and exudates of the tonsillar pillars. Facial tenderness and erythema are sometimes seen in children with maxillary or frontal sinusitis. The teeth and gingiva should be examined for evidence of inflammation or abscess. Nuchal rigidity can be a sign of meningitis, intracranial hemorrhage, or in rare cases, a brain tumor. If a child has a ventricular shunt, assessment of shunt function should be performed when appropriate (see Chapter 135).

Examining the skin is also important for the child with headaches. Because the skin and central nervous system have a common embryologic origin, cutaneous lesions are sometimes seen with neurologic disorders. For example, a child with numerous hyperpigmented spots scattered over the body (café au lait spots) most likely has neurofibromatosis. Similarly, children with tuberous sclerosis will almost always have several small, hypopigmented spots (ash leaf spots) that are more apparent when viewed under a Wood's ultraviolet lamp.

Every child with a complaint of headaches needs a complete neurologic examination. Any new focal finding suggests the presence of a focal lesion, such as a tumor, hemorrhage, or in rare cases, stroke. Table 55.5 lists the most common neurologic abnormalities found on physical examination in a study of 3,291 children with brain tumors. Some children with migraine headaches develop focal neurologic abnormalities as part of their migraine syndrome (e.g., ophthalmoplegia), but parents can normally confirm that this is not a new problem. As mentioned previously, the mental status of a child with headaches must always be carefully assessed. A diminished level of consciousness may be the result of encephalitis, a large intracranial hemorrhage, or significantly elevated ICP. To the extent that the child can cooperate, cranial nerve function should also be evaluated. Cranial nerve abnormalities may result from an elevated ICP or direct compression by a mass lesion. Sensory and motor function should be examined, although here again the ability of a younger patient to cooperate may be limited. A reasonable evaluation can be accomplished by observing the child's gait while walking and/or running and by assessing the child's dexterity in performing age-appropriate activities, such as transferring a toy from hand to hand and tying shoelaces. Any evidence of gait abnormalities or deficits in fine motor coordination warrants further investigation.

TABLE 55.5

NEUROLOGIC EXAMINATION FINDINGS MOST COMMONLY SEEN IN CHILDREN WITH BRAIN TUMOR HEADACHES

Papilledema
Abnormal eye movements
Ataxia
Abnormal tendon reflexes
Defect in visual examination

Laboratory and Radiographic Testing

By far, most children presenting in an acute-care setting with headache as the chief complaint will not require any laboratory tests. Most will have minor problems, such as otitis media, viral illness with low-grade fevers, or tension headaches. Laboratory testing is not necessary in such cases. Certainly, the child with a possible serious infectious process causing headaches can require a variety of tests, including a complete blood cell count, blood cultures, and a lumbar puncture. Yet these patients are more likely to have other symptoms such as high fever and lethargy, rather than headache, as the primary complaint. When a lumbar puncture is necessary, it is important to remember that a head CT scan should be obtained first if the patient is suspected of having a lesion that could lead to subsequent cerebral herniation (e.g., a large intracranial mass). Symptoms that would be suggestive of such a condition include focal neurologic deficits, papilledema, and mental status depression with unilateral papillary dilation. This is generally considered prudent practice despite the fact that considerable controversy exists about whether herniation is ever actually *caused* by a lumbar puncture, even if temporally related. For suspected idiopathic intracranial hypertension (i.e., a patient with papilledema who has a negative head CT), an opening pressure measurement should be obtained when the lumbar puncture is performed. Serum electrolytes, blood urea nitrogen, creatinine, and a urinalysis should be obtained for any child with headaches who is found to have an elevated blood pressure. The patient with a ventricular shunt who has fever and headaches will likely require a shunt tap by a neurosurgical consultant. Finally, a child with a suspected subarachnoid hemorrhage should undergo a lumbar puncture if the head CT scan is negative. This is necessary because a small hemorrhage may not be detected by CT, and in such cases, blood in the cerebrospinal fluid (CSF) is the only diagnostic finding. However, this is an uncommon situation in the pediatric population.

As with laboratory testing, few children with headaches who come to the ED will require an emergent imaging study. In general, plain radiographs of the skull are of little or no value for these patients. A child with a ventricular shunt may require a shunt series, but this includes radiographs of the entire course of the shunt and not simply skull radiographs. Likewise, sinus radiographs are rarely indicated in pediatric patients because the diagnosis is almost always made on clinical grounds. Occasionally, a child with multiple episodes of an apparent sinus infection will require a CT scan of the sinuses, but this is normally done as an outpatient.

The two imaging modalities that are most widely used clinically to obtain detailed information about intracranial abnormalities are CT and MRI. Both tests have advantages and disadvantages. At present, CT is more readily available on an

emergent basis (many EDs have a dedicated scanner). Scanning time is also much shorter for CT, and the potentially unstable patient can be more easily observed. These characteristics make CT the test of choice to evaluate patients at risk for problems such as intracranial hemorrhage, cerebral edema, and herniation syndrome. CT is especially useful for patients with head trauma. However, CT does not offer the quality of image resolution provided by MRI. Smaller lesions, particularly those of the posterior fossa and brainstem, are more reliably detected by MRI. This is true even when the CT scan is performed using contrast material. Consequently, MRI is superior for children suspected of having a brain tumor who have a normal neurologic examination and no signs of elevated ICP. If these patients have a normal head CT scan in the ED, they will likely also require an outpatient MRI. Such duplication of testing is costly and usually unwarranted. While the use of MRI in the acute management of stroke has lead to a substantial increase in overall scanning capacity, limited availability continues to be the main drawback of MRI. Nonemergent MRI scans are often difficult to obtain from the ED even in large institutions. As discussed in the following, the emergency physician must take these and other factors into account in determining which, if any, imaging modality is indicated for a child with headaches.

Treatment and Disposition

Patients with headaches caused by a potentially life-threatening process (e.g., meningitis, encephalitis, ruptured vascular anomaly) require specific treatment approaches discussed elsewhere in this textbook. A patient with pseudotumor cerebri requires drainage of CSF to reduce the ICP, which, in turn, often relieves the headache pain. Children with headaches that are presumptively diagnosed as benign can almost always be successfully treated with acetaminophen or ibuprofen. The various options available for treating pediatric migraine patients are described in Chapter 96.

Although most children complaining of headache can be safely discharged from the ED with an appropriate follow-up plan, some will require admission to the hospital for further evaluation and treatment. For example, a child with headaches who is found to be significantly hypertensive must be admitted both for management of the blood pressure and investigation of the underlying cause. Any patient with pseudotumor cerebri who also has decreased visual acuity requires emergent evaluation by an ophthalmologist and possibly a surgical procedure to relieve the pressure on the optic nerve. Patients with migraine who have intractable headache pain may also warrant admission to receive a more effective analgesic regimen. The child with a ventricular shunt who has severe headaches will usually require a shunt series, a CT scan of the head, and neurosurgical evaluation to assess the need for possible shunt revision. If neurosurgical consultation is not immediately available, the patient should be transported to an appropriate receiving facility.

A potentially confusing issue that the emergency physician will inevitably face is how to properly manage a child who is suspected of having a brain tumor. Should all these patients have a brain imaging study in the ED? As discussed previously, the resolution of even a contrast-enhanced head CT scan is inferior to MRI for detecting certain types of tumors. Also, a small but finite risk is associated with the administration of contrast material. However, obtaining a nonemergent MRI from the ED may not be an available option. What then is the appropriate diagnostic approach?

In general, a child with headaches who is suspected of having a brain tumor should undergo a head CT scan in the ED if there are any signs or symptoms of elevated ICP. These include an altered mental status, visual changes, persistent vomiting, papilledema, and focal neurologic deficits. Because mass lesions that cause elevated ICP are usually larger and more easily detectable, the reduction in image resolution with CT is less likely to result in missing an abnormality in such cases. Of note, if the CT scan is normal in a child with headache and new focal deficits on neurologic examination, it may be necessary to obtain an emergent MRI to exclude the diagnosis of stroke (e.g., arterial dissection), although this may simply represent the first presentation of a complex migraine syndrome.

However, what about the child with a suspicious history (e.g., increasing frequency or duration of pain, headaches that awaken the child from sleep or occur every morning) who has a normal neurologic examination and no signs of elevated ICP? In most cases, if MRI is not available for a nonemergent scan from the ED, such patients can be safely discharged with an outpatient MRI scheduled within 24 to 48 hours. A delay in diagnosis of 1 or 2 days is usually acceptable if this allows the appropriate diagnostic study to be performed. Obviously, parents must be clearly instructed that any sign of deterioration, such as mental status changes or persistent vomiting, requires that the child be immediately returned to the ED for a reevaluation.

CHAPTER 56 ■ PAIN—JOINTS

RICHARD J. SCARFONE, MD

Arthritis and arthralgia are common reasons for children to seek care in the emergency department (ED). Arthritis is joint inflammation marked by swelling, warmth, and limitation of motion, whereas arthralgia is simply joint pain without signs of inflammation. Establishing a diagnosis for the child with joint pain is challenging because the differential diagnosis is lengthy (Table 56.1), clinical and laboratory findings are rarely specific for a particular disease, and disease patterns for many of the etiologies are often highly variable among different patients. Among the most common causes of joint pain in children are infections, trauma, and postinfectious conditions (Table 56.2), whereas those most likely to be life-threatening are due to systemic disease and malignancy (Table 56.3). This chapter serves as a guide to an approach to the child with arthritis or arthralgia, with an emphasis on historical points and physical examination findings that can serve to narrow the diagnostic possibilities.

DIFFERENTIAL DIAGNOSIS

The possible causes of joint complaints in children are extensive (Table 56.1). The initial differential diagnosis usually focuses on the most common etiologies (Table 56.2). Children from 6 to 24 months of age have the highest incidence of nongonococcal bacterial (septic) arthritis, and boys are affected twice as often as girls. Septic arthritis results primarily from the hematogenous dissemination of an organism into the joint or the bony metaphysis. The diagnosis of septic arthritis of the hip should not be delayed because pressure in the joint space will compromise the vascular supply to the femoral head, leading to necrosis (see Chapter 92).

Osteomyelitis involving the distal end of long bones may manifest as arthralgia with or without objective signs of joint inflammation. Children with sickle cell anemia and type 1 diabetes mellitus are at higher risk for osteomyelitis. Onset of symptoms is typically more indolent compared to that in septic arthritis.

In the first 10 days of illness, children with Kawasaki disease may have arthritis or arthralgia, often involving smaller joints in the hand. Beyond that time, involvement of larger joints of the lower extremities is more common. If an arthrocentesis is performed, the synovial fluid analysis resembles that seen with septic arthritis with 100,000 to 300,000 white blood cells (WBCs) per cubic millimeter (mm^3). However, synovial fluid Gram stain and cultures will be negative among children with Kawasaki disease (see Chapter 101).

In the absence of a clear history of a tick bite, Lyme disease may be a challenging diagnosis to establish because only about 40% to 70% of children have the characteristic erythema migrans rash, constitutional symptoms may be mild, and serologic tests will be normal in the early stages of disease.

Transient (also called toxic) synovitis is a poorly understood inflammation of the hip joint, afflicting children 3 to 6 years of age. The diagnosis is typically made on clinical grounds, and this self-limited disease does not result in joint destruction. When the hip is involved, the challenge for clinicians is to distinguish transient synovitis from septic arthritis.

Reactive, or postinfectious, arthritis is probably more common than septic arthritis. Arthritis following various enteric infections is not rare in children, and joint complaints after parvovirus B19 infection are seen among adolescents. *Chlamydia trachomatis* infection of the genitourinary tract should be considered in any sexually active adolescent with new-onset arthritis. With postinfectious arthritis, antimicrobial treatment does not modify the disease course.

Traumatic injuries to a joint may cause periarticular swelling or an effusion indicative of a hemarthrosis. In addition, ligamentous or tendon injuries will result in joint pain and impaired range of motion. Serum sickness and Henoch-Schonlein purpura are marked by characteristic rashes.

EVALUATION AND DECISION

Figure 56.1 depicts an algorithm for the diagnostic approach to the child with joint pain. The evaluation should include inquiries about the specific joint(s) involved, symptom duration, and history of trauma, fever, rash, tick bites, sexual risk factors, intravenous drug use, and recent illnesses. The child's past medical and family histories should be reviewed. A family history of systemic lupus erythematosus (SLE), inflammatory bowel disease, or rheumatoid arthritis increases the child's risk for these diseases.

A comprehensive physical examination should be performed with particular attention paid to a search for rashes, heart murmurs, and abdominal abnormalities. Assessment of the affected joint(s) should determine if it is warm, swollen, or tender as well as its range of motion.

A complete blood cell (CBC) count and differential, C-reactive protein, and erythrocyte sedimentation rate (ESR) are indicated for the febrile child with signs of joint inflammation, especially in the absence of trauma. Additional laboratory studies, such as an antistreptolysin-O titer or antinuclear antibody (ANA) test, should be guided by the history and physical examination. Radiographs of the affected joint are particularly useful in the setting of trauma or acute monoarthritis without an obvious cause, although ultrasound is more sensitive than plain radiographs in detecting an effusion. The Ottawa knee rules can be used to guide the decision to obtain radiographs

of the knee following injury. In a recent study, the rules were found to be 100% sensitive in detecting fractures while eliminating the need for about one-third of the radiographs. Most febrile children with monoarthritis and joint effusions will need an arthrocentesis to assist in determining the etiology. Magnetic resonance imaging is most useful to detect subtle fractures not visualized on plain films and to help establish a diagnosis of osteomyelitis.

A key initial point in the history is whether trauma preceded the pain. It is easy to be led astray by parents trying to recall what traumatic event could have led to the child's symptoms. The clinician should be mindful that if the mechanism was not severe enough to prevent the child from continuing an activity, it is unlikely to be the cause of a significantly swollen and painful joint. However, if there was a definite traumatic event preceding the onset of symptoms, particularly in the absence of fever, one can proceed with that aspect of the algorithm.

A radiograph will detect fractures or a slipped capital femoral epiphysis (SCFE). Classically, a SCFE occurs in the obese adolescent boy with hip or knee pain (see Chapters 114 and 125), although it should be considered in any child 8 to 14 years of age with hip or knee pain. Importantly, only about half of children will report preceding trauma and there may be bilateral disease in about one third of children. Plain radiographs (including the frog-leg view of the hip) showing a widened epiphysis and caudal displacement of the femoral head establish the diagnosis.

Metaphyseal corner fractures resulting in joint pain are highly suggestive of inflicted injury. These typically occur in children age 3 years or less and there may not be a clear history of trauma. These fractures result from traction or torsion forces such as occurs when the arms or legs are pulled or swung violently.

Radiographs may also aid in determining whether swelling is caused by a joint effusion or is simply soft-tissue swelling outside the joint space, a distinction that is often difficult to make on physical examination alone. In the setting of acute trauma and in the absence of fever, an effusion is indicative of a hemarthrosis and is rarely a diagnostic or therapeutic indication for performing an arthrocentesis. Such a patient will typically experience only temporary relief from the aspiration of fluid, followed by a reaccumulation of blood. Clinicians must have a high index of suspicion for hemarthrosis in the child with hemophilia or other clotting disorder who presents with joint swelling, even without a clear history of trauma.

In the absence of an effusion, inquiries about the duration of symptoms should be made. Children with conditions such as bursitis, tendonitis, and Osgood-Schlatter disease typically have chronic, low-grade pain and may inadvertently come to

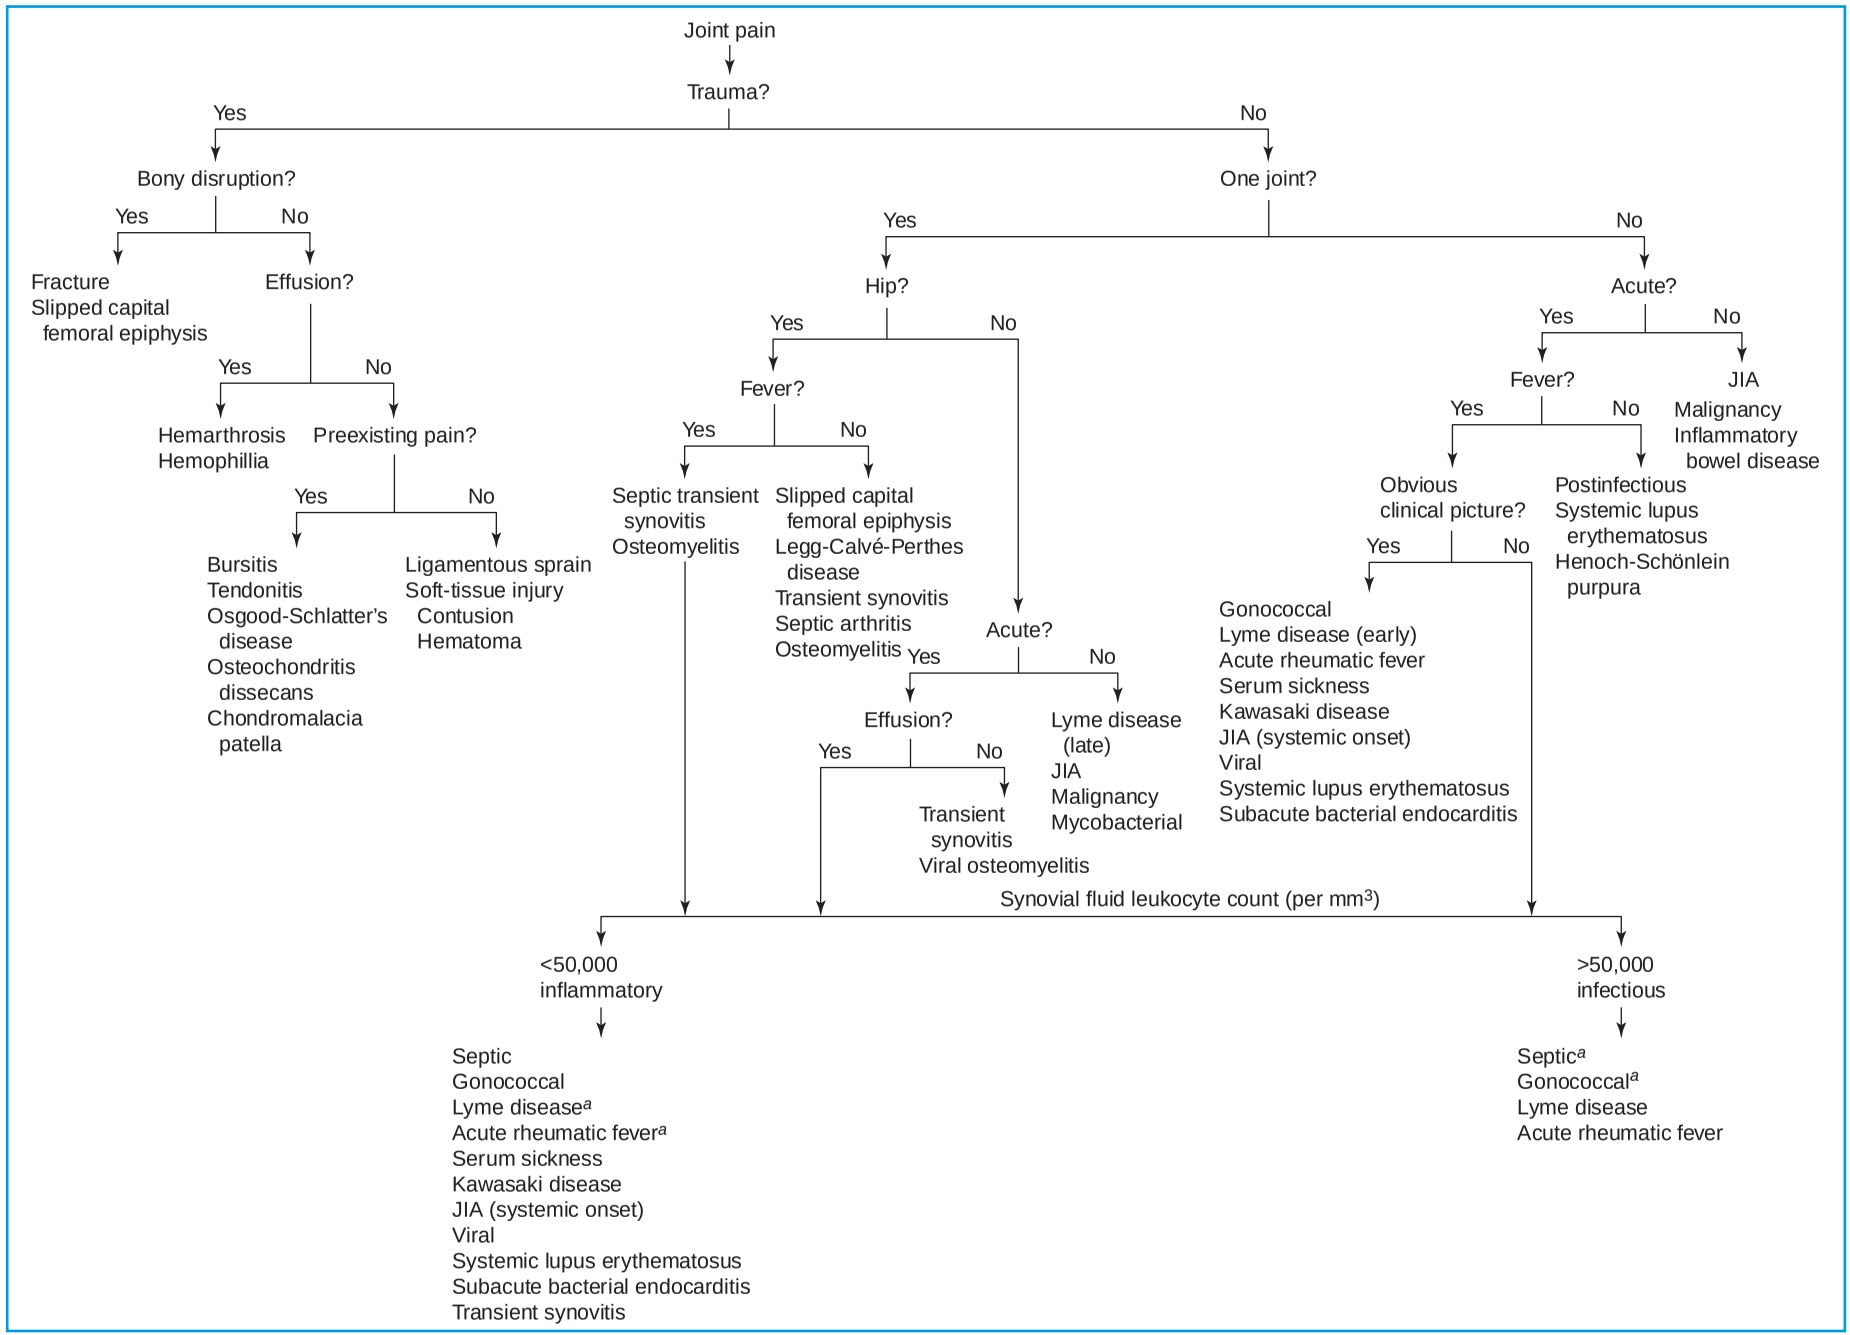

FIGURE 56.1 A diagnostic approach to joint pain. JIA, juvenile idiopathic arthritis. [a]Most likely leukocyte count.

medical attention after minor trauma. New-onset periarticular swelling and pain immediately after acute trauma suggests ligamentous or other soft-tissue injury.

In the absence of trauma, monoarthritis of the hip may represent a true orthopedic emergency. Septic hips require operative drainage to prevent osteonecrosis and the most important prognostic factor is the length of delay between the onset of infection and the institution of therapy. Unlike most other causes of fever and arthritis, septic arthritis involves only a single joint in more than 90% of affected children; 80% of these are hip, knee, or ankle infections. The absence of fever does not preclude the diagnosis; just 60% to 70% of children with septic arthritis are febrile at presentation. A child with septic arthritis of the hip will typically maintain external rotation of the hip, resist even the slightest range of motion and be unable to ambulate. In fact, if the child allows full range of motion, the diagnosis is highly unlikely. Neonates, on the other hand, will often present with thigh swelling, pseudoparalysis, and external rotation at the hip.

A child with acute onset of monoarthritis of the hip or any other large joint, marked by an effusion and severely restricted range of motion, with or without fever, needs an arthrocentesis. The study may be performed with ultrasound guidance and the synovial fluid should be analyzed for cell count and differential, glucose and protein, Gram stain, and culture. *Staphylococcus aureus* is the most common infecting agent for older children, whereas group B *Streptococcus* and gram-negative enteric organisms must also be considered in neonates. In recent years, clinicians are encountering a greater prevalence of community-associated methicillin-resistant *Staphylococcus aureus* as a causative agent. In two large series, about half of the children with septic arthritis of the hip had negative synovial fluid cultures. In these cases, children with synovial fluid WBC counts greater than 50,000 per mm^3 and positive blood cultures were presumed to have septic arthritis and managed accordingly.

In contrast to septic arthritis, children with transient synovitis of the hip usually appear well, may be afebrile or have only mildly elevated temperatures, often are able to bear weight but have a limp, and allow almost complete range of motion of the affected joint. A prospective study of over 150 children presenting with an irritable hip found that just 2% of children had septic arthritis if all of these four risk factors were absent: fever > 38.5°C, refusal to bear weight, ESR > 40 mm per hour, and WBC > 12,000 cells per mm^3.

Often, based on clinical findings, a physician can make a diagnosis of transient synovitis without the need for laboratory testing or arthrocentesis. In more equivocal cases, inflammatory markers may be helpful. The absence of all four factors listed above has a very high negative predictive value in excluding septic arthritis. The presence of one or more risk factors, especially in an ill-appearing child, justifies further diagnostic work-up, including an arthrocentesis.

Inflammatory markers are usually elevated in patients with osteomyelitis, as well. In contrast to those with septic arthritis, children with osteomyelitis have a more subacute onset of pain, are less likely to be febrile, will have greater range of motion at the joint, and may not have signs of joint inflammation.

Legg-Calvé-Perthes disease, a condition of uncertain cause, occurs overwhelmingly in boys, with an onset between 4 and 8 years of age. The pain, which may be localized to the hip or referred to the thigh or knee, is insidious in onset. The aseptic necrosis of the femoral head will be manifest on plain radiographs as a small, osteopenic femoral head with a widened joint space, although films obtained early in the clinical course may be normal.

Historical and physical examination findings help narrow the choices among the many causes of polyarthritis (Tables 56.4 and 56.5). The ill-appearing adolescent with migratory arthritis, tenosynovitis involving the extensor tendons of the wrist or ankle, and scattered crops of vesiculopustules on an erythematous base should be strongly suspected for gonococcal arthritis. This occurs three to five times more often in girls, often during

TABLE 56.4

DISTINGUISHING CLINICAL FEATURES OF ETIOLOGIES OF POLYARTHRITIS

Disease	Clinical characteristics
Gonococcal	Adolescent, tenosynovitis, rash
Lyme	Tick bite, erythema migrans, endemic region, seasonality
Acute rheumatic fever	Recent streptococcal infection, extreme migratory pain, carditis
Serum sickness	Urticaria, angioedema
Kawasaki disease	Prolonged fever, rash, conjunctivitis, mouth changes
Subacute bacterial endocarditis	Congenital heart disease, fever, new murmur, splinter hemorrhages
Systemic lupus erythematosus	African-American female, skin, renal disease
Henoch-Schönlein purpura	Purpura below the waist, nephritis, abdominal pain, scrotal swelling
Inflammatory bowel disease	Abdominal pain, diarrhea, weight loss, anemia

menstruation. Of note, few patients report lower abdominal pain or vaginal discharge concurrently, and cultures of blood and synovial fluid are typically negative. The highest yield for establishing the diagnosis is by Gram stain of the skin lesions showing gram-negative intracellular diplococci or by recovering the organism from the cervix, rectum, or throat. Joint involvement with Lyme disease has two distinct patterns. In early disseminated disease when erythema migrans is the principal clinical sign, the child may develop episodic migratory polyarthritis, affecting mainly large joints. However, more typically at this stage, the child has arthralgia without signs of joint inflammation. Weeks to months (mean 4 to 6 weeks) after the tick bite, half of untreated children develop an intermittent monoarthritis, usually of the knee. The joint is significantly swollen but only mildly painful, and patients are usually afebrile at this stage and without a history of trauma. Extremely painful, migratory joint inflammation involving multiple joints in a child with recent evidence of a group A streptococcal infection should raise the concern for acute rheumatic fever. Evidence of carditis, erythema marginatum, subcutaneous nodules, or a positive serology for antistreptococcal antibodies supports the diagnosis. The presence of diffuse urticaria and angioedema accompanying arthralgia or arthritis, especially 3 to 10 days after initiation of an antibiotic, helps distinguish serum sickness from other causes of polyarthritis and fever. Kawasaki disease is characterized by high and persistent fever, conjunctival injection without exudate, mouth and lip swelling and cracking, swelling and erythema of the hands and feet, a nonspecific rash, and lymphadenopathy. About 30% of patients will also develop arthritis or arthralgia, with about one-third of these having onset in the first 10 days of illness. Both small interphalangeal joints and large weight-bearing joints may be involved. Daily temperature spikes exceeding 40°C, especially if accompanied by a transient pink rash, suggest systemic-onset juvenile rheumatoid arthritis (JRA), one of the categories of juvenile idiopathic arthritis (JIA). A common viral-related arthritis is that caused by hepatitis B infection. The arthritis precedes the symptoms of hepatitis and resolves when the jaundice appears. Parvovirus B19 is the causative agent of erythema infectiosum; about 5% of affected children will complain of transient, bilateral joint inflammation. Joint manifestations due to this virus can also occur in the absence of a rash causing a sudden onset of symmetric, self-limited polyarthritis, particularly in the hands. With subacute bacterial endocarditis, musculoskeletal symptoms are variable, ranging from asymptomatic joint effusions to frank arthritis of up to three joints. Preexisting congenital heart disease, a prolonged fever, a new murmur, and splinter hemorrhages may all be clues to the diagnosis of this rare entity in children.

A joint aspiration is rarely necessary to establish a diagnosis for a child with polyarthritis and fever. If an arthrocentesis is obtained, typically the synovial fluid will be sterile and the leukocyte count will characterize the process as inflammatory, although some disease processes may yield counts that could be consistent with either inflammatory or infectious causes (Fig. 56.1).

Postinfectious arthritis is one of the more common causes of acute polyarthritis without fever. One to 2 weeks after an illness (especially *Chlamydia trachomatis, Shigella*, or *Salmonella*) or urogenital infection (Reiter's syndrome), a child may develop an asymmetric joint inflammation predominantly involving large joints of the lower extremities. The severity of the antecedent illness has little correlation with the arthritis, and the intensity of synovitis and fever is mild or absent at this stage. As with many of the diseases discussed to this point, SLE has a variable clinical presentation with regard to musculoskeletal involvement. In fact, no two patients have an identical pattern of immune complex formation or clinical disease expression. A symmetric polyarthritis involving peripheral joints of the hands or feet may be seen. However, small effusions of the knee are also common with active disease, and the arthritis may also be intermittent or migratory. Patients with this type of arthritis are usually afebrile, yet high fever may be a prominent finding. Further, although arthritis is one of several diagnostic criteria, it is uncommon for patients with SLE to present with isolated arthritis. Arthritis of the small joints, a positive test for ANA, and abnormalities of the skin, kidneys, or central nervous system should raise the clinician's suspicion for SLE.

Henoch-Schönlein purpura (HSP) is rarely a diagnostic challenge, thanks to the presence of petechiae and purpura in the characteristic below-the-waist distribution. Affected children may also have polyarthritis or arthralgia, colicky abdominal pain, and nephritis. As with the rash, periarticular swelling usually involves joints below the waist.

Chronic arthritis is less common than acute arthritis in children younger than age 16 years, with an incidence of 20 to 150 cases per 100,000. JIA is a newer term used to classify chronic childhood arthritis. It encompasses all of the diseases referred to as JRA, as well as other causes of idiopathic arthritis. Subclassifications of disease are based on the patient's age at onset of symptoms, duration and pattern of arthritis, and presence or absence of systemic signs such as fever or rash. This term describes children younger than age 16 years with joint inflammation for at least 6 weeks, in whom other causes have been eliminated. That they appear at several points in the diagnostic algorithm reflects their diversity. Tests for rheumatoid factor or ANA may assist in establishing a specific diagnosis. These are difficult diagnoses for ED physicians to establish based on a single patient encounter; children with chronic arthritis should be referred to a rheumatologist.

In the absence of fever, chronic pain of one or more joints may also indicate malignancy. Specifically, leukemia or neuroblastoma can both present with true joint swelling, as can bony tumors. Pallor, adenopathy, weight loss, and other constitutional complaints, as well as anemia or cytopenias, would support this diagnosis.

A large joint oligoarthritis occurs as an extraintestinal complication of inflammatory bowel disease in about one-third of children, usually during times of active disease. Clues to the diagnosis include abdominal pain, hematochezia, anemia, and weight loss.

In summary, this review of joint pain in children should serve as a guide to the diagnostic evaluation. The clinician must choose from many different causes, each with variable and nonspecific characteristics. In addition, laboratory studies are rarely specific for a particular disease. However, by asking the appropriate questions, performing a careful physical examination, selectively obtaining adjunct studies, and developing pattern recognition skills, the clinician can follow the correct diagnostic path.

CHAPTER 57 ■ PAIN—SCROTAL

CATHERINE E. PERRON, MD

Acute scrotal swelling or pain in a child should be considered a potential surgical emergency. Although some causes of acute scrotal swelling may be benign and require no more than observation and reassurance to the patient and parent, other causes may lead to the rapid loss of a testis if diagnosis and treatment are delayed. The patient with such a complaint should be evaluated promptly. Many diagnoses in cases of scrotal pain are most reliably made clinically, differentiating by age, historical features relating to the evolution of pain and associated symptoms, and physical examination findings.

PATHOPHYSIOLOGY

The anatomic structures contained in the scrotum include the testes; the epididymis; appendages of the testis; and the nerve, vascular, and lymphatic structures that constitute the spermatic cord and traverse the inguinal canal into the scrotum (Fig. 57.1). The anatomy of the testicle, its related structures, and the layers of tissue that surround each testicle in the scrotum may each relate to the pathology seen in this area. The descent of the testis, at approximately 32 to 40 weeks' gestation, through the inguinal canal from the abdomen to its eventual position in the scrotum, also contributes to the risk of pathology in the scrotum and associated groin area. The testis descends within the process vaginalis, which is an out-pouching of the peritoneal cavity. After the descent of the testis, the abdominal portion of the process vaginalis closes and the remaining portion, called the *tunica vaginalis*, is a potential space that encompasses the anterior two-thirds of the testicle. Within this space, fluids of various etiologies can collect. Pathophysiologic causes of acute conditions of the scrotum include ischemia, inflammation, trauma, and tumor. Since these processes often alter blood flow to structures within the scrotum, appropriate imaging modalities, when correlated with clinical history and examination, are often useful in coming to the correct diagnosis.

DIFFERENTIAL DIAGNOSIS

Table 57.1 lists the principal causes of acute scrotal swelling, and Table 57.2 provides the most common diagnoses by age.

Causes of Painful Scrotal Swelling

Torsion of the Testis

Testicular torsion is the most significant condition causing acute scrotal pain and represents a true surgical emergency. As a common cause of acute, painful scrotal swelling in children, testicular torsion accounts for approximately 30% of cases of acute scrotal pain. Testicular torsion is more common in the newborn period and during the early stages of puberty. Approximately two-thirds of the cases of intravaginal torsion occur in children between the ages of 12 and 18 years, overlapping the peak incidence of appendage torsion (see also Chapter 124).

Torsion results from an inadequate fixation of the testis to the intrascrotal subcutaneous tissue (Fig. 57.2), resulting in the so-called "bell-clapper" deformity. The testis, which hangs more freely within the tunica vaginalis in this deformity, may rotate, producing torsion of the spermatic cord, venous engorgement of the testis, and subsequent arterial infarction (Fig. 57.3).

The sudden onset of severe scrotal pain and tenderness, often with radiation to the abdomen, and associated nausea and vomiting is typical. Often, these episodes have their onset in the early morning. At other times, they may be associated with sports activity or mild testicular trauma that may be perceived by the patient as the cause of the pain. A history of trauma is often misleading in patients with testicular torsion. The patient may recall prior episodes of similar pain that resolved spontaneously, suggesting intermittent torsion and spontaneous detorsion.

With torsion of the testis, typically the testis is acutely swollen and diffusely tender and usually lies higher ("horizontal or transverse lie") in the scrotum than the contralateral testis. Since the pain may be referred to the abdomen, it is essential that the genitalia are examined carefully in every child who complains of abdominal pain. There may be overlying erythema of the skin of the scrotum. The cremasteric reflex (retraction of the testis with stroking of the inner thigh) is usually absent with testicular torsion but may be present in early or incomplete torsion. The cremasteric reflex may be absent in infants younger than 30 months. Urinalysis is usually negative.

Time is important in establishing the diagnosis of torsion of the testis. If a testis has been twisted sufficiently to fully obstruct its blood supply for more than 6 to 12 hours, surgical detorsion is unlikely to salvage the gonad. It is impossible to determine clinically, however, whether the torsion has been partial or total. Therefore, it is an oversimplification to assume that if symptoms have been present for more than 6 to 12 hours, an irreversible situation has developed that would preclude any attempt at testicular salvage. The duration of symptoms does not always determine functional recoverability.

Although the diagnosis continues to be established most reliably by a skilled examiner familiar with acute scrotal lesions in children, diagnostic imaging studies may be valuable, particularly in cases where the diagnosis is uncertain.

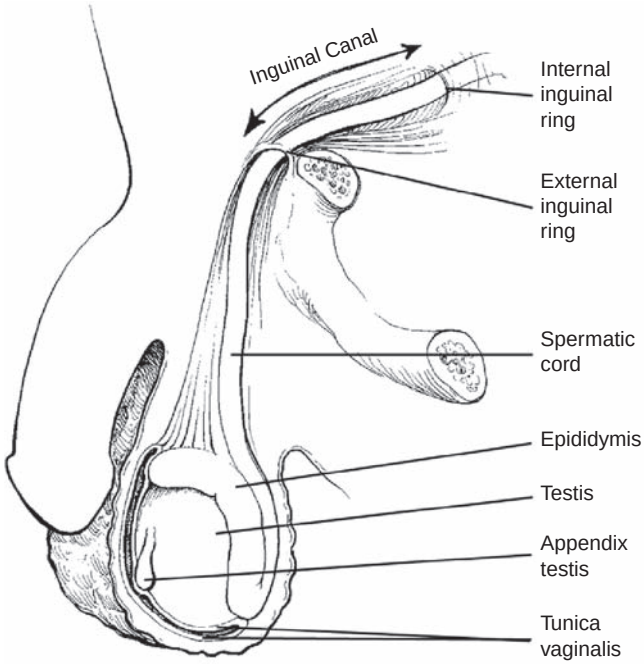

FIGURE 57.1 Anatomy of the scrotal contents.

Color Doppler sonography or nuclear testicular scanning reveals decreased or absent arterial blood flow within the affected testicle when compared with the other. It must be stressed that, if the history and physical examination strongly suggest testicular torsion or if any appreciable time would be lost in arranging for these studies, the preferred course is to proceed with surgical exploration or an attempt at manual detorsion (Fig. 57.4) if surgical intervention is not readily available.

Trauma

Color Doppler flow ultrasound can assess anatomy and blood flow (Fig. 57.5). Swelling and fluid collections can be localized by ultrasound, which can be particularly helpful in trauma. Ultrasound has become the standard of imaging for the acute scrotum as it is now more widely available and has anatomic detail and time advantages over the testicular nuclear perfusion scans. Limitations associated with Doppler sonography must also be recognized, particularly related to small, lower flow prepubertal testes and the operator-dependent nature of this test. False-negative ultrasounds may occur from spontaneous detorsion or in cases of late torsion in which a severe degree of overlying scrotal edema may be associated with sufficient, increased vascularity to obscure the underlying ischemic testis. The testicular nuclear perfusion scan with technetium-99 pertechnetate is less time efficient but another possible imaging modality that also has limitations. Technetium is injected and the scrotum scanned. Impeded blood flow to the torsed testicle results in a cold spot. The presence of a hydrocele, abscess, hematoma, or scrotal hernia may result in

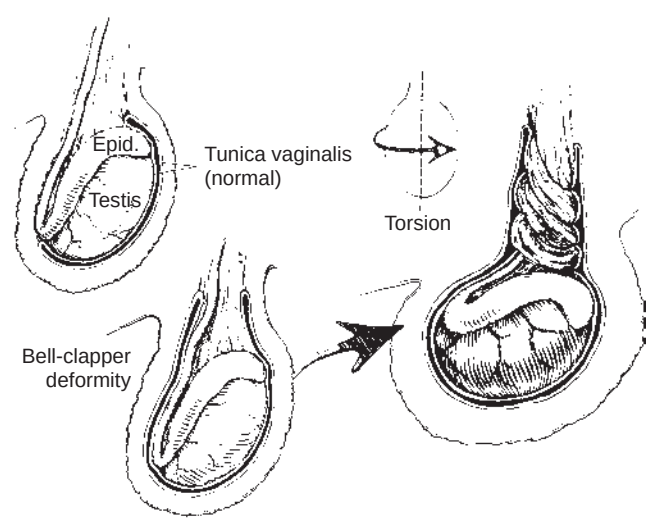

FIGURE 57.2 Torsion testis. Abnormality of testicular fixation—bell-clapper deformity—permits torsion of spermatic vessels with subsequent infarction of the gonad. Epid., epididymis.

FIGURE 57.3 Torsion of testis. **A:** Swollen, diffusely tender testis high in the scrotum (from twisting of cord structures). **B:** Surgically exposed testis showing torsion of cord structures. Testis was infarcted and was removed.

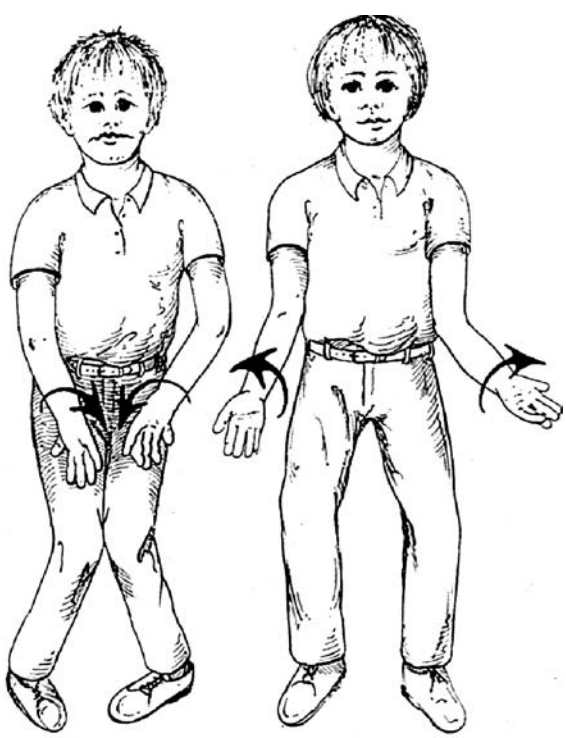

FIGURE 57.4 Torsion of testis. Because torsion typically occurs in a medial direction, manual detorsion should be attempted initially by rotating the testis outward toward the thigh.

decreased counts on that side of the scrotum and may be confused with torsion of the testis. False-negative scans may occur for similar reasons as ultrasound related to edema and increased vascularity of late torsion obscuring an ischemic testis. Another pitfall encountered with use of both sonography and nuclear scan is incomplete or intermittent torsion in which the study may indicate normal, increased, or decreased flow, depending on timing.

The therapy for testicular torsion is surgical exploration, detorsion, and fixation of both the torsed and contralateral testis. A nonviable testis requires orchiectomy and fixation of the contralateral testis. If a child is seen within a few hours of the onset of his torsion, before severe scrotal swelling has ensued, it may be possible to accomplish detorsion of the

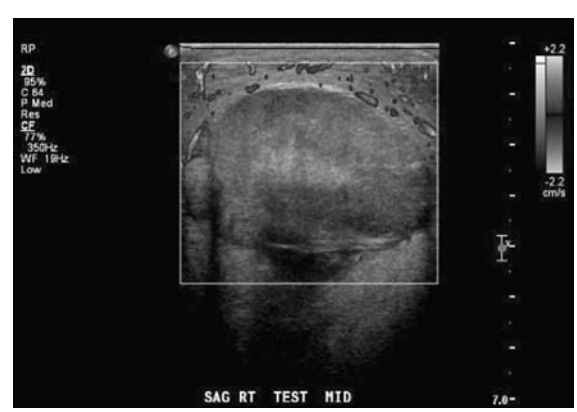

FIGURE 57.5 Torsion of testis (several days old). Ultrasound reveals enlarged testicle and Doppler flow demonstrates no flow to necrotic testis.

spermatic cord manually and thus restore blood supply to the testis. Ideally, this is undertaken by a physician experienced with the technique. The Doppler ultrasound stethoscope provides a noninvasive evaluation of testicular blood flow and is a useful adjunct in manual detorsion of the testis. Initial examination reveals decreased arterial flow to the affected testis, compared with the contralateral one. Intravenous fentanyl (1 to 3 μg per kg) or morphine (0.1 mg per kg) is administered just before attempting detorsion. Because torsion typically (in two-thirds of cases) occurs in a medial direction, detorsion should initially be carried out by rotating the testis outward toward the thigh (Fig. 57.4). Relief of pain and reposition of the testis in a lower position in the scrotum suggests a successful outcome. This can be confirmed with the Doppler stethoscope or color Doppler ultrasound by noting a return of normal arterial pulsations to the testis. Although successful completion of manual detorsion may avoid the necessity of an emergency anesthetic for surgical reduction, it does not remove the necessity for surgical fixation of the testis to prevent the recurrence of this condition. An orchiopexy of the affected testis, as well as of the contralateral one, which is malfixed in more than 50% of cases, is recommended during the same procedure.

Torsion of Testicular Appendage

Several vestigial embryologic remnants are commonly attached to the testis or epididymis that may twist around their base, producing venous engorgement, enlargement, and subsequent infarction. Appendage torsion is most common in boys of ages 7 to 12 years but can occur at any age. Scrotal pain is the usual presenting feature, although the pain is typically less severe and more indolent in onset than the pain associated with testicular torsion. Although there may be associated nausea, vomiting, and diaphoresis, these symptoms are less common than with torsion of the testis (see Chapter 124).

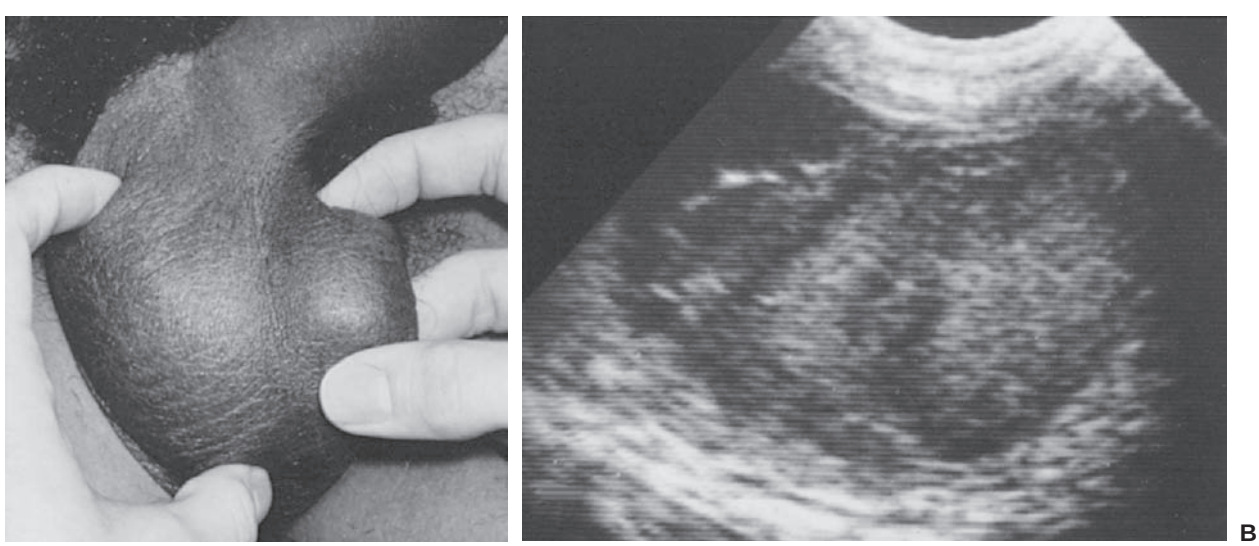
If the child is seen early after the onset of pain, scrotal tenderness and swelling may be localized to the area of the twisted appendage, typically on the superior lateral aspect of the testis. It may be possible to hold the testis gently and have the patient point to the specific point of pain. If this site is indicated to be the upper pole of the testis with the remainder of the testis being nontender, the diagnosis of torsion of a testicular appendage is likely. Although the classic "blue dot" sign of an infarcted appendage may be visible, it often cannot be seen because of overlying edema. In some cases evaluated later in the clinical course, the degree of scrotal tenderness and edema increases to the point at which differentiation from torsion of the testis becomes difficult. In early and late presentations, the cremasteric reflex should be intact. Color Doppler sonography or nuclear scanning demonstrates normal or increased flow to the affected testicle or epididymis compared with the opposite side, representing the inflammation that occurs with torsion of the appendage. Occasionally, surgical exploration may be required to be certain that a torsion of the testis is not present.

If the examiner is confident in the diagnosis of torsion of an appendix testis, surgical exploration is not needed. The child should be sent home with analgesic/antiinflammatory medications, support to the scrotum, and instructions to rest quietly. The pain usually resolves in 2 to 12 days, but in most cases, pain should improve somewhat within a few days. The patient should be reevaluated clinically within 48 hours. In most cases, the child's pain will have lessened, and nothing further is indicated. Occasionally, however, a child will seem to have a disproportionate degree of discomfort from the torsion of these tiny appendages. For these children, removal of the appendage may shorten their morbidity. Contralateral scrotal exploration for this condition is not indicated.

Trauma/Hematocele

In children, most trauma to the scrotum results from a direct blow to the perineum or a straddle injury that forcefully compresses the testicle against the pubic bone. Penetrating injuries are less common, and the small size and greater mobility of the prepubertal testis make testicular injuries rare in this group.

Scrotal trauma includes a spectrum of injuries that ranges from minimal scrotal swelling to rupture of the testis with a tense, blood-filled scrotum (Fig. 57.6A). Urgent surgical



A B

FIGURE 57.6 Rupture of testis. **A:** Testicular swelling and tenderness following kick to scrotum. **B:** Ultrasound examination of testis—central linear sonolucent area reflects site of testicular rupture. Surgical repair resulted in a well-preserved gonad.

evaluation should be undertaken, unless the testis clearly can be felt to be normal and without significant tenderness. Often scrotal ultrasound examination is useful (Fig. 57.6B). When any question of testicular rupture remains, surgical exploration is indicated. This approach is based on two facts: (i) a ruptured testis has the best salvage rate when surgically repaired and (ii) testicular torsion may present with a spurious history of trauma (see Chapter 112).

A hematocele, or blood within the tunica vaginalis, may represent severe testicular injury. An obvious ecchymosis of the scrotal wall in the setting of trauma suggests a hematocele. Sonography can identify the fluid collection within the tunica because blood is more echogenic than hydrocele fluid. Scrotal exploration is indicated if testicular rupture is present, or in cases of large hematoceles, which heal more readily after surgical drainage.

Scrotal trauma can also result in an intratesticular hematoma or laceration of the tunica albuginea. Ultrasound can assist in determining the location of blood. Any question or indication of testicular laceration requires surgical exploration and drainage of the hematoma with repair of the laceration. If the tunica albuginea can be determined to be intact, no surgical intervention is necessary.

Traumatic epididymitis is local inflammation, resulting from blunt trauma to the scrotum, which usually occurs within a few days. Typically, short-lived acute pain associated with trauma is followed by a pain-free period after which pain returns. On examination, scrotal erythema, edema, and tenderness of the epididymis may be found. In this noninfectious variety of epididymitis, the urinalysis is negative. Sonography is helpful to rule out any more severe injury and will demonstrate hyperemia associated with the inflammation. Treatment is supportive.

If a scrotal laceration is present, it is essential that the testis and spermatic cord be evaluated for possible injury. This may require an examination under general anesthesia or an inguinal cord block with more severe injuries. For simple scrotal lacerations, careful hemostasis and closure of the laceration with chromic catgut is sufficient.

Epididymitis/Orchitis

Epididymitis is an infection or inflammation of the epididymis, which is most commonly seen in adolescents and adults. In sexually active adolescents, it is commonly associated with *Chlamydia trachomatis*; *Neisseria gonorrhea, Escherichia coli, Mycobacterium*, and viruses also contribute to cases. In HIV-infected males, *Mycobacterium*, cytomegalovirus, and *Cryptococcus* should also be considered. Epididymitis is seen less frequently in prepubertal boys, in whom it is often associated with a urinary tract infection caused by structural abnormalities of the urinary tract.

The onset of swelling and tenderness is typically more gradual than with torsion of the testis or a testicular appendage. Associated symptoms of urinary frequency, dysuria, penile discharge, or fever may be present. Early on, the epididymis may be selectively enlarged and tender, readily distinguished from the testis. With time, inflammation spreads to the testis and surrounding scrotal wall, making localization impossible. Although elevation of the scrotum relieves pain in epididymo-orchitis (Prehn's sign) but causes increased pain in torsion in adults, this finding has not been found to be reliable in children. The cremasteric reflex should be preserved.

FIGURE 57.7 Epididymitis. Ultrasound image of enlarged epididymis seen on left side of image, testis on right. Color Doppler flow ultrasound reveals increased blood flow to inflamed epididymis.

Although white cells in the urinary sediment are seen more often in epididymitis than in torsion, they are not consistently present. A urinalysis and culture of the urine should always be obtained. The Centers for Disease Control and Prevention recommends a Gram stain and culture of urethral discharge or intraurethral swab, or nucleic acid amplification tests for *N. gonorrhea* and *C. trachomatis* and a urinalysis and culture. Color Doppler sonography typically demonstrates an increase in size and blood flow to the affected testis and epididymis (Fig. 57.7). Nuclear scan shows increased activity in the affected testis. Initial treatment for epididymitis includes antibiotics, analgesics, scrotal support, elevation, and bed rest. In sexually active adolescent males, in whom the most likely cause is chlamydia and gonorrhea, ceftriaxone (250 mg IM in single dose) plus doxycycline (100 mg PO twice a day for 10 days) is recommended. Patients allergic to cephalosporins and/or tetracyclines, or in whom enteric organisms are suspected, can be treated with ofloxacin (300 mg PO twice a day for 10 days) or levofloxacin (500 mg PO once a day for 10 days). Of note, doxycycline is not recommended for patients younger than 8 years of age, and fluoroquinolones are approved for use in patients younger than 18 years of age only for complicated urinary tract infection, unless no other alternatives exist. In prepubertal boys, bacteria responsible for urinary tract infections should be considered. Treatment choices that cover coliforms and attain adequate levels in epididymal tissue include trimethoprim-sulfamethoxazole, cephalexin, or tetracycline. The patient should be warned that this process is frustratingly slow to resolve and that he may have several weeks of gradually subsiding discomfort and scrotal swelling (see Chapter 124).

At any age when epididymitis is associated with a urinary tract infection and in all prepubertal boys with epididymitis, referral for urologic follow-up and urinary tract imaging with sonogram and voiding cystourethrogram are necessary to rule out a structural problem.

Orchitis

Orchitis is an inflammation or infection of the testis resulting from the extension of epididymitis, rarely as hematogenous spread of a systemic bacterial infection, or following certain viral infections, including mumps. Other viruses implicated

include adenovirus, Epstein-Barr virus, coxsackievirus, and echoviruses. Although rare before puberty, orchitis occurs in about 18% of postpubertal boys with mumps parotitis. In 70% of cases, it is unilateral. It results in testicular atrophy, but not necessarily sterility, in 50% of affected testes. Fortunately, it is much less common since the advent of vaccine against mumps. The onset of mumps orchitis occurs from 4 to 6 days after parotitis manifests. Although rare, orchitis has been reported in the absence of parotitis. Adrenocorticotropic hormone and corticosteroids in adults may produce some degree of local relief of symptoms, but the course of mumps orchitis is not altered.

Causes of Painless Scrotal Swelling

Hydrocele

An accumulation of fluid within the tunica vaginalis that surrounds the testis—a hydrocele—may be seen with torsion of the testis or an appendage, epididymitis, trauma, or tumor. In these cases, examination of the underlying testis is abnormal. If the testis can be felt to be normal and the hydrocele is not associated with any abnormality of the overlying scrotal soft tissues, it is much more likely to be a simple hydrocele. In the infant, this is the result of fluid being left in place after the processus vaginalis has closed. When the size of the hydrocele has no history of waxing or waning, it is considered a noncommunicating, simple hydrocele, and it may simply be observed. Usually, the fluid will be reabsorbed in the first 12 to 18 months of life.

If the hydrocele has a clear-cut history of changing in size (often with crying or exertion), particularly if it is associated with thickening of the cord structures as they are felt against the pubic tubercle (the silk-glove sign), then the processus vaginalis is patent and the diagnosis is that of a communicating hydrocele (Fig. 57.8). Here the patent processus vaginalis does not generally close spontaneously and may enlarge to permit the development of hernia. Surgical exploration and high ligation of the processus vaginalis with a wide opening of the tunica vaginalis to complete the decompression of the hydrocele is appropriate treatment. Because a scrotal hernia may be confused with a hydrocele, aspiration should never be carried out in children, except by an experienced urologist.

FIGURE 57.8 Hydrocele. Waxing and waning of size indicates a communicating hydrocele with a patent processus vaginalis, requiring surgical correction.

Occasionally, a hydrocele of the cord presents as a scrotal swelling just above the testis. Differentiation from an incarcerated hernia may be difficult and occasionally may require surgical exploration. Ultrasound may also be helpful in determining the nature of the swelling. Surgical treatment like that for a hydrocele of the testis is appropriate.

Hernia

Although most inguinal hernias present in children with a mass in the groin, occasionally the hernia may extend and present as a scrotal swelling. An incarcerated hernia may produce pain in some patients. The diagnosis and treatment of inguinal hernias are discussed in Chapter 121.

Varicocele

A usually painless scrotal swelling, called a *varicocele,* is caused by a collection of abnormally enlarged spermatic cord veins and is most commonly found on routine examination of asymptomatic boys ages 10 to 15 years. Most varicoceles occur on the left, representing spermatic vein incompetence caused by the left spermatic vein draining into the renal vein at a sharp angle, whereas the right spermatic vein drains into the inferior vena cava.

On occasion, a varicocele can present with mild pain or discomfort. The hemiscrotum appears full but does not have overlying skin changes. The testis and epididymis should be palpated to be normal. A mass of varicose veins described as "a bag of worms" can be appreciated above the testicle. Standing examination often reveals the varicocele, which is more prominent when standing. Doppler ultrasound is diagnostic, demonstrating both normal flow to the testis and the collection of tortuous veins. Most varicoceles can be managed conservatively under observation by a urologist. Some large varicoceles may require internal spermatic vein ligation or testicular vein embolization and may have some impact on testicular size and fertility. Most varicoceles are asymptomatic and benign. Inferior vena cava obstruction should be considered when the patient is prepubertal or if the varicocele is acute in onset, right sided, or remains unchanged in the supine position. Patients determined to have a varicocele, especially when they present with discomfort, should be referred for urologic follow-up.

Spermatocele

Located above and posterior to the testicle in postpubertal boys, spermatoceles are sperm-containing cysts of the rete testes, ductuli efferentes, or epididymis. Multiple or bilateral spermatoceles may occur. On examination a small, nontender mass that transilluminates may be appreciated distinct from and posterior to the testicle. These masses must be differentiated from a hydrocele or tumor. Sonography may confirm the location distinct from the testis and help distinguish a spermatocele from tumor. Referral to an urologist is indicated for the excision of large uncomfortable spermatoceles or for aspiration

to differentiate a hydrocele from a spermatocele. Otherwise, no specific treatment is needed (see Chapter 124).

Idiopathic Scrotal Edema

Idiopathic scrotal edema is a rare entity that represents only 2% to 5% of acute scrotal swellings in otherwise normal children. Typically, a prepubertal child presents with the rapid onset of painless but notable edema of the scrotal wall that may be bilateral and may extend up onto the abdominal wall. The skin of the scrotum may be erythematous. The child is usually afebrile, and urinalysis is negative. Through the edematous scrotum, the testes can be felt to be normal in size and nontender. This edema of the scrotal wall is of unknown origin, although it is believed to represent a form of angioneurotic edema. Insect bites, allergic reactions, cellulitis, and contact dermatitis can also be contributors to localized scrotal swelling. No specific therapy for idiopathic scrotal edema has been demonstrated to be effective. Bed rest and scrotal elevation may help. Children spontaneously begin to improve within 48 hours, regardless of treatment. Cellulitis, allergic reactions, and contact dermatitis should be appropriately treated. Occasionally, scrotal edema is seen secondary to diseases that cause generalized edema and/or ascites, such as nephrosis and cirrhosis.

Henoch-Schönlein Purpura

Occasionally, a child may be seen with a petechial rash on the scrotum as the initial presentation of this systemic vasculitic syndrome, characterized by nonthrombocytopenic purpura, arthralgia, renal disease, abdominal pain, and gastrointestinal bleeding. More typically, the rash begins on the lower extremities or buttocks and later may involve the scrotum. If the associated swelling is not great, the cord structures and testes can be felt to be uninvolved and normal. In other cases with severe swelling, surgical exploration may be necessary to rule out testicular torsion, which rarely has been noted to coexist. When skin lesions are present, the diagnosis of Henoch-Schönlein purpura (HSP) must be suspected. Occasionally, the acute scrotum is the dominant presenting symptom. Ultrasound may help rule out testicular torsion in these instances. A more detailed discussion of the management of this disease can be found elsewhere in this text (see Chapters 65 and 85).

Kawasaki Disease

Another vasculitis that can produce scrotal swelling and mild pain is Kawasaki disease, which has characteristic features, including fever, adenopathy, rash, conjunctivitis, and irritability. Although discussed in detail elsewhere (see Chapter 101), it is important to note the association of scrotal swelling with this systemic disease to avoid unnecessary surgical explorations or delay in diagnosis of the underlying vasculitis.

Testis Tumor

Testicular or paratesticular tumors are rare in young children. However, in young males of ages 15 to 35 years, it is the most common solid tumor and represents 20% of cancers diagnosed in males. Testicular cancer usually presents as painless, unilateral, and firm to hard scrotal swellings. They may be discovered by the patient or physician on physical examination. Some patients report an achy feeling, and in rapid-growing tumors associated with hemorrhage or infarction, acute scrotal pain may be reported. Leukemic infiltration of the testis may present bilaterally. The mass does not transilluminate, but an associated reactive hydrocele may do so. In children younger than 2 years of age, the tumor usually is a yolk sac carcinoma, or teratoma. After puberty, germinal cell tumors, as found in the adult population, are seen. Evaluation of a solid testicular mass involves an initial testicular ultrasound examination usually followed by surgical exploration through a groin incision to permit control of the spermatic vessels and a possible radical inguinal orchiectomy.

Antenatal Torsion Testis (Newborn)

A newborn boy may present with a painless, smooth, testicular enlargement that does not transilluminate and is usually dark in color. There should be no or minimal edema of the overlying scrotum. This presentation, in approximately 70% of newborn cases of torsion, usually represents prenatal, extravaginal torsion of the testis (twisting of the entire testis, spermatic cord, and tunica vaginalis), and most commonly occurs during the late period of embryonic development, as the testis descends into the scrotum. At this time, the testicular tunics are not yet attached to the scrotal tissue, and torsion of the entire testis with its tunics can occur. Because fixation of these tissues occurs during the first and second weeks of life, postnatal torsion of a previously normal testis in the neonatal period also occurs, but less frequently (30%). Even though the conventional course of action has been surgical exploration, salvage of the testis believed to have torsed in the prenatal period has been rare; therefore, management remains controversial. It has been argued that the contralateral testis may be malfixed and at risk for subsequent torsion, and therefore, should undergo surgical fixation. Torsion has been reported rarely, however, and current practice is simply to observe these children. After 4 to 6 months, the torsed testis has usually been reabsorbed. Exploration is indicated in the case of rare, bilateral torsion or in newborn boys with suspected postnatal torsion to attempt salvage.

EVALUATION AND DECISION

Although this chapter is entitled scrotal pain, the most efficient approach to the differential diagnosis is through consideration of the important entities causing painful versus painless scrotal swelling. This approach is outlined in Fig. 57.9. Testicular torsion, torsion of an appendage, orchitis, epididymitis, and trauma-related injuries to the scrotum or testicles are further discussed as the common etiologies for painful scrotal swelling. Hemorrhage into a tumor, incarcerated hernias, HSP, and Kawasaki disease may cause either painful or painless scrotal swelling. No one aspect of the history or physical examination may be diagnostic, but collectively the clinical findings often suggest a diagnosis. More recently available adjunctive radiologic studies may be helpful when the clinicians are fully aware of their capabilities and limitations, and they are readily available so as not to delay necessary surgical intervention.

Initial Approach

As a first step in the evaluation of the child with a complaint of scrotal swelling or pain, the physician should determine

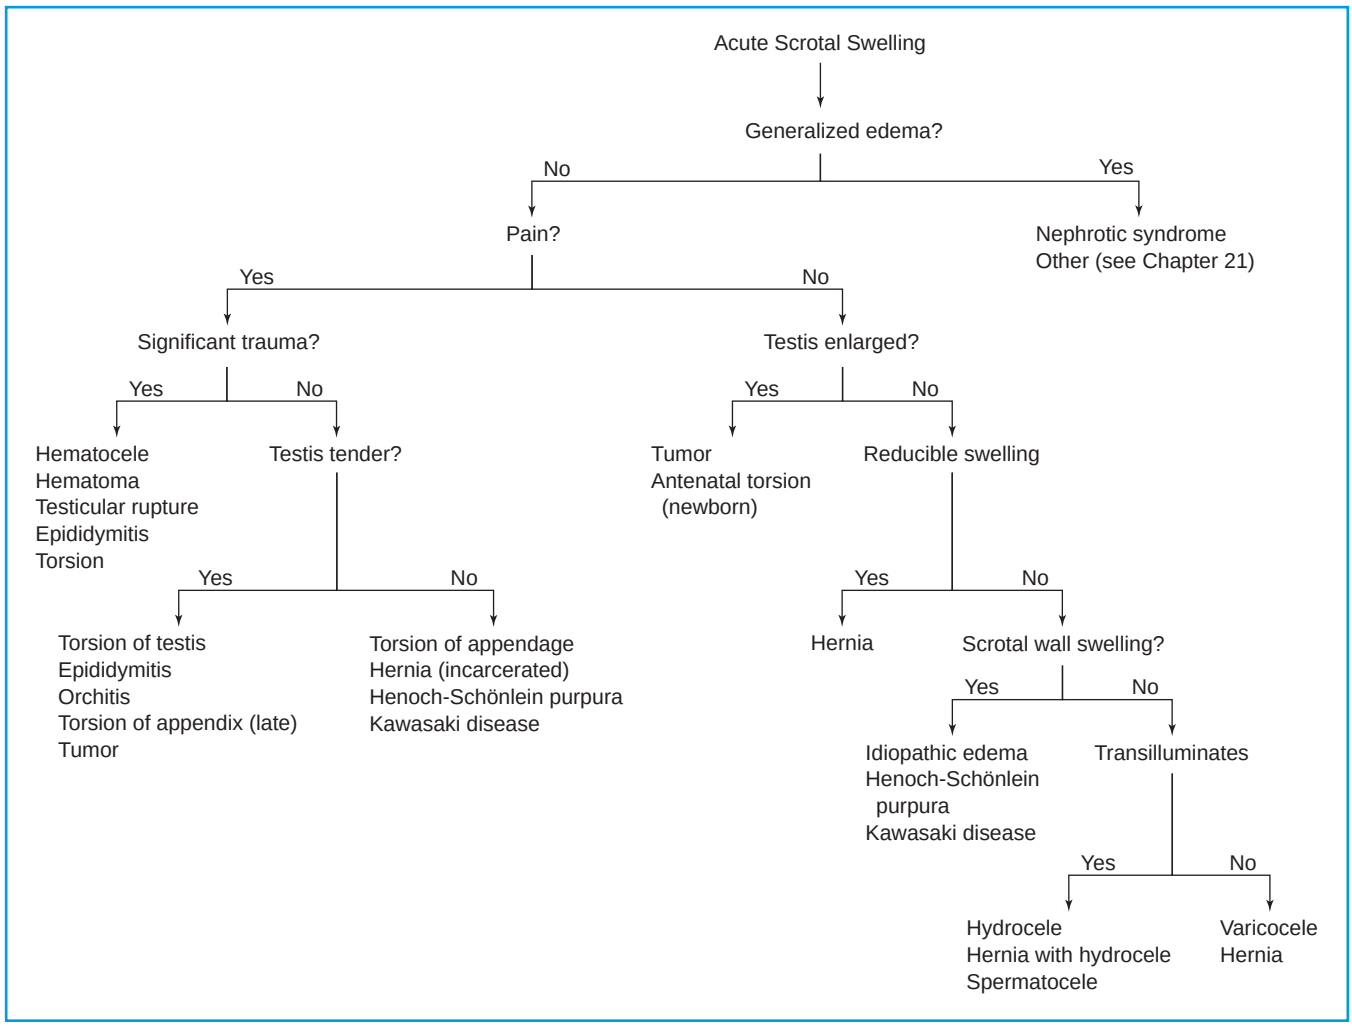


FIGURE 57.9 Diagnostic approach to acute scrotal swelling.

whether the child is suffering from a generalized edematous state, such as the nephrotic syndrome. When the problem is localized to the scrotum, patients can be divided into those who have a painless swelling and those who are experiencing pain.

In the immediate neonatal period, antenatal torsion may cause painless scrotal enlargement. In infancy, the most common causes of painless scrotal swelling (Table 57.2) are hernias and hydroceles; a hernia is often reducible. Beyond infancy, the physician must consider hernia, tumor, spermatocele, and varicocele when evaluating painless scrotal swelling determined to be within the scrotum. Kawasaki disease, HSP, and idiopathic scrotal edema involve the scrotal sac and cause swelling that is either painless or mildly painful.

Painful swelling may follow a well-documented injury, in which case the likely diagnoses are hematocele, hematoma, testicular rupture, and traumatic epididymitis. The physician should bear in mind that boys with testicular torsion often give a history of having had an incidental minor injury. Nontraumatic scrotal pain raises the suspicion of a testicular torsion, if the testis is tender. Unless the diagnosis of a systemic disorder (HSP, Kawasaki disease) is obvious, another structure such as an appendage is reliably determined to be the source of pain within the scrotum, the patient is an adolescent with the classic signs of epididymitis, or an incarcerated hernia is reduced, imaging via Doppler ultrasound or nuclear scan is usually indicated. All patients in whom torsion is suspected, after an initial evaluation by the emergency physician, require a surgical consultation.

History

The age of the child should be considered in evaluating scrotal pain and/or swelling, but overlaps in characteristic age at presentation exist. Testicular torsion occurs in the newborn or early pubertal age range. Torsion of an appendage of the testis, HSP, idiopathic scrotal edema, and Kawasaki disease commonly occur in the prepubertal age group. Epididymitis is more common in adolescents but may occur in prepubertal boys.

Historical features regarding swelling, pain, and associated symptoms should be considered. A history of change in testicular or scrotal size should be determined. If there is pain associated with scrotal swelling, the examiner should determine its onset and severity. Pain is abrupt in onset and severe in testicular torsion, whereas the pain of appendage torsion and epididymitis may be less severe and more gradual. Questions

about recent activity and behavior may indicate milder pain or more insidious course. Children may have difficulty pinpointing the onset of pain and even the exact location of their pain because they may not initially localize sensation to the scrotum, but rather complain of lower abdominal pain. An embarrassed adolescent may not have reported scrotal pain earlier. Inquiry about prior episodes of pain should be made. Nausea and vomiting often accompany testicular torsion, and fever and symptoms of urinary tract infection may suggest epididymitis or other inflammatory diseases (vasculitides).

A history of trauma should always be addressed, recognizing the difference between significant trauma associated with severe acute pain and minor trauma to which the pain of torsion may mistakenly be attributed by the patient. Prior scrotal pain may also indicate intermittent torsion.

A history of sexual activity should be sought. History regarding prior genitourinary surgeries should be elicited because predisposition to urinary tract infections and epididymitis may be related to genitourinary abnormalities or prior instrumentation. Prior surgery for hernias, hydroceles, and undescended testis, unless associated with other genitourinary or anorectal abnormalities, does not suggest a predisposition to infection. In addition, torsion can occur despite prior scrotal surgeries believed to secure the testis.

Physical Examination

Examination of the child with scrotal pain and/or swelling should be both careful and organized. Initial observation of the patient's gait, resting position, and facial expression are helpful. Writhing or an especially quiet supine posture versus active movement may best indicate the degree of pain. Observation of associated skin changes, presence and location of swelling, and the natural position of the testicle in the scrotum while standing should then be appreciated. The cremasteric reflex elicited by stroking the upper inner thigh should cause the testicle to elevate when intact. Next, the lower abdomen, inguinal canal, and cord should be palpated. Finally, the scrotum and its contents should be sequentially palpated. Asking the patient to localize his pain with one finger at this time may be especially helpful. The unaffected hemiscrotum should always be palpated first. Knowledge of the location and specific attempt at palpation of the appendix testis and epididymis is beneficial before palpation of the testis itself (Fig. 57.2). Use of a cotton-tipped swab to discretely localize tenderness in these areas may be helpful, and also less threatening to the anxious, uncomfortable patient. Appreciation of swelling, tenderness, and consistency should be noted for all intrascrotal structures. Transillumination may be helpful in some cases (Fig. 57.9).

Imaging Modalities

Color Doppler imaging with pulsed Doppler allows both visualization of scrotal anatomy and intratesticular arterial blood vessel flow determination and comparison. This study can differentiate scrotal wall from testicular blood flow. With appropriate experience, Doppler imaging has comparable accuracy to that of nuclear scanning. This study is noninvasive and requires less preparation, making it more readily available. The operator-dependent nature of the study, the technical challenges presented by the very young patient with small, low-flow testes, and the need for clinical correlation must be heeded. Torsion is diagnosed when blood flow is diminished or absent, as compared with the contralateral testis. In cases of torsion of a testicular appendage or epididymitis, blood flow is increased to the affected area. For trauma, ultrasound can help localize blood, fluid collections, or swelling. Any doubt in interpretation or concern about the adequacy of the signal should result in consideration of surgical exploration.

Technetium-99 pertechnetate radioisotope scanning has been used previously to assess testicular blood flow. In a child with torsion, little or no isotope appears in the testis, whereas normal or increased activity in the affected testis is associated with epididymitis and appendage torsion. This study provides no information about anatomy and, in addition to a procedure time of approximately 30 minutes, often requires some time in gathering staff, achieving intravenous access, and preparing the isotope. The interpreter of this study must also be confident in differentiating blood flow to the testis versus the scrotal wall.

Magnetic resonance imaging of the scrotum has recently been proposed in cases of trauma to localize blood collections and determine the integrity of underlying structures when ultrasound is equivocal.

CHAPTER 58 ■ PALLOR

SONAL N. SHAH, MD, MPH

Pallor, or the absence of skin coloration, is a relatively common problem in childhood. Throughout the world, the presence of pallor is often used as a screening tool to identify illness. The development of pallor can be acute and associated with a life-threatening illness, or it can be chronic and subtle, occasionally first noted by someone who sees the child infrequently. The onset of pallor can provoke anxiety for parents who are familiar with descriptions of the presentation of leukemia in childhood. In some instances, only reassurance may be needed, as in the case of a light-complexioned or fair-skinned, nonanemic child. Even if there is a hematologic cause for the pallor, it is often a temporary condition readily amenable to therapy. However, pallor can portend a severe disease, and especially when acute in onset, can herald a true pediatric emergency for which rapid diagnosis and treatment are essential.

The degree of pallor depends on the concentration of hemoglobin in the blood and the distribution of blood in the blood vessels of the skin. Any condition that decreases the concentration of hemoglobin or alters the distribution of blood away from the body's surface may present as pallor. Clinically, pallor caused by anemia can usually be appreciated when the hemoglobin concentration is below 8 to 9 grams per deciliter, although the complexion of the child and the rapidity of onset may influence this value. The hematologic causes for pallor in children are discussed later, and further details regarding their management may be found in Chapter 91. Nonhematologic causes of pallor are outlined briefly in Table 58.1.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the major hematologic causes of pallor in children is outlined in Table 58.2. The concentration of hemoglobin in the blood can be lowered by three basic mechanisms: decreased erythrocyte or hemoglobin production, increased erythrocyte destruction, and blood loss. The most common causes of pallor and anemia seen in the emergency department (ED) are iron deficiency and blood loss (Table 58.3), but several less common diseases remain important considerations.

Decreased Production of Hemoglobin and Red Cells

Nutritional Anemias

Nutritional iron deficiency is the most common cause of decreased hemoglobin production in children. A peak in the prevalence of iron deficiency anemia occurs between 12 and 24 months of age, when dietary iron content is often insufficient to meet the demands of a rapidly increasing red cell mass. Premature infants are more susceptible to developing iron deficiency anemia because iron stores at birth are less than those found in term infants, whereas the growth (and therefore, expansion of the red cell mass) of the premature infant is often faster than that of term infants. The early exhaustion of iron stores in premature babies may result in pallor by 6 months of age, whereas in normal infants, signs of iron deficiency anemia are uncommon before 10 to 12 months of age.

A thorough history and physical examination will provide important clues in the diagnosis of iron deficiency anemia. History suggestive of a lack of iron in the diet may be readily apparent or may be recognized only after careful questioning, particularly regarding the daily consumption of cow's milk. The infant with severe iron deficiency is usually irritable and very pale. A compensatory increase in cardiac output is seen, which, when coupled with conditions that increase systemic demands on the heart (such as fever), may provoke the development of congestive heart failure (see Chapter 82).

Serum hemoglobin concentration may be as low as 2 grams per deciliter in severe iron deficiency anemia. Red blood cells are markedly microcytic and hypochromic. Variation in red cell size and shape is usually present, and elongated, pencil-like cells are particularly common. Although the percentage of reticulocytes may be elevated moderately, the absolute reticulocyte count is low.

As the diagnosis of iron deficiency as the cause for an anemia can often be made on the basis of the history alone, treatment is usually instituted before confirmatory laboratory studies are available. Free erythrocyte protoporphyrin, the protein species to which iron is chelated to form mature hemoglobin, is increased in iron deficiency anemia and readily assayed. Thus, this test is particularly useful in the evaluation of the severely anemic child. Measurements of serum iron and ferritin levels have too long of a turnaround time to be of much value in the emergency management of anemia, but are valuable confirmatory tests.

Other nutritional anemias, such as vitamin B_{12} or folic acid deficiency, are uncommon in children in the United States. When present, these anemias are likely associated with particular conditions such as a grossly altered diet, extended hyperalimentation, intestinal resection, or chronic diarrhea. Affected infants usually present with failure to thrive and developmental delay. Older patients more commonly exhibit weight loss, constipation, and weakness. The diagnosis of vitamin B_{12} or folic acid deficiency may be suggested by the finding of anemia with megaloblastic features. Megaloblastic anemia is characterized by normochromic, macrocytic red blood cells, hypersegmented neutrophils, and an elevated serum level of lactic dehydrogenase. Unusual inborn alterations of B_{12} and

folic acid absorption and metabolism may cause symptoms similar to those of the nutritional megaloblastic anemias. Megaloblastic anemia is rarely severe enough to be life-threatening. The diagnosis is confirmed by the finding of low serum levels of folic acid or vitamin B_{12} and the response to folic acid or vitamin B_{12} replacement therapy.

Hypoplastic and Aplastic Anemia

Pallor is usually the first sign of aplastic or hypoplastic anemia. These anemias may be congenital or acquired. Congenital aplastic anemias are most commonly part of larger syndromes, with the two major syndromes recognized being Diamond-Blackfan and Fanconi's anemia.

Diamond-Blackfan syndrome is a congenital hypoplastic anemia commonly detected in the first few months of life. The anemia can be severe at the time of diagnosis. The red cells are normocytic or macrocytic. The reticulocyte count is characteristically low with a leucopenia noted in approximately 10% of affected patients. Thrombocytopenia occurs only rarely. Associated congenital anomalies include microcephaly, cleft palate, web neck, and thumb irregularites. The diagnosis is made by examination of a bone marrow aspirate evidencing markedly reduced or absent erythrocyte precursors with normal marrow cellularity.

Fanconi's anemia is an autosomal recessive condition that results in progressive bone marrow failure generally after age 3 or 4 years. Fanconi's anemia is characterized by a normochromic or macrocytic anemia as well as reductions in both white cell and platelet counts, in contradistinction to Diamond-Blackfan syndrome. Other phenotypic abnormalities

PALLOR WITH ANEMIA

I. Decreased Erythrocyte or Hemoglobin Production
  A. Nutritional deficiencies
    1. Iron deficiency
    2. Folic acid and vitamin B_{12} deficiency or associated metabolic abnormalities
  B. Aplastic or hypoplastic anemias
    1. Diamond-Blackfan anemia
    2. Fanconi's anemia
    3. Aplastic anemia[a]
    4. Transient erythroblastopenia of childhood
    5. Malignancy: leukemia, lymphoma, neuroblastoma[a]
  C. Abnormal heme and hemoglobin synthesis
    1. Anemia of chronic disease
    2. Lead poisoning[a]
    3. Sideroblastic anemias
    4. Thalassemias
II. Increased Erythrocyte Destruction
  A. Erythrocyte membrane defects: hereditary spherocytosis, elliptocytosis, stomatocytosis, pyknocytosis, paroxysmal nocturnal hemoglobinuria
  B. Erythrocyte enzyme defects
    1. Defects of hexose monophosphate shunt: G6PD deficiency most common
    2. Defects of Embden-Meyerhof pathway: pyruvate kinase deficiency most common
  C. Hemoglobinopathies
    1. Sickle cell syndromes[a]
    2. Unstable hemoglobins
  D. Immune hemolytic anemia
    1. Autoimmune hemolytic anemia[a]
    2. Isoimmune hemolytic anemia[a]
    3. Infection
      a. Viral: mononucleosis, influenzas, coxsackievirus, measles, varicella, cytomegalovirus
      b. Bacterial: *Escherichia coli, Pneumococcus, Streptococcus*, typhoid fever, *Mycoplasma*
    4. Drugs: antibiotics
    5. Inflammatory and collagen vascular disease
    6. Malignancy[a]
  E. Microangiopathic anemias
    1. Disseminated intravascular coagulation[a]
    2. Hemolytic uremic syndrome[a]
    3. Cavernous hemangioma
III. Blood Loss
  A. Severe trauma[a]
  B. Anatomic lesions
    1. Meckel's diverticulum
    2. Peptic ulcer
    3. Idiopathic pulmonary hemosiderosis[a]

G6PD, glucose-6-phosphate dehydrogenase.
[a]Conditions that are known to present with acute, life-threatening anemia or are associated with other serious abnormalities.

associated with Fanconi's anemia include hyperpigmentation or hypopigmentation, microcephaly, strabismus, small stature, mental retardation, and anomalies of the thumbs and radii. The diagnosis may be made in the proper clinical context by the presence of increased chromosomal breakage in lymphocytes cultured in the presence of DNA cross-linking agents.

Acquired aplastic anemia can also present with severe pallor in children. The anemia is usually associated with granulocytopenia and thrombocytopenia. Acquired aplastic anemia is often idiopathic but has been associated with exposure to certain drugs and chemicals (e.g., chloramphenicol, felbamate, lindane, gold, benzene, pesticides), radiation, and viral infections (especially hepatitis). The diagnosis is made by an examination of the bone marrow.

Transient erythroblastopenia of childhood (TEC) is a condition that is often associated with a recent viral illness and is characterized by moderate to severe anemia caused by diminished red cell production. The age at presentation can vary from infancy to 10 years, with a median of 18 to 26 months. The mean corpuscular volume (MCV) is usually normal at the time of diagnosis. The reticulocyte count is decreased, and a Coombs test is negative. The anemia of TEC may be associated with a normal or moderately decreased white cell count and a normal platelet count. Bone marrow examination shows an initial reduction or absence of erythrocytic precursors followed by erythroid hyperplasia during recovery. Transient erythroblastopenia that occurs in the first 6 months of life may be difficult to distinguish from Diamond-Blackfan anemia. Spontaneous recovery ultimately confirms the diagnosis of TEC.

Hypoplastic anemia can be the presenting symptom of childhood malignancies. The pallor can be severe, and although all three cell lines of the bone marrow are usually affected, anemia may be the only notable hematologic abnormality. The diagnosis can be suspected from the presence of other symptoms or findings, such as lymphadenopathy, bruising, limb pain, gum bleeding, or an abdominal mass.

Red cell aplasia may develop in patients with underlying hemolytic anemias such as hereditary spherocytosis or sickle cell (SC) disease, usually in association with parvovirus B19 infection. Decreased red cell production in the face of ongoing hemolysis causes an exacerbation of the anemia. The elevated reticulocyte count usually seen in hereditary hemolytic anemias falls to inappropriately low levels, often less than 1%. Although platelets and white cells are generally unaffected, they may be mildly decreased. Red cell transfusions are appropriate if the anemia is associated with cardiovascular compromise or if continuing reticulocytopenia indicates that the anemia is likely to become severe before the usual spontaneous recovery after 3 to 7 days. Patients with decreased erythrocyte production from a condition such as iron deficiency anemia or human immunodeficiency virus (HIV) infection may also experience a transient aplastic crisis from parvovirus B19 infection. Hematologically normal children with underlying (though sometimes unrecognized) immunologic disorders may also develop parvovirus-induced anemia as a result of prolonged viremia.

Disorders of Heme and Globin Production

Pallor may be the presenting sign of nonnutritional disorders of hemoglobin synthesis, including the sideroblastic anemias and thalassemia syndromes. These disorders are characterized by a microcytic, hypochromic anemia. Sideroblastic anemia may be inherited (sex linked) or acquired such as in cases of alcohol, chloramphenicol, or isoniazid exposure, copper deficiency, and zinc toxicity. Although the etiology can be diverse, the inciting factors share a final common pathway, which is a defect in the synthesis of heme in the red cell precursor. As a result, iron use within the developing red cell is abnormal, accounting for the presence of diagnostic ringed sideroblasts in the bone marrow. The serum iron and ferritin levels are often markedly elevated.

In the thalassemias, production of the globin portion of the hemoglobin molecule is impaired because of genetic defects in heme chain synthesis. The anemia is hypochromic and microcytic with an elevated reticulocyte count. Cooley's anemia (β-thalassemia major) presents with severe pallor usually between 6 and 12 months of age, as fetal hemoglobin levels decline and the normal rise in adult hemoglobin (HbA) levels is compromised by a reduced or absent β-globin production. The anemia is the result of a unique combination of decreased hemoglobin synthesis and, as a result of imbalanced α and β globin chain production, accelerated red cell destruction. Consequently, erythropoietic hyperplasia of the bone marrow and extramedullary hematopoiesis occur. In severe β-thalassemia major, extramedullary hematopoiesis within craniofacial bones leads to a spectrum of characteristic facial features including prominence of frontal and parietal bones, depression of the nasal bridge, and protrusion of the upper teeth, resulting in so-called "chipmunk facies." Bone marrow hyperplasia results in thinning of the cortex, widening of the medullary spaces, and osteoporosis. There is delayed skeletal maturation. This constellation of characteristic facies, bony abnormalities, presence of hepatosplenomegaly and characteristic red cell morphology, including marked variation in red cell shape, usually makes this diagnosis readily apparent. Although β-thalassemia is often associated with Mediterranean ancestry, this disease and other thalassemias (e.g., E-β thalassemia, HbH disease) are also seen commonly in children of Southeast Asian, Indian, Pakistani, Arab, and Chinese ethnicity.

Lead poisoning affects heme synthesis, but significant anemia is unusual unless blood lead levels are markedly elevated. Iron deficiency is common in children with increased lead levels and usually accounts for the microcytic anemia found in these patients. If a concomitant hematologic disorder cannot be found in the anemic patient with plumbism, particular care should be given to the possibility of severe lead intoxication.

Systemic Disease

Numerous disorders that are not primarily hematologic may be associated with pallor and anemia due to decreased production of hemoglobin or red cells. Occasionally, pallor is the only presenting finding of a serious systemic disorder. Chronic inflammatory diseases, such as juvenile idiopathic arthritis (JIA) and ulcerative colitis, are often accompanied by a normocytic or microcytic anemia related to impaired iron utilization by hematopoetic cells. The serum iron is reduced; however, low iron-binding capacity distinguishes this anemia of chronic inflammation from the anemia of iron deficiency. Similar clinical and laboratory findings may be associated with chronic infections such as HIV and subacute bacterial endocarditis. Other diseases in which anemia may be a prominent component include chronic renal disease, hyperthyroidism, and hypothyroidism. The anemia in these disorders is not severe enough to

be considered a hematologic emergency unless complicated by other hematologic abnormalities. However, anemia may be the first clue to an underlying disease in which early treatment may improve the outcome substantially.

Increased Red Cell Destruction

The numerous conditions associated with shortened red cell survival can be congenital, as in the case of the hemoglobinopathies and membrane and enzyme defects. Acquired causes of shortened red cell survival include autoimmune hemolytic anemia, drug-associated hemolytic anemias, disseminated intravascular coagulation (DIC), and hemolytic–uremic syndrome (HUS). The hemoglobin levels in these disorders can be normal, slightly depressed, or so low as to be life-threatening. The steady state hemoglobin concentration is determined by a balance between the severity of the defect and the bone marrow's ability to respond to the presence of a shortened red cell survival. Compensation is achieved by an increase in erythrocyte production as is evident from the elevated reticulocyte count that is usually found in these conditions.

When the child with increased red cell destruction cannot compensate and make more red blood cells, this may result in a severe, life-threatening exacerbation of the underlying anemia (e.g., as is the case with acquired red cell aplasia from parvovirus B12 as discussed above). An aplastic crisis should be suspected in a patient with a known hemolytic anemia who develops increasing pallor and anemia associated with a reticulocyte count depressed in relation to its normally elevated baseline. The differential diagnosis of these underlying hemolytic conditions that result in red cell destruction is presented below.

Membrane Disorders

The degree of pallor associated with anemia caused by erythrocyte membrane abnormalities depends on the hemoglobin level. Hereditary spherocytosis, the most common of the membrane disorders, is usually characterized by well-compensated chronic hemolysis, which becomes clinically apparent only when the hemolysis is exacerbated by intercurrent infection. In rare instances, patients with hereditary spherocytosis may develop significant anemia, jaundice, and pallor in the newborn period. Moderate or severe anemia is less common in the other membrane disorders, such as hereditary elliptocytosis and hereditary stomatocytosis. The anemia of the erythrocyte membrane disorders is accompanied by reticulocytosis. A direct antiglobulin (Coombs) test will be negative. Red cell morphology usually permits the diagnosis to be made from the peripheral smear. Because these disorders are often inherited in an autosomal dominant fashion, a family history of anemia, splenomegaly, splenectomy, or cholecystectomy may be helpful. However, a particularly severe form of spherocytosis occurs as an autosomal recessive disorder, and even some children with more typical disease lack an informative family history. Consequently, the diagnosis should not be dismissed in the absence of other affected family members.

Infantile pyknocytosis is a hemolytic anemia seen during the first few months of life and is characterized by distorted and contracted erythrocytes and burr cells. The disorder may be associated with pallor and hyperbilirubinemia. Spontaneous recovery usually occurs by 6 months of age.

Enzyme Disorders

Erythrocyte enzymatic defects, such as pyruvate kinase deficiency and certain variants of glucose-6-phosphate dehydrogenase (G6PD) deficiency, may be associated with pallor due to increased red blood cell destruction. G6PD deficiency is the most common human enzyme defect, with predominance in people of Middle Eastern, South Asian, and African descent. This regional distribution is likely explained by the protection G6PD deficiency confers against malaria. In G6PD deficiency, pallor may be accentuated by acute hemolytic crises after exposure to oxidant stress (e.g., naphthalene-containing mothballs, antimalarials, sulfonamides, aspirin, methylene blue, or acidosis). Although alterations in red cell morphology are sometimes found in these enzyme disorders, assays of specific enzymes or substrates are required for definitive diagnosis.

Hemoglobinopathies

Pallor may result from the low hemoglobin level found in patients with sickle cell anemia and related hemoglobinopathies. Acute accentuation of pallor can result from an aplastic crisis, a complication of hemolytic disorders that is particularly common in sickle cell anemia. During an aplastic crisis, the normally elevated reticulocyte count may fall to zero, and the hemoglobin level may fall as low as 1 to 2 grams per deciliter, resulting in severe pallor and signs of high-output cardiac failure.

The sequestration crisis of sickle cell anemia (HbSS) and related hemoglobin disorders (SC disease, S-β^0 thalassemia, S-β^+ thalassemia) is a true hematologic emergency. The presence of increased pallor and acute enlargement of the spleen in a patient with a sickling disorder should prompt immediate investigation of possible sequestration crisis. The condition results from pooling of red cells and plasma in the spleen resulting in sudden and severe anemia with associated hypovolemia. Emergent intervention is warranted as untreated cases may rapidly lead to death. Although this complication rarely occurs in children with homozygous sickle cell disease or S-β^0 thalassemia after the age of 5 years, sequestration crises may occur much later in children with sickling disorders such as SC disease or S-β^+ thalassemia, in which early splenic infarction is less common.

Immune Hemolytic Anemia

Pallor caused by autoimmmune hemolytic anemia is usually acute in onset and may be associated with severe anemia. Symptoms include jaundice, dark urine, splenomegaly, and cardiovascular derangement. The presence of only moderate anemia (6 to 8 grams per deciliter) at diagnosis should not detract from consideration of this disease as a hematologic emergency because brisk hemolysis may result in a sudden, additional fall in hemoglobin level. Autoimmune hemolytic anemia is usually, but not always, characterized by a positive direct antiglobulin (Coombs) test and an increased reticulocyte count. Spherocytes are commonly seen in the peripheral smear. Other causes of immune hemolytic anemia include infections, drug exposure, inflammatory diseases, and malignancies.

Microangiopathic Anemia

Alterations in the normal laminar flow of blood through the vascular system may cause increased red cell destruction. In DIC, abnormal fibrin deposition within small blood vessels results in mechanical injury to the erythrocytes. Thrombocytopenia and

clotting abnormalities, which often herald the onset of DIC, may also contribute to the anemia via blood loss. The main diagnostic findings are red cell fragments in the peripheral blood smear, platelet and clotting abnormalities typical of a consumptive coagulopathy (see Chapter 91), and the clinical features of an underlying entity such as septic shock or extensive trauma, with which DIC is associated.

The increased red cell destruction in HUS and thrombotic thrombocytopenic purpura (TTP) is also caused by intravascular fibrin deposition. Thrombocytopenia and uremia may lower the hemoglobin concentration even further via blood loss, impaired red cell production, shortened red cell survival, and increased plasma volume. In some instances, anemia may be severe despite only mild uremia and absent thrombocytopenia, leaving doubt about the correct diagnosis. In more typical cases, however, the diagnosis is readily apparent from the findings of oliguria, central nervous system abnormalities, increased blood urea nitrogen, thrombocytopenia, and abnormalities of red cell morphology on peripheral blood smear, including fragments and helmet cells.

Another form of microangiopathic anemia involves the proliferation of blood vessels within a cavernous hemangioma that may trap red cells or initiate a localized consumptive coagulopathy, causing erythrocyte destruction. Anemia in these cases is rarely severe unless the thrombocytopenia, which is more typical of the disorder, causes chronic blood loss.

Blood Loss

Although sudden, massive hemorrhage is usually accompanied by signs of hypovolemic shock, the repeated loss of smaller amounts of blood may be associated with few findings other than pallor. The finding of iron deficiency anemia despite normal dietary iron intake or iron supplementation may be a clue to the presence of chronic blood loss from the gastrointestinal (GI) tract or within the lungs.

EVALUATION AND DECISION

The initial assessment of the child with pallor should include an immediate determination of the degree of illness. Rapid treatment may be imperative for the severely ill child. In the presence of hypovolemic shock, immediate support of vascular volume is required. When high-output cardiac failure from severe anemia occurs, transfusion with small aliquots of packed red cells is necessary. Only after these initial therapeutic efforts have been completed can a thorough evaluation of the anemia proceed.

If the child with pallor is not acutely ill, a deliberate search for the cause of pallor should be undertaken (Fig. 58.1). This may be accomplished by obtaining a thorough yet focused history, performing a detailed physical examination, and ordering appropriate laboratory investigations. The history should focus on several major components. First, particular attention should be paid to the time of onset of pallor. The slow development of pallor suggests diminished red cell production, as is found in bone marrow aplasia or iron deficiency. However, the acute onset of pallor is consistent with the brisk hemolysis of autoimmune hemolytic anemia or the splenic sequestration of sickle cell disease.

After establishing the time course of the anemia, the history can be directed toward more narrow categories of anemia or specific diseases. A detailed dietary history, with particular attention to milk intake, is important in young children with suspected iron deficiency as excessive consumption of cow's milk often results in iron deficiency. Vitamin B_{12} deficiency may accompany strict vegetarian diets from which meat and egg products are excluded and may occur in breast-fed infants of vegetarian mothers or mothers with pernicious anemia. Nutritional folic acid deficiency is rare and can usually be readily deduced from the presence of severe dietary alterations and evidence of other vitamin deficiencies.

The family history helps in the diagnosis of hemoglobinopathies and inherited disorders of red cell membranes and enzymes. Because results of previous hemoglobin testing may have been explained inadequately or recalled inaccurately, a negative family history or newborn screening for hemoglobinopathies should not preclude evaluation of the patient's hemoglobin phenotype if a sickling disorder is suspected. The presence of a microcytic anemia unresponsive to iron in the parents suggests a thalassemic disorder. A history of splenomegaly, splenectomy, or cholecystectomy in family members may help identify a hemolytic disorder such as hereditary spherocytosis or pyruvate kinase deficiency.

Finally, a well-directed review of systems is essential in looking for systemic disorders such as chronic renal disease, hypothyroidism, or JIA. Pallor may be the presenting complaint in these and other disorders.

In the examination of the anemic patient, pulse and blood pressure (BP) should be measured to be sure hypovolemic shock and high-output cardiac failure are neither present nor imminent. If anemia or volume loss is mild, tachycardia may be present with a preserved BP. A systolic flow murmur is often heard if the hemoglobin level is below 8 grams per deciliter. In the severely anemic patient, pallor of the skin and mucous membranes is usually readily apparent. When anemia is less severe or when the skin color is dark, pallor may be appreciated only in the nail beds, palmar surfaces and palpebral conjunctivae. Lymphadenopathy and splenomegaly may suggest a malignancy or an infectious disease such as mononucleosis. When splenomegaly occurs without lymphadenopathy, however, attention is drawn to hemolytic disorders such as hereditary spherocytosis and autoimmune hemolytic anemia or hemoglobinopathies (e.g., sickling disorders or thalassemia major). Scleral icterus may also be present in these disorders of shortened red cell survival. The finding of an unusually large and firm spleen in the absence of increasing scleral icterus suggests that red cells are being sequestered (e.g., splenic sequestration crisis of sickle cell disease, hypersplenism).

The skin in a patient with pallor should be examined for evidence of underlying disorders. The presence of hemangiomas might suggest microangiopathic anemia. If increased bruising or bleeding accompanies pallor, multiple blood elements are probably affected. The circulation time of platelets is short in comparison with that of red cells. Therefore, clinical findings of thrombocytopenia are often present by the time pallor develops in patients with acquired aplastic anemia, Fanconi's anemia, and acute leukemia. Clinical evidence of thrombocytopenia may also suggest micorangiopathic anemia as described earlier. Careful auscultation of the abdomen and head may detect unseen hemangiomas. Sources of internal or external blood

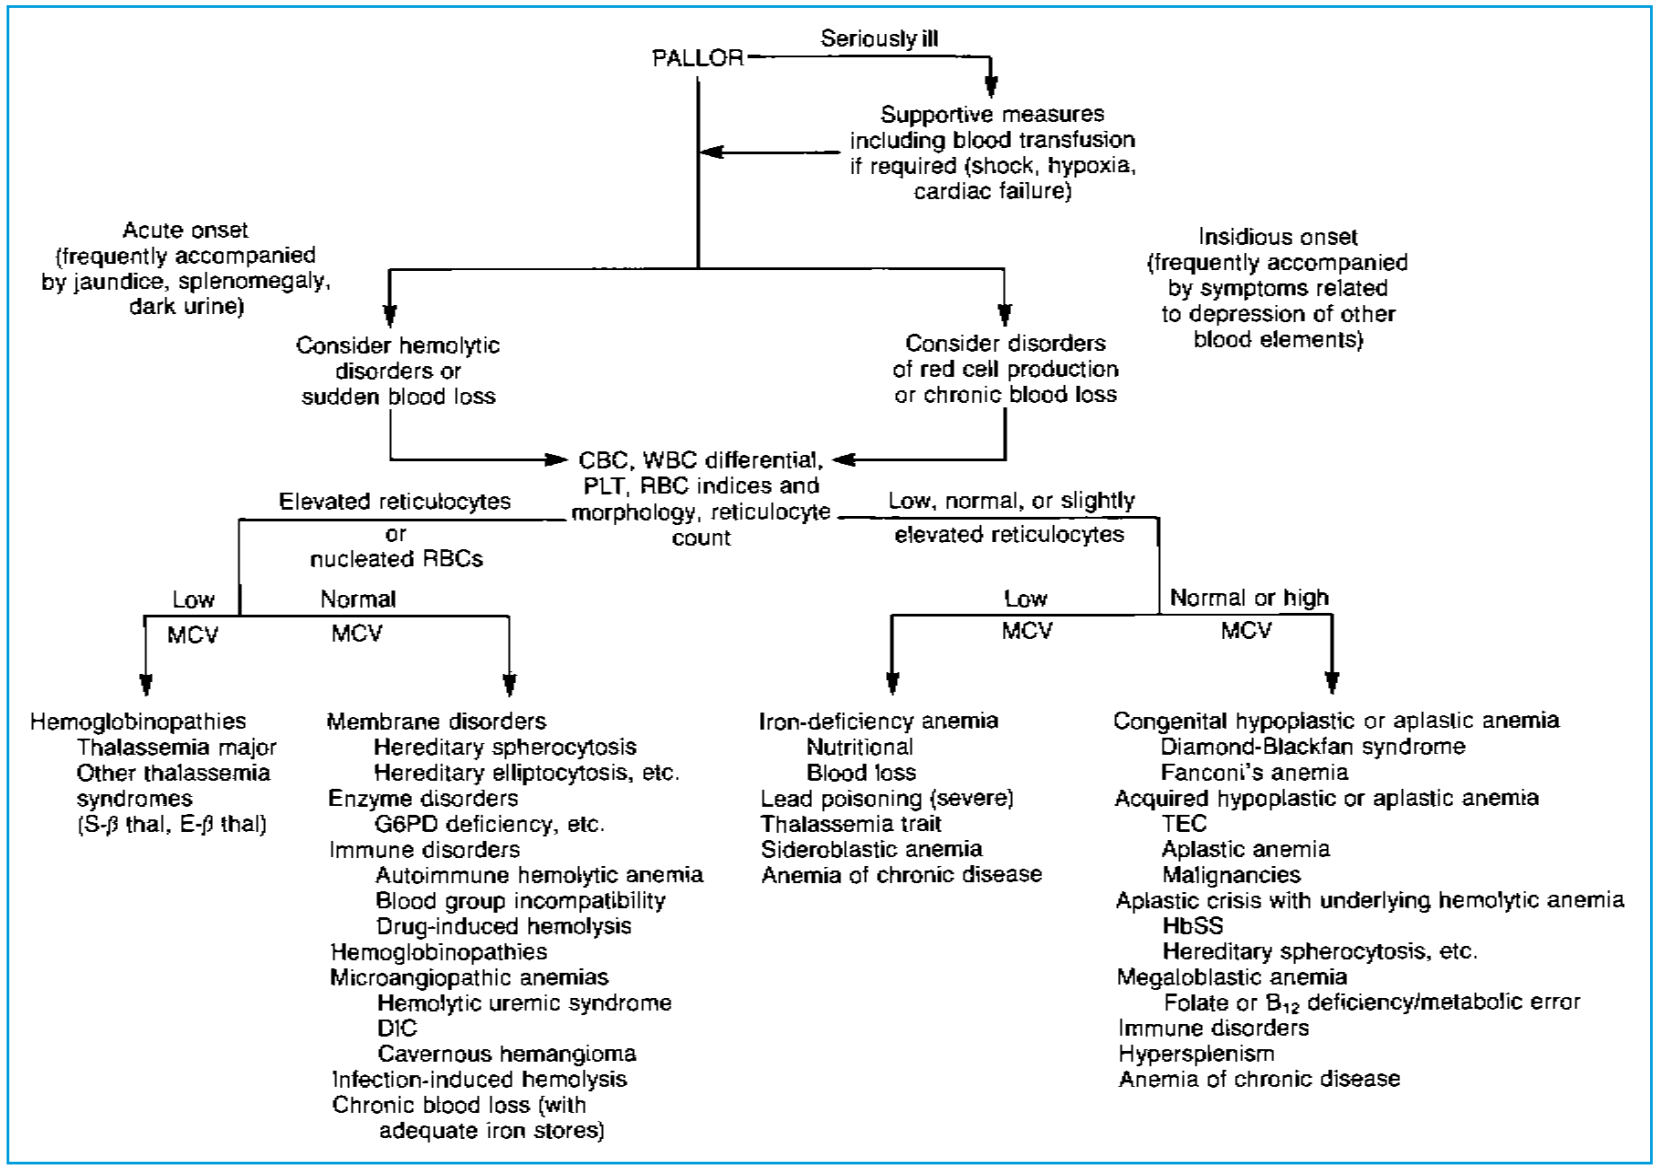

FIGURE 58.1 The diagnostic approach to pallor. CBC, complete blood cell; WBC, white blood cell; PLT, platelet; RBC, red blood cell; MCV, mean corpuscular volume; G6PD, glucose-6-phosphate dehydrogenase; DIC, disseminated intravascular coagulation; TEC, transient erythroblastopenia of childhood; HbSS, sickle cell anemia.

loss should be carefully sought. Chronic GI bleeding may escape detection until iron deficiency anemia develops. Similarly, small pulmonary hemorrhages associated with idiopathic pulmonary hemosiderosis are often mistaken for other pulmonic processes until several recurrences of iron deficiency anemia suggest a hidden site of blood loss. Bony abnormalities associated with red cell disorders include frontal bossing from compensatory expansion of the bone marrow in hemolytic diseases and radial and thumb anomalies found in some patients with Fanconi's anemia.

Numerous classifications of anemia have been used to assist the physician in the laboratory investigation of pallor. Historically, the reticulocyte count and the MCV have been helpful measurements in categorizing causes of anemia. The reticulocyte count can be performed rapidly and, as shown in Fig. 58.1, distinguishes anemias caused by impaired red cell production (e.g., iron deficiency, hypoplastic anemia) from those caused by shortened red cell survival (e.g., hemoglobinopathies, membrane disorders). The MCV provides a quick, accurate, and readily available method of distinguishing the microcytic anemias (iron deficiency, thalassemia syndromes) from the normocytic (membrane disorders, enzyme deficiencies, autoimmune hemolytic anemia, most hemoglobinopathies) or macrocytic (bone marrow/stem cell failure, disorders of B_{12} and folic acid absorption or metabolism) anemias.

The reticulocyte count and MCV should be interpreted with caution. As shown in Fig. 58.1, disorders of shortened red cell survival are not always characterized by an increased reticulocyte count. For example, reticulocytopenia may occur in autoimmune hemolytic anemia, despite active hemolysis and increased erythropoiesis in the bone marrow. Chronic hemolytic disorders, such as sickle cell anemia or hereditary spherocytosis, may first be detected during an aplastic crisis when the reticulocyte count is low. Unless the underlying disorder is recognized, the physician may be misled by this finding. Furthermore, because the reticulocyte count is expressed as a percentage of total red cells, it must be indexed for the degree of anemia. The easiest way to calculate the reticulocyte index is to multiply the reticulocyte count by the reported hemoglobin or hematocrit [HCT pt (patient)] divided by normal hemoglobin or hematocrit [HCT nl (normal)]:

$$\text{Reticulocyte index} = \text{Reticulocyte count} \times \frac{\text{HCT (pt)}}{\text{HCT (nl)}}$$

For example, a reticulocyte count of 5% in a child with severe iron deficiency anemia and a hematocrit of 6% is not elevated when corrected for the degree of anemia (5% × 6%/33% = 0.9%). The normal reticulocyte index is between 1.0 and 2.0.

The MCV varies with age, necessitating the use of age-adjusted normal values (Table 58.4). In addition, the measured MCV represents an average value. If microcytic and macrocytic red cells are present in the peripheral blood as, for example, in a patient with combined iron deficiency and B_{12} deficiency, the MCV may remain normal. Therefore, the peripheral smear should be examined carefully to determine whether the MCV reflects a single population of red cells of uniform size, or two or more populations of distinctly different size. The red cell distribution width is elevated in the presence of increased variation in red cell size.

As shown in Fig. 58.1, the reticulocyte count and MCV help in the initial classification of anemia but leave the physician with broad categories of disease, rather than specific diagnoses. In many instances, the history and physical examination, when coupled with these laboratory measurements, permit identification of a particular disorder. Additional laboratory studies and careful examination of the peripheral smear may be required, however, and can be performed readily when the patient is in the ED. The application of these procedures to diseases that are commonly encountered or that are associated with unusually severe anemia is discussed next.

TABLE 58.4

AGE-RELATED VALUES FOR MEAN CORPUSCULAR VOLUME

Increased Reticulocytes and Low Mean Corpuscular Volume

The thalassemia syndromes associated with moderate or severe anemia can be recognized by the distinctive abnormalities of red cell morphology. In Cooley's anemia (β-thalassemia major), the red cells are generally small but vary markedly in size and shape. Many cells appear to contain little or no hemoglobin; the central pallor of the red cell by light microscopy extends to the cell membrane. Nucleated red cells, basophilic stippling, and polychromasia reflect active erythropoiesis. The parents of an affected child usually have a low MCV characteristic of thalassemia trait.

Children with HbS-β-thalassemia often have microcytic red cells, although the alterations of red cell morphology are not as dramatic as in Cooley's anemia. Sickled forms are often but not always present. Target cells are common. The solubility tests are positive because of the presence of HbS. Hemoglobin electrophoresis reveals HbS (single sickle allele) and reduced (less than 50%) or absent HbA (normal adult hemoglobin).

Increased Reticulocytes and Normal Mean Corpuscular Volume

Most membrane disorders can be readily identified by the characteristic changes in red cell shape that lend their names to the diseases (e.g., spherocytosis, elliptocytosis, stomatocytosis).

When the diagnosis of a membrane disorder is uncertain, examination of the parents' peripheral smears may be helpful because, in many cases, the inheritance pattern is autosomal dominant.

Abnormalities of red cell morphology are less striking in erythrocyte enzymatic defects. Blister cells and cells with asymmetric distribution of hemoglobin may be found, however, during episodes of active hemolysis in G6PD deficiency. If transfusion is necessary, a pretransfusion sample should be saved for assay of specific enzymes.

The reticulocyte count is usually markedly elevated in autoimmune hemolytic anemia but may be normal or only slightly elevated during the first days of the disease. In rare instances, reticulocytopenia persists. Spherocytes are usually present on the peripheral smear. Clumping of red cells from agglutination may be seen. This agglutination sometimes causes a falsely elevated MCV because the electronic counter measures the volume of red cell couplets or triplets. The direct antiglobulin test is positive in 90% of cases. Patients with a negative direct antiglobulin test present a challenging diagnostic problem because the initial findings may be similar to those in hereditary spherocytosis.

The recognition of homozygous sickle cell disease (HbSS) is usually accomplished by the finding of sickled red cells on the peripheral smear. Rarely, however, such cells are absent, even during an acute illness. Target cells are commonly found in sickle cell disease but are more prominent in HbSC. Solubility tests are positive. Hemoglobin electrophoresis reveals the presence of the abnormal hemoglobin(s) and the absence of HbA. This confirmatory test takes less than 30 minutes to complete and should be performed when important therapeutic decisions depend on the result.

Red cell fragments are found in those diseases characterized by microangiopathic anemia. In HUS or TTP, thrombocytopenia is present, renal or neurologic function is usually impaired, and thrombotic complications may be present. The platelet count is also low in DIC, and clotting studies are abnormal. If intravascular hemolysis is severe, as in anemia associated with certain artificial cardiac valves, hemosiderin may be detected in the urinary sediment.

Low, Normal, or Slightly Elevated Reticulocytes and Low Mean Corpuscular Volume

In severe iron deficiency anemia, red cells are markedly microcytic and hypochromic and show substantial variation in size and shape. Elongated red cells (pencil forms) are common. Platelet count is often increased but may occasionally be decreased. As discussed previously, the erythrocyte protoporphyrin concentration is usually increased in iron deficiency, although values are lower than those found in severe lead poisoning.

Anemia is uncommon in lead poisoning but, when present, resembles the anemia of iron deficiency in its red cell morphology. Basophilic stippling is found in a small percentage of cases. The erythrocyte protoporphyrin is markedly elevated, and the rapid measurement of this compound helps the physician in the ED to distinguish severe lead poisoning, which requires hospitalization and intensive chelation, from iron deficiency, which usually can be treated on an outpatient basis.

Low, Normal, or Slightly Elevated Reticulocytes and Normal or Elevated Mean Corpuscular Volume

With the exception of mild macrocytosis, red cell morphology is usually normal in childhood disorders of bone marrow or stem cell failure. Thrombocytopenia and neutropenia are present in aplastic anemia and Fanconi's anemia. Although the platelet count and white count occasionally may be low in patients with Diamond-Blackfan syndrome, the red cells are most severely affected. Erythropoiesis is most severely affected in TEC and acquired pure red cell aplasia, although neutropenia may accompany the former disorder.

The clinical features at the onset of acute leukemia may closely resemble those of aplastic anemia. The presence of blast cells in the peripheral smear may indicate a diagnosis of leukemia, but examination of a bone marrow aspirate is required to distinguish these disorders definitively as well as to characterize the type of leukemia. This procedure is rarely performed in the ED. Therapy, such as corticosteroids, which might interfere with the interpretation of the bone marrow aspirate, should be withheld until a definitive diagnosis has been made.

As discussed, children with hemolytic disorders may escape detection until pallor is noted during an aplastic crisis when the reticulocyte count is similar to that found in primary disorders of red cell production. An underlying hemolytic disease such as sickle cell anemia or hereditary spherocytosis can usually be recognized during an aplastic crisis, however, by finding characteristic red cells on the peripheral smear. In the autosomal dominant disorders of the red cell membrane, the presence of abnormal erythrocytes in the peripheral blood of one of the parents may support the diagnosis. Solubility tests for HbS or hemoglobin electrophoresis should be performed to detect sickling disorders.

The MCV is usually increased in megaloblastic anemias unless other nutritional disorders are present. Hypersegmentation of the polymorphonuclear leukocytes is characteristic. In severe or long-standing megaloblastic anemia, neutropenia and thrombocytopenia may also be found. In such cases, the findings in the peripheral blood may be similar to those of aplastic anemia or even acute leukemia; examination of the bone marrow and measurement of specific nutrients (B_{12}, folic acid) are necessary to distinguish these disorders.

CHAPTER 59 ■ PALPITATIONS

JAMES F. WILEY II, MD, MPH

Palpitations represent a disagreeable perception of the heartbeat by the patient. Descriptions commonly given include "pounding," "fluttering," "jumping in the chest," or a sensation of the heart "stopping." In adults, palpitations frequently arise from serious underlying cardiac pathology. In children, most etiologies are benign. Pediatric patients demonstrate a high degree of variation in their sensitivity to changes in the heart rate (HR) or rhythm. A patient who actually has trivial cardiac events may express severe symptoms while children with a significant arrhythmia may remain asymptomatic. The challenge to the emergency physician is to determine which complaint can be managed in the emergency department (ED) and which merits further consideration by a cardiologist.

PATHOPHYSIOLOGY

The heart is innervated by the vagus nerve (cranial nerve X) and the sympathetic ganglion. Cardiovascular reflexes (e.g., vasovagal bradycardia) are transmitted by the vagus nerve. Pain sensation (e.g., related to myocardial ischemia) travels through afferent fibers associated with the sympathetic ganglia. In most patients, the sensation of the heartbeat is not felt. Children with documented arrhythmias, such as supraventricular tachycardia (SVT) and stable ventricular tachycardia, may not complain of any symptoms. Even patients with heart murmurs audible to the unassisted ear can learn to ignore this obvious cue.

Patients with palpitations often relate an indirect perception of increased force of cardiac contraction, tachycardia, or irregular heartbeat. Increased force of the contraction is often detected when the patient is supine. At times, it may be described as a rushing or pounding in the ears, particularly when the ear is pressed against a pillow. Caffeine or alcohol consumption, illicit drug use, exercise, and emotional arousal can produce this sensation of a large ventricular stroke volume.

Patients with premature contractions and a compensatory pause may describe the feeling that their hearts "flip-flop" or "stop." Many patients with premature atrial or ventricular contractions notice the subsequent beat after the initial "short" beat because of the increased stroke volume ejected. Other patients may complain of a choking or full sensation in the neck. Jugular venous pulsation associated with right atrial contraction against a closed tricuspid valve (atrioventricular (AV) block with or without atrial tachycardia) can present in this way.

True cardiac arrhythmias arise from various mechanisms that are discussed in Chapter 84.

DIFFERENTIAL DIAGNOSIS

Many conditions may produce palpitations (Table 59.1). Most children with palpitations do not have significant cardiac pathology (Table 59.2). However, many life-threatening conditions can come to medical attention because of abnormal cardiac sensation (Table 59.3). Wolff-Parkinson-White (WPW) syndrome and the prolonged QT syndrome are two potentially lethal diseases that may be diagnosed on a resting electrocardiogram (EKG). A patient with palpitations during exercise should also raise concern for hypertrophic cardiomyopathy, SVT, ventricular tachycardia, or myocardial ischemia. In addition, palpitations in children with known congenital heart disease are frequently caused by a serious cardiac arrhythmia.

Diagnosis of noncardiac causes of life-threatening palpitations, including hypoxemia, hypoglycemia, hyperkalemia, and hypocalcemia, can be made by characteristic EKG changes, serum electrolyte determinations, rapid bedside glucose, and oxygen saturation measurements.

Hyperdynamic Cardiac Activity

Increased HR and contractility are physiologic responses to catecholamine release, like that which may occur with exercise, emotional arousal, hypoglycemia, and pheochromocytoma. Similarly, increased cardiac work accompanies conditions that increase the basal metabolic rate such as fever, anemia, and hyperthyroidism. Sympathomimetic and anticholinergic drugs are among a group of commonly available substances that directly modulate the autonomic nervous system, causing tachycardia, hyperdynamic cardiac activity, and palpitations (Table 59.4).

Postural orthostatic tachycardia syndrome (POTS) describes a form of orthostatic intolerance characterized by tachycardia (more than 30 beats per minute over baseline or more than 120 beats per minute in adults) typically without hypotension upon standing. POTS is commonly seen in teenage girls and manifests as palpitations, dizziness, and tremulousness. The diagnosis may be made when no other serious cause for symptoms is found and the patient has replication of symptoms with head-up tilt table testing. Volume repletion, increased salt diet, and/or fludrocortisone may attenuate symptoms in affected patients.

Sinus Bradycardia

Low basal metabolic rate associated with hypothyroidism may present with a slow HR and sinus rhythm. Similarly, in the

absence of significant sympathetic nervous system input, the HR may be slow. This state may be responsible for the sinus bradycardia associated with sleep or with ingestion of drugs such as clonidine, sedative-hypnotics, or narcotics. Advanced physical training results in a highly efficient heart with high ventricular ejection fraction and sinus bradycardia.

True Cardiac Arrhythmias

SVT represents the most common tachyarrhythmia of childhood (see Chapter 84). Possible underlying causes include drug exposure, congenital heart disease, and WPW syndrome. Sympathomimetics in cough and cold preparations are the most common drugs to incite SVT in children. As of 2008, the U. S. Food and Drug Administration recommends that over-the-counter cough and cold preparations not be used in children younger than 2 years. Also, palpitations with cardiac arrhythmias have occurred following ingestion of sympathomimetic additives to unregulated dietary supplements, such as ephedra (and its congeners, often advertised as "ephedra-free" products) and high caffeine energy drinks. Cardiac lesions associated with SVT include Ebstein's anomaly, repaired dextrotransposition of the great arteries, and single ventricle lesions status post-Fontan operation. Up to 75% of patients with WPW syndrome have a shortened P-R interval or delta wave on resting EKG (see Chapter 84). However, approximately 50% of children with SVT have no physical findings and no EKG abnormalities between episodes. In these patients, descriptions of abrupt onset and rapid termination of palpitations ("like a light switch") can often be elicited.

Infection, especially viral myocarditis and acute rheumatic fever, constitutes one of the most common causes of acquired ventricular tachycardia in children with normal cardiac anatomy. Similarly, ingestion of drugs that block fast sodium channels and/or potassium channels (e.g., tricyclic antidepressants, phenothiazines, and antiarrhythmic agents) is a preventable cause of torsades de pointes (polymorphic ventricular tachycardia) and unstable ventricular tachycardia in the otherwise normal child (Table 59.4). Palpitations associated with

exercise may be caused by ventricular tachyarrhythmias that occur in conjunction with hypertrophic cardiomyopathy or myocardial ischemia (usually secondary to congenital anomalies of the coronary arteries). Patients with the prolonged QT syndrome have a genetically determined predisposition to fatal ventricular arrhythmias that can be detected by calculation of the corrected QT interval on a resting 12-lead EKG (see Chapter 84). Patients who have undergone ventriculotomy for tetralogy of Fallot comprise another group who are at high risk for ventricular arrhythmias as a result of the postoperative development of scarring in the right ventricular outflow tract. Finally, electrolyte disturbances, particularly hyperkalemia, hypocalcemia, and hypomagnesemia, may be causative in a child with palpitations and ventricular tachycardia (see Chapter 100).

Premature atrial contractions produce the most common arrhythmia of childhood, with 50% of normal children experiencing at least one premature atrial contraction per day. Premature ventricular contractions (PVCs) also account for many reports of irregular heartbeat. Although this arrhythmia can herald serious underlying pathology, patients with an unremarkable history, normal physical examination, and unifocal PVCs that disappear with exercise do not require further evaluation. Patients with significant sinus or AV node dysfunction as a cause of an irregular or slow heartbeat often have a history of syncope or seizure, slow HR (25 to 50 beats per minute) on examination, a pulmonic flow murmur, or signs of congestive heart failure. Patients who have undergone intraatrial repairs (d-transposition of the great arteries and atrial septal defect) are at highest risk for these potentially life-threatening arrhythmias.

EVALUATION AND DECISION

The ill-appearing child with palpitations requires rapid assessment for the presence of hypoxemia, shock, hypoglycemia, or an existing life-threatening arrhythmia. Further evaluation should include measurement of hemoglobin, serum glucose (Dextrostick), serum electrolytes, calcium, and pulse oximetry or arterial blood gas. The presence of heart disease should be assessed by a 12-lead EKG and rhythm strip, followed by continuous monitoring, frequent vital signs, and chest radiograph (Fig. 59.1). Specific arrhythmias should be treated as outlined in Chapter 84.

The asymptomatic child with palpitations by history may also have an intermittent or continuing arrhythmia. Continuous cardiac monitoring and a resting 12-lead EKG performed while the patient is in the ED increase the likelihood that this abnormality will be detected. Patients with repeated episodes of palpitations may benefit from 24-hour ambulatory (Holter) or longer-term event monitoring, and warrant referral to a pediatric cardiologist. Any patient with a history of syncope, congenital heart disease, or particularly, postoperative or exercise-induced palpitations is at greater risk for having a true cardiac arrhythmia as the cause of his or her symptoms. Similarly, the presence of a short P-R interval with the typical delta wave morphology of WPW syndrome or a prolonged corrected Q-T interval (see Chapter 84) indicates the need for evaluation and consultation by a pediatric cardiologist.

The presence or recent history of fever or an upper respiratory infection should prompt the emergency physician to look for signs and symptoms of myocarditis or acute rheumatic fever. Myocarditis describes inflammation of the muscle wall of the heart. Multiple organisms can cause this pathology, with the most common identified agent being coxsackie virus. Clinical features of this disease are fever, tachycardia out of proportion to activity or degree of fever, pallor, cyanosis, respiratory distress secondary to pulmonary edema, muffled heart sounds with gallop, and hepatomegaly caused by passive congestion of the liver. The EKG findings are nonspecific and include low-voltage QRS complexes (less than 5 mm total amplitude in limb leads), "pseudoinfarction" pattern with deep Q waves and poor R-wave progression in the precordial leads, AV conduction disturbances that range from P-R prolongation to complete AV dissociation, and tachyarrhythmias such as ventricular tachycardia and SVT. A child with palpitations and clinical findings suggestive of myocarditis requires emergent supportive care (see Chapter 3), echocardiography, and admission to a unit capable of intensive monitoring and rapid treatment of cardiac arrhythmias and hemodynamic instability.

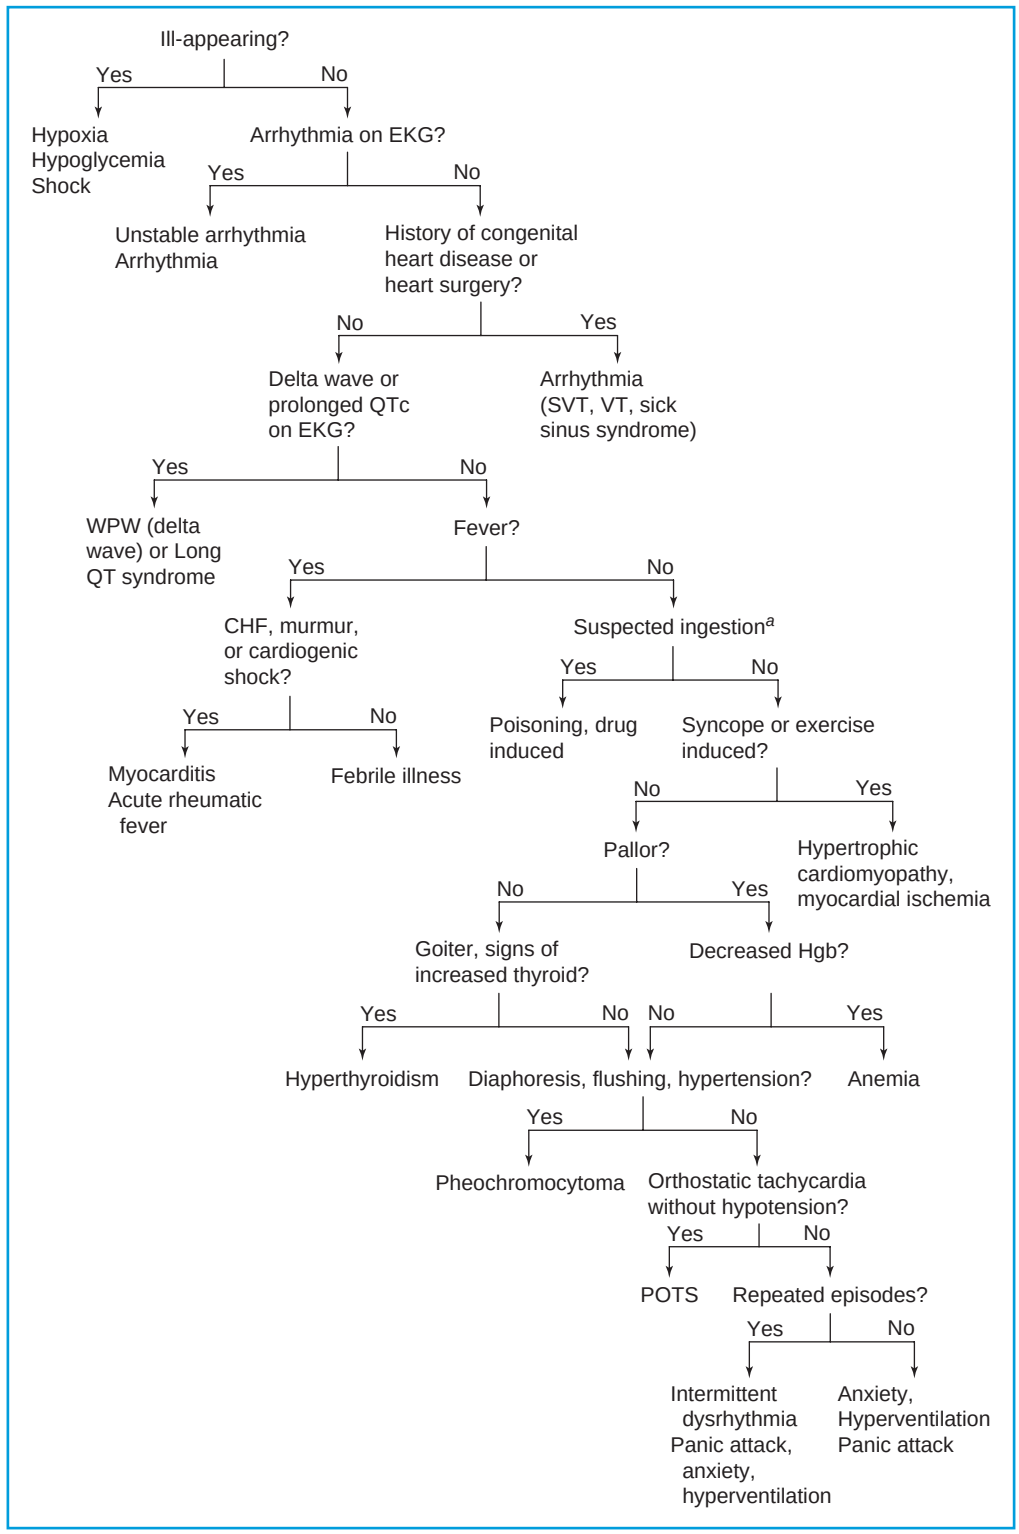

FIGURE 59.1 A diagnostic approach to palpitations. EKG, electrocardiogram; SVT, supraventricular tachycardia; VT, ventricular tachycardia; WPW, Wolff-Parkinson-White; CHF, congestive heart failure; Hgb, hemoglobin; POTS, postural orthostatic tachycardia syndrome. [a]Especially caffeine, diet supplements, herbal preparations, sympathomimetic medications, cocaine, or amphetamines.

Acute rheumatic fever follows pharyngeal streptococcal infection and is an inflammatory disease that targets the heart, vessels, joints, skin, and central nervous system (CNS). Diagnosis and management of acute rheumatic fever are discussed separately (see Chapter 84).

A detailed history of recent medications or precipitating events may reveal the cause of palpitations in some patients. Ingestion of highly caffeinated beverages (including soft drinks and energy drinks), cough and cold preparations, herbal preparations, dietary supplements, "health" drinks with herbal additives, illicit drugs, and a smoking history should be ascertained. The patient's emotional state before the onset of palpitations should be discussed to determine the likelihood of anxiety or emotional arousal as the cause of symptoms (see Chapter 131). The presence of diaphoresis, hypertension, and headache should encourage the assessment for pheochromocytoma, whereas widened pulse pressure and thyroid enlargement suggest hyperthyroidism (see Chapter 86). Anemia may be the cause of symptoms in a patient with pallor (see Chapter 91).

In some patients, an exact cause of palpitations cannot be determined at the time of ED evaluation. Patients with a single episode should have close follow-up arranged with their primary care physicians and should be instructed to return for further evaluation if symptoms recur. Patients with multiple episodes of palpitations deserve further evaluation and consultation with a pediatric cardiologist.

CHAPTER 60 ■ POLYDIPSIA

RONALD I. PAUL, MD

Polydipsia, or excessive thirst, is an uncommon complaint in children. Although fluid consumption varies greatly among individuals, pathologic conditions exist when excessive drinking of fluids interferes with daily life or is accompanied by bizarre behavior, such as drinking from a toilet bowl. Polydipsia is routinely accompanied by urinary frequency (see Chapter 75). Other accompanying symptoms depend on the underlying cause.

PATHOPHYSIOLOGY

The sensation of thirst and subsequent fluid intake is influenced by complex mechanisms that involve the hypothalamus, extracranial thirst receptors, and kidneys. As water is lost from the body, thirst centers in the hypothalamus are stimulated by an increase in serum osmolality. In response to signals from the hypothalamus, the pituitary gland releases an antidiuretic hormone, vasopressin, which causes reabsorption of water in the collecting ducts of the kidney. In addition to physiologic controls of thirst, cortical involvement and social conditioning also play a role and may be responsible for the wide variability in fluid consumption.

DIFFERENTIAL DIAGNOSIS

Diabetes mellitus (DM) is the single most common cause of polydipsia (Table 60.1). Additional prominent symptoms of DM include weight loss and polyuria. Other common causes of polydipsia include sickle cell anemia and diabetes insipidus (DI) (Table 60.2). In sickle cell anemia, chronic sickling of cells in the medulla of the kidney results in a limited ability to concentrate urine and mild polydipsia. In DI, a wide variety of lesions in the hypothalamus and neurohypophysis result in a deficiency of antidiuretic hormone. Inherited forms of nephrogenic DI may be autosomal dominant, autosomal recessive, or X-linked recessive. In instances in which the cause of DI cannot be readily determined, patients are diagnosed as idiopathic. These patients need frequent reevaluations because many are later diagnosed with intracranial tumors.

Less common metabolic and endocrine causes of polydipsia include electrolyte imbalances, catecholamine excess, and cystinosis. Primary renal causes of hyposthenuria include interstitial nephritis, renal tubular acidosis, medullary cystic disease (nephrophthisis), and obstructive uropathy. In nephrogenic DI, the renal tubule is unresponsive to antidiuretic hormone. Patients with nephrogenic DI usually have onset of symptoms in infancy and present with recurrent episodes of dehydration, fever, failure to thrive, and psychomotor retardation. Pharmacologic causes of polyuria and polydipsia include methylxanthines and diuretics. In addition, chronic lithium therapy may result in nephrogenic DI.

Primary polydipsia is diagnosed when the ingestion of water is in excess of that needed to maintain water balance. It can be caused by an inappropriate psychological thirst drive (psychogenic polydipsia or compulsive water drinking) or by hypothalamic damage that alters thirst but not antidiuretic hormone release (neurogenic polydipsia).

Most children with polydipsia have serious but nonacute problems. Potential life-threatening conditions may develop in certain circumstances (Table 60.3). Patients with DI or nephrogenic DI may develop severe dehydration if water is withheld for prolonged periods. Conversely, urgent management of hypernatremia is usually unnecessary if patients are able to drink and may be harmful if it is of chronic duration. Diabetic ketoacidosis may be an initial presentation of patients with DM, and can result in extreme electrolyte and acid–base imbalances. Patients with primary polydipsia who overload their kidneys' ability to excrete free water may present with hyponatremic seizures. Many of the brain lesions that cause DI can become life-threatening. Patients with severe brain injury often develop DI toward the end of life.

EVALUATION AND DECISION

When evaluating a child with polydipsia, the physician should seek information from the parent regarding the quantity of fluid taken each day and whether the child has used any unusual methods to satiate thirst. A history of nocturnal polydipsia and polyuria is helpful because most children with psychogenic polydipsia do not wake in the middle of the night for fluids. A medical history should include questions on growth and development, as well as past episodes of severe dehydration. Inquiries should be made about known causes of polydipsia such as sickle cell disease, DM, chronic kidney disorders, head trauma, and medications (Fig. 60.1). The physical examination should include a careful evaluation for known systemic and intracranial causes of DI.

If the history and physical examination are not revealing, a urinalysis should be obtained. In almost all cases of polydipsia, the urine-specific gravity will be low (less than 1.010). A specific gravity greater than 1.020 should represent appropriate thirst. If the urinalysis is abnormal, DM, sickle cell disease or trait, or an intrinsic renal disorder should be suspected. If the urinalysis is normal, electrolytes, calcium, and renal function tests may reveal conditions associated with electrolyte imbalances. Patients with DI or nephrogenic DI may have hypernatremia if they are examined when dehydrated. A

hemoglobin electrophoresis may be needed to determine whether the patient has sickle cell disease or trait. However, patients with sickle cell disease usually have the diagnosis confirmed before the development of tubular dysfunction and polydipsia. Computed tomography and magnetic resonance imaging scans may be necessary to diagnose intracranial abnormalities.

Patients suspected of having primary polydipsia, DI, and nephrogenic DI require further testing that can be dangerous. These tests should be performed in controlled settings and are usually inappropriate in the emergency department.

Patients with primary polydipsia should respond to a water deprivation test by increasing their urine gravity and osmolality. Patients with DI and nephrogenic DI should have rapid weight loss while continuing to excrete urine with a low specific gravity. They may become severely dehydrated if the weight loss is in excess of 3% to 5%. Constant observation should be maintained during the water deprivation test to ensure patients do not covertly consume water and to prevent severe dehydration. A trial of intranasal desmopressin (DDAVP) should distinguish between DI and nephrogenic DI because patients with antidiuretic hormone-deficient DI will respond to the exogenous hormone.

Unfortunately, even these tests are fraught with some inaccuracies. Patients with primary polydipsia who have chronic overhydration and diminished capacity to concentrate urine may have a blunted response to water deprivation. In addition, patients with DI and nephrogenic DI may produce a hypertonic urine if the glomerular filtration rate is decreased as severe dehydration ensues. Radioimmunoassay for antidiuretic hormone can be helpful in confusing cases.

CHAPTER 61 ■ RASH—ECZEMATOUS

TODD A. FLORIN, MD, AND JAMES M. CALLAHAN, MD

Pediatricians often use the terms *eczema* and *atopic dermatitis* interchangeably. However, *eczema* is often used more generally to describe a complex of signs and symptoms, including erythema, edema, vesiculation, scaling, and pruritus. This use of the term is more appropriate because many disease processes and exposures may cause eczematous rashes (see Chapter 85). The distinct forms of eczema are labeled by cause, pattern, or associated conditions such as atopy. Acute eczema consists of erythema, edema, exudation, clustered papulovesicles, scaling, and crusting. Chronic eczema is characterized by lichenification, changes in skin pigmentation, and excoriation. Diagnosis of the underlying cause of the eczematous eruption relies on historical and dermatologic features, as histology is typically not specific.

DIFFERENTIAL DIAGNOSIS

Atopic Dermatitis

Atopic dermatitis (see Chapter 85) is by far the most common cause of an eczematous rash in children (Tables 61.1 and 61.2). It is a chronic or relapsing condition characterized by pruritic eczematous eruptions and occurs in 10% to 20% of all children. There is often a personal or family history of allergic rhinitis, hay fever, or asthma. Most patients have the onset of symptoms before age 6 months, with up to 90% developing symptoms by 5 years of age. Dry conditions or frequent bathing often lead to exacerbations. Stress, sweating, and exposure to environmental allergens may also precipitate flares. Infants and young children may experience worsening symptoms with exposure to certain foods.

Diagnosis is not based on any single defining criteria, but rather has its basis in essential, important, and associated features. Several groups have developed diagnostic criteria, including a United Kingdom Working Party (Table 61.3A) and the American Academy of Dermatology (Table 61.3B). The broad differential diagnosis requires the exclusion of other skin conditions that present in a similar fashion such as seborrheic dermatitis, scabies, contact dermatitis, impetigo, psoriasis, nutritional deficiencies (i.e., zinc), immune deficiencies, and cutaneous lymphoma.

With acute flares, lesions are poorly demarcated, erythematous, scaly, and often weepy and crusted. Chronic lesions are thickened, hyperpigmented, and often excoriated. Distribution varies by age. Infants have lesions on the cheeks, trunk, diaper area, and extensor surfaces. Children show involvement of the feet and flexor areas, such as the antecubital and popliteal fossae and the neck. In adolescents and adults, flexor areas, hands, and feet are usually involved. Xerosis (dry skin), ichthyosis vulgaris (inherited fishlike scaling), keratosis pilaris (chicken-skin appearance caused by cornified plugs in the upper hair follicles), infraorbital eyelid folds (Dennie-Morgan sign), hyperlinear palms, pityriasis alba (scaly hypopigmented patches), and follicular accentuation may be seen. The pruritus of atopic dermatitis often results in a cycle of excoriation, potentially resulting in microbial colonization and secondary infection. Superimposed bacterial (*Staphylococcus aureus* or group A streptococcus), fungal, and viral infections (eczema herpeticum caused by herpes simplex virus) are common.

Particularly severe or persistent symptoms should prompt consideration of an underlying systemic disorder associated with eczematous eruptions.

Contact Dermatitis

Contact dermatitis (see Chapter 85) is an inflammatory reaction of the skin caused by an allergic stimulus or primary irritant. Acute eruptions have intense pruritus, severe erythema, edema, vesicles, and erosions with serous discharge and crusting. A sharp demarcation between involved and unaffected skin usually exists. Subacute reactions have mild erythema, dry scale, less vesiculation, and mild thickening of the skin. Chronic exposures may result in lichenification, fissures, scales, excoriations, and hyperpigmentation. Vesicles are rare.

Allergic Contact Dermatitis

Allergic contact dermatitis is caused by a classic delayed T-cell–mediated hypersensitivity reaction (type IV). Repeated exposure causes an allergic sensitization. The eruption is delayed after the initial exposure for up to 7 to 10 days. Repeated exposures can cause the rapid appearance of an acute dermatitis (within 12 hours). Rhus dermatitis, caused by an oleoresin in the sap of poison ivy, poison oak, or poison sumac plants, is the most common cause of allergic contact dermatitis in the United States. Delayed exposure may occur because of contact with objects that have had contact with the plants. Typical presentation includes pruritus and erythema followed by development of papules, vesicles and bullae, usually in a streak-like arrangement. Burning of plants leads to aerosolization of the allergen, and may cause a widespread and severe outbreak on exposed skin surfaces. Other plants, flowers, pollens (especially ragweed), clothing, shoes, metals (e.g., nickel in jewelry), cosmetics, adhesive tape, and latex-containing products can also cause an allergic contact dermatitis. Nickel dermatitis occurs on earlobes as a result of nickel-containing earrings and on the abdomen due to pant buttons. Shoe dermatitis, the only form of allergic dermatitis to affect the soles (in contrast to irritant dermatitis, which does affect palms and soles),

usually occurs on the dorsal surfaces on the feet, sparing interdigital spaces, in a symmetric manner.

Allergic contact dermatitis is rare in infants because of their impaired ability to react to allergens. By age 3 to 8 years, children react to allergens in a fashion similar to adults. The distribution, shape, and pattern of the rash, and exposure history, may elucidate the cause. Airborne processes (e.g., smoke-containing rhus oleoresin) cause a problem on exposed surfaces, including eyelids, whereas a photoallergic contact dermatitis involves sun-exposed areas [e.g., rash resulting from use of a sunscreen that contains paraaminobenzoic acid (PABA)].

Irritant Contact Dermatitis

A primary irritant dermatitis is a nonallergic reaction of the skin caused by a single exposure or a series of brief contacts with an irritating substance. Strong soaps and detergents, citrus juices, saliva, urine, stool contents, fiberglass particles or other abrasive materials, and bubble baths are common causes in children. Perioral irritant contact dermatitis occurs as a result of excessive drooling or lip licking, typically presenting as a sharply demarcated rash around the mouth. Juvenile plantar dermatosis is a form of irritant contact dermatitis resulting from alternating excessive hydration and rapid moisture loss of the feet. This presents with extensive skin fissuring and glazed appearance of the planter surface of the foot, largely in prepubertal children who wear occlusive footwear. It may be treated with emollients. Frictional lichenoid dermatitis is likely

U.K. WORKING PARTY DIAGNOSTIC CRITERIA FOR ATOPIC DERMATITIS

The diagnosis of atopic dermatitis is established when a history of an itchy skin condition exists and at least three of the following criteria are met:
- History of involvement of the skin creases such as folds of elbows, behind the knees, front of ankles, or around the neck (including cheeks in children younger than 10 years of age)
- A personal history of asthma or hay fever (or family history of atopic disease in children younger than 4 years of age)
- A history of general dry skin in the last year
- Visible flexural eczema (or eczema of the cheeks/forehead and outer limbs in children younger than 4 years of age)
- Onset before the age of 2 years (not used if the child is younger than 4 years of age)

Source: From Williams HC, Burney PGJ, Pemborke AC, et al. The UK Working Party's diagnostic criteria for atopic dermatitis. III. Independent hospital evaluation. *Br J Dermatol* 1994;131:406–416.

TABLE 61.3B

AMERICAN ACADEMY OF DERMATOLOGY CONSENSUS CONFERENCE FEATURES OF ATOPIC DERMATITIS

Essential Features (must be present)
Pruritus
Eczematous skin changes with chronic or recurring history, typical morphology, and distribution
- Face, neck, extensor involvement in infants and children
- Flexural lesions in any age group
- Sparing of groin and axillary regions

Important Features (seen in most cases, support the diagnosis)
Early age at diagnosis
Personal or family history of atopy

Associated Features
Atypical vascular responses (e.g., facial pallor, white dermographism, delayed blanch response)
Keratosis pilaris/hyperlinear palms/ichthyosis
Ocular/periorbital changes
Other regional findings (e.g., perioral changes/periauricular lesions)
Perifollicular accentuation/lichenification/prurigo lesions

Source: From Eichenfield LF, Hanifin JM, Luger TA, et al. Consensus conference on pediatric atopic dermatitis. *J Am Acad Dermatol* 2003;49(6):1088–1095.

related to friction and presents as shiny papules at the elbows, knees, and back of the hands, and occurs more frequently in individuals with atopic dermatitis.

Nummular Eczema

Nummular eczema presents as coin-shaped plaques that are erythematous and contain tiny vesicles, crusts, and at times, excoriations. Lesions occur on the extensor surfaces of the hands, arms, and legs. They may be single or multiple and are often symmetric. Nummular eczema seems to be related to dry skin and irritation rather than to atopy but can be seen in atopic individuals. Differential diagnosis includes dermatophyte infection, impetigo, and granuloma annulare.

Asteatotic Eczema

Asteatotic eczema, also called *winter eczema, xerotic eczema*, and *eczema cracquele*, is a pruritic condition in which the skin is dry and cracked with red fissures and scale. The skin has the appearance of cracked porcelain. The most common sites are the extensor surfaces. It tends to occur in adolescents during the winter and is associated with overbathing and low humidity.

Dyshidrotic Eczema

Dyshidrotic eczema, also called *pompholyx*, involves the hands and feet. There is sudden onset of pruritic, tiny, clustered, deep-seated vesicles that look like tapioca. With time, scaling, lichenification, and painful fissures occur. Lesions appear on the palms, soles, and lateral fingers. The process may be acute, chronic, or persistent and may be provoked by stress. It may be associated with hyperhidrosis. Approximately 50% of patients have an atopic background. The disorder may be confused with allergic contact dermatitis and with dermatophyte infections. Acute presentations may be treated with wet dressings and topical corticosteroids.

Seborrheic Dermatitis

Seborrheic dermatitis (see Chapter 85) is a problem of infants, adolescents, and adults, and is characterized by nonpruritic, erythematous, greasy, yellow or salmon-colored plaques. These occur on the scalp, face (nasolabial folds, eyebrows, eyelids, sideburns, beard), postauricular areas, axilla, groin, and presternal area. The scalp (cradle cap) or diaper area is usually involved first in infants between 2 and 12 weeks of age. The rash may spread to the face, trunk, and neck (Fig. 61.1). Postinflammatory changes in pigmentation are common. It clears by 8 to 12 months of age and then recurs after the onset of puberty. Seborrheic dermatitis may be confused with atopic dermatitis or psoriasis. Although common in infancy, only about 10% of patients will have recurrence. Rash that is particularly severe, associated with petechiae or systemic signs or symptoms, or recalcitrant to therapy, should prompt consideration of an underlying systemic illness or immunodeficiency. Severe seborrheic dermatitis has been reported as an early sign of acquired immune deficiency syndrome (AIDS) in adolescents.

FIGURE 61.1 Seborrheic dermatitis in an infant, with scalp and body involvement. (Courtesy of the Walter W. Tunnessen Pediatric Image Library, which is supported by the Foerderer Foundation.)

Lichen Simplex Chronicus

Lichen simplex chronicus refers to a chronic, localized lesion resulting from repeated rubbing and scratching. It has a predilection for the sites that are easily reached, such as the arms, legs, ankles, neck, and the anogenital area. It is rare in young children but fairly common in adolescents and adults. It may occur in a preexisting area affected by dermatitis. Typical lesions are single or multiple oval plaques from 5 to 15 cm in size. The skin is reddened and slightly edematous. Chronic lesions consist of well-demarcated areas of dry, thickened, scaly, hyperpigmented or hypopigmented plaques. Marked pruritus occurs.

Autoeczematization

Autoeczematization occurs in the presence of an initial active eczematous rash. The patient later develops a more extensive eczematous eruption as a result of autosensitization or autoeczematization. A specialized form of this process is seen with dermatophyte infection—in particular, tinea capitis—and is called a *dermatophytid* or *id reaction.*

Photoallergic Reactions

Photoallergic reactions may occur after systemic or topical administration of various drugs or chemicals that absorb radiant energy, primarily in the ultraviolet A range. These reactions may manifest as acute, subacute, or chronic dermatitis in sun-exposed areas. Common agents implicated include phenothiazines, sulfonamides, thiazides, sunscreen components such as PABA, and some fragrances.

Infectious Causes of Eczematous Rashes

Eczematous rashes can result from primary skin infections caused by multiple organisms. Fungi, viruses, and parasites are the most common causes in children. Pityriasis rosea is believed to result from a viral infection.

Dermatophyte Infections

Skin infection caused by a dermatophyte, also called *tinea* or *ringworm*, may cause eczematous lesions. The typical lesion of tinea corporis is an annular, erythematous, scaling plaque. These may be indistinguishable from nummular eczema. A raised vesicular or pustular border suggests tinea corporis. Likewise, tinea pedis and tinea manus may be eczematous and vesicular, and may mimic dyshidrotic eczema. These may occur in prepubertal children, although not as commonly as in adults. Tinea capitis presents with scaly, discrete patches of hair loss with black dot hairs and occipital adenopathy. However, it may appear identical to seborrheic dermatitis with greasy yellow scale and should be ruled out with potassium hydroxide (KOH) preparation before making the diagnosis of seborrhea, especially in any child younger than age 12.

Scabies

The eruption of scabies (see Chapter 85) is polymorphic with papules, vesicles, nodules, excoriations, crusts, and eczematous plaques. Only a small percentage of patients have the classically described linear tracts or burrows. *Norwegian scabies*, a severe form usually seen in immunosuppressed patients, is characterized by heavy crusting and hyperkeratosis. Infants often have similarly severe infestations, possibly related to a delay in diagnosis or use of topical steroids in a mistaken attempt to treat an atopic process.

Infants and young children have lesions on the palms, soles, face, and scalp. The lesions may become generalized. Older children and adults tend to have involvement of the finger webs, flexural regions, breasts, and genital area. Diagnosis is confirmed by visualization of the mites, eggs, or fecal pellets from skin lesion scrapings. However, despite excellent specificity, a high false-negative rate exists. Diagnosis in the absence of confirmed mites is based on clinical features.

Molluscum Contagiosum

The characteristic lesion of molluscum (see Chapter 85) is not eczematous, but rather, is a dome-shaped, umbilicated waxy papule with a central plug. Often, patients develop a surrounding area of dermatitis that may represent a delayed hypersensitivity reaction to a viral antigen. At times, the distinctive papules are barely noticeable within larger eczematous plaques.

Pityriasis Rosea

Pityriasis rosea (see Chapter 85) commonly occurs in epidemics, primarily in the spring and autumn. Patients may develop the characteristic herald patch first, then an extensive papulosquamous eruption on the trunk (Fig. 61.2, see also color plate). Lesions may have a "Christmas tree" distribution on the back. In African-American children, an "inverse distribution" of the lesions occurs, involving the proximal extremities, neck, inguinal and axillary areas, with sparing of the trunk. Adolescents may exhibit a similar rash as a manifestation of secondary syphilis (see Chapter 84).

FIGURE 61.2 Pityriasis Rosea. (Courtesy of the Walter W. Tunnessen Pediatric Image Library, which is supported by the Foerderer Foundation.)

Diaper Dermatitis

Diaper dermatitis (see Chapter 85) is possibly the most common cutaneous problem of infancy. It is not a specific diagnosis, but a group of disorders provoked by the moist, occluded, irritated environment of the diaper region (Table 61.4). Often, a combination of etiologies exists in one patient. This can be thought of as a spectrum of primary dermatitis, induced by irritation or friction, and secondary dermatitis, caused by other etiologies. These processes frequently coexist.

Primary Diaper Dermatitis: Irritant Contact Dermatitis, Friction Dermatitis, and Intertrigo

Primary, or occlusion, diaper dermatitis is the most common rash of the diaper area, and is a result of the disruption of the barrier function of the skin. Factors contributing include irritation from stool, urine, chemicals, soaps, heat, moisture, and sweating. This leads to erythematous plaques with minimal scale on the thighs, buttocks, perineum, and lower abdomen with sparing of the creases. Friction dermatitis is seen on the inner thighs, genitals, buttocks, and abdomen as a mild erythema with a shiny surface. Intertrigo results from rubbing and irritation by diapers in a hot climate or from excessive clothing. Erythematous, macerated, exudative plaques appear in the inguinal and intergluteal folds.

Secondary Diaper Dermatitis: Infectious Etiologies

Confluent beefy red plaques with sharp borders and a fine white scale along the periphery, and pinpoint satellite papules and pustules, characterize monilial diaper dermatitis (Fig. 61.3, see also color plate). Candidal diaper dermatitis usually begins in the perianal area and spreads to the perineum and inguinal folds. In severe cases, it extends to the buttocks, legs, abdomen, and back.

Infections with *Staphyloccocus aureus* and group A *Streptococcus* are the most common bacterial infections of the diaper region. Impetigo, folliculitis, cellulitis, or infectious intertrigo may all occur. If bullae are present, *S. aureus* should be considered.

TABLE 61.4

CAUSES OF DIAPER DERMATITIS

Irritant dermatitis	Psoriasis

Intertrigo	Langerhans cell histiocytosis
Candida	Acrodermatitis enteropathica

FIGURE 61.3 Candida moniliasis. (Courtesy of the Walter W. Tunnessen Pediatric Image Library, which is supported by the Foerderer Foundation.)

Secondary Diaper Dermatitis: Inflammatory Etiologies

Atopic Dermatitis. Atopic dermatitis may present in the diaper region with a similar appearance to primary diaper dermatitis. However, it is more chronic and recalcitrant to therapies for contact or frictional dermatitis. There is often evidence of personal or family history of atopy.

Psoriasis. Psoriatic diaper rashes demonstrate bright red, well-demarcated plaques, often with dry, silvery scales (Fig. 61.4). A family history and further cutaneous evidence of psoriasis (scalp involvement, nail dystrophy or pitting, intergluteal erythema, and postauricular erythema) are often present.

Seborrheic Dermatitis. When the diaper area is involved with seborrheic dermatitis (see Chapter 85), erythema and a greasy yellow scale are seen, especially in the creases. Similar lesions elsewhere aid in diagnosis.

Langerhans Cell Histiocytosis. The infantile form of Langerhans cell histiocytosis, formerly called Letterer-Siwe disease, often presents with a diaper rash. It is seborrheic in distribution with yellow-crusted plaques, infiltrative and hemorrhagic papules, and vesicles.

FIGURE 61.4 Diaper area psoriasis with well-demarcated bright red plaques.

TABLE 61.5

SYSTEMIC ILLNESSES ASSOCIATED WITH ECZEMATOUS RASHES

Exfoliative dermatitis	Hyperimmunoglobulinemia E syndrome
Human immunodeficiency virus infection	Langerhans cell histiocytosis
Wiskott-Aldrich syndrome	Immune dysregulation, polyendocrinopathy, enteropathy X-linked (IPEX)

Acrodermatitis Enteropathica. Acrodermatitis enteropathica, resulting from an inherited problem with zinc absorption, demonstrates bright red plaques in periorificial regions, including the diaper area. The plaques have a serpiginous, erosive border and look much like candida or psoriasis. Patients have associated alopecia, diarrhea, and failure to thrive. A similar eruption has been reported in some infants with cystic fibrosis.

Eczematous Rashes Associated with Systemic Illnesses

Several systemic illnesses may include eczematous rashes as one of their manifestations (Table 61.5). When a patient presents with an eczematous rash that is recalcitrant to treatment, severe, or associated with systemic signs or symptoms, these diagnoses should be considered. Absence of a family history of atopy may also suggest serious disease. Fever, failure to thrive, diarrhea, hepatosplenomegaly, and recurrent infections may be clues to an underlying process.

Exfoliative Dermatitis

Exfoliative dermatitis, or erythroderma, is an inflammatory condition in which generalized erythema and scaling exist. It may be idiopathic or a manifestation of underlying dermatologic or systemic disease (Table 61.6). Medication reactions may result in toxic epidermal necrolysis (TEN), a severe bullous disorder (see Chapter 85). The drug reaction with eosinophilia and systemic symptoms (DRESS) syndrome is a medication reaction that presents with a morbilliform or erythrodermic rash, in addition to fever, eosinophilia, lymphadenopathy, and visceral involvement. Several types of dermatitis (atopic, contact, and seborrheic) may cause an exfoliative dermatitis, as well as the more unusual dermatoses such as pityriasis rubra pilaris (a diffuse, salmon-colored papulosquamous eruption) and pemphigus foliaceus (a superficial blistering disorder). Netherton's syndrome, often confused with atopic dermatitis, presents with erythroderma, bamboo hair, ichthyosis, eczematous eruption, and failure to thrive. Infectious causes include staphylococcal scalded skin syndrome, human immunodeficiency virus, and toxic shock syndrome.

When exfoliative dermatitis is seen in an infant, an immune deficiency should be excluded (Fig. 61.5). These immunocompromised infants often have diarrhea, organomegaly, recurrent infections, and failure to thrive. They may have various immune

TABLE 61.6

CAUSES OF EXFOLIATIVE DERMATITIS/ ERYTHRODERMA

Dermatologic Disorders
- Atopic dermatitis
- Seborrheic dermatitis

- Leiner's disease

Infections
- Human immunodeficiency virus
- Staphylococcal scalded skin syndrome
- Scarlet fever
- Toxic shock syndrome

Other Disorders
- Leukemia and lymphoma
- Netherton's syndrome

problems, including defective yeast opsonization, impaired neutrophil mobility, elevated serum IgE, and hypogammaglobulinemia. Exfoliative erythroderma may be the cutaneous presentation of other immune disorders such as Wiskott-Aldrich syndrome, Omenn's syndrome, severe combined immunodeficiency syndrome, HIV infection, and graft-versus-host disease. An exfoliative dermatitis is the only eczematous process that may be potentially life-threatening in the acute phase because of temperature instability, fluid losses through the skin, high-output heart failure, pneumonia, and sepsis.

HIV Infection

About half of children with HIV infection have a "seborrheic-looking" dermatitis. Unlike seborrhea, this often persists past age 6 months. Severe, atopic-appearing rashes may also be seen. The diaper area is the most often affected. Children with HIV infection may also have recurrent bacterial infections, diarrhea, failure to thrive, lymphadenopathy, and hepatosplenomegaly, as well as developmental delay. In addition, dermatitis resulting from infectious causes may be particularly severe or difficult to treat.

FIGURE 61.5 Infant with exfoliative erythroderma and immunodeficiency. (Courtesy of the Walter W. Tunnessen Pediatric Image Library, which is supported by the Foerderer Foundation.)

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome is an X-linked, recessive disorder in which children have thrombocytopenia, eczematous rashes, and immunodeficiency. These patients often develop petechial or purpuric rashes. They have recurrent infections, often caused by encapsulated organisms. Patients may also have autoimmune disorders. Eczematous rashes are usually severe and recalcitrant to therapy.

Hyperimmunoglobulin E Syndrome

Hyperimmunoglobulin E (IgE) syndrome, or Job's syndrome, is characterized by extremely high IgE levels, repeated cutaneous infections, and chronic dermatitis. The rash usually resembles atopic dermatitis. A personal or family history of atopy usually exists, as well as recurrent skin infections, extreme elevation of the serum IgE, impaired neutrophil chemotaxis, and peripheral blood eosinophilia. A subset of patients, usually women, have a tendency to develop large, cold, chronic, and recurrent staphylococcal abscesses of skin and bone, which cause severe scarring.

Langerhans Cell Histiocytosis

Langerhans cell histiocytosis often presents as a seborrheic-appearing rash in the diaper area, scalp, postauricular, and axillary regions. The eruption is usually more severe than usual cases of seborrhea, is resistant to therapy, and tends

to recur. Cutaneous nodules and purpura are suggestive. Hepatosplenomegaly, lymphadenopathy, anemia, thrombocytopenia, and osseous lesions are associated findings.

EVALUATION AND DECISION

The most important points in reaching an accurate diagnosis of an eczematous rash include the distribution of the lesions, the duration of the disease, and the patient's age (see Fig. 61.6A).

Generalized

If a patient presents with a generalized eczematous process, red and scaly from head to toe, this suggests exfoliative dermatitis or erythroderma (Figs. 61.5 and 61.6B). This unusual condition is not a specific diagnosis but instead has multiple causes. It can be a manifestation of an underlying dermatologic process, an infection, a drug reaction, or a systemic illness. Skin biopsy is often necessary for diagnosis. In infancy, an immune dysfunction should be considered, especially if the patient has diarrhea, recurrent infections, or failure to thrive.

Acute Onset or Chronic Problem

The next step in determining a diagnosis is deciding if the rash is of acute onset or has been present for a period of time (Fig. 61.6A). Although not all conditions can be classified exclusively in this way (e.g., atopic dermatitis is a chronic disease but it is often characterized by acute symptomatic flares), this is a useful construct in reaching a diagnosis. Infectious causes mostly present acutely. Eczematous rashes due to systemic diseases are often chronic.

Extensive But Not Generalized

Eruptions that may be extensive but with some areas of noninvolved skin include atopic dermatitis, seborrheic dermatitis, scabies, autoeczematization reactions, pityriasis rosea, or contact dermatitis (Fig. 61.6A). A family or personal history of atopy, a history of flares and remittance, extreme pruritus, and a distribution compatible with the patient's age suggest atopic dermatitis. No specific laboratory tests aid in diagnosis. Seborrheic dermatitis is seen only in infancy and after puberty. Features that help distinguish seborrhea from atopic dermatitis in infancy include minimal pruritus; salmon-colored, greasy plaques; and predominant involvement of the scalp and intertriginous regions. Scabies may be distinguished from atopic dermatitis by a history of acute onset, contacts with recent onset of a pruritic eruption, and polymorphous appearance. Occasionally, children with scabies have a chronic rash that has been diagnosed as atopic dermatitis, without a history of rash in contacts. One should always be suspicious of scabies, especially if a child aged 3 years or older presents with the recent onset of an eczematous, pruritic rash. Id reactions can be extensive. A history of an initial contact dermatitis or scaly scalp (tinea capitis) followed by a widespread eczematous rash suggests an autoeczematization reaction. Id reactions tend to be worse in areas near the initial rash. An allergic or irritant contact dermatitis could be extensive, depending on the exposure. Eruptions that are unusually severe, persistent, recalcitrant to treatment, or associated with systemic signs should prompt consideration of an underlying systemic illness. With these processes, the skin findings may be extensive such as that seen with Hyper-IgE syndrome or immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) or more localized (e.g., the diaper and postauricular areas in children with Langerhans cell histiocytosis).

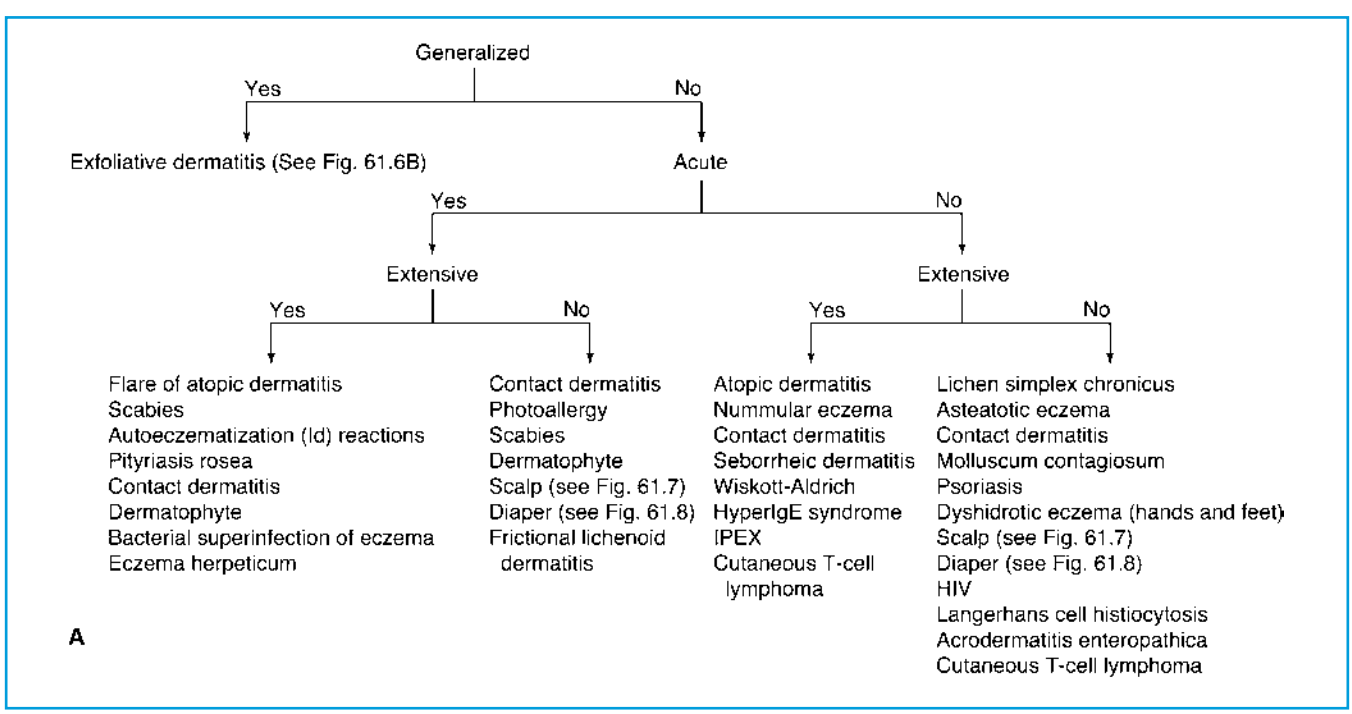

FIGURE 61.6 **A:** Diagnostic approach to the child with an eczematous process. (*continued*)

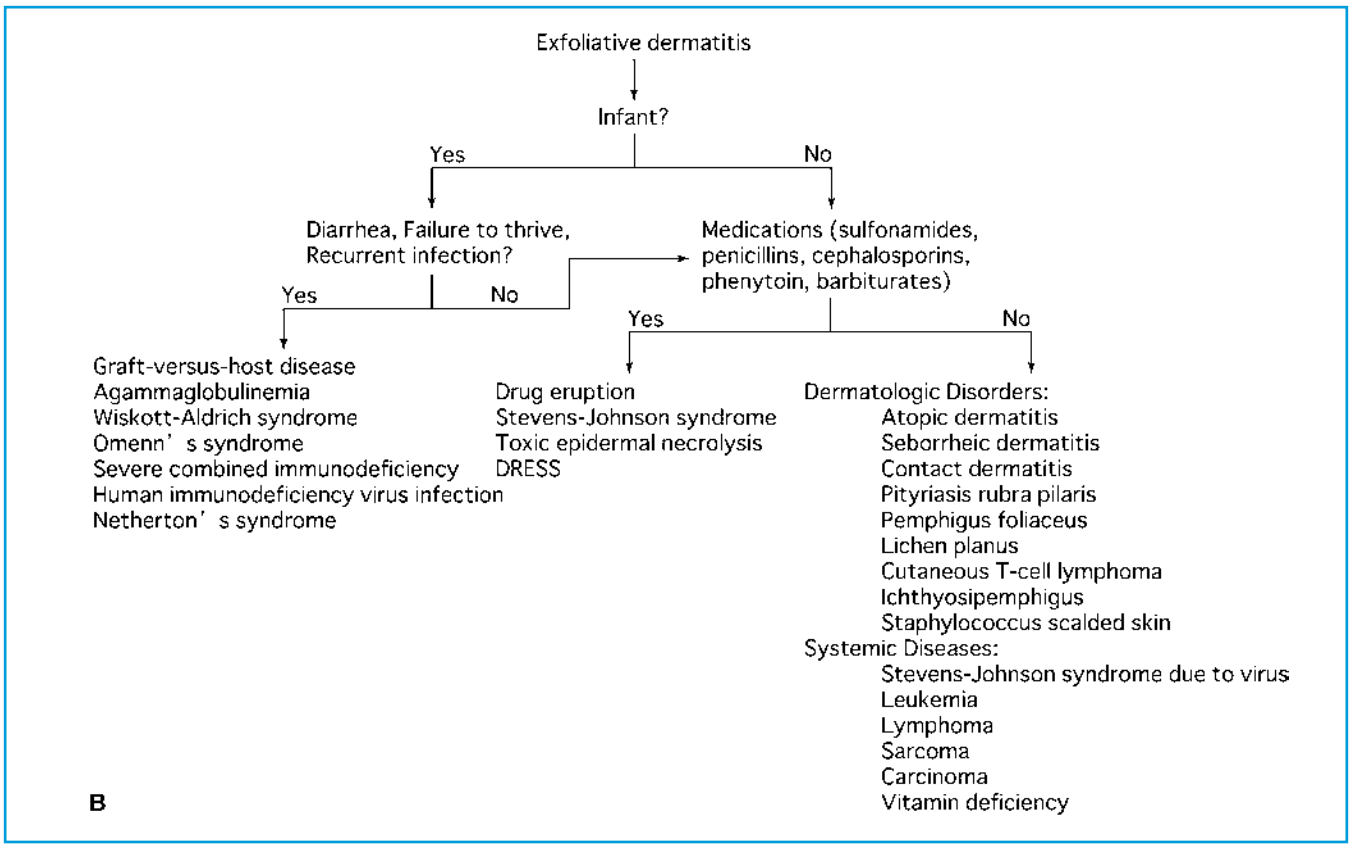

FIGURE 61.6 (*Continued*) **B:** Diagnostic approach to the child with an exfoliative dermatitis.

Localized

If an eczematous process is localized to one or a few areas, contact dermatitis, nummular dermatitis, asteatotic eczema, lichen simplex chronicus, photoallergy, scabies, molluscum, or a dermatophyte infection should be considered. The diagnosis of a contact dermatitis is made based on the appearance and distribution of the dermatitis and aided by a history of allergen contact. It is often difficult for patients to determine the allergen because of the delayed onset. Therefore, it is important for the physician to suggest some of the more common agents such as poison ivy or oak and nickel. Linear lesions suggest poison ivy or oak exposure. Patch testing may be useful if the allergen is unclear.

Photoallergy is suggested by dermatitis in sun-exposed areas. A raised, slightly vesicular, scaly border implies tinea corporis. However, it is often helpful to perform a KOH preparation with all these conditions because tinea corporis may mimic any of them. A chronic, pruritic, lichenified plaque suggests lichen simplex chronicus, although an irritant or allergen could play a role. Eczema within the setting of dry skin, especially on the extensor extremities, suggests asteatotic eczema. In a patient with onset of localized eczematous plaques, one should inspect the skin for the tiny, dome-shaped papules of molluscum.

Sometimes systemic illness may present with relatively localized skin findings. Psoriasis may be relatively localized to the scalp, intergluteal, and postauricular areas in addition to areas that are prone to epidermal injury such as extensor surfaces of the hand and elbows. Associated findings such as nail dystrophy and bright red plaques with a silvery scale suggest this diagnosis. HIV infection may be manifested by a seborrheic-like dermatitis. Cutaneous T-cell lymphoma is very rare in children but may be either localized or extensive depending on the stage of disease.

Hands and Feet

The possibilities for diagnosis when an eczematous process involves the hands and/or feet are psoriasis, dyshidrotic eczema, contact dermatitis, or tinea pedis/manum. A thorough family history, history of exposure, and a KOH preparation may be useful.

Scalp

In children with scaly scalp, the child's age and character of the scale can be helpful (Figs. 61.1 and 61.7). Newborns often have cradle cap, a manifestation of seborrheic dermatitis, psoriasis, or rarely, atopic dermatitis. Look carefully at the remainder of the infant's skin for greasy yellow or bright red plaques. Cradle cap often persists for several months and may last up to 2 years. In any child with a scaly scalp between 2 years of age and puberty, tinea capitis must be excluded, even in the absence of hair loss. In teenagers, tinea is less likely and seborrhea is again possible. Psoriasis can occur at any age, characterized by a thick yellow scale that adheres to the hair.

Diaper Area

In diaper dermatitis, morphology of the lesions is important (Figs. 61.3 and 61.8). A bright red, well-demarcated plaque with scale could be psoriasis, candida, or acrodermatitis

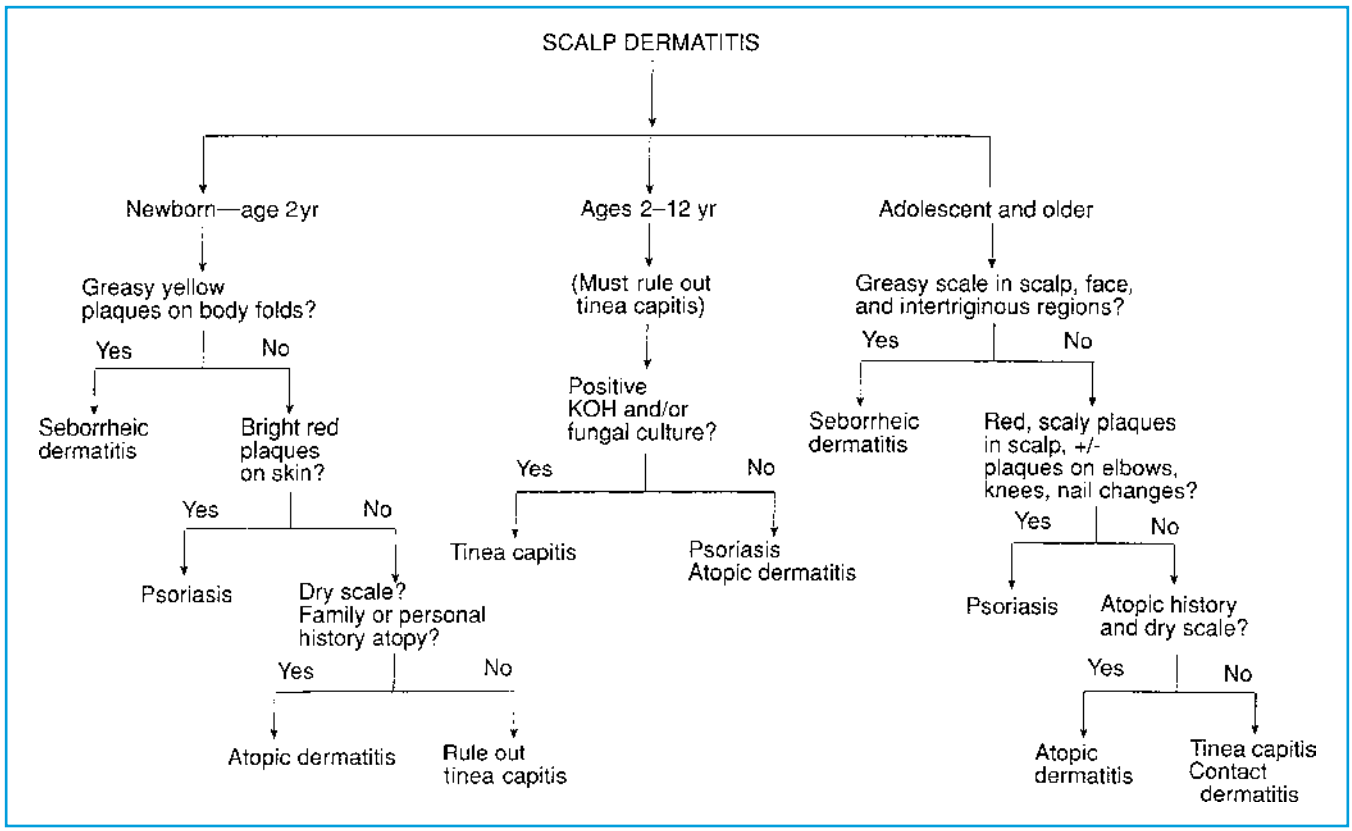

FIGURE 61.7 Diagnostic approach to the child with a scaly scalp.

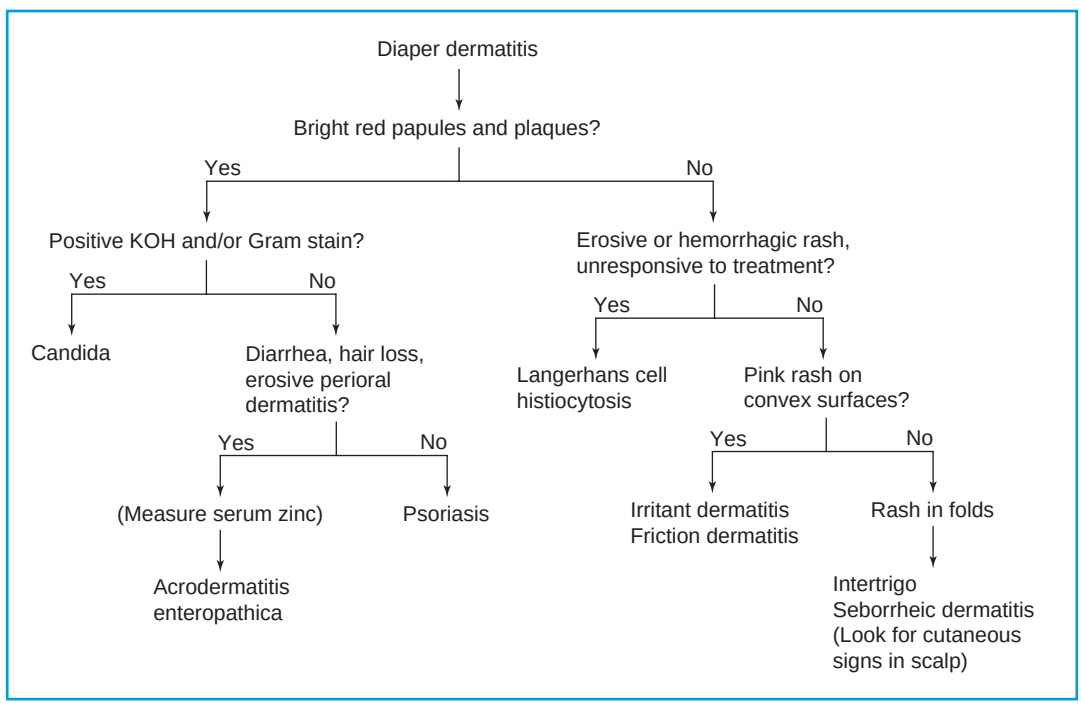

FIGURE 61.8 Diagnostic approach to diaper dermatitis.

FIGURE 61.9 Persistent vesicles and nodules in a patient with Langerhans cell histiocytosis.

enteropathica. Look at the rest of the skin to see if other sites are involved that suggest psoriasis. A KOH preparation or Gram stain may be useful to look for the spores and pseudohyphae of Candida. Hair loss, diarrhea, and a perioral eruption suggest acrodermatitis enteropathica, which could be confirmed by performing serum zinc levels. The most important diagnosis to exclude is Langerhans cell histiocytosis (Fig. 61.9). A persistent, erosive, or hemorrhagic diaper rash that is unresponsive to treatment is suspicious. Examine for hepatosplenomegaly, scalp, and gingival involvement. If the rash is more subtle, pink, and scaly, it could be caused by irritation from urine or stool or by friction. Intertrigo would involve the folds and could be macerated or infected secondarily. Greasy, yellow plaques with cradle cap suggest seborrheic dermatitis.

CHAPTER 62 ■ RASH—MACULOPAPULAR

KAREN D. GRUSKIN, MD

Maculopapular rashes are common in pediatric practice, and children often present to the emergency department (ED) for their evaluation and treatment.

Before beginning a discussion of specific causes of maculopapular rashes, it is important to define the clinical characteristics of these types of rashes. A *papule* is a small, solid, mostly elevated lesion that is usually less than 1 cm in diameter. *Macules* are circumscribed flat lesions that differ from surrounding skin because of their color. Both papules and macules may have any size, shape, or color. Commonly, a rash may have papular and macular components, which leads to the term *maculopapular rash*.

The causes of maculopapular rashes are diverse (Table 62.1) and range from benign to life-threatening (Table 62.2). Common causes include viral exanthems, contact dermatitis, insect bites, and scabies (Table 62.3). The diagnostic approach to these disorders is based on the presence or absence of fever, characteristic clinical appearance, location, and chronicity (Fig. 62.1). Some of these conditions have very characteristic clinical appearances (Table 62.4); however, manifestations of these illnesses can be sufficiently variable that a proportion of the cases are difficult to diagnose.

DIFFERENTIAL DIAGNOSIS

Presence of Fever

The potentially life-threatening maculopapular rashes (Table 62.2) are all acute illnesses most commonly associated with fever and significant systemic symptoms. Hence, most patients with these illnesses will appear toxic. Erythema multiforme (EM) and rubeola have recognizable clinical appearances, whereas Kawasaki disease (KWD), Rocky Mountain spotted fever (RMSF), and dengue fever require a high level of clinical suspicion. Other, less severe, febrile illnesses associated with maculopapular rashes are listed in Fig. 62.1.

Potentially Life-threatening Illnesses

Erythema Multiforme

EM is believed to result from an immune-mediated acute hypersensitivity reaction to exposure to a sensitizing antigen (see Chapter 85). Common offenders include drugs, especially trimethoprim-sulfamethoxazole, cefaclor, and phenytoin (more recently, lamotrigine and abacavir have also been implicated); foods, especially nuts and shellfish; and infections by any number of viral, bacterial, protozoal, or fungal organisms. Herpetic and *Mycoplasma pneumoniae* infections rank among the most common infectious causes.

The rash of EM is characterized by diffuse erythematous macules with central clearing, often called a *target* or *iris lesion*. Lesions may also include erythematous papules, macules, urticarial raised lesions, vesicles, and/or bullae. The distribution is most commonly symmetric and may be noted anywhere on the body with a predilection for the hands and feet, including palms and soles. Lesions may appear in isolation or as a more confluent rash. In the past, patients were classified as having EM minor or EM major/Stevens-Johnson syndrome (SJS). Current theory proposes that EM, SJS, and toxic epidermal necrolysis (TEN) represent a continuum of disease with increasing skin involvement, morbidity, and mortality. EM is primarily a benign, self-limited process whereas TEN is associated with a high fatality rate. EM minor is characterized by cutaneous involvement alone or mucosal involvement that is limited to one surface (usually the mouth) and minimal systemic symptoms. SJS is characterized by extensive skin and mucosal involvement associated with significant systemic symptoms, including fever, chills, and malaise. Skin involvement can progress to sloughing with significant extravascular fluid losses. The term *TEN* is used in cases of severe skin sloughing. Conjunctivitis and keratitis are common features and can lead to permanent corneal scarring. Pulmonary, cardiac, and renal involvement may occur especially in severe cases.

Treatment is predominantly supportive (see Chapter 85). Due to extensive epidermal sloughing, patients with severe SJS or TEN behave similarly to burn patients, and transfer to a pediatric burn unit should be considered. Potentially inciting drugs should be immediately discontinued. For mild cases with pruritus, antihistamines may provide some relief. Oral topical applications of 1:1 mixtures of diphenhydramine and Maalox may provide pain relief from oral lesions. In severe cases, patients require aggressive fluid support and narcotic pain relief. Systemic steroids and intravenous immunoglobulin therapy (IVIG) are of unproven benefit. In fact, some reports suggest a possible increase in morbidity with steroid therapy. Conversely, other data indicate that IVIG may be of benefit in severe cases; however, more studies are required to prove efficacy. Patients with ocular involvement should undergo ophthalmologic evaluation.

Kawasaki Disease

KWD is a well-described illness of unknown cause assumed to be infectious in origin because of its epidemiologic and clinical presentation. However, no infectious agent has been identified and new research suggests that instead an infectious agent initiates an immune cascade that causes the symptoms of KWD

Pityriasis lichenoides
Lichen nitidus

(see Chapter 101). Most common in children younger than 5 years, the diagnosis is based on an unremitting fever of at least 5 days' duration and four of the five following features: (i) rash; (ii) nonexudative bulbar conjunctivitis with limbal sparing; (iii) red cracked lips, strawberry tongue, and erythematous oropharynx; (iv) erythema, swelling, and/or induration of peripheral extremities; and (v) a solitary unilateral cervical lymph node of greater than 1.5-cm diameter.

The most commonly associated rash is a generalized pruritic urticaria-like exanthem with raised erythematous plaques; however, the rash may also present with an erythematous maculopapular, morbilliform, scarlatiniform, or erythema marginatum-like pattern. The exanthem may be fleeting or persist for 2 to 3 days. During the later stages of the acute phase, periungual desquamation and peeling of the palms, soles, or perineal area develop. Other complications include

sterile pyuria, hepatic dysfunction, arthritis, aseptic meningitis, pericardial effusion, hydrops of the gallbladder, and myocarditis. No laboratory studies are included among the diagnostic criteria; however, certain findings may support the diagnosis. Systemic inflammation causes elevated erythrocyte sedimentation rates and C-reactive protein. Leukocytosis is common with a left shift followed in the second week by marked elevation of platelets (greater than 750,000 per mm^3). Other abnormal laboratory results may include a normocytic, normochromic anemia; sterile "mononuclear" pyuria (requires microscopic urine examination as dipstick for leukocyte esterase will be negative); elevation of transaminases; cerebrospinal fluid mononuclear pleocytosis without hypoglycorrhachia or protein elevation; and, hyponatremia (serum sodium lesser than 135 mEq per L) that is associated with an increased risk of coronary artery aneurysms.

The acute phase is usually self-limited but requires accurate diagnosis to prevent the development of coronary artery aneurysms that occur in approximately 20% of cases without therapy. There is an increasing recognition of incomplete disease seen in patients with fever and fewer than four of the previously listed clinical features. Because of the potential for development of coronary artery aneurysms, index of suspicion must remain high and children with possible incomplete disease should be considered candidates for therapy. Atypical disease is more common in children younger than 6 to 12 months of age. A small percentage of those patients who develop aneurysms progress to heart failure, valvular regurgitation, or myocardial infarction, which may prove fatal.

Consultation with a specialist with KWD expertise, usually a pediatric cardiologist or rheumatologist, is recommended prior to initiating therapy. Therapy consists of antiinflammatory agents, specifically high-dose intravenous immunoglobulin (IVIG) and aspirin. Therapy is most often protective against aneurysm development if started during the first 10 days of symptoms. Sadly, there are an increasing number of affected children exhibiting resistance to IVIG therapy who require a second dose for persistent fever and a smaller subset who will not respond to additional doses (for details, see Chapter 101).

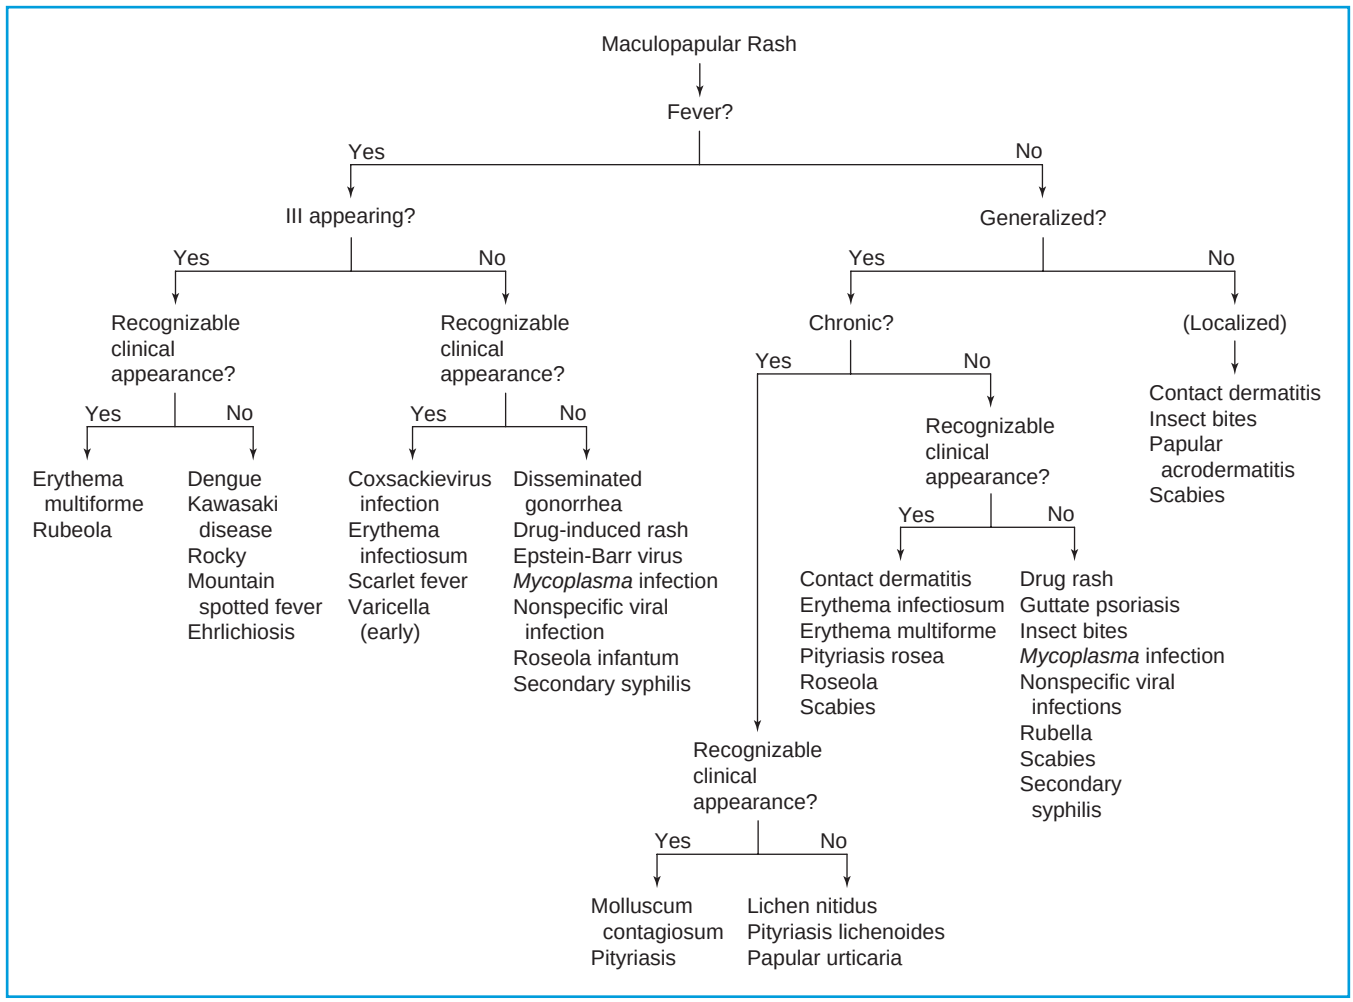

FIGURE 62.1 Diagnostic approach to maculopapular rash.

Measles (Rubeola)

Measles was one of the most common viral exanthems before the advent of the measles vaccine (see Chapter 92). The illness is transmitted by direct contact with droplets from a person infected with the causative RNA-containing paramyxovirus. The incubation period is 10 to 14 days. In its classic form, measles has a highly characteristic natural history. Two to 3 days after the onset of the prodromal symptoms of cough, coryza, conjunctivitis and fever, Koplik spots occur in the mouth, followed 12 to 24 hours later by the cutaneous exanthem. Most typically, Koplik spots appear as pinpoint white lesions on a red base on the buccal mucosa adjacent to the molars; however, they may be seen on any of the mucosal surfaces of the oral cavity except the tongue.

The measles exanthem begins on the head as reddish maculopapules and spreads caudally during the next 4 to 5 days. Within 1 to 2 days of its appearance, the discrete maculopapular lesions coalesce to produce the confluent phase of the rash. Hence, within 2 to 3 days of onset, the rash on the face becomes confluent, whereas the rash on the lower extremities still consists of individual maculopapules. Modified measles occurs in children who have received serum immunoglobulin after exposure to measles. Measles may still occur, but the incubation period may be delayed up to 21 days. The symptoms, although following the usual progression, will be milder. A faint rash and mild febrile illness may occur 7 to 10 days after immunization with the live attenuated measles vaccine.

Diagnosis may be confirmed by testing for measles IgM antibody. No specific therapy exists; however, vitamin A supplementation has been recommended in geographic areas with a high deficiency rate or high measles fatality rate (greater than

1%), as well as in children with severe disease or underlying immunodeficiency. Newer data suggest that Vitamin A is only beneficial in patients younger than 2 years and when two doses of 200,000 units are given on 2 consecutive days. Serious complications from measles that may lead to mortality include pneumonia, acute encephalitis, and a delayed development of subacute sclerosing panencephalitis. Some investigators suggest that there may be a role for prophylactic antibiotics to prevent these complications; however, additional studies are needed to confirm the benefit of any specific antimicrobial therapy. Improved vaccine programs are the answer to limiting and hopefully someday eradicating this disease.

Rocky Mountain Spotted Fever

RMSF, one of the most virulent infections identified in humans, is caused by *Rickettsia rickettsii* transmitted by the bite of a tick (see Chapter 84). Although initially confined to the Rocky Mountain states (hence, its name), confirmed cases have been reported from all parts of the United States with varying tick vectors. RMSF is associated with a fatality rate of 5% with antimicrobial treatment and 13% to 40% without such therapy. The primary determinants in patient outcome are early diagnosis and treatment. The best outcomes are associated with the initiation of doxycycline therapy by day five of illness.

The rash of RMSF begins on the third or fourth day of a febrile illness as a maculopapular eruption on the extremities, most commonly the wrists and ankles. Over the next two days, the rash becomes generalized by spreading centrally to involve the back, chest, and abdomen. Initially, the rash consists of erythematous macules that blanch on pressure; they then become more confluent and purpuric. Notably, the hemorrhagic lesions predominate in the peripheral distribution, involving the palms of the hands and the soles of the feet. The severity of the rash is proportional to the severity of the disease.

All patients with RMSF have some degree of vasculitis that is the basis for many of the associated systemic symptoms. An overall toxic appearance is common. Systemic signs and symptoms include fever, headache, myalgia, conjunctivitis, vomiting, seizures, myocarditis, heart failure, shock; periorbital, facial, or peripheral edema; and disseminated intravascular coagulation or purpura fulminans.

Most commonly, the diagnosis is based on clinical presentation with a history of potential tick exposure. The causative organism is not routinely cultured because of the danger to laboratory personnel. Diagnosis is best made by a serologic test such as indirect immunofluorescence antibody (IFA) assay. Antibodies can be detected 7 to 10 days after onset of illness. Some reference laboratories are now offering polymerase chain reaction (PCR) testing. Thrombocytopenia, hyponatremia and increased aminotransferases usually develop as the disease process progresses but antibiotics should hopefully have been started prior to the development of these findings.

Doxycycline is the drug of choice for therapy in patients of all ages, despite its risk for potentially staining developing teeth at a dose of 4 mg per kg per day in two divided doses (maximum of 100-mg b.i.d.), intravenously or orally. Chloramphenicol is a less optimal alternative and is not effective against ehrlichiosis, which is a common "look-alike" to RMSF. Therapy is continued until the patient is afebrile for at least 2 to 3 days, which usually equals about 7 to 10 days of antibiotic therapy.

Ehrlichiosis

Ehrlichiosis is another tick-borne disease with increasing prevalence that is most common during the warmer months when ticks are most prevalent. Nomenclature has undergone multiple changes. Currently, disease in the United States is due to three distinct obligate intracellular bacteria: *Ehrlichiosis chaffeensis* (human monocytic ehrlichiosis or HME); *Anaplasma phagocytophilum* agent (human granulocytic anaplasmosis or HGA); or *Ehrlichia ewingii* (*E. ewingii* ehrlichiosis). Infections with any of these bacteria cause an illness very similar to RMSF, although usually less serious and with better outcomes. In addition to fever and rash, systemic symptoms seen in both illnesses include altered mental status, headache, chills, malaise, arthralgia, nausea, and vomiting. Rash is a less consistent feature of ehrlichiosis but when present may be macular, maculopapular, or petechial and is more commonly seen in pediatric patients infected with *E. chaffeensis*. Unlike RMSF, rash may occur anywhere on the body and is less commonly seen on the palms and/or soles. Vasculitis is less prominent, and leukopenia, anemia, and hepatitis are more common in ehrlichiosis than in RMSF. Complications of ehrlichiosis infection include pneumonia, bone marrow suppression, respiratory failure, encephalopathy, meningitis, disseminated intravascular coagulation, and renal failure.

Diagnosis may be made via culture from blood or CSF, indirect IFA assay showing a fourfold or greater change between acute and convalescent antibiody titers, PCR or detection of intraleukocytoplasmic cluster of bacteria (morula) in conjunction with a single IFA titer greater than and equal to 64. Presumptive diagnosis may be made if examination of peripheral blood smear shows the presence of a morulae or a single IFA result greater than or equal to 64. Supportive laboratory data include increased liver transaminases, thrombocytopenia, lymphopenia, leukopenia, hyponatremia, anemia, and lymphocytic CSF pleocytosis with increased protein concentration.

As for RMSF, doxycycline is the drug of choice for therapy in patients of all ages and at the same dose (see above). Therapy is continued until the patient is afebrile for at least 2 to 3 days and for a minimum total course of 5 to 10 days. Clinical improvement is usually apparent within 3 days, and if not, an alternative diagnosis should be sought. Disease may be more severe or even fatal in untreated patients. Early initiation of therapy minimizes morbidity and mortality.

Dengue Fever

Dengue fever is caused by four dengue viruses transmitted by Aedes mosquitos and is seen in tropical and subtropical areas of almost all continents (including areas of Puerto Rico and the Caribbean basin). The incidence of severe dengue is increasing and may be related to global warming. Many cases are asymptomatic. In symptomatic cases, initial constitutional symptoms include sudden onset of high fever, severe headache, myalgia, arthralgia, and abdominal pain. During the course of fever that lasts 2 to 7 days, back and leg pain may be severe, hence, the disease's nickname "breakbone" fever. The development of a hemorrhagic vasculitis, most common in patients younger than 15 years, leads to the more concerning subtype called dengue hemorrhagic fever. The term dengue shock syndrome is used in even more severe cases when increased vascular permeability leads to shock. Encephalopathy, hepatitis,

myocardiopathy, intestinal bleeding, and pneumonia are other complications.

Two distinct rashes may be seen, which coincide with the disease's biphasic fever pattern. The first rash is a generalized, transient, macular rash that blanches under pressure and is seen within the first 24 to 48 hours of the onset of systemic symptoms. The second rash coincides with or occurs 1 to 2 days after defervescence and is a generalized morbilliform or maculopapular rash, sparing the palms and soles.

Diagnosis is based on clinical suspicion and potential exposure based on the virus's geographic distribution. Serologic testing is available as is viral isolation and measurement of serum immunoglobulin antibodies in paired serum specimens obtained 4 weeks apart. Treatment is supportive, and may require aggressive fluid management and pain control. Since a pulse pressure less than or equal to 10 mm Hg has been associated with a worse prognosis, normal saline should be bolused with intensive monitoring to keep the pulse pressure greater than or equal to 30 mm Hg. There are some data from the adult literature suggesting intravenous immunoglobulin and/or plasma exchange may be of benefit is severe cases.

Causes of Other Maculopapular Rashes Associated with Fever

Among non–life-threatening illnesses associated with fever and maculopapular rash are coxsackievirus infections, erythema infectiosum, scarlet fever, and early varicella. Harder to diagnose are rashes associated with Epstein-Barr virus, *Mycoplasma* infections, roseola infantum, disseminated gonorrhea, secondary syphilis, nonspecific viral eruptions, and drug-induced rash. The latter two diagnoses are particularly important to consider in sexually active or potentially abused children.

Coxsackievirus Infections

Coxsackievirus infections of groups A and B (multiple types) can all cause maculopapular exanthems. The classic exanthem of coxsackievirus A16 infection, also appropriately called *hand-foot-mouth disease*, is common and easily recognized. Infections may occur in epidemics, most commonly in the late summer or early fall. Multiple infected members within a household are common.

Coxsackievirus A16 infection begins with a prodrome of low-grade fever, anorexia, mouth pain, and malaise, followed within 1 to 2 days by an oral enanthem and then shortly thereafter by a maculopapular exanthem. The oral lesions begin as small red macules, most often located on the palate, uvula, and anterior tonsillar pillar, which evolve into small vesicles that ulcerate and heal over a 1- to 6-day period. The exanthem begins as maculopapular lesions that develop into small crescent or football-shaped vesicles on an erythematous base. These vesicles, which may be pruritic or mildly tender, are usually located on the dorsal and lateral aspects of fingers, hands, and feet but may develop on the buttocks, arms, legs, and face. The lesions either reabsorb over 2 to 7 days or ulcerate and scab.

The other types of coxsackievirus all cause similar or even indistinguishable exanthems, which may more commonly involve the face, trunk, and proximal extremities. Often, children with these exanthems will be diagnosed with nonspecific viral infections. Other symptoms attributed to coxsackievirus infection include aseptic meningitis and less commonly myopericarditis, encephalitis, or paralysis. Severe and/or persistent infections may be seen in immunocompromised hosts.

Diagnosis is usually made clinically, although the virus can be easily cultured. PCR assays are available for CSF specimens. The virus is commonly shed for weeks. Coxsackievirus infections are usually self-limiting, so no specific treatment is necessary. IVIG with high antibody titer or pleconaril (a new antiviral drug currently under clinical investigation and available for compassionate use only) may be considered for immunocompromised patients or in life-threatening neonatal infections.

Erythema Infectiosum (Fifth Disease)

Erythema infectiosum is a benign disease caused by parvovirus B19, the same virus that can causes aplastic crises in patients with sickle cell anemia. For the normal, nongravid host, fifth disease is usually of no consequence, with the only systemic symptom being fever in 15% to 30% of cases. On the face is a characteristic, intensely erythematous, "slapped cheek" rash often with a relative circumoral pallor. In addition, a symmetric maculopapular, lacelike rash is seen on the arms and then trunk, buttocks, and thighs, which may be pruritic. In its acute phase, the rash usually lasts only for a few days but can wax and wane in intensity with environmental changes (e.g., exposure to heat or sunlight) for weeks and sometimes months. In a small subset of patients, parovirus B19 causes the atypical papular purpuric gloves and socks syndrome (PPGSS) with a typically painful purpuric exanthem limited to the hands and feet. Immunocompromised children or those with hemolytic anemias can develop red cell aplasia and symptoms associated with a chronic anemia.

Diagnosis is usually made on a clinical basis alone but may be confirmed in an immunocompetent host by measuring parvovirus B19–specific IgM antibody. PCR is the best modality for diagnosis in an immunocompromised host. No specific therapy is necessary in immunocompetent hosts. For a chronic infection in an immunodeficient patient, IVIG therapy should be considered. Because parvovirus is associated with fetal anemia, congestive heart failure and hydrops-exposed pregnant women should be referred to their physicians to discuss possible parvovirus antibody testing.

Scarlet Fever

Scarlet fever is caused by phage-infected group A streptococcus that makes an erythrogenic toxin. This disease is still seen with regularity but does not appear to be any more serious than group A streptococcal infection without rash. Scarlet fever is most commonly associated with streptococcal pharyngitis but may occur in association with pyoderma or an infected wound.

The diagnosis of scarlet fever can be made clinically in a child with signs and symptoms of pharyngitis who has a fine, raised, generalized maculopapular rash. The skin has a coarse or sandpapery feel on palpation. Typically, there is sparing of the circumoral area, leading to circumoral pallor. There is usually a bright erythema of the tongue and hypertrophy of the papillae, leading to the term *strawberry tongue*. Pastia's lines, bright red, orange, or even hemorrhagic lines, can occasionally be seen in the axillae or antecubital fossa. The rash generally lasts 3 to 5 days, followed by brownish discoloration and peeling of the skin as small

flakes to entire casts of the digits. A rapid streptococcal test or throat culture should be sent to confirm infection. Various antibiotic regimens provide effective treatment (see Chapter 84).

Varicella (Chickenpox)

Although varicella is an easily recognizable vesiculobullous eruption, on occasion, the earliest phase can be confusing. The initial skin manifestations of varicella virus infection are small, red macules. Some of the lesions remain as macules, but most progress to papules and then the characteristic umbilicated, tear-shaped vesicles. The earliest lesions appear on the chest and spread centrifugally, but there are many exceptions to the pattern of spread. Occasionally, a child with mild chickenpox may have only a few scattered macules with only one or two progressing to the more typical vesicular lesions. Of children receiving varicella vaccine, 7% to 8% may develop a mild maculopapular or varicelliform rash within 1 month of vaccination (see Chapter 84).

Epstein-Barr Virus

Between 5% and 15% of patients with Epstein-Barr viral infection, otherwise known as infectious mononucleosis, will have an erythematous maculopapular eruption. Infection in young children is usually asympomatic or so mild that diagnosis is not sought. Older patients between 15 and 25 years of age are more likely to present for evaluation. In addition, 50% to 100% of patients with infectious mononucleosis develop a maculopapular rash after receiving concurrent ampicillin or amoxicillin-containing antibiotics—most commonly for an incorrectly diagnosed streptococcal pharyngitis.

The illness begins insidiously with headache, malaise, and fever, followed by sore throat, membranous tonsillitis, and lymphadenopathy. Splenomegaly is common. The exanthem occurs within 4 to 6 days as a macular or maculopapular morbilliform eruption most prominent on the trunk and proximal extremities. An enanthem consisting of discrete petechiae at the junction of the hard and soft palate occurs in approximately 25% of patients. A small subset of patients develop more serious disease often involving the central nervous system.

Diagnosis is often presumed clinically but may be supported by an absolute increase in atypical lymphocytes, a positive heterophile antibody (monospot) test (obtained after the first week of symptoms) or confirmed by serology. The heterophile antibody test is less sensitive in children younger than 4 years of age. The illness is most commonly self-limited, requiring no therapy, but due to the frequency of associated splenomegaly, affected children should not be allowed to participate in contact sports until fully recovered and the spleen is no longer palpable. Amoxicillin should be avoided for any concurrent infections. Corticosteroids may be considered for patients with particularly severe tonsillitis (see Chapter 84).

Mycoplasma Infections

Infections with *Mycoplasma* pneumoniae may cause maculopapular rashes in up to 15% of cases. The classic clinical presentation is of a child with malaise, low-grade fever, and prominent cough. The cough is initially nonproductive but may become productive, particularly in older children, and may persist for 3 to 4 weeks. Physical examination may show bilateral rales. Roentgenographic examination of the chest, if abnormal, most commonly shows diffuse nonspecific infiltrates.

Diagnosis can be suggested by serum cold hemagglutinins, which are present in more than 50% of cases by the beginning of the second week. If further confirmatory studies are needed, acute and convalescent serum sera should be assayed for specific mycoplasmal antibodies by complement fixation or immunofluorescence. Erythromycin, clarithromycin, or azithromycin is the treatment of choice (see Chapter 84).

Roseola Infantum

Roseola infantum, also called *exanthem subitum* or *sixth disease*, is attributed to primary infection with human herpes virus (HHV)-6. The illness is characterized by the onset of a maculopapular rash that appears following a 3- to 4-day febrile illness. The fever is characteristically high. The rash is widely disseminated, appearing as discrete, small, pinkish macules that rarely coalesce, beginning on the trunk and then extending peripherally. The rash may last for hours to days. The occurrence of the rash within 24 hours of defervescence rather than the morphologic appearance of the rash leads to the correct diagnosis. The rash can appear very similar to that seen in measles, but the child with roseola appears well and no longer febrile. Diagnosis is made clinically and care is supportive.

Disseminated Neisseria Gonorrhea

Disseminated *Neisseria gonorrhoeae* should be considered in sexually active or potentially abused children, especially if associated with a history of vaginal or penile discharge. A distinct minority of patients develop disseminated gonorrhea infection through hematogenous spread. Disseminated gonorrhea may cause a range of cutaneous lesions, including small erythematous papules, petechiae, or vesicle-pustules on a hemorrhagic base. These cutaneous lesions usually develop on the trunk but may occur anywhere on the extremities.

An etiologic diagnosis can be established by demonstration of the organism on Gram stain of the skin lesion, positive blood culture, or positive culture of oral or genital sites. Based on resistance patterns, recommended current therapy is ceftriaxone 50 mg per kg per day (maximum 1 g per day) until clinical improvement is seen, at which point it can be changed to an oral antibiotic, such as cefixime, ciprofloxacin, ofloxacin, or levofloxicin, for a total of a 7-day course. Quinolones should not be used for infections in men who have intercourse with men or in those with a history of recent foreign travel or partners' travel, or infections acquired in other areas with increased resistance. Concomitant sexually transmitted diseases should be sought and treated empirically (see Chapters 84 and 94).

Secondary Syphilis

One needs a high level of suspicion when viewing rashes in sexually active (or potentially abused) children to make the diagnosis of secondary syphilis, caused by the spirochete *Treponema pallidum*. Manifestations of secondary syphilis usually occur 6 to 8 weeks after the appearance of the primary lesion, which may have gone unnoticed. The exanthem extends rapidly and is usually pronounced, lasting for only hours or persisting for several months.

The rash of secondary syphilis is characterized by a generalized cutaneous eruption, usually composed of brownish,

dull-red macules or papules that range in size from a few millimeters to 1 cm in diameter. They are generally discrete and symmetrically distributed, particularly over the trunk, where they follow the lines of cleavage in a pattern similar to pityriasis rosea. Papular lesions on the palms and soles, as well as the presence of systemic symptoms, such as general malaise, fever, headaches, sore throat, rhinorrhea, lacrimation, and generalized lymphadenopathy, help differentiate secondary syphilis.

Acquired syphilis is sexually contracted from direct contact with ulcerative lesions of the skin or mucous membranes of an infected individual. Diagnosis may be presumed after a positive nontreponemal test, such as the VDRL slide test, rapid plasma reagin test, or the automated reagin test. Diagnosis should be confirmed by a treponemal test, such as the fluorescent treponemal antibody absorption test, the microhemagglutination test for *Treponema palladium*, or the *T. palladium* immobilization test. Definitive diagnosis may also be made by identifying spirochetes by microscopic dark-field examination or direct fluorescent antibody tests of lesion exudate or tissue. Penicillin is the treatment of choice unless contraindicated, in which case tetracycline, doxycycline, ceftriaxone, or erythromycin may be substituted. Length of therapy should be based on duration and stage of infection. Concomitant sexually transmitted diseases should be sought and treated empirically. HIV testing is recommended for patients with secondary syphilis (see Chapters 84 and 94).

Nonspecific Viral Exanthems

Many times, a specific diagnosis cannot be made even after considering such factors as exposure history, history of preceding illness, description of eruption, time and site of onset, character of initial lesion, progression, distribution patterns, and occurrence of mucosal lesions. This should not be surprising, given the large number of viruses that can be associated with macular or maculopapular eruptions. In particular, enteroviruses and adenoviruses can cause a macular or maculopapular eruption. In fact, enterovirus 71 is now known to be the cause of a subset of cases of hand-foot-mouth disease. There is little to distinguish the rash caused by one of these viruses from that of another, based on the location and morphology, with the exception of those viral infections previously discussed. One usually arrives at the diagnosis of nonspecific viral exanthem in a child in whom other diagnoses have been excluded and who may have signs of associated illness or systemic features such as fever. If specific diagnosis is required, it can be determined by viral isolation and/or a rise in diagnostic titer.

Drug-Induced Rash

Multiple drugs can cause maculopapular rashes in susceptible patients. Most commonly, these rashes have an abrupt onset, are generalized, and may be accompanied by systemic signs such as fever, arthralgia, lymphadenopathy, and hepatomegaly. It is often difficult to distinguish drug eruptions from viral exanthems. This is especially true when an emergency physician is faced with a child who recently was started on one or several medications, often including antibiotics, who now presents with the emergence of a new rash associated with or following a viral-type illness.

The diagnosis of drug eruption depends on a carefully obtained history, including the duration and frequency of all medications taken by the child during the week preceding the onset of the rash. The presence of eosinophilia suggests, but does not confirm, the diagnosis. Often, the final diagnosis is left to the intuition of the physician. In the case of a severe eruption, the potentially offending drug should be discontinued. In milder cases, which more closely resemble nonspecific viral exanthems, a physician may opt to continue therapy as long as the rash does not worsen, with the distinct exception of lamotrigine and abacivir. Regardless of the extent of the rash, both drugs should be discontinued, not reintroduced, and immediately referred to the appropriate specialist for management. The disadvantage of simply discontinuing any other potentially offending drug is that the patient is often labeled as "allergic" to the drug for life. In addition, reactions may be caused by preservatives or dyes in a drug preparation and not by the drug itself.

Illnesses Associated with Maculopapular Rashes without Fever

Maculopapular rashes associated with nonfebrile illnesses tend to be benign. Erythema infectiosum, EM, *Mycoplasma* infections, roseola infantum, secondary syphilis, and nonspecific viral exanthems, which in mild cases may not be associated with fever, have been previously discussed. In approaching the acute afebrile disorders associated with maculopapular rash, it is useful to distinguish between those that cause generalized eruptions and those that cause localized ones. Disorders not usually associated with fever but that cause generalized eruptions include rubella, guttate psoriasis, and pityriasis rosea. Conditions that cause mostly local eruptions include papular acrodermatitis (Gianotti-Crosti syndrome), contact dermatitis, insect bites, and scabies. The chronic duration of some maculopapular rashes not associated with fever helps to lead to the correct diagnosis; examples include lichen nitidus, molluscum contagiosum, papular urticaria, pityriasis lichenoides (Mucha-Habermann disease), and pityriasis versicolor. Molluscum contagiosum, pityriasis rosea, pityriasis versicolor, and forms of contact dermatitis also present with clinically recognizable rashes.

Generalized Eruptions Without Fever

Guttate Psoriasis

About one-third of psoriasis cases begin in the first two decades of life among individuals with a genetic predisposition. The guttate form commonly occurs in younger age groups. The rash is characterized by multiple small discrete round or oval macules or papules (up to 1 cm in diameter) with a loosely adherent scale. The lesions develop predominantly on the trunk, but the face and scalp may be involved. The distal extremities, palms, and soles are usually spared. The lesions of guttate psoriasis are less hyperkeratotic as other types of chronic psoriatic plaques and may respond better to standard psoriasis therapy.

Pityriasis Rosea

Pityriasis rosea is a benign, self-limited condition that most commonly affects older children and adolescents, although it can occur at younger ages. The cause is unknown but is likely to be viral (see Chapter 99).

Pityriasis rosea follows a characteristic clinical course. The initial lesion, the herald patch, is an oval-shaped plaque that

occurs in about 80% of cases. The center of the lesion is flat, whereas the borders are raised, red, and scaly. The herald patch can occur anywhere on the body but is most commonly seen on the trunk, neck, or proximal extremities. The herald patch is often mistaken for tinea corporis. One to 2 weeks later, a more generalized, sometimes pruritic, rash erupts. The rash is most dense on the trunk, neck, and proximal limbs. The face and distal extremities are relatively spared but may be involved in younger children. Individual lesions are erythematous papulosquamous ovals that often resemble smaller versions of the herald patch. The long axes of the ovals tend to orient along the lines of cleavage, creating a characteristic "Christmas tree" distribution along the patient's posterior trunk. Atypical distributions (predominantly peripheral) and other individual lesions (papules, vesicles, pustules, urticarial, or purpuric lesions) can occur.

Rubella

Rubella is rarely seen in the postvaccine era in the United States. In a classic case of rubella, the rash, similar to measles, begins on the head and spreads caudally. The progression occurs over 2 to 3 days, and typically, the rash is entirely gone by the fourth day. The rash always remains macular and never becomes confluent, which is an important distinguishing characteristic. One-third of all rubella virus infections are clinically silent (i.e., they have no exanthem). The rash of rubella may show extensive variation in location, progression, and duration, at times disappearing within 12 hours or being localized to one part of an extremity without any progression.

Unlike measles, in which systemic toxicity and fever are the rule, fever is uncommon. Associated symptoms and complaints in rubella include joint pain and adenopathy (most commonly suboccipital, postauricular, and cervical). Arthralgia that occurs with a viral exanthem is highly characteristic for rubella. Diagnosis is based on clinical presentation, and treatment is supportive.

Localized Eruptions without Fever

Contact dermatitis, insect bites, papular acrodermatitis, and scabies usually present in a localized distribution; however, all may appear as a more generalized eruption in extensive cases.

Contact Dermatitis

Contact dermatitis may be caused either by a primary exposure to an irritant or by an acquired delayed hypersensitivity response to a sensitizing substance (see Chapter 99). In the former case, it is termed an *irritant contact dermatitis*, whereas the latter is referred to as a true *allergic contact dermatitis*. Although distinct in etiology, both rashes usually are localized and assume the pattern of an irritating or a sensitizing agent. A sharp demarcation commonly exists between the involved and uninvolved skin areas. Affected skin is erythematous with variable numbers and combinations of macules, papules, vesicles, and/or bullae.

Irritant dermatitis arises from direct contact with agents such as detergents, soaps, acids, alkalis, or rough sheets/clothes. This disorder often is seen in infancy when the skin is relatively thin and susceptible to mechanical or chemical irritation. Allergic contact dermatitis, exemplified by rhus dermatitis (e.g., poison ivy, poison oak) or nickel dermatitis (jewelry, wristwatches), is more common in older children after exposure to the offending agents.

Diagnosis depends on obtaining a thorough history of exposure and the presence of a characteristic localized pattern of rash. Treatment for both types of these dermatitides includes eliminating exposure to offending irritants, providing topical or systemic antipruritic agents, and for more severe cases, providing topical or systemic steroids (see Chapter 99).

Insect Bites

Virtually all children experience insect bites. Mosquitoes, fleas, and bedbugs are the most common offenders. Diagnosis depends on the season, the climate, exposure to animals, and distribution and appearance of the lesions. In temperate climates, mosquito bites occur exclusively in the warmer months of the year, whereas flea and bedbugs afflict patients yearround. Often, a series of bites occurs in groups, causing a maculopapular appearance. Local reactions can be extensive and take several days to resolve. Care is aimed at minimizing discomfort with topical or systemic antihistamines and/or topical steroids.

Papular Acrodermatitis (Gianotti-Crosti Syndrome)

Papular acrodermatitis is an eruption of unclear cause that has been associated with hepatitis B, EBV, and other viral infections in young children. In the pediatric population, 85% are younger than 3 years. The eruption may follow a low-grade fever or mild upper respiratory symptoms.

The eruption consists of flesh-colored papules that occur anywhere on the body but often concentrate on the extensor surfaces of the arms, legs, and buttock. Lesions are particularly prominent over the elbows and knees. The rash usually lasts 2 to 8 weeks and then disappears. No treatment is needed for the cutaneous eruption; however, a subset of patients with cutaneous lesions develops generalized lymphadenopathy and hepatosplenomegaly. These children should be evaluated for hepatitis and follow-up in 2 weeks is recommended for patients with only cutaneous involvement to exclude hepatitis (see Chapter 93).

Scabies

Scabies is a contagious infestation of the *Sarcoptes scabiei* female mite that selects a favorable body site, burrows beneath the stratum corneum, and deposits eggs along the way. In older children and adults, the usual sites of infestation include the anterior axillary lines, the areolae, the lower part of the abdomen, buttocks, genitals, wrists, interdigital webs, and ankles. In young children, the lesions are usually more diffuse and may also occur on the palms, soles, scalp, and neck (see Chapter 99).

The pathognomonic primary lesion may be visible as a linear, gray-brown, threadlike burrow a few millimeters in length, with a central black dot (the mite). More frequently, the lesions appear as erythematous papules that may be excoriated and possibly secondarily infected because of intense pruritus. On occasion, generalized urticarial or "id" reactions develop.

Diagnosis is usually based on clinical suspicion, although definitive confirmation can be made by identifying the adult mite on microscopic examination of a scraping of suspicious

burrows. The treatment of choice in children over 2 months of age is the topical application of permethrin 5% cream, which may be repeated in 2 weeks, if necessary. Pruritus often persists for several weeks after the mites have been eradicated. It is advisable to treat close family members or personal contacts with or without evidence of infestation. Because mites are unable to survive away from their human hosts or at high temperatures, clothing, bedding, and stuffed animals should be laundered in hot water (greater than 50°C, or 120°F) or stored away for several days in plastic bags. Antihistamines provide symptomatic relief for itching that often continues for several weeks despite of successful treatment. Treatment options for nonresponders to permethrin include crotamiton 10%, ivermectin and lindane; however, these therapies are not universally approved for scabies and need to be used with caution.

Chronic Eruptions without Fever

Chronic eruptions are defined as those that are usually present for a minimum of 2 weeks.

Lichen Nitidus

Lichen nitidus is a relatively rare, benign skin disorder that occurs predominatly in preschool and school-age children. It is believed to perhaps be a variant of lichen planus. The eruption consists of groups of tiny, shiny, flesh-colored papules. The lesions commonly occur in lines of local trauma (Kobner's phenomenon) and are most often seen on the trunk, abdomen, forearm, and genitalia. There is no known effective treatment, and the eruption can last for years.

Molluscum Contagiosum

Molluscum contagiosum is caused by a viral infection and consists of discrete flesh-colored papules, usually 2 to 3 mm in diameter, with umbilicated centers (see Chapter 99). Axillary lines of the trunk, abdomen, genital region, inner aspect of the thighs, and the face are the most common sites of presentation, although any hair-free surface may be involved. Usually, a child will have approximately ten scattered lesions; however, on occasion, some may have many more. The lesions tend to persist anywhere from 2 weeks to 1.5 years and may be spread by autoinoculation. Spread can occur between individuals involved in contact sports. The lesions are asymptomatic, with the exception of a minority of patients who develop an inflammatory reaction. When deemed necessary, treatment involves techniques such as liquid nitrogen, curettage, or topical cantharidin or imiquimod (see Chapter 99).

Papular Urticaria

Papular urticaria, a benign condition seen most commonly in young children, is manifested by a chronic or recurrent papular eruption caused by a sensitivity reaction to insect bites. The lesions are usually papules with a central punctum that may rest on an urticarial base. The lesions are most commonly seen in the warm months, when exposure to insects is most intense. Diagnosis is usually made clinically. Treatment is aimed at minimizing exposure to insect bites and providing therapy with simple sedation, topical calamine, or topical corticosteroid to minimize pruritus (see Chapter 99).

Pityriasis Lichenoides (Mucha-Habermann Disease)

Pityriasis lichenoides, or Mucha-Habermann disease, is a relatively rare disorder of unknown cause that can appear in childhood and young adulthood. There are two forms: acute and chronic. The acute disease is characterized by a macular, papular, or papulovesicular rash that is often distributed most heavily on the trunk and upper arms. The lesions occur in successive crops rapidly evolving into vesicular, necrotic, and even purpuric lesions, which may leave pocklike scars. Resolution occurs spontaneously but may take several weeks to months and recurrences may occur. Parents may describe these recurrences as "he keeps getting the chickenpox." The more chronic form may evolve from the acute form or may arise de novo and often lasts for several years. There is no established therapy.

Pityriasis Versicolor

Pityriasis Versicolor (formly Tinea versicolor) is a superficial skin disease caused by the fungus *Pityrosporum orbiculare*, formerly called *Malassezia furfur* (see Chapter 99). Although adolescents and young adults are most commonly affected, the disorder can occur at any age. The distribution of scaly macular lesions is patchy and occurs most commonly over the upper trunk and proximal arms. Occasionally, the face and other areas of the body can become involved. In summer, affected areas are relatively hypopigmented compared to the surrounding unaffected skin because the organism blocks tanning. In winter, the affected areas appear darker than the unaffected skin because the fungus causes mild erythema. This phenomenon of variable coloration of the affected skin gives the disease its name.

The diagnosis is often made by recognition of the characteristic rash. Wood's light examination in a darkened room produces a reddish-brown fluorescence. Microscopic examination of scrapings will demonstrate characteristic hyphae and spores in grapelike clusters ("spaghetti and meatballs" appearance). Initial treatment usually consists of selenium sulfide shampoos weekly for 3 weeks and then monthly for 3 months. Oral antifungal therapy is another option but has not been approved for this usage. Infection may recur and repigmentation may take several months.

EVALUATION AND DECISION

In approaching a child with a maculopapular exanthem, the initial steps are to take a history and to fully examine all cutaneous surfaces. The most important historical features include the duration of the rash (acute or chronic), initial distribution, extent of spread (generalized or localized), ill contacts (including sexual partners of adolescent patients), and any associated systemic symptoms, including fever. The physical examination should include a careful systematic inspection of all mucocutaneous surfaces, with special attention paid to involvement of the oropharynx, palms and soles, extensor or flexor surfaces, scalp, and trunk.

For patients who do not appear ill, certain exanthems will have distinctive patterns that will immediately strike the examiner and make the diagnosis readily apparent. EM, rubella, coxsackievirus infections, erythema infectiosum, scarlet fever, varicella, molluscum contagiosum, pityriasis versicolor, pityriasis

rosea, and roseola all have recognizable clinical appearances. Many of these illnesses have characteristic distributions or associated signs and symptoms that aid in their diagnoses. If the pattern of the rash does not evoke immediate recognition from the examiner, a more methodical approach is indicated, as outlined in Fig. 62.1.

For patients with maculopapular rash who appear particularly ill, the potential diagnoses of rubeola (measles), EM, KWD, RMSF, ehrlichiosis, and dengue fever should spring to mind.

Acutely Ill-appearing Patients

Rubeola and EM both have characteristic rashes that are often associated with oral involvement. Patients with rubeola may have a history of an ill contact and several days of cough, coryza, conjunctivitis, and escalating fever. EM may present with a history of the recent introduction of a medication. KWD should be considered in children who have been febrile for more than 5 days and who have or have had conjunctivitis, red lips/strawberry tongue, a solitary enlarged cervical lymph node, and a rash. Clues to the possibility of RMSF, ehrlichiosis, or dengue fever may be obtained from a travel history or known cases within the geographic location. Patients with RMSF may have history of tick bite, and the hemorrhagic rash characteristically remains more peripherally distributed involving the palms and soles. Often confused with RMSF is ehrlichiosis, which may also present with history of tick bite and is clinically similar to RMSF but is associated with fewer vasculitic-type symptoms. Dengue fever should be considered in patients with a biphasic fever pattern and musculoskeletal pain.

Other Generalized Febrile Eruptions

An acute, generalized febrile maculopapular exanthem is usually the result of a nonspecific viral or streptococcal (scarlet fever) infection. The disorders that are seen in acutely ill-appearing patients, discussed previously, may present as milder versions and should be considered as possible causes in less acutely ill febrile children with generalized eruptions. Other viral and bacterial infections may require a higher index of suspicion and confirmatory studies.

Nonspecific viral exanthems most characteristically consist of multiple, closely spaced small papules. The finding of pharyngitis, a strawberry tongue, or intensely erythematous lines in the antecubital fossae points to scarlet fever; however, a throat culture or rapid screening test for streptococcal infection should still be obtained.

Coxsackievirus infections, erythema infectiosum, and early varicella should be able to be diagnosed based on their clinical appearance. It should be remembered that the eruption of varicella is initially maculopapular; however, close inspection usually reveals a few vesicles by the time the child is brought to medical attention.

The final considerations in febrile patients with generalized maculopapular rash are Epstein-Barr virus infections (infectious mononucleosis), *Mycoplasma* infections, roseola infantum, disseminated gonorrhea, and secondary syphilis. The exanthem of infectious mononucleosis should be suspected in the child or, more commonly, in the adolescent who has streptococcal negative pharyngitis and/or history of taking ampicillin or a closely related antibiotic. For children with nonspecific viral symptoms with prominent cough, *Mycoplasma* infection may be the diagnosis. Roseola infantum should be considered in the child who develops maculopapular rash after fever has defervesced. Finally, disseminated gonorrhea and secondary syphilis should be considered in sexually active adolescents and appropriate tests should be sent for confirmation.

Generalized Afebrile Eruptions

Although nonspecific viral illnesses that cause rash are more often than not associated with fever, a minority of children with viral exanthems remain afebrile. Often, no specific diagnosis is possible. Again, the appearance of a diffuse rash in an infant or toddler immediately after the defervescence of a high fever indicates the clinical diagnosis of roseola. Similarly, pronounced posterior occipital lymphadenopathy in an unvaccinated child suggests rubella. If a child is taking any medications, drug rash must be considered. Because a drug reaction is difficult to exclude initially, consideration for discontinuing medications is warranted in severe cases. Also common, pityriasis rosea is distinguished by its characteristic predominantly truncal distribution along the skin folds. Rarely does guttate psoriasis present acutely with a diffuse maculopapular eruption.

Localized Eruptions

The most common causes for acute, localized maculopapular eruptions are contact dermatitis and insect bites. Contact dermatitis may be caused by irritation or allergy. History may be helpful in establishing a diagnosis, as in the case of a child who returns from camp with an allergic dermatitis on the arms and legs (rhus dermatitis or poison ivy) or a teenager who gets an irritant dermatitis of the wrist after wearing a new watch. Irritant reactions are usually exclusively maculopapular, whereas allergic eruptions may become vesicular or eczematous and may also have a characteristic linear appearance. The papules of insect bites are usually isolated lesions, as opposed to the confluent rash seen in contact dermatitis. In temperate climates, insect bites occur most commonly in the summer, but the possibility of bedbugs or fleas should not be overlooked during the colder months. Scabies is a relatively common and potentially difficult diagnosis. Linear lesions and involvement of the web spaces are characteristic; however, often a diagnostic scraping or presumptive therapy is indicated. Gianotti-Crosti syndrome is a rare disorder that produces primarily an eruption limited to the distal extremities. Any of the causes of localized eruptions may appear more generalized in extensive or severe cases.

Chronic Eruptions

Chronic maculopapular eruptions are usually, and more appropriately, seen by physicians in settings other than the ED. However, parents may become acutely concerned about a real or perceived change in a chronic eruption; thus, the emergency physician should be familiar with the more common disorders.

The most commonly seen of the chronic maculopapular eruptions are papular urticaria, molluscum contagiosum, and pityriasis versicolor. Papular urticaria is most common in warm weather but may occur at any time of the year; the characteristic lesions

have an urticarial wheal around a central papule. The papules of molluscum contagiosum have an easily recognizable umbilicated central core. Pityriasis versicolor consists of hypopigmented and hyperpigmented areas, predominantly on the trunk. This diagnosis can be confirmed by microscopy or culture. Although uncommon, secondary syphilis needs to be considered in any sexually active patient and a serologic test performed as indicated.

CHAPTER 63 ■ RASH—PAPULAR LESIONS

PAUL J. HONIG, MD, LESLIE CASTELO-SOCCIO, MD, PHD, AND ALBERT C. YAN, MD

Physicians are often confronted by parents who are concerned about "bumps" on their child's skin surface. Most parents will be comforted by a physician's reassurance and recommendations for treatment. Obviously, therapeutic interventions cannot be made until a definitive diagnosis is made. The following algorithm is used to help practitioners diagnose varying papular lesions (Fig. 63.1 and Table 63.1).

PAPULES WITH A CHARACTERISTIC CLINICAL APPEARANCE

Many conditions can be diagnosed on sight. The experienced eye can easily distinguish milia from molluscum contagiosum (MC) and warts from the uncommon xanthoma. Papules caused by bites are localized to exposed surfaces (face and extremities), are often clustered into crops of three or four lesions (the so-called "breakfast, lunch, and dinner" pattern), and classically demonstrate small central puncta. Several clues make the process of separating these entities from one another easier (see "Papules with a Noncharacteristic Clinical Appearance" section).

The distinction between flat warts and xanthomas is more subtle. At times, it is impossible to tell the difference. Because warts are caused by the human papillomavirus, a scratch through any of the lesions may inoculate the virus along the scratch line. This produces flat-topped papules in a linear distribution (a quasi-Koebner's phenomenon—i.e., appearance of the primary eruption located elsewhere on the body at sites of trauma). Therefore, linearly arranged yellow, tan, or flesh-colored flat-topped papules should arouse suspicion of the presence of flat warts, especially if the lesions are distributed on the face, backs of the hands, and knees—favored sites for flat warts. Xanthomas are unusual during childhood. When present, however, they usually are associated with elevations of serum lipids, which gives these lesions their often yellowish hue, especially when diascopy is applied; this can be accomplished by applying a glass slide to a lesion, which may accentuate the yellow color of the lesion. A lipid profile can be helpful in distinguishing these two flat-topped papules from one another. If all else fails, the help of a dermatologist experienced in caring for children can be sought. This is true for any of the entities discussed in this chapter. Skin biopsy is a valuable tool available to the dermatologist and may be required to differentiate many of the entities discussed here.

Milia

Milia are 1- to 2-mm firm, white papules. They are produced by retention of keratinous and sebaceous material in follicular openings. Newborns often have milia on their face. Fortunately, they frequently disappear by the age of 1 month. Milia can also arise from skin trauma, and can be seen in scars after burns and in healed wounds in patients with epidermolysis bullosa. Persistent milia may be a manifestation of the oral-facial-digital syndrome, hereditary hypotrichosis (Marie-Unna type), and certain rare ectodermal dysplasias (Basan's syndrome). Because lesions that are not associated with syndromes disappear spontaneously, no therapy is indicated.

Molluscum Contagiosum

For additional information about MC, see Figure 85.42.

Warts

For additional information about warts, see Chapter 85.

Xanthomas

Papules, plaques, nodules, and tumors that contain lipid are called *xanthomas*. These lesions can appear on any skin surface and are often associated with disturbances of lipoprotein metabolism (Table 63.2).

The most interesting, but the most rare, of hyperlipidemias that arise in the pediatric (infancy to adolescence) age group are the Fredericksen type I hyperlipidemias. This is caused by lipoprotein lipase or apoliprotein II deficiency or by the presence of inhibitors of lipoprotein lipase. Fifty percent of patients present with episodic abdominal pain that may be acute at times. Malaise, anorexia, fever, and leukocytosis may be present. The cause of the pain is unclear; however, pancreatitis and splenic infarcts have been hypothesized. Eruptive xanthomas occur in more than 50% of the patients. These are 1- to 4-mm yellow/orange papules that appear in crops on the face, extremities, and buttocks. Their sudden appearance causes significant concern. Hepatosplenomegaly is also commonly present, as are lipemia retinalis and creamy plasma. Patients are found to have increased chylomicrons, slightly elevated cholesterol, and significantly elevated triglycerides. With age, patients develop elevated, very low density lipoproteins. Secondary diseases include pancreatitis and diabetes. Dietary modification is the most effective treatment for this disease.

The homozygous form of type IIa hyperlipidemia is seen in children. An elevated low-density lipoprotein, significantly elevated cholesterol, and mildly elevated triglycerides characterize this disorder. Tendinous and tuberous xanthomas and xanthelasmas are seen clinically. The plane xanthomas (xanthelasmas)

TABLE 63.1

Xanthomas

may be misinterpreted as flat warts when seen in skin areas away from the eyelids. Secondary disorders include hypothyroidism and nephrotic syndrome. Patients die of atherosclerotic coronary artery disease in their twenties and thirties. Low-density lipoprotein apheresis, liver transplantation, and lipid altering medications are among the current therapies available for this disorder.

Insect Bites

For additional information about insect bites, see Chapter 85.

PAPULES WITH A NONCHARACTERISTIC CLINICAL APPEARANCE

When the diagnosis is not obvious, the algorithm presented in Figure 63.1 can be used.

Presence of White or Translucent Core

Milia and MC have white cores. Sidelighting and a magnifying glass may be needed to see the core within the central portion of the papule in MC. Therefore, it is essential to sidelight all papules about which one is not sure. The obvious white core in milia fills the entire papule rather than a small central portion of the papule (as in MC). The other differentiating point is that milia are hard and beady white; MC are more fleshy. As MC lesions age and desiccate, the central core often retracts resulting in a central umbilication.

Absence of White or Translucent Core

Rapid Growth of Hemangioma-like Lesions

Hemangiomas generally present within the first month of life. Two lesions that may mimic hemangiomas generally manifest after this period. These lesions are the pyogenic granuloma and Spitz nevus. They are differentiated by the fact that the Spitz nevus has a red, smooth, dome-shaped surface, as opposed to the

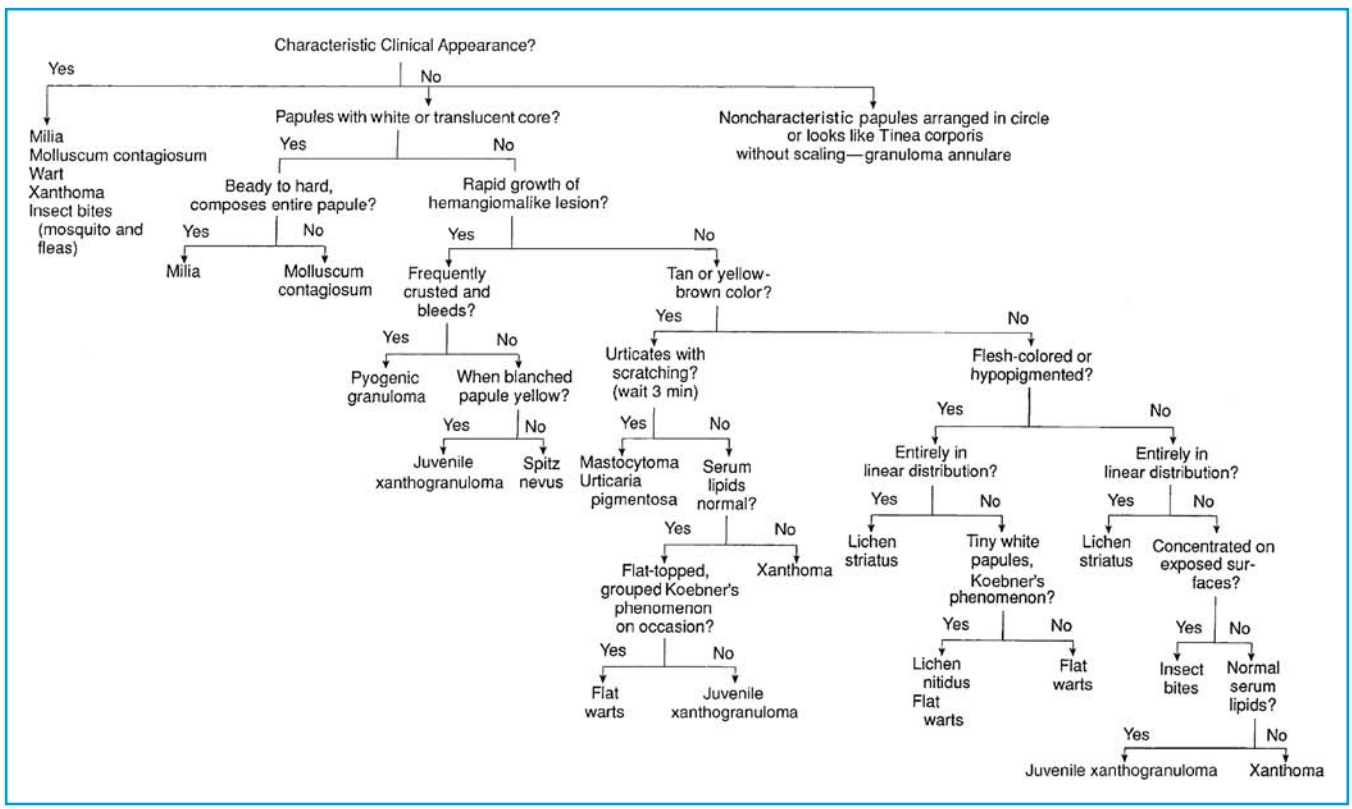

FIGURE 63.1 Approach to the diagnosis of papular lesions.

TABLE 63.2

HYPERLIPIDEMIAS

Type	Age of onset	Clinical presentation	Inheritance
I	Early childhood	Eruptive xanthomas Abdominal pain Hepatosplenomegaly Creamy plasma	AR
IIa	Early childhood	Tendinous xanthomas Xanthelasmas Tuberous xanthomas Corneal arcus	AD
IIb	Early childhood	Same as IIa	AD
III	Adulthood	Palmar xanthomas Tendinous xanthomas Associated diseases: thyroid, renal, liver, diabetes	AR
IV	Adulthood	Obesity and insulin resistance Tuberous xanthomas Eruptive xanthomas	AD
V	Adulthood	Same as IV	AR

AR, autosomal recessive; AD, autosomal dominant.

crusted granular surface of a pyogenic granuloma. The last differentiating point is the common occurrence of bleeding of pyogenic granulomas following minor trauma. Juvenile xanthogranulomas (JXGs) are typically yellow but can be red and appear suddenly. These are firm rather than spongy (like a hemangioma). The characteristic underlying color can often be elicited by using diascopy to blanch the lesion to reveal the yellow color.

Spitz Nevus. Spitz nevi appear suddenly between 2 and 13 years of age. Preferred sites of growth include the cheek (15%) (Fig. 63.2), shoulder, and upper extremities. The lesion has a pink to red surface because of numerous dilated blood vessels. Pressure produces blanching of this pink to red color. The lesions can reach a size of 1.5 cm in diameter but are completely benign. Pigmented Spitz nevi, another variant of Spitz nevi, often appear black in the skin rather than pink-red, and their appearance is often worrisome for malignant melanoma. Because the histologic appearance of these lesions can be confused easily with a malignant melanoma, an experienced histopathologist should interpret the findings. Most clinicians still recommend that Spitz nevi be removed surgically.

Pyogenic Granuloma. For additional information about pyogenic granulomas, see Figure 99.38.

Juvenile Xanthogranuloma. JXGs can be confused with urticaria pigmentosa or xanthomas. Numerous yellow or reddish-brown papules appear on the face (Fig. 63.3) and upper

FIGURE 63.2 Red papule that appeared 2 months ago and grew rapidly to this size (Spitz nevus).

FIGURE 63.3 Blanching erythematous papule on the ala nasi of this child. Biopsy showed this lesion to be a juvenile xanthogranuloma.

trunk in the first year of life. The number of lesions may increase until the child is 18 months to 2 years of age. Serum lipid levels are normal, and the Darier's sign (urtication after scratching—see "Mastocytoma, Urticaria Pigmentosa" section) is negative. The lesions often disappear spontaneously after 2 years of age; therefore, intervention is generally unnecessary. When JXGs are multiple, particularly on the head and neck, evaluation of the eyes for intraocular JXGs is recommended because of their potential for visual impairment. The presence of JXGs in a young child with neurofibromatosis (type 1) has been a marker associated with an increased risk of juvenile myelomonocytic leukemia.

No Hemangioma-like Lesion: Yellow, Tan, or Brown Papule

The yellow, tan, and brown papules include the lesions seen in urticaria pigmentosa (a single, large lesion is called a *mastocytoma*), flat warts, xanthomas, insect bites, and JXGs.

A first step to differentiate the various papules from one another is to scratch them. If hiving of a scratched lesion (Darier's sign) occurs within a short period of time (3 to 5 minutes), the lesion must contain mast cells (i.e., a mastocytoma or urticaria pigmentosa). Make sure to scratch normal skin to rule out the presence of dermographism. The latter condition will produce a false-positive Darier's sign. When no urtication occurs, blood should be drawn to check lipid levels. If lipid levels are normal, the next step is to differentiate two of the entities (i.e., flat warts and JXGs). Flat warts tend to be grouped, are flat topped, and can be autoinoculated in scratch lines (pseudo-Koebner's phenomenon). Lesions characteristic for JXGs are not flat topped, tend to be singular in number (or when multiple are scattered about), and do not demonstrate the Koebner's phenomenon (recapitulation of the eruption in traumatized areas). JXG lesions may also look like xanthomas. Unlike xanthomas, however, abnormal lipid levels do not occur with JXGs.

Mastocytoma, Urticaria Pigmentosa

Parents who bring children with mastocytomas or lesions of urticaria pigmentosa to the physician generally describe a single yellow–tan–brown lesion that was present at or soon after birth (mastocytoma) or multiple pigmented papules that erupt during the first year of life (urticaria pigmentosa). One important clue is a history of these lesions becoming red (Fig. 63.4), hivelike, or blistered. The lesions may ooze and form crusts much like impetigo; however, they do not respond to antibacterial preparations.

Physical examination of the lesion provides the next clue. The surface has a peau d'orange appearance at times. Some papules are often yellow and are easily mistaken for xanthomas. When they are tan to brown, they are believed to be raised moles. The clincher is finding a positive Darier's sign (histamine-induced erythema, swelling, and urtication secondary to scratching and subsequent degranulation of mast cells).

Table 63.3 lists medications and physical stimuli that cause mast cell degranulation and histamine and/or prostaglandin D_2 release. These agents should be avoided.

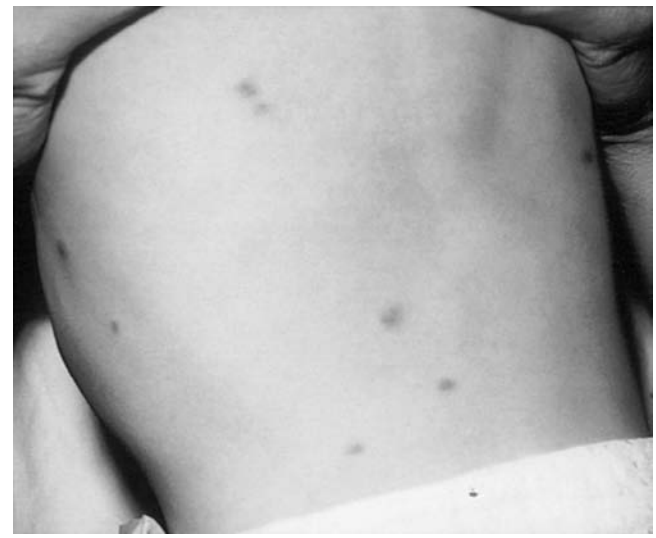

FIGURE 63.4 Erythematous papules representative of urticaria pigmentosa. They will urticate with scratching (Darier's sign).

When large amounts of these mediators are released, generalized flushing, persistent diarrhea, or hypotension may ensue. Children with these symptoms require therapy directed against histamine and prostaglandin D_2. The H_1-receptor antagonists (chlorpheniramine, hydroxyzine, or diphenhydramine) and H_2-receptor antagonists (cimetidine, ranitidine, or famotidine) or occasionally combined H_1- and H_2-receptor antagonists (cyproheptadine or doxepin) may be required. In addition, nonsteroidal antiinflammatory drugs such as indomethacin or ibuprofen may be required to inhibit prostaglandin biosynthesis. Children who suffer from persistent histamine-induced diarrhea may benefit from the addition of oral cromolyn sodium. An epinephrine pen should be provided for patients with systemic disease or extensive symptoms.

Fortunately, with aging, the skin is no longer reactive, and most of the lesions disappear completely.

TABLE 63.3

MEDICATIONS AND PHYSICAL STIMULI TO BE AVOIDED IN PATIENTS WITH URTICARIA PIGMENTOSA

Medications	Physical stimuli
Alcohol	Rubbing of the skin
Aspirin	Extremes of water temperature

Warts and Xanthomas

For additional information about warts and xanthomas, see previous "Warts" and "Xanthomas" sections of this chapter.

LESIONS THAT ARE NOT YELLOW, TAN, OR BROWN: FLESH-COLORED LESIONS

Three entities may present as flesh-colored papules: lichen striatus, lichen nitidus, and flat warts. When the papules are arranged linearly, streaming down an extremity or across the face or neck, lichen striatus should be considered. If the papules are not arranged linearly but are tiny pinpoint, flesh-colored papules, lichen nitidus should be considered, especially if a Koebner's phenomenon is present. Flat warts may be flesh colored.

Lichen Striatus

Lichen striatus is an asymptomatic eruption of unknown cause. The flat-topped papules are arranged linearly and may be confluent. Lesions may occur in a wide band but remain characteristically linear or more accurately curvilinear patterns corresponding to lines of Blaschko. The lesions are flesh colored to erythematous in Caucasians and hypopigmented in African Americans. The eruption follows the long axis of an extremity (Fig. 63.5) or may involve any other part of the skin surface (especially the face). Because the eruption resolves spontaneously within 2 years, no treatment is necessary.

Lichen Nitidus

Lichen nitidus is characterized by tiny, pinpoint, flat-topped, flesh-colored papules (Fig. 63.6). The papules are often grouped and are found in scratch lines (i.e., the Koebner's phenomenon). Although any skin surface may be involved, the trunk and genitalia are common sites. The lesions are often asymptomatic but may occasionally itch. The lesions persist for variable periods and generally do not respond to therapy.

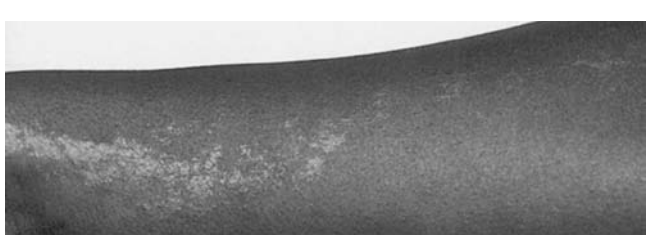

FIGURE 63.5 Hypopigmented papules running linearly along the long axis of the arm in a child with lichen striatus.

FIGURE 63.6 Tiny flesh-colored to hypopigmented papules in a child with lichen nitidus. Note that the papules are arranged linearly (Koebner's phenomenon).

Flat Warts

See section about flat warts in Chapter 85.

NON–FLESH-COLORED LESIONS

Lichen striatus can be composed of hypopigmented or erythematous papules arranged linearly. Red papules not arranged linearly and concentrated on exposed surfaces usually indicate the presence of insect bites. JXGs can be yellow or reddish-brown. They can be hypopigmented and brown-orange in African-American children. Xanthomas may be yellow or yellow-red. As discussed previously, the serum lipid levels are normal in patients with JXG and elevated in children with xanthomas.

NONCHARACTERISTIC PAPULES

Papules Arranged in Circles—Looks Like Tinea Corporis without Any Scaling

Granuloma Annulare

Granuloma annulare is believed to be an idiosyncratic response to trauma. The location of the changes (i.e., the shins, forearms, back of hands, ankles, and dorsum of the feet) seems to confirm this hypothesis. This skin change may begin as a flesh-colored or violaceous papule that clears centrally as the margins advance, or it may appear as a group of papules arranged in a ringlike configuration (Fig. 63.7). The central portion of the lesion is dusky or hyperpigmented. The key point on physical examination is the lack of scaling. This physical finding distinguishes granuloma annulare from tinea corporis and cannot be stressed enough. The border is firm on palpation, unlike tinea corporis. The rings can be 5 cm in diameter or larger.

A potassium hydroxide test would be definitive in ruling out tinea corporis. It would be difficult to obtain scales from a granuloma annulare lesion using this procedure. It is important

FIGURE 63.7 Note erythematous to violaceous papules arranged in a circle in this child with granuloma annulare.

to diagnose this entity correctly because one can reassure parents that three-fourths of lesions clear spontaneously within a 2-year period. Recurrences are common until children outgrow this tendency. Too often, treatment for tinea corporis is instituted unnecessarily for what is really granuloma annulare.

If this algorithm has not helped in making a diagnosis, a consultant should be called. Many entities can be difficult to differentiate. A dermatologist can often resolve the matter, however, with a skin biopsy sent for histologic review.

CHAPTER 64 ■ RASH—PAPULOSQUAMOUS LESIONS

PAUL J. HONIG, MD, LESLIE CASTELO-SOCCIO, MD, PHD, AND ALBERT C. YAN, MD

PAPULOSQUAMOUS ERUPTIONS

Of skin conditions seen in a pediatric dermatology clinic, 10% are papulosquamous (i.e., have a papular and scaling component). The algorithm contained in this chapter should be used as a guide to differentiate these disorders (Table 64.1 and Fig. 64.1). Each key point that distinguishes one disease from another is discussed here.

Presence or Absence of Pruritus

The initial symptom that should be considered is pruritus. Pruritus is absent in the six conditions listed in Table 64.2. Palmar involvement is prominent in secondary syphilis and papulosquamous drug eruptions but is rare in pityriasis rosea. A positive rapid plasma reagin (RPR) test helps differentiate syphilis from pityriasis rosea and a drug eruption. Pityriasis rosea begins with a herald patch, followed by a truncal eruption in a "Christmas or fir tree" distribution. Finally, the Koebner's phenomenon separates lichen nitidus from other entities.

Conditions That Lack Pruritus

Drug Eruption—Papulosquamous

The diagnosis of a drug eruption is based on the history of current or recent intake of a medication and the disappearance of the eruption after discontinuation of the medication. Drug eruptions may manifest in a form that mimics lichen planus, pityriasis rosea, pityriasis rubra pilaris (PRP), psoriasis, seborrheic dermatitis, and syphilis (Table 64.3). The cutaneous manifestations of a drug eruption that resemble one of the previously described disorders, however, will be atypical (e.g., lack of a herald patch and typical truncal distribution in a pityriasis rosea look-alike drug eruption or lack of a violaceous color and feathery white buccal changes in a lichenoid drug eruption). Remember that drug eruptions may or may not itch and may or may not have palmar and plantar involvement.

Lichen Nitidus

Lichen nitidus is a common disorder of children, seen especially in African Americans. There is a 4:1 male:female predominance. Lichen nitidus involves the abdomen, genitalia (shaft and glans), and extremities with tiny, pinpoint, sharply demarcated, flat-topped, flesh-colored papules. Often, these lesions are closely grouped and are linear. Linear grouping of lesions is caused by the Koebner's phenomenon (Table 64.4; appearance of the primary lesion at sites of trauma), which often occurs in lichen nitidus (Fig. 64.2). The lesions generally are nonpruritic. The course is variable, and the cause is unknown. Therapy is not warranted.

Nummular Eczema (Xerosis)

For more information about nummular eczema, see Chapter 85.

Parapsoriasis

Parapsoriasis is an uncommon pediatric skin condition. When it occurs, however, the course is chronic and, on rare occasions, may progress to cutaneous lymphoma. The appearance of this eruption is easily mistaken for nummular eczema, psoriasis, tinea corporis, or a lichenoid change. Small oval scaling, erythematous (Fig. 64.3) to yellow-brown macules are concentrated on the trunk. The skin lesions are asymptomatic, and the patient feels healthy.

Treatment is unnecessary because the disease is asymptomatic. Topical steroids may be helpful but may not entirely clear the skin changes. The eruption clears spontaneously after varying periods.

Pityriasis Rosea

For more information about pityriasis rosea, see Chapter 85.

Secondary Syphilis

The secondary phase of syphilis is a great mimicker. Therefore, one must suspect this condition to make the correct diagnosis. The eruption may be localized to the trunk, palms, and soles, as well as to any other skin surface. Other clues should be sought by history and physical examination (a primary chancre, condyloma lata, or white mucous patches on the tongue, buccal, and labial surfaces). Generalized lymphadenopathy is usually present. It may be difficult to differentiate secondary syphilis and pityriasis rosea; however, Table 85.11 (see Chapter 85) may be helpful in separating the two entities clinically.

A positive RPR or fluorescent treponemal antibody makes the diagnosis. Remember, a false-negative RPR can occur with antibody excess (the prozone phenomenon). Therefore, dilution of the specimen by the laboratory should be requested if the presence of syphilis is highly suspected. This simple maneuver will result in a positive test for the presence of syphilis.

Color of the Skin Eruption and Pruritus

The eye can discern subtle differences in color. A pruritic papulosquamous eruption that does not look erythematous should suggest one of four disorders. First, a violaceous (bluish-red) or purple appearance generally indicates lichen planus or a lichenoid drug eruption. However, tones of yellow or salmon

TABLE 64.1

PAPULOSQUAMOUS SKIN DISORDERS

Lichen nitidus	Pityriasis rosea
Nummular eczema	Secondary syphilis

(orange-red) suggest the presence of seborrheic dermatitis or an unusual disorder called PRP. The latter two diseases can be differentiated by looking for yellow thickening of the palms and soles (i.e., in PRP) or knowing that seborrheic dermatitis classically occurs before 12 months of age or after puberty. Lichen nitidus is obvious when tiny, discrete, flesh-colored papules (white papules in African Americans) are found, with some arranged linearly (Koebner's phenomenon).

Violaceous or Yellow- or Salmon-colored (Orange-red) Eruptions or Flesh-colored (Nonerythematous) Eruptions

Lichen Planus

Lichen planus is seen occasionally in pediatric patients as a chronic, pruritic, reddish-blue (violaceous) to purplish eruption. Two percent to 3% of cases occur in patients younger than 20 years of age.

The eruption generally involves the flexors of the wrist, forearms, and legs, especially the dorsum of the foot and ankles. The highly pruritic lesions appear as small, violaceous, shiny, flat-topped, polygonal papules (Fig. 64.4). These qualities may be recalled with the alliterative mnemonic of the five

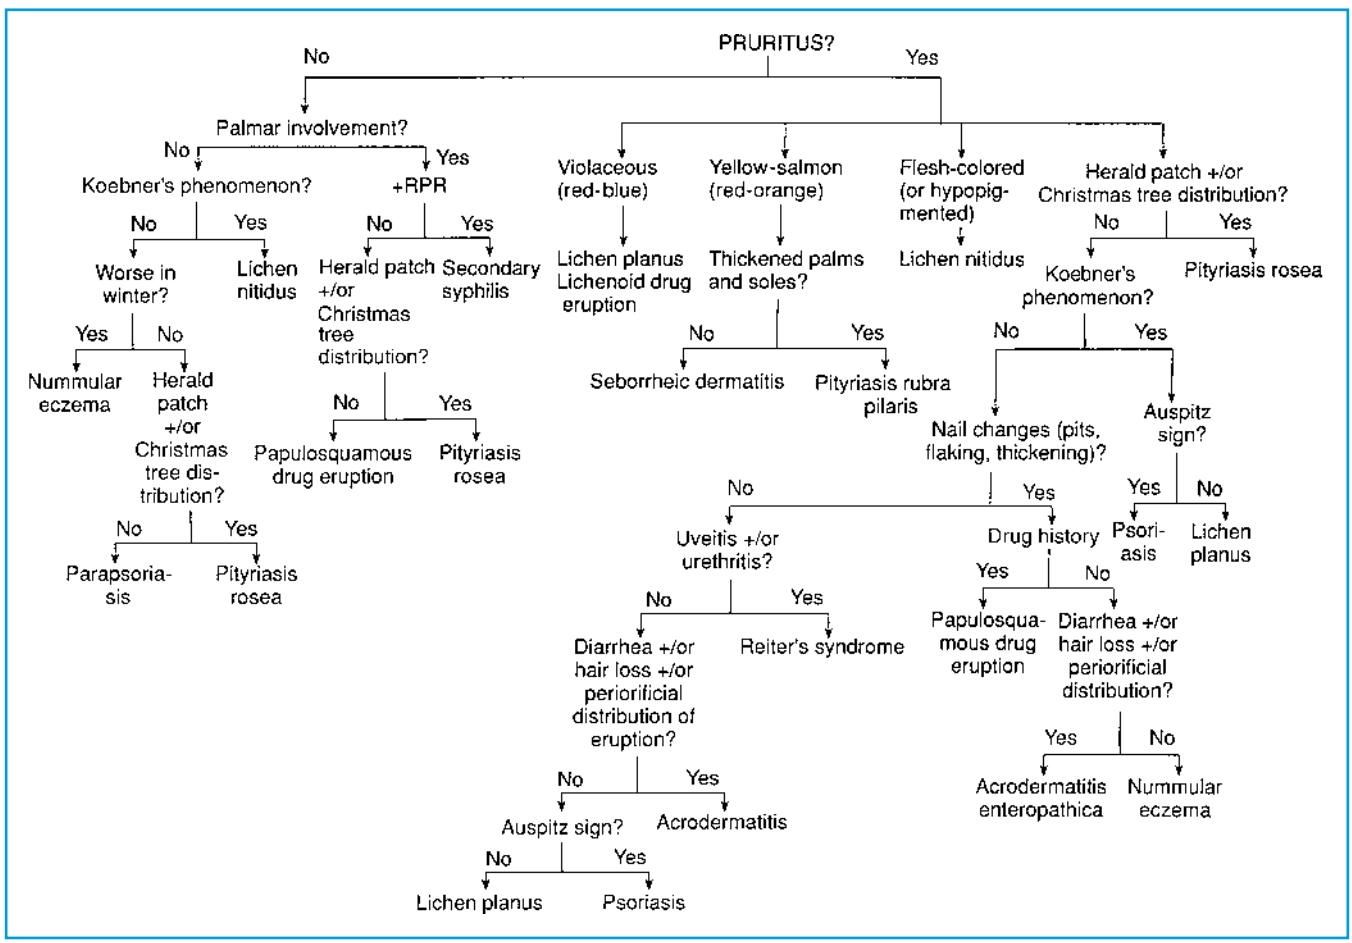

FIGURE 64.1 Algorithm to distinguish papulosquamous lesions. RPR, rapid plasma reagin test.

TABLE 64.3

DRUG ERUPTIONS THAT MAY MIMIC OR INDUCE VARIOUS PAPULOSQUAMOUS LESIONS

Lichen Planus

β-Blockers
Lithium
? Nonsteroidal antiinflammatory drugs

*p*s: *p*ruritic, *p*urplish, *p*lanar, *p*olygonal *p*apules. Some add a sixth p indicating a predilection for so-called "private" areas such as penis or vulva. The surface of these papules may have white cross-hatching, called Wickham's striae. Lesions may occur in sites of trauma or injury (Koebner's phenomenon). The scalp may be involved, often resulting in a scarring alopecia, called lichen planopilaris and can result in pseudopelade. It is important to examine the buccal mucous membranes and the genital areas for a reticulated or lacelike pattern of white papules or streaks. This finding is characteristic for lichen planus. The nails are often pitted, dystrophic, or ridged (pterygium nails). The lesions in lichen planus can be vesicular or bullous. Hypertrophic and linear lesions occur but are less common. Persistent, severe, postinflammatory hyperpigmentation is common in African Americans. In two-thirds of patients, the lesions clear within 8 to 15 months. The cause of the disorder is unknown. Topical therapy with steroids can be helpful, and treatment with oral steroids may be necessary for extremely symptomatic patients. For chronic cases, ultraviolet light phototherapy can be an effective adjunct to therapy.

Seborrheic Dermatitis

For more information about seborrheic dermatitis, see Chapter 85.

TABLE 64.4

CONDITIONS THAT FEATURE KOEBNER'S PHENOMENON

Lichen nitidus
Lichen planus
Psoriasis

Pityriasis Rubra Pilaris

PRP is characterized by follicular papules and yellow-orange skin that surrounds islands of normal skin. Of patients with PRP, 30% are children.

The onset of the disease is gradual, beginning in the scalp and spreading to involve the face and ears. Acuminate follicular papules with keratotic plugs occur on the back of the fingers, side of the neck, and extensors of the extremities. The skin is generally salmon-colored and scaly. As the eruption progresses, it surrounds islands of normal skin. Yellow thickening of the palms and soles is characteristic (Fig. 64.5). In contrast to psoriasis, nail pitting is rarely ever observed in PRP. Three subtypes have been described: The familial form has its onset in infancy and childhood, a localized type is found in

FIGURE 64.2 Note flesh-colored papules in this African-American patient with lichen nitidus. The Koebner's phenomenon also is seen (papules arranged linearly in a scratch).

FIGURE 64.3 Red, scaling lesions on arm of child with parapsoriasis.

FIGURE 64.5 Hyperkeratosis of palms and islands of normal skin seen in this child with pityriasis rubra pilaris.

60% of cases, and the acquired form occurs in persons older than 15 years. The cause of this disease is unknown, although it is a disorder of keratinization. The condition responds to vitamin A and its derivatives.

Differentiating the Pruritic, Red Papulosquamous Lesions

Pityriasis rosea also should be included in this part of the algorithm. Because the rash of pityriasis rosea may or may not itch, the first differentiating point is to inquire about a history of a herald patch and look for the characteristic Christmas tree distribution (along lines of skin cleavage known as Langer's lines). If one or both is present, a diagnosis of pityriasis rosea is made. If not, one must look for the Koebner's phenomenon. The Koebner's phenomenon is defined as the appearance of the existing rash in areas of traumatized skin (e.g., in scratches, abrasions, blistered sunburns). This phenomenon is discussed further in the "Psoriasis" section of this chapter.

Another clue to the presence of psoriasis is the finding of abnormal nails (e.g., nail pits, flaking, thickened nails). Reactive arthritis (formerly known as Reiter's syndrome) and acrodermatitis enteropathica may also manifest nail abnormalities. These entities can be differentiated from one another by a history or finding of uveitis and/or urethritis (reactive arthritis) or diarrhea and/or hair loss (acrodermatitis enteropathica).

FIGURE 64.4 Note child with red-blue color of flat-topped papules representative of lichen planus.

Psoriasis

Psoriasis is a chronic papulosquamous disease that makes up 4% of all skin disorders encountered in children. The female:male ratio is 2:1. There is a predisposition for involvement of the scalp, perineum (particularly in infants), and the extensor surfaces of the body, particularly the elbows and knees.

One-third of adults with psoriasis experience onset of disease in childhood or adolescence. Psoriasis occurs in 12% of children before the age of 10 years. The major human leukocyte histocompatibility antigens (HLAs) are important genetic markers of psoriasis. Of these, HLA-B13, HLA-BW17 and HLA-CW6 are associated with early onset of disease. The HLA-B13 and HLA-CW6 antigens are associated with a history of antecedent streptococcal infections. The HLA-BW17 antigen is more commonly identified with extensive skin involvement and a strong familial history.

Psoriasis occurs in three forms during childhood: guttate, erythrodermic, and pustular. Any or all of these types may develop with silvery scales into the chronic, plaque-type psoriasis (Fig. 64.6). When a scale is removed, pinpoint areas of bleeding occur on the surface (Auspitz sign). Guttate psoriasis is the most common form, occurring in childhood. Guttate or droplike erythematous papules are scattered over the body. The characteristic silvery scale is only minimally expressed, and the lesions may appear quite red. This form is often preceded by a streptococcal infection. Infants often have involvement in the diaper area as well. Erythrodermic psoriasis is less common and more severe. Onset may be abrupt or gradual, with a diffuse erythema and severe desquamation. In the

FIGURE 64.6 Plaque-type psoriasis in this infant. Note scaling in scalp.

growing child, there may be associated failure to thrive. Pustular psoriasis is rare and the least commonly occurring form of psoriasis seen in children and may begin in intertriginous areas. Various size sterile and superficial pustules develop on an erythrodermic background. Avoidance of systemic steroids may be prudent in patients with psoriasis because withdrawal of systemic steroids can precipitate pustular flares of the disease.

Characteristically small, pitted lesions are seen on the nails in 25% to 50% of patients in all forms of the condition. Eighty percent of children have scalp involvement, especially at the hair margins. A small number of patients develop arthritis between 9 and 12 years of age; some develop it before the onset of the skin eruption. The distal interphalangeal joints of the hands and feet are involved most often. Therapy with topical agents, including steroids, tar derivatives, vitamin A (tazarotene) and D (calcipotriene) derivatives, emollients, and ultraviolet light, help slow the turnover rate of the epidermis. For severe cases, patients may be treated with systemic immunomodulating agents, including methotrexate, cyclosporine, acitretin, and recently approved biological modifiers that address specific targets in T-cell physiology.

Reactive Arthritis

The skin changes seen in reactive arthritis look much like those in psoriasis. A symmetric arthritis of major joints, uveitis, and urethritis complete the syndrome. Although most cases occur in young adult men, on occasion, the syndrome will be seen in adolescents. Only ten cases have been reported in children younger than 12 years of age. Ninety percent of patients are HLA-B27 positive. A postinfectious cause has been hypothesized.

The palms and soles are the major sites of involvement. Yellow, scaly, hyperkeratotic lesions appear on an erythematous base in those locations. The skin lesions may begin as macules, vesicles, or pustules. The palmar plantar changes have been called *keratoderma blennorrhagicum*. The scalp and penis also are characteristically involved with psoriasiform lesions. Erythema and superficial ulcerations may be present in the mouth. Abnormalities of the nails (e.g., dystrophy, onycholysis) are common. (See the "Reactive Arthritis" section for therapy recommendations.)

TABLE 64.5

ACRODERMATITIS ENTEROPATHICA

Differential Diagnosis	
Mucocutaneous candidiasis	Histiocytosis X
Biotin deficiency	Multiple carboxylase deficiency
Cystic fibrosis	Psoriasis
Essential fatty acid deficiency	Seborrheic dermatitis
Glucagonoma syndrome	Anorexia nervosa
Ornithine transcarbamylase deficiency	Chronic bullous dermatosis of childhood

Acrodermatitis Enteropathica

Acrodermatitis enteropathica is characterized by skin rash, diarrhea, and alopecia. The condition is caused by zinc deficiency, with plasma zinc levels less than 50 *mc*g per dL. This may result from low zinc intake, increased zinc losses from malabsorption, and an autosomal recessive genetic defect in the ability to absorb zinc via zinc transporters in the gastrointestinal tract. The disease generally begins around 9 months of age (1 week to 20 months). Rarely, older children develop this condition as a result of inflammatory bowel disease, cystic fibrosis, inborn errors of metabolism, and anorexia nervosa.

The infant usually presents with a psoriasiform diaper eruption, followed by similar involvement of periorificial (eyes, ears, nose, and mouth) and acral skin. The skin is often eroded and crusted but involved areas often are sharply demarcated. These changes may be confused with a severe candida infection (Table 64.5) or impetigo. Because of involvement of the digits and periungual tissues, paronychia and nail dystrophies are often present. Hair is lost from the scalp, brows, and lashes. The children are irritable, photophobic, and apathetic. Growth retardation is common. Rapid growth and correction of zinc deficiency occurs with zinc sulfate or gluconate 0.5 to 1 mg per kg of elemental zinc per day (often given in divided doses to improve gastrointestinal tolerability), and the dose titrated depending on the response to therapy.

If this algorithm does not lead to a clear diagnosis, many of the entities can be clarified with a skin biopsy or referral to a dermatologist.

CHAPTER 65 ■ RASH—PETECHIAE AND PURPURA

REBECCA L. VIEIRA, MD

Petechiae and purpura refer to blood within the skin or mucosal membranes. Because of their common underlying pathophysiology and overlapping differential diagnoses, petechiae and purpura are often considered together. Purpura, from the Latin *purpura*, meaning "purple" describes lesions between 0.3 and 1 cm in size. Lesions less than 0.3 cm are referred to as petechiae and are usually bright red. The term ecchymoses includes lesions greater than 1 cm. Petechial, purpuric and ecchymotic lesions do not blanch, a characteristic that distinguishes them from vascular dilation and vascular anomalies. Parents and patients often describe petechiae and purpura simply as "rash." However, the finding of petechiae, purpura, or unexplained ecchymoses by a physician should raise concern, as they may be the presenting signs of many diseases, some benign and others life-threatening, some treated easily and others requiring complex therapy.

Patients presenting critically ill with petechiae or purpura will obviously require immediate evaluation and intervention. However, even in well-appearing children these findings could be the first signs of potentially life-threatening conditions. The etiology of petechiae and purpura should be established as rapidly as possible, as in many conditions early treatment will lead to a more favorable outcome. An understanding of the pathophysiology, a careful history and physical examination, and an appropriate laboratory evaluation will often help establish the diagnosis. This chapter presents the initial assessment and differential diagnosis of children with petechiae, purpura, and ecchymoses. The management of emergency situations associated with these symptoms is discussed in Chapter 91.

PATHOPHYSIOLOGY

Normal hemostatis involves complex interactions between the vasculature, platelets, and soluble clotting factors. Defects or deficiencies in any of these components can lead to abnormal bleeding resulting in petechiae, purpura, and ecchymoses. Normally, when a blood vessel is injured, vasoconstriction and retraction occur immediately and decrease blood flow to the affected area. Facilitated by von Willebrand factor, platelets adhere to the subendothelium of the damaged wall and, in response to the exposed subendothelial collagen, release adenosine diphosphate. This reaction causes platelet aggregation at the site of the injury and the formation of a platelet plug that is responsible for primary hemostasis. Acquired and congenital conditions that disrupt normal collagen synthesis or decrease vascular integrity affect this early stage of hemostatis. Alternatively, a decrease in the number of circulating platelets or an alteration in platelet metabolism and aggregation can also prevent normal primary hemostasis and can result in pathologic bleeding.

Normally, primary hemostasis is followed by the formation of a fibrin clot (secondary hemostasis) through the activation of the coagulation cascade. There are two main pathways of the coagulation cascade (Fig. 65.1). The intrinsic pathway is activated by the exposed collagen of a damaged vessel. This initiates a sequence of enzymatic reactions, beginning with the binding of factor XII to the exposed subendothelium. The extrinsic pathway is activated by tissue thromboplastin. Both pathways ultimately trigger the common pathway, resulting in the formation of a fibrin clot at the site of the injury. Factors XII, XI, IX, and VIII are involved exclusively in the intrinsic pathway, whereas factor VII is involved solely in the extrinsic pathway. Factors X, V, II (prothrombin), and I (fibrinogen) contribute to both pathways. As is the case with primary hemostasis, alterations in secondary hemostasis may result from intrinsic abnormalities of the clotting factors or from abnormalities related to systemic diseases.

Disruption of any aspect of normal hemostasis may result in abnormal bleeding leading to petechiae, purpura or ecchymoses. A basic understanding of normal hemostasis enables the physician to categorize petechial and purpuric disorders into the following categories: loss of vascular integrity, platelet disorders, and coagulation deficiencies. In general, patients with vasculitic disorders present with palpable purpura, patients with platelet disorders present with petechiae and abnormal mucosal bleeding, and patients with coagulation disorders are prone to ecchymoses and hemarthrosis.

DIFFERENTIAL DIAGNOSIS

Petechiae and purpura may result from loss of vascular integrity, thrombocytopenia, disorders of platelet function, or deficiencies of clotting factors. The most common causes of petechiae and purpura include trauma, infections, Henoch-Schönlein purpura (HSP), and idiopathic (or immune) thrombocytopenic purpura (ITP) (Table 65.1). Infections can affect normal hemostasis at many different stages in the process and are thus discussed separately.

Infection

Petechiae and purpura can be the initial manifestation of numerous infectious processes. Infection can disrupt normal hemostasis by several mechanisms. Even minor infections can cause significant thrombocytopenia from decreased platelet production or antiplatelet antibody formation, while severe

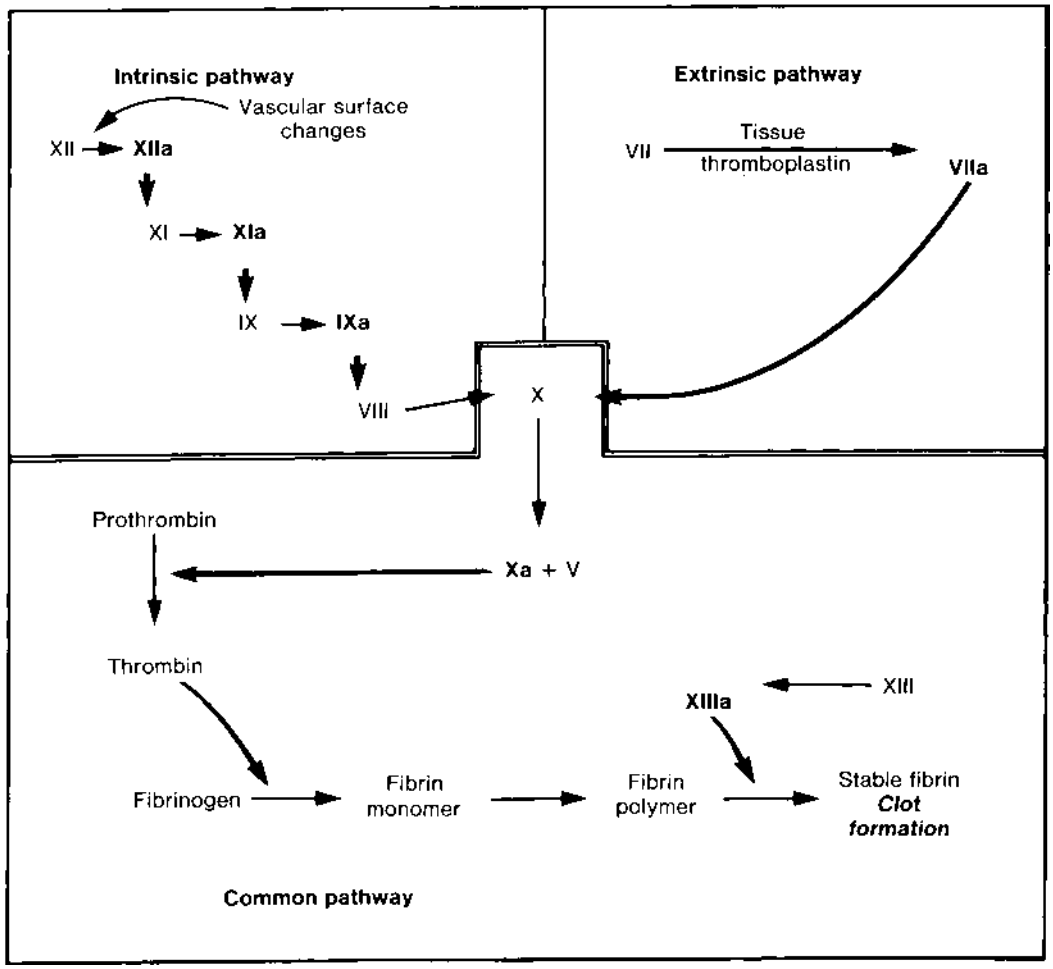

FIGURE 65.1 A simplified version of the coagulation cascade. An abnormality in the extrinsic pathway results in a prolonged prothrombin time (PT). An abnormality in the intrinsic pathway results in a prolonged partial thromboplastin time (PTT). An abnormality in the common pathway results in prolongation of both the PT and the PTT.

infections and sepsis can lead to disseminated intravascular coagulation (DIC, discussed later in this chapter). Vascular integrity can be disrupted by the infecting agent or by the body's reaction to the agent. Capillary damage that results in petechiae or purpura sometimes occurs with the common viral exanthems. In addition, the child with infectious mononucleosis, bacterial endocarditis, rickettsial infection, or a streptococcal infection can present with petechiae in the absence of coagulation or platelet abnormalities. Rocky Mountain spotted fever should be strongly considered when a patient from an endemic area presents with a petechial rash, especially when it involves the hands and feet, when there is a history of tick exposure, and when the symptoms occur between the months of April and October.

TABLE 65.1

COMMON CHILDHOOD CAUSES OF PETECHIAE AND PURPURA

Disruption of Vascular Integrity
Trauma
Viral infections
Henoch-Schönlein purpura
Rickettsial infection
Platelet Deficiency or Function Disorders
Idiopathic (immune) thrombocytopenic purpura
Sepsis
Drug-associated disorders
Factor Deficiencies
Hemophilia

The most serious infection that can cause petechiae and purpura is meningococcemia, and this disorder should be considered in all febrile and ill-appearing children with petechial or purpuric lesions. The rapidity with which meningococcemia can progress warrants the institution of antibiotic therapy in any moderately ill child with petechiae or purpura until results of cultures are available. Purpura fulminans is a particularly severe hemorrhagic condition that is caused in part by loss of vascular integrity in association with DIC. It is characterized by the sudden onset of large ecchymoses and the rapid development of gangrene of the extremities. Purpura fulminans may accompany meningococcemia as well as other forms of bacterial sepsis, scarlet fever, varicella, and rubeola.

Petechiae or purpura of the newborn in association with jaundice, microcephaly, and/or hepatosplenomegaly should raise the suspicion for a congenital TORCH (toxoplasmosis, syphilis, rubella, CMV, herpes, or HIV) infection.

Loss of Vascular Integrity

Petechiae and purpura can be caused by numerous disorders that disrupt vascular integrity (Table 65.2). The most common cause of loss of vascular integrity is trauma, resulting in local ecchymoses at the injured site. In a child with normal hemostatic function, ecchymoses should be limited to areas that are often bumped during normal play, such as the shins and forehead. The finding of significant ecchymoses in a child without a history that explains the pattern of injury or in an infant who cannot yet crawl should raise the concern for child abuse. That being said, children with disorders of hemostasis can develop significant bruising after minor trauma.

Numerous drugs and toxins can cause petechiae and purpura as a result of increased capillary fragility or vasculitis. Drugs that have been implicated include the sulfonamides, iodides, belladonna, bismuth, mercurial compounds, the penicillins, and chloral hydrate. Corticosteroid treatment can cause benign purpura, especially striated purpuric lesions just above the buttocks. The lesions often resolve with discontinuation of corticosteroid therapy. The appearance of these lesions in a child not taking corticosteroids should raise the suspicion for endogenous corticosteroid production, as in Cushing's disease. Vitamin C deficiency (scurvy) can also present with findings ranging from scattered petechiae to substantial ecchymoses, particularly on the lower extremities. Scurvy is rare in the United States but can be seen in patients who receive hyperalimentation with inadequate vitamin C supplementation or in patients with iron overload. The lesions of scurvy heal rapidly after the administration of vitamin C.

Purpura that results from an IgA-mediated, small vessel vasculitis may be the presenting sign of HSP. The classic constellation of symptoms associated with HSP includes palpable purpura of the buttocks, lower back, and lower extremities, arthritis, GI complaints, and renal disease. The purpuric lesions are often accompanied by pink or brownish-pink macules or maculopapules that may later develop central areas of hemorrhage. The platelet count, prothrombin time (PT), and partial thromboplastin time (PTT) are normal in uncomplicated HSP, distinguishing it from many other more serious causes of purpura.

Rare disorders of childhood that may be associated with purpura from loss of vascular integrity include Langerhans cell histiocytosis and Ehlers-Danlos syndrome. Langerhans cell histiocytosis is a histiocytic disorder characterized by brown, crusted vesiculopapular skin lesions that often are purpuric. Petechiae may also be present. Ehlers-Danlos syndrome is an unusual defect in collagen synthesis resulting in decreased vascular integrity. Complications can range from capillary hemorrhage to rupture of major blood vessels.

Petechiae can develop in otherwise healthy children after forceful coughing or retching as a result of increased venous back pressure. In such cases petechiae should be limited to head and neck areas.

TABLE 65.2

CAUSES OF CHILDHOOD PETECHIAE AND PURPURA SECONDARY TO DISRUPTION OF VASCULAR INTEGRITY

Trauma: accidental, child abuse[a]
Infection: viral exanthems, infectious mononucleosis, bacterial endocarditis,[a] rickettsial disease,[a] streptococcal infection
Drugs and toxins[a]
Henoch-Schönlein purpura
Vitamin C deficiency
Langerhans cell histiocytosis
Ehlers-Danlos syndrome
Miscellaneous: acute glomerulonephritis, rheumatic fever, collagen vascular diseases

[a]Conditions that may be life-threatening.

Platelet Disorders

Thrombocytopenia

Thrombocytopenia in childhood may result from decreased platelet production, shortened platelet survival, or platelet sequestration (Table 65.3). Certain illnesses and drugs can cause thrombocytopenia by more than one mechanism. Consequently, detailed investigation may be required to determine the mechanism of thrombocytopenia and the appropriate treatment.

Increased Platelet Destruction

An important cause of thrombocytopenia in childhood is ITP. The thrombocytopenia in ITP results from antibody-mediated destruction of platelets. Although ITP occurs in children of all ages, most cases are seen between the ages of 2 and 6 years. ITP is usually characterized by the acute onset of petechiae and ecchymoses, although symptoms occasionally occur more gradually. Epistaxis occurs in 10% to 20% of cases. Patients with ITP may have a history of a mild viral illness in the preceding 1 to 6 weeks. Associated disorders include infectious mononucleosis, cytomegalovirus (CMV) infection, rubeola, mumps, varicella, and HIV. ITP has also been observed following immunization to rubeola and rubella. In older children, ITP may be the first manifestation of a systemic immunologic disorder such as systemic lupus erythematosus.

The physical examination of the child with ITP reveals few abnormalities other than petechiae, purpura and/or ecchymoses. Enlargement of the spleen occurs rarely. The platelet count is usually less than 20,000 per mm^3. In the absence of prolonged bleeding or antibodies to other hematologic elements, the hemoglobin concentration and white blood cell (WBC) count are normal. A bone marrow aspirate is sometimes performed, because rarely the clinical presentation of aplastic anemia or acute leukemia can be indistinguishable from ITP. A bone marrow aspirate is particularly important if treatment with corticosteroids is contemplated because this therapy may obscure the diagnosis of acute leukemia, thereby delaying appropriate therapy. More than 80% of pediatric patients with ITP recover spontaneously in a matter of weeks to months.

TABLE 65.3

CAUSES OF CHILDHOOD PETECHIAE AND PURPURA SECONDARY TO PLATELET AND COAGULATION ABNORMALITIES

Platelet Disorders
Thrombocytopenia
- Decreased platelet survival
  - Immune mediated
    - Idiopathic (immune) thrombocytopenic purpura[a]
    - Collagen vascular diseases[a]
    - Drug induced[a]
    - Sepsis[a]
  - Disseminated intravascular coagulation[a]
  - Hemolytic uremic syndrome[a]
  - Thrombotic thrombocytopenic purpura[a]
  - Wiskott-Aldrich syndrome[a]
- Decreased platelet production
  - Malignancies (leukemia, neuroblastoma)[a]
  - Sepsis: viral and bacterial[a]
  - Drugs (bone marrow suppression)[a]
  - Aplastic anemia, thrombocytopenia and absent radii (TAR) syndrome, Fanconi anemia[a]
  - Megaloblastic anemias
- Platelet sequestration
  - Congestive splenomegaly
  - Large hemangiomas (Kasabach-Merritt syndrome)
  - Glycogen storage diseases
- Disorders of platelet function
  - Congenital
  - Glanzmann thrombasthenia[a]
  - Bernard-Soulier syndrome
- Acquired (drug induced): aspirin, antihistamines, phenothiazines, guaifenesin

Factor Deficiencies
Congenital: Deficiencies or alterations of every coagulation factor have been reported. Von Willebrand disease, factor VIII deficiency (hemophilia A), and factor IX deficiency (hemophilia B) are most common.[a]
Acquired: Disseminated intravascular coagulation, vitamin K deficiency, warfarin therapy, liver disease, renal disease, congenital heart disease, circulating anticoagulants[a]

[a]Conditions that are known to present with acute, life-threatening bleeding or are associated with other serious abnormalities.

The association of immune-mediated thrombocytopenia with autoimmune hemolytic anemia or neutropenia is called Evans syndrome. Unlike ITP, patients with Evans syndrome are likely to have a chronic relapsing course.

In neonates, isoimmune thrombocytopenic purpura results from maternal antibodies crossing the placenta, leading to the destruction of fetal platelets. In autoimmune thrombocytopenia both fetal and maternal platelets are destroyed by circulating maternal antibodies.

Microangiopathic disorders, such as DIC (discussed later), hemolytic uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP), cause platelet destruction and consumption resulting in thrombocytopenia and purpura. HUS is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and acute renal injury. Patient with HUS classically present with pallor, petechiae, or purpura, and signs of renal failure, usually following a prodrome of abdominal pain and diarrhea. Toxin-producing organisms, such as *Escherichia coli* 0157:H7, cause endothelial damage that activates localized clotting, leading to platelet aggregation and consumption. TTP resembles HUS but occurs more commonly in adults than in children. Neurologic findings are usually more prominent in TTP, while renal failure is more commonly associated with HUS.

Infants with Wiskott-Aldrich syndrome, an X-linked recessive immunodeficiency disorder, may develop thrombocytopenic purpura beginning in the newborn period. An intrinsic platelet abnormality results in both shortened platelet survival and abnormal platelet function in patients with this disease.

Numerous drugs have been reported to cause thrombocytopenia by the formation of platelet antibodies with resultant increased platelet destruction. The drugs causing immune-mediated thrombocytopenia that are most commonly used in children include sulfa compounds (including trimethoprim-sulfamethoxazole), valproic acid, and phenytoin.

Decreased Platelet Production

Diseases associated with bone marrow abnormalities may present with thrombocytopenia, petechiae, and purpura. Most notable in this group are the leukemias and metastatic neuroblastoma. Decreased platelet production may also result from abnormal development of the hematopoietic stem cell, as is the case with aplastic anemia, Fanconi anemia, thrombocytopenia and absent radii (TAR) syndrome, and some megaloblastic anemias. Although pancytopenia is often present at the time of diagnosis of bone marrow disorders, thrombocytopenia may precede notable alterations in other cell lines in the peripheral blood.

Numerous drugs have been associated with thrombocytopenia due to decreased platelet production. Any drug capable of causing general bone marrow suppression can produce thrombocytopenia (e.g., carbamazepine, chloramphenicol). Valproic acid causes dose-related suppression of platelet production in addition to sporadic, immune-mediated platelet destruction.

The circulating platelets in disorders of platelet production are usually older and metabolically less active than those found in most diseases of shortened platelet survival. Consequently, spontaneous petechiae and purpura often appear at platelet counts of 25,000 to 40,000 per mm^3 in leukemia or aplastic anemia but are unusual in ITP unless the platelet count is less than 20,000 per mm^3.

Platelet Sequestration

Splenomegaly from numerous causes (e.g., portal hypertension, glycogen storage diseases) can result in the sequestration of platelets and thrombocytopenia. In patients with these disorders, the spleen is markedly enlarged and very firm. Petechiae and purpura resulting from platelet sequestration alone are rare because the platelet count usually does not fall below 40,000 per mm^3. Bleeding may occur, however, when the platelet sequestration is associated with liver disease and clotting abnormalities.

In Kasabach-Merritt syndrome thrombocytopenia results from the sequestration and consumption of platelets in large hemangiomas, sometimes leading to life-threatening hemorrhage.

Disorders of Platelet Function

A clinical picture similar to that seen with thrombocytopenia can occur with a normal platelet count in the presence of a qualitative or functional platelet abnormality. These disorders can be congenital or acquired. When congenital, they may present in infancy with petechiae or ecchymoses or with prolonged oozing after circumcision or venipuncture. Glanzmann thrombasthenia is an autosomal-recessive disorder in which the platelet count is normal, but the platelet glycoprotein IIb/IIIa complex is either deficient or dysfunctional. In patients with Glanzmann thrombasthenia, bleeding time is prolonged and platelet aggregation and adhesion are absent. In Bernard-Soulier syndrome, the glycoprotein Ib/IX/V complex on the platelet surface is absent or abnormal, resulting in defective platelet adhesion and prolonged bleeding time. The combination of mild thrombocytopenia and abnormally large platelet is common in Bernard-Soulier syndrome.

Aspirin is the best known of the drugs that cause platelet dysfunction. A single dose of aspirin can irreversibly alter platelet function by blocking the normal pathway of thromboxane-induced platelet aggregation. Nonsteroidal antiinflammatory drugs have a similar mechanism of action, but the effects are reversible and the disruption of platelet function is less pronounced. Platelet dysfunction has also been associated with antihistamines, phenothiazines, valproic acid, and guaifenesin. In the absence of thrombocytopenia or other underlying bleeding disorders, these drugs cause few, if any, clinical problems.

Both uremia and liver disease can affect normal coagulation in many different ways, including acquired platelet dysfunction, which can lead to petechiae, purpura, and abnormal bleeding in these patients.

Factor Deficiencies

Purpura and ecchymoses can be the presenting signs of congenital or acquired deficiencies of coagulation factors. The most common congenital deficiencies are von Willebrand disease, hemophilia A (factor VIII deficiency), and hemophilia B (factor IX deficiency, Christmas disease).

Congenital Deficiencies

Children with hemophilia are often detected when they develop purpura or ecchymoses either spontaneously or after mild trauma. The diagnosis of hemophilia should also be entertained in newborns who develop excessive bleeding after circumcision and in infants with prolonged bleeding from lacerations of the mouth. Prompt recognition of the disorder at this early age allows for careful surveillance, appropriate treatment, and early genetic counseling for parents.

Although hemophilia A and B have an X-linked recessive mode of inheritance, the de novo appearance of coagulopathy is not uncommon, particularly in children with severe hemophilia A (factor VIII activity less than 1%). Therefore, a family history of affected males may be helpful in establishing the diagnosis of hemophilia, but the absence of such a history does not eliminate this diagnostic possibility. Coagulation tests in children with hemophilia A and B reveal a prolonged PTT and normal PT. The bleeding time is usually normal. Specific factor assays will define the particular abnormality. The diagnosis of factor IX deficiency is complicated in young infants because the low factor IX levels found in normal infants during the first few days of life may overlap with the factor IX levels found in mild hemophilia B.

Less common congenital factor deficiencies in children include fibrinogen, prothrombin, and factors V, VII, X, XI, and XIII. As in hemophilia, specific factor assays will identify the particular abnormality. Alterations in fibrinogen function (dysfibrinogenemias) are also associated with purpura. Fibrinogen levels determined by clotting assay are usually moderately reduced in dysfibrinogenemias.

Von Willebrand disease is a family of bleeding disorders caused by a deficiency or defect in von Willebrand factor. Von Willebrand factor is required for platelet adhesion during primary hemostasis and serves as a carrying protein for factor VIII, thus also affecting secondary hemostasis. The severity of this autosomal dominant disorder is extremely variable among affected persons. Although some patients may have spontaneous purpura and ecchymoses, others remain asymptomatic and are discovered only after the diagnosis of von Willebrand disease in a close relative leads to laboratory investigation of other family members. Occasionally, von Willebrand disease is uncovered when an acquired alteration of hemostasis is superimposed on the inherited abnormality. For example, bruising occurs very easily after aspirin ingestion in many patients with von Willebrand disease. As in other disorders that affect platelet function, bleeding from mucosal surfaces (epistaxis, menorrhagia) is prominent in von Willebrand disease. The laboratory abnormalities in von Willebrand disease are variable and may fluctuate from week to week in the same patient. In its classic form, the disease is characterized by prolongation of the bleeding time, increased PTT, decreased levels of factor VIII coagulant activity and von Willebrand factor antigen, and diminished aggregation of normal platelets when ristocetin is added to the patient's plasma (von Willebrand or ristocetin cofactor activity). In practice, however, only one or two of the laboratory abnormalities may be found and several tests may be required to confirm the diagnosis of von Willebrand disease.

Acquired Deficiencies

Causes of acquired deficiencies of clotting factors include DIC, liver disease, vitamin K deficiency, circulating anticoagulants, uremia, and cyanotic congenital heart disease. DIC is a potential complication of infection (bacterial, viral, or rickettsial), extensive burns, severe trauma, malignancies (especially acute promyelocytic leukemia), heat stroke, and some insect and snake envenomations (in the latter, the coagulopathy is often multifactorial, see Chapter 83). In DIC, the intravascular consumption of clotting factors may cause petechiae and purpura secondary to factor depletion and, in severe cases, may lead to widespread, rapidly progressing purpuric lesions (purpura fulminans) associated with thrombosis or emboli. Although other signs of serious illness are usually present in the child with purpura caused by DIC, fever and petechiae or purpura may be the only significant findings in the early stages of severe bacterial infections such as meningococcemia. Further investigations and appropriate therapy should proceed rapidly in such instances. Laboratory abnormalities in DIC include one or more of the following: a decreased platelet count, prolonged PT and PTT, decreased fibrinogen level, and elevated fibrin split products. A microangiopathic anemia with red cell fragmentation may also be present.

TABLE 65.4

COMPARISON OF LABORATORY VALUES IN DISSEMINATED INTRAVASCULAR COAGULATION, LIVER DISEASE, AND VITAMIN K DEFICIENCY

						Factor		
	PT	PTT	Fibrinogen	FSP	Platelet count	V	VII	VIII
DIC	↑	↑	↓	↑	↓	↓	↓	↓
Vitamin K deficiency	↑	↑	N	N	N	N	↓	N
Liver disease	↑	↑	N to ↓	N to ↑	N to ↓	↓	↓	N to ↑

PT, prothrombin time; PTT, partial thromboplastin time; FSP, fibrin split products; DIC, disseminated intravascular coagulation; ↑, increased or prolonged; ↓, decreased; N, normal.

Synthesis of coagulation factors occurs in the liver, with the exception of von Willebrand factor. Thus, congenital and acquired hepatocellular disorders can result in decreased factor production and coagulopathy. Vitamin K is necessary for the activation of coagulation factors VII, IX, X, and prothrombin, and thus plays a vital role in secondary hemostasis. Coagulopathies caused by severe hepatocellular disease or vitamin K deficiency can present with some of the same clinical and laboratory findings as DIC. A comparison of the laboratory values in these three disorders is shown in Table 65.4.

Hemorrhagic disease of the newborn, with clinical manifestations that range from purpura to intracranial hemorrhage, may occur in infants who do not receive prophylactic vitamin K at birth. This may be the case with babies who are born at home or who have unexpected complications during delivery. Vitamin K deficiency in newborns can result from inadequate stores of vitamin K due to maternal deficiency or exclusive breastfeeding. In older children, vitamin K deficiency may occur with malabsorption or chronic diarrhea. Purpura caused by warfarin (Coumadin) therapy or ingestion can resemble vitamin K deficiency clinically.

Circulating anticoagulants in children are associated with viral infections, malignancies, and collagen vascular disorders. They are usually characterized by a prolonged PTT that fails to correct with the addition of normal plasma. Because most acquired inhibitors in children, particularly lupus anticoagulants, are not associated with increased bleeding, the identification of an inhibitor in a patient with purpura should not preclude an investigation of other coagulation abnormalities.

Numerous coagulation abnormalities have been demonstrated in vitro in patients with renal disease and uremia. However, bleeding is most commonly related to altered platelet function rather than to defects in the fluid phase of coagulation. Abnormalities that resemble those found in DIC have been associated with cyanotic congenital heart disease, and the severity of the coagulopathy is generally related to the degree of polycythemia.

EVALUATION AND DECISION

Patients with petechiae, purpura, and unexplained ecchymoses require timely and thorough evaluation. The diagnostic approach is outlined in Figure 65.2. The initial approach should be dictated by the general appearance of the child and the presenting vital signs. It goes without saying that a well-appearing child with normal vital signs can be approached with less urgency than a febrile, lethargic child or a child with signs of impending respiratory or cardiovascular failure.

The evaluation of critically ill children with petechiae and purpura should occur after restoring and maintaining adequate ventilation and perfusion, administering early antibiotics, if indicated, and identifying and controlling life-threatening hemorrhage, often with the administration of blood products. The most important early studies include CBC, PT, PTT, blood cultures, and typing and cross-matching of blood.

In the well-appearing child, the evaluation of petechiae and purpura can proceed in an orderly fashion. The recent and past medical history should be reviewed carefully with the parents and child. The presence or history of fever should raise the suspicion for an infectious process. Acute onset of petechiae or purpura after a recent viral illness or immunization is consistent with an acquired disorder such as ITP or a circulating anticoagulant. Recurrent petechiae and purpura since infancy, however, suggests an inherited abnormality of platelets or clotting factors. Specific inquiries about past surgeries, dental extractions, or significant trauma should be made because the absence of bleeding under these conditions would be unusual in most inherited disorders of even moderate severity. When previous bleeding has occurred, the site of bleeding may be helpful in establishing the alteration in the hemostatic mechanisms. Hemarthroses, a common problem in severe hemophilia, are rarely associated with platelet abnormalities. Conversely, petechiae and subconjunctival hemorrhages are commonly found in children with platelet disorders but occur rarely in hemophilia. The parents of a child with petechiae or purpura should be questioned closely regarding the recent use of any medications, including over-the-counter drugs and home remedies.

The family history should be reviewed for bleeding disorders. A positive family history in male relatives on the maternal side suggests factor VIII or factor IX deficiency. A history of bleeding or bruising in numerous family members of both sexes suggests a condition with dominant inheritance such as von Willebrand disease. As noted earlier, however, a negative family history does not preclude the diagnosis of von Willebrand disease or hemophilia.

A careful review of systems should also be obtained to evaluate for underlying conditions such as uremia, hepatic disease, congenital heart disease, or malabsorption that might be associated with a coagulopathy.

During the physical exam, particular attention should be paid to the skin, and all areas of the skin and mucus

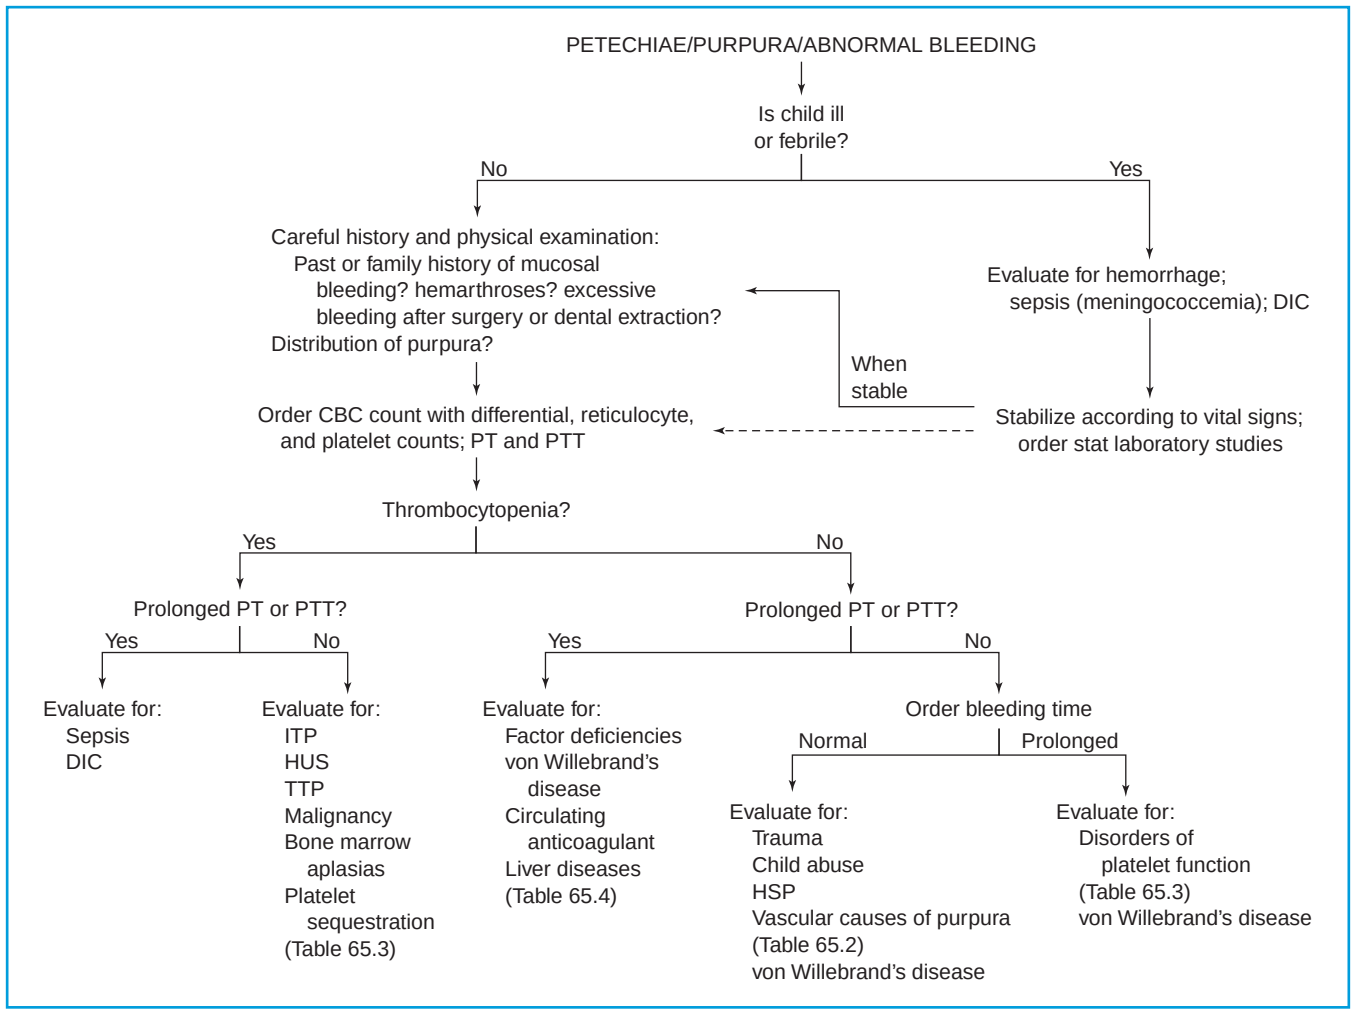

FIGURE 65.2 The approach to the child with petechiae, purpura, or abnormal bleeding. CBC, complete blood cell; PT, prothrombin time; PTT, partial thromboplastin time; DIC, disseminated intravascular coagulation; ITP, idiopathic (immune) thrombocytopenic purpura; HUS, hemolytic uremic syndrome; TTP, thrombotic thrombocytopenic purpura; HSP, Henoch-Schönlein purpura.

membranes should be examined. The distribution of purpura should be noted. Purpura on the lower extremities and buttocks or dependent regions suggests HSP, while purpuric lesions on the palms and soles are often seen with rickettsial infections. When the purpuric or ecchymotic lesion has an unusual shape, such as a folded cord or belt, child abuse should be suspected. A careful neurologic exam is important when there is suspicion of head trauma in the face of a coagulopathy. The eyes should be examined for the presence of conjunctival, scleral, or retinal hemorrhage. Additionally, the presence of lymphadenopathy or hepatosplenomegaly should be evaluated. Lymphadenopathy may be present in certain malignancies (leukemias) or viral infections (infectious mononucleosis, CMV) that can present with petechiae and purpura. Hepatomegaly may signal an underlying hepatic disorder that can cause a coagulopathy. Splenomegaly can be seen in infectious mononucleosis, leukemia, hepatic disease, and the glycogen storage diseases. Inflammation or synovial thickening of the large joints is consistent with the hemarthroses seen in hemophilia.

The laboratory approach to patients with petechiae and purpura is also influenced by the initial presentation and history. All patients who presents with petechiae, purpura, and unexplained bruising should have a complete blood cell count with a differential and platelet count, a PT, and a PTT. In most hospitals, these tests can be performed quickly so therapy can be chosen or modified on the basis of the results. A decreased hematocrit or hemoglobin concentration may indicate past or present blood loss, red blood cell destruction, or bone marrow failure. The WBC count can provide information suggestive of sepsis or leukemia. Atypical lymphocytes are seen with many viral infections, especially mononucleosis.

Causes of abnormal screening coagulation studies (platelet count, PT, PTT, bleeding time) are outlined in Table 65.5. Depending on the results of these initial tests and the clinical impression derived from the history and physical examination, a more sophisticated laboratory evaluation can be undertaken. If emergency therapy is required before the cause of abnormal bleeding is known, pretreatment plasma should be saved for later investigation of disorders such as von Willebrand disease

TABLE 65.5

TESTS COMMONLY USED IN THE INITIAL EVALUATION OF PETECHIAE, PURPURA OR SUSPECTED BLEEDING DISORDERS

Platelet Count (normal 150,000–500,000/mm^3)
- Decreased: increased platelet destruction, decreased platelet production, platelet sequestration, some platelet function disorders (Table 65.3)

Prothrombin Time (normal range may vary between laboratories)
- Prolonged: disseminated intravascular coagulation; vitamin K deficiency; warfarin ingestion; deficiencies of factors II, V, VII, X; abnormalities of fibrinogen; liver disease; renal disease; congenital heart disease

Activated Partial Thromboplastin Time (normal range may vary between laboratories)
- Prolonged: disseminated intravascular coagulation; von Willebrand disease; deficiencies of factors II, V, VIII, IX, X, XI, XII; abnormalities of fibrinogen; vitamin K deficiency; heparin therapy or sample contamination; liver disease; congenital heart disease

Fibrinogen (normal >150 mg/100 mL)
- Decreased: disseminated intravascular coagulation, liver disease, L-asparaginase therapy, dysfibrinogenemia, afibrinogenemia

Fibrin Split Products (normal <1:20)
- Increased: disseminated intravascular coagulation, liver disease

Bleeding Time (modified Ivy) (normal <8 min, 30 s)
- Prolonged: idiopathic thrombocytopenic purpura (early) and other thrombocytopenias, von Willebrand disease, platelet function disorders

or other inherited factor deficiencies. Other laboratory studies that may be performed include an antinuclear antibody titer as a screening test for collagen vascular disorders and a reticulocyte count and direct antiglobulin (Coombs) test to detect immune hemolytic anemia.

The emergency management of children with petechiae and purpura is discussed in detail in Chapter 91. However, the general principles are straightforward. When petechiae and purpura is associated with a serious underlying disorder such as meningococcemia, treatment of that disorder is usually the first priority. Treatment of the coagulopathy is based on the degree and site of bleeding and the actual hemostatic defects. In primary disorders of hemostasis, appropriate replacement therapy is used when the specific alteration is known. When the disease has not been fully defined, broad treatment with one or more blood products may be required while further laboratory studies are performed.

CHAPTER 66 ■ RASH—URTICARIA

WILLIAM J. LEWANDER, MD, AND EMILY A. ZAJANO, MD

Urticaria is a common cutaneous vascular reaction experienced by nearly 20% of the population at some time during their lives. The etiology remains unknown in the majority of cases. Urticaria is usually acute and transient, but is classified as chronic if it persists for longer than 6 weeks. Although chronic urticaria is sometimes associated with physical agents or systemic illnesses [i.e., viral hepatitis, juvenile rheumatoid arthritis, systemic lupus erythematosus (SLE), lymphoma], the etiology remains unknown in more than 75% of cases.

Urticarial lesions appear as erythematous papules or wheals from edema in the upper dermis with a surrounding flare of erythema caused by vasodilation. They are pruritic, multiple, and of varying size and shape. Individual lesions are transient, usually lasting 12 to 24 hours or less. They often appear suddenly, resolve almost completely, and may reappear. The cutaneous distribution varies, but lesions secondary to physical agents are generally concentrated in areas of direct stimulation (i.e., dermographism).

Urticaria may be accompanied by angioedema and is associated with systemic symptoms from direct visceral involvement or from symptoms secondary to the release of circulating chemical mediators. Lesions of angioedema are often nonpruritic and involve deeper dermal and subcutaneous tissues with swelling that may involve the lips and eyelids. The respiratory, cardiovascular, and gastrointestinal systems may be involved, resulting in a potential life-threatening reaction. Signs and symptoms may include hoarseness, stridor, shortness of breath, wheezing, and general respiratory distress (from laryngospasm and bronchospasm), as well as hypotension, nausea, vomiting, diarrhea, and abdominal pain.

PATHOPHYSIOLOGY

Urticaria is characterized by superficial dermal edema, vasodilation and transudation of fluid and red blood cells, dilated lymphatics, and a mononuclear perivascular infiltrate. Angioedema occurs when these changes involve the deeper portion of the dermis and subcutaneous tissue. Urticaria and angioedema may occur independently or in association. Angioedema is mediated through mast-cell degranulation or via kinin-mediated pathway. Urticaria can be seen in conjunction with angioedema when it occurs via mast-cell degranulation. The release of histamine and various other vasoactive and chemotactic substances from mast cells and basophils appears to play a central role in the pathogenesis.

Acute urticaria is often triggered by infections, medications, and food reactions. Papular urticaria is a form of acute urticaria from hypersensitivity to insect bites. Chronic urticaria can be associated with autoimmune processes, but is more commonly idiopathic. Autoimmune urticaria is mediated by antibodies directed against either the IgE high-affinity receptor or the IgE molecule directly.

DIFFERENTIAL DIAGNOSIS

As shown in Table 66.1, urticaria may be classified on the basis of the mechanism responsible for its formation or, if unknown, as idiopathic.

Multiple factors—both immunologic and nonimmunologic—are capable of initiating the release of these mediators that result in the histopathologic findings described. The type I hypersensitivity reaction that involves the interaction of an antigen with a mast cell– or basophil-bound IgE with release of histamine represents the most common immunologic mechanism. However, type III (immune complex) reactions can also stimulate mediator release through activation of the complement system. Examples include urticaria seen in association with viral hepatitis, infectious mononucleosis, serum sickness, SLE, and some reactions to blood products. Nonimmunologic causes of urticaria include direct mast cell–releasing agents (i.e., opiates, radio contrast media) and agents that presumably alter arachidonic acid metabolism (i.e., aspirin, nonsteroidal antiinflammatory agents, azo dyes). Angiotensin-converting enzyme inhibitors are believed to enhance bradykinin synthesis.

Genetic factors are important in several relatively rare causes of urticaria and angioedema, including hereditary angioedema, familial cold, and localized heat urticaria. The most common etiologies of urticaria are listed in Table 66.2. Although idiopathic urticaria is the most common form, it is a diagnosis reached mainly by exclusion.

EVALUATION AND DECISION

Urticaria is diagnosed by its characteristic appearance and is only rarely confused with erythema multiforme, certain vasculitides (i.e., Henoch-Schönlein purpura), urticaria pigmentosa, or infectious exanthems.

Following clinical recognition, the patient should be evaluated for the presence of an associated systemic reaction that involves cardiopulmonary compromise (outlined in Fig. 66.1). Any form of urticaria that involves the airway or cardiovascular system is potentially life-threatening. Following any needed stabilization of cardiopulmonary compromise, evaluation for a specific etiology should begin with a thorough history and physical examination. Although the cause often remains unknown, Tables 66.1 and 66.2 outline the general classifications and most common identifiable causes of urticaria. In the

TABLE 66.1

CLASSIFICATION OF URTICARIA/ANGIOEDEMA

Immunologic
IgE dependent
- Specific antigen sensitivity
- Physical: dermographism, cold, cholinergic, heat, solar
- Contact

Complement mediated
- Serum sickness
- Reaction to blood products
- Hereditary angioedema
- Systemic lupus erythematosus

Nonimmunologic
Direct mast cell–releasing agents
- Opiates
- Radiocontrast media

Agents that alter arachidonic acid metabolism
- Aspirin and nonsteroidal antiinflammatory agents
- Azo dyes and benzoate preservatives
- Angiotensin-converting enzyme inhibitors

Idiopathic

Adapted from Soter NA. Acute and chronic urticaria and angioedema. *J Am Acad Dermatol* 1991;25:146–154.

context of acute onset, the patient and family must be questioned about specific precipitants, including drugs, foods, and hymenoptera stings. Febrile patients must be examined for clinical findings suggestive of viral and streptococcal infection, mononucleosis, and hepatitis. Latex allergy is uncommon in the general population, but health care workers and children with spina bifida appear to be at high risk for latex allergy. These patients may experience urticaria, conjunctivitis, bronchospasm, and anaphylaxis following contact with or inhalation of latex antigens. Laboratory tests are generally not helpful or necessary in the evaluation of acute urticaria.

TABLE 66.2

COMMON CAUSES OF URTICARIA/ANGIOEDEMA[a]

Foods
- Peanuts
- Eggs
- Chocolate
- Shellfish
- Milk
- Strawberries
- Food dyes and preservatives

Drugs
- Penicillin
- Opiates
- Radiocontrast media
- Aspirin and nonsteroidal antiinflammatories
- Angiotensin-converting enzyme inhibitors

Insect Bites
- Hymenoptera venom

Infections
- Hepatitis
- Streptococcus
- Infectious mononucleosis
- Mycoplasma
- Parasitic infection
- Upper respiratory infection

Physical Agents
- Cold
- Heat
- Dermographism
- Latex

[a]Essentially all may be life-threatening if accompanied by systemic reaction (see text).

Patients with chronic urticaria must be questioned about exposure to parasites, hepatitis, or a family history of urticaria and must be examined for findings suggestive of collagen–vascular disease or thyroid disease. Laboratory tests that may be useful in the evaluation of chronic urticaria include complete blood cell count with differential, erythrocyte sedimentation rate, urinalysis, monospot, antinuclear factor, liver function tests, and thyroid studies. Decreased levels of C_1 esterase inhibitor are found in hereditary angioedema. Stool for ova and parasites should be sent if there is eosinophilia present or if symptoms are consistent with parasitic infection. Provocative tests may be tried cautiously if certain physical urticarias are suspected.

If the etiology of chronic urticaria cannot be determined or if a severe systemic reaction occurs, then referral to an allergist should be considered after initial treatment is instituted.

MANAGEMENT

The initial management of urticaria follows assessment of the patient for a systemic reaction (e.g., anaphylaxis) with cardiopulmonary compromise (i.e., stridor, wheezing, hypotension; see Chapter 82). If cardiopulmonary compromise is present, airway, breathing, and circulation should be stabilized. Medications that may be used include oxygen, epinephrine (1:1,000) (0.01 mg per kg intramuscularly, maximum dose 0.5 mg, may be repeated every 15 minutes), diphenhydramine 1 mg per kg intravenously/intramuscularly, and volume resuscitation followed by vasopressors (i.e., continuous infusion epinephrine) if there is no response. Systemic corticosteroids (i.e., methylprednisolone 1 to 2 mg per kg) are slow to work but may block or reduce late-phase reactions. H_2-blockers may also play a role.

Although any precipitating factor may result in urticaria accompanied by a systemic reaction, cold, cholinergic and solar urticaria, and hereditary angioedema have been associated with severe attacks. Mortality from hereditary angioedema has been reported to be as high as 30% and generally results from airway obstruction. Danazol®, an attenuated androgen, is the preferred long-term prophylactic treatment. Acute attacks often require careful airway management, infusions of fresh frozen plasma, or concentrates of partly purified C_1 esterase inhibitor, and supportive care.

The general management of the more common presentation of urticaria without systemic involvement consists of removing or avoiding the inciting agent (if it can be identified) and providing symptomatic relief with antihistamines of the H1 class. The two most commonly used oral medications are hydroxyzine (Atarax® or Vistaril®, 2 mg per kg per day) and diphenhydramine (Benadryl®, 5 mg per kg per day) each in three to four divided daily doses for at least 3 to 5 days. Second-generation H1 antagonists can also be used, with the benefit of decreased CNS side effects due to decreased penetration of the blood–brain barrier. Cetirizine (Zyrtec®, dosing is age dependent) and loratadine (Claritin®) are a second-generation H1 antagonist used commonly in pediatric chronic urticaria. Cyproheptadine (Periactin®, 0.5 mg per kg per day

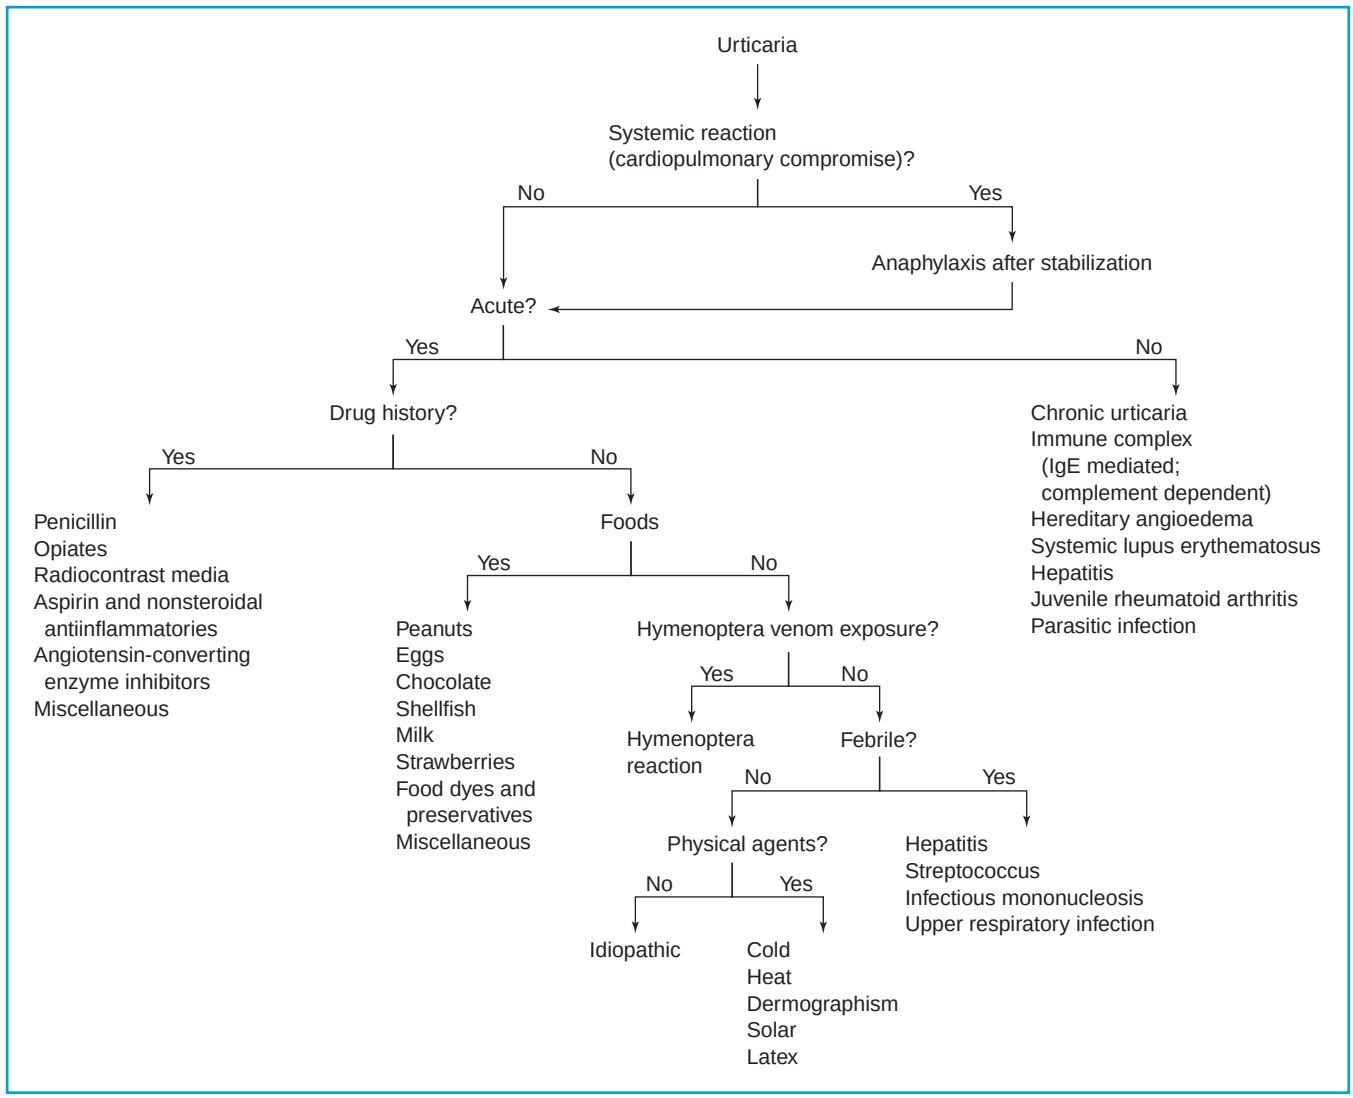

FIGURE 66.1 Algorithm for the evaluation of urticaria.

in three to four divided doses) has also been found to be effective. If there is severe pruritus, a rapidly progressing urticarial rash, or angioedema, then more rapid relief may be achieved with epinephrine (1:1,000) 0.01 mg per kg intramuscularly (maximum dose 0.5 mg) and diphenhydramine, 1 mg per kg IM. Systemic corticosteroids are inconsistent in their benefit, but they may suppress the appearance of new urticarial lesions and are indicated primarily in severe, inadequately controlled cases in which an infectious origin has been excluded.

Recurrent or persistent urticaria sometimes responds to cimetidine (Tagamet®, 20 to 30 mg per kg per day) in four divided oral doses, or cetirizine (Zyrtec®), dose dependent upon age. Cimetidine has numerous clinically important drug-drug interactions and caution should be used when adding cimetidine to an existing drug regimen.). Following or concurrently with treatment, an effort should be made to determine the etiology (Tables 66.1 and 66.2) so that the patient can avoid the precipitating agent.

CHAPTER 67 ■ RASH—VESICOBULLOUS

PAUL J. HONIG, MD, LESLIE CASTELO-SOCCIO, MD, PHD, AND ALBERT C. YAN, MD

Basic to all vesicobullous (blistering) disorders is the disruption of cellular attachments. Blister formation, therefore, follows intracellular degeneration, intercellular edema (spongiosis), or damage to the anchoring structures associated with the basement membrane (hemidesmosomes, basal lamina, anchoring fibrils). The location of these changes, as seen in Table 67.1, can help the physician ascertain a specific diagnosis. When histologic information is not readily available or nondefinitive, however, the historical and clinical features of the case must be relied on.

Such an approach is outlined in Figure 67.1. The key features used in this algorithm to distinguish the various entities are a characteristic clinical appearance, chronicity and/or presence at birth, associated fever or systemic illness, distribution of lesions, and the child's age. The diagnosis of vesicobullous lesions in children younger than 1 month of age is not discussed in this chapter. Figure 67.1 also outlines the frequency and potential severity of these diseases.

CHARACTERISTIC CLINICAL APPEARANCE

Many times, the appearance of a rash is so characteristic that a diagnosis becomes obvious. Such is the case with the conditions listed in Table 67.2.

Linear or geometric areas of vesiculation are the best clues to the presence of allergic contact dermatitis (see Chapter 99). The shape of the dermatitis provides the information that helps identify the offending agent. A history of playing in a shrubbed area, camping, hiking, or being near burning leaves is helpful. Because children brush against poison ivy leaves, vesicles often are in a line and on exposed surfaces (e.g., the face, extremities). A round group of vesicles on the back of the wrist would point to contact sensitivity to nickel contained in the metal case of a wristwatch.

Dermatomal distribution of vesicles or bullae usually indicates the presence of herpes zoster. On rare occasions, in infants, the same dermatomal appearance may represent zosteriform herpes simplex infections. A positive Tzanck smear indicates the presence of the herpes virus. Viral cultures, rapid slide tests using monoclonal antibodies, or more and more commonly, polymerase chain reaction tests are utilized to differentiate herpes simplex from herpes zoster.

Target or iris lesions are pathognomonic of erythema multiforme. The lesion has a dusky center that may blister and has successive bright red bordering rings. At times, a doughnut-shaped blister occurs. This contrasts with annular urticaria where incompletely round (arcuate or polycyclic) wheals are observed and individual lesions typically resolve within less than 24 hours.

Pigmented lesions that blister after stroking or trauma (Darier's sign) indicate the release of histamine from a mast cell collection. This collection may be isolated (mastocytoma of the wrist) or generalized (urticaria pigmentosa). Blistering of such lesions generally occurs only until 2 years of age. After this time, only urtication occurs.

A delicate "tear drop" vesicle is characteristic of varicella (chickenpox). Lesions usually begin on the upper trunk and neck. A progression through papules, vesicles, and crusts occurs rapidly (6 to 24 hours). All stages are present in an area at any given time. Mucous membranes are involved. Fever and malaise are usually present but are variable. Variola (smallpox) may initially resemble varicella. However, following the initial enanthem, the rash begins on the face and spreads to arms and then legs and trunk. In contrast to the lesions of varicella, variola lesions are monomorphic because they progress from macules to papules and pustules, with all the lesions in the same stage of evolution. The pustules are classically umbilicated.

DURATION

If there is no characteristic clinical appearance, the duration of the rash must be considered. If it has been present for 4 weeks or more, it should be considered chronic. Rashes that come and go but take not more than 4 weeks to disappear completely are not considered chronic.

Chronic Rash (Duration 4 Weeks or More)

If the blistering disease has been present since birth (congenital), consider the diagnoses listed in Table 67.3.

Epidermolysis Bullosa Syndromes

Blisters usually occur in areas predisposed to trauma or friction (Fig. 67.2). See Table 67.4 for differentiation of the various types.

Urticaria Pigmentosa

Mast cell disease (mastocytoma or urticaria pigmentosa) may cause blistering until 2 years of age. The pigmented solitary lesion most often occurs on the arm near the wrist (Fig. 67.3). Lesions may be generalized. When a pigmented lesion feels infiltrated, the physician should think of this cause. Gentle mechanical irritation of such lesions causes urtication or blistering (Darier's sign).

TABLE 67.1

PATHOLOGIC DIAGNOSIS OF VESICOBULLOUS ERUPTIONS

Type of blister	Site of formation	Disease
Subcorneal blister	Subcorneal	Impetigo Staphylococcal scalded skin syndrome
Blister from intracellular degeneration	Upper epidermis	Bullous congenital ichthyosiform erythroderma Epidermolysis bullosa of hands and feet Friction blisters
Spongiotic blister	Intraepidermal	Incontinentia pigmenti
Viral blister	Intraepidermal	Variola Herpes simplex Varicella-herpes zoster
Blister from degeneration of basal cell	Subepidermal	Epidermolysis bullosa simplex Lichen planus Lupus erythematosus
Blister from degeneration of basement zone	Subepidermal	Epidermolysis bullosa, dystrophic type Urticaria pigmentosa Bullous pemphigoid Dermatitis herpetiformis Erythema multiforme, dermal type Drug-induced toxic epidermal necrolysis

Epidermolytic Hyperkeratosis (Congenital Bullous Ichthyosiform Erythroderma)

Epidermolytic hyperkeratosis, an autosomal-dominant trait, is categorized under the ichthyotic syndromes. Children with this problem have recurrent bullous lesions during infancy and childhood. The skin has a background of erythema and scaling, and peels. The flexures are always affected with thickening of the skin (hyperkeratosis), as are the palms and soles; findings that develop in response to chronic trauma; erosions; and healing.

Incontinentia Pigmenti

Incontinentia pigmenti, a rare condition, occurs almost exclusively in females. Inflammatory vesicles and bullae erupt in crops in a linear or curvilinear distribution (especially on the extremities) for the first several weeks to months of life (Fig. 67.4). These affected areas then go on to a warty stage. Finally, swirl-like pigmentation occurs but not necessarily in the areas previously involved with warty or blistering lesions. During the vesicobullous stage, a high degree of peripheral eosinophilia occurs (18% to 50%). Because of the multisystem organ involvement often seen in incontinentia pigmenti, children with this condition should seek consultation with dermatologists or geneticists, who can help determine what other system evaluations may be necessary (such as neurology, ophthalmology, dentistry or oral-maxillofacial surgery, or immunology).

If the blistering is noncongenital, chronic bullous dermatosis of childhood (Fig. 67.5), dermatitis herpetiformis, and bullous pemphigoid should be considered. These conditions can be differentiated as outlined in Table 67.5.

Child Who Is Ill

When the blistering lesions occur acutely, it must be determined whether the child is febrile or ill. Conditions that cause such systemic findings with associated blisters include those listed in Table 67.6.

Varicella (Chickenpox)

For more information about varicella, see the discussion under "Characteristic clinical appearance."

Variola (Smallpox)

Although international efforts have been successful at eradicating smallpox, more recent geopolitical events have raised the spectre of bioterrorism and the potential for smallpox to be employed as a biological weapon. For more information about smallpox, see the section immediately preceding and Chapter 7.

Hand-foot-mouth Disease

Caused by coxsackievirus A16 and enterovirus 71, hand-foot-mouth disease is fairly characteristic. Vesicles are present on the palms, on the soles, and in the mouth. Other parts of the body may be involved. Fever, malaise, and abdominal pain may be present. Other coxsackie strains such as A5 and A10 less commonly cause hand foot and mouth disease.

Viral (Nonspecific) and Other Causes

Vesicles have been described in association with other coxsackievirus types (A4, A5, B1, B4), echovirus, reovirus, and *Mycoplasma pneumoniae* infections. These children are usually ill.

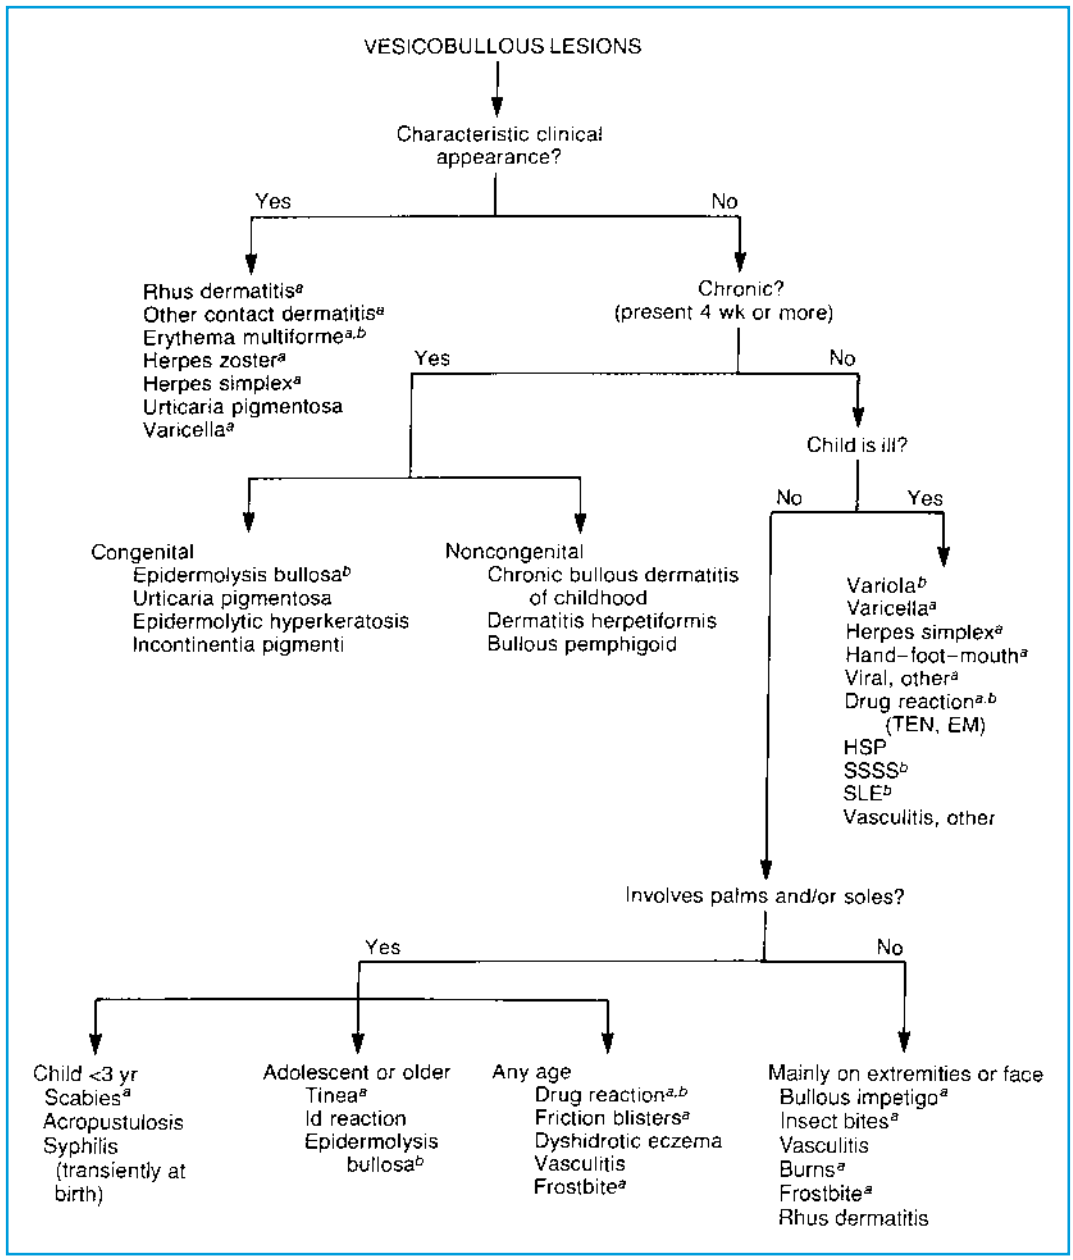

FIGURE 67.1 The diagnostic approach to the child with vesicobullous lesions. TEN, toxic epidermal necrolysis; EM, erythema multiforme; HSP, Henoch-Schönlein purpura; SSSS, staphylococcal scalded skin syndrome; SLE, systemic lupus erythematosus. [a]Common. [b]Potentially life threatening.

FIGURE 67.3 Infant with mastocytoma that has blistered because of trauma.

Drug Reactions

The presence of vesicles or bullae may indicate a drug reaction. Involvement of palms, soles, mucous membranes, or the presence of target lesions are other possible clues that indicate this problem. Therefore, the intake of prescribed and over-the-counter preparations must be investigated.

Drug-induced toxic epidermal necrolysis (TEN) may be associated with blisters. Histology that shows separation of dermis from epidermis excludes the staphylococcal-induced problem. Also, the staphylococcal scalded skin syndrome (SSSS) rarely occurs in children older than 6 years of age. A drug reaction should be considered in children older than 6 years. The histology of SSSS demonstrates separation just below the stratum corneum.

Children with severe drug reactions may be very toxic appearing. High fevers, malaise, joint problems, and the like can occur.

Henoch-Schönlein Purpura

Children with Henoch-Schönlein purpura (HSP) may have blisters because of the severe inflammation of blood vessels (vasculitis) in the typical distribution that occurs in this condition. Associated systemic problems include arthritis, abdominal pain, kidney disease (hematuria and/or proteinuria), and seizures.

Nonspecific Vasculitis

Children with vasculitic blisters, at times hemorrhagic, may be sick with fever, malaise, and other symptoms. Some go on to

TABLE 67.4

EPIDERMOLYSIS BULLOSA SYNDROMES

	Type	Typical inheritance	Clinical features	Electron microscope
Nonscarring	Epidermolysis bullosa simplex	Autosomal dominant	Bullae present at birth or early infancy; in areas of trauma; improves in adolescence; no mucous membrane involvement; nail involvement (20%)	Cleavage through basal cell layer above basement membrane
	Recurrent bullous eruption of hands and feet (Weber-Cockayne disease)	Autosomal dominant	May present in first 2 years of life but usually not before adolescence or early adulthood	Epidermal cleavage may be anywhere from suprabasal to lower granular cell layer
	Junctional epidermolysis bullosa (Herlitz disease)	Autosomal recessive	Usually at birth; spontaneous bullae and large areas of erosion	Cleavage at junction of dermis and epidermis (above basement membrane)
Scarring	Dominant dystrophic epidermolysis bullosa (dominant dermolytic bullous dermatosis)	Autosomal dominant	Early infancy and later; little or no involvement of hair and teeth; mucous membrane lesions and nail dystrophy	Dermal–epidermal separation beneath basement membrane
	Recessive dystrophic epidermolysis bullosa (recessive dermolytic bullous dermatosis)	Autosomal recessive	Present at birth; widespread scarring and deformity; severe involvement of mucous membranes and nails	Separation at dermal–epidermal junction (beneath basal lamina)

FIGURE 67.4 Linear arrangement of lesions (blisters in some cases) in a child with incontinentia pigmenti.

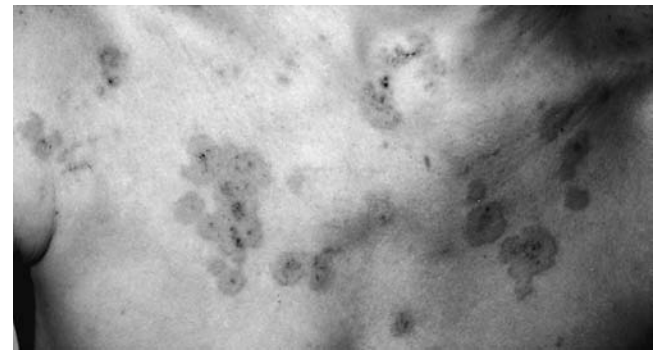

FIGURE 67.5 Chest of patient with chronic bullous dermatosis of childhood. Notice the resemblance to erythema multiforme.

well-defined collagen vascular disease, whereas others smolder, with no diagnosis ever being made.

Herpes Simplex

Primary infection with this virus may cause fever and regional lymphadenopathy. The first encounter for young children is usually herpetic gingivostomatitis. Vesicles involve the lips and the rest of the mouth. These children are often uncomfortable and commonly refuse to eat or drink.

Herpes progenitalis may produce fever and local lymphadenopathy as well. Characteristic clusters of vesicles occur on an erythematous base.

Often, erosions or ulcerations evolve on the vulva or penis. Diagnosis can be confirmed by a Tzanck smear that shows aggregates of multinucleated giant cells (see Chapter 99), a rapid slide test (immune-specific immunofluorescent antibody placed on cells scraped from the blister base), viral culture, or polymerase chain reaction.

Systemic Lupus Erythematosus

Although not characteristic, bullous lesions can occur in systemic lupus erythematosus (SLE). Multisystem involvement suggests the diagnosis. Laboratory confirmation, which may include a skin biopsy and lupus band test, in conjunction with the complete clinical picture, is necessary for diagnosis.

Palm and Sole Involvement

If the child is not ill, the physician should search for blisters on the palms and soles. The child's age helps differentiate some disorders (Table 67.7).

CHILD YOUNGER THAN 3 YEARS

Scabies

Infants and very young children can have vesicobullous lesions on the palms (Fig. 67.6), soles, head, and face. It is important to not be misled by this distribution and appearance. Generally, the mother or father or other close family contact is also infested and exhibits the typical appearance of this disorder.

TABLE 67.5

NONCONGENITAL CHRONIC BLISTERING DISEASE

	Bullous disease of childhood	Bullous pemphigoid	Dermatitis herpetiformis
Type of lesions	Large, tense, clear bullae; annular plaques with active vesicular borders	Large, tense bullae	Grouped papulovesicles, bullae, or urticarial lesions
Distribution	Scalp, lower trunk, genitals, buttocks, inner thighs	Trunk and flexor surfaces of extremities	Back, buttocks, scalp, extensor surface of extremities, often symmetric
Pruritus	None to severe	Mild	Intense
Mucous membrane involvement	Usually not	Yes	No
Duration	Months to years	Months to years	Months to years
Immunofluorescence	+ or – Linear IgA basement membrane (+ circulating IgA)	+ Linear IgG on basement membrane (+ circulating IgG)	+ Granular IgA at tips of dermal papilla of uninvolved perilesional skin
Treatment	Corticosteroids and dapsone	Corticosteroids	Sulfapyridine or dapsone

Viral (nonspecific) + other
Drug reaction (toxic epidermal necrolysis, erythema multiforme)
Henoch-Schönlein purpura
Nonspecific vasculitis
Herpes simplex
Staphylococcal scalded skin syndrome
Systemic lupus
Atypical measles

Acropustulosis of Infancy

The appearance of pruritic vesicopustules between 2 and 10 months of age on the palms and soles (Fig. 67.7), typically in African-American children, suggests acropustulosis of infancy. Vesicles often involve the lateral aspects of the fingers, palms, and soles. This condition was commonly diagnosed as dyshidrotic eczema in the past. Some speculate a relationship with antecedent scabies infestation in a subset of patients and may refer to this phenomenon as postscabetic pustulosis in this setting. Cyclic eruptions occur every 2 to 3 weeks, lasting 7 to 10 days. Spontaneous disappearance occurs at 2 to 3 years of age. Treatment with topical steroids may moderate some of the pruritus.

Syphilis

Congenital syphilis may produce transient blisters on the palms and soles immediately after birth. "Snuffles," rhagades, condyloma lata, and violaceous to reddish-brown macules on the palms and soles may be observed. Hepatosplenomegaly is often present. Osteochondritis is an early and common sign.

FIGURE 67.6 Blisters on hands of child infested with scabies.

Severe tenderness of a limb may cause pseudoparalysis of Parrot. The dilutional serologic test for syphilis is always positive in children with clinical manifestations.

ADOLESCENT OR OLDER

Tinea Pedis or Manus

Certain organisms that cause tinea pedis or manus (e.g., Trichophyton mentagrophytes) induce a severe inflammatory reaction on the hands and feet. Vesicobullous lesions erupt on the palms, instep, or medial aspect of the foot. A potassium hydroxide (KOH) preparation or dermatophyte screen (fungal culture) confirms the presence of hyphae in either location.

"Id" Reaction

If an adolescent's palms have blisters, the physician should look at the feet. Patients with tinea pedis may have allergic

FIGURE 67.7 Note vesicles and pustules on child with acropustulosis of infancy.

reactions to dissemination of antigen typified by blistering on uninvolved areas, characteristically on the palms. Because this represents a reaction to antigen and not to the intact organism, KOH preparation of the lesions on the palms will be negative for fungus.

Epidermolysis Bullosa of the Hands and Feet

For more information, see "Epidermolysis Bullosa Syndromes" section in this chapter (Table 67.4).

ANY AGE

Drug Reaction

For more information about drug reactions, see "Child Who Is Ill" section in this chapter.

Friction Blisters or Burns

Blistering on the palms and soles appears after trauma to the skin. The trauma is often related to a new activity (e.g., golfing, rowing, football) or to new, possibly poorly fitted, shoes.

Occasionally, accidental burns or burns secondary to child abuse are seen. Abused children may have had cigarette burns or have had their feet dipped in scalding water.

Dyshidrotic Eczema (Pompholyx)

A recurrent rash with episodes of vesicles that involve the palms, soles, and lateral aspects of the fingers is called dyshidrotic eczema. On occasion, large bullae occur. The problem is generally bilateral. Often, there is a personal or family history of atopy. A KOH preparation or fungal culture of scrapings from the palms or soles is generally negative.

Vasculitis

Vasculitis, also called HSP, may involve the palms and/or soles. See "Child Who Is Ill" section in this chapter for more information.

Frostbite (Pernio)

Fingers, toes, feet, nose, cheeks, and ears are affected by extreme cold. After exposed areas are damaged by the cold temperature, symptoms occur on rewarming. Erythema, swelling, and burning pain occur at first, followed by vesicles and bullae [at times hemorrhagic (Fig. 67.8)] within 24 to 48 hours.

Extremities

If there is no involvement or minimal involvement of the palms and soles and the rash is concentrated on the extremities, insect bites, vasculitis, burns, frostbite, and bullous impetigo should be considered.

FIGURE 67.8 Frostbite. Child played in the snow for a prolonged period on a cold day wearing sneakers.

INSECT BITES

Insects generally bite exposed skin surfaces. Therefore, heaviest involvement occurs on the head, face, and extremities. Mosquito bites occur in the warm weather months, whereas flea bites occur throughout the entire year. Historical information includes contact with pets, camping trips taken, and involvement in outdoor activities. When blisters are present, the more characteristic urticarial papules are usually present in other locations. If not, confusion with bullous impetigo is easily ruled out with a Gram stain or bacterial culture. In the case of bullous insect bites, these would be negative for bacteria.

VASCULITIS

Concentration of hemorrhagic bullae on the extremities and buttocks indicates HSP. The lower extremities are the area most often involved because of settling of immune complexes and cryoglobulins in that location.

BURNS

Exposed areas are commonly involved. Children accidentally rub against hot objects, causing burns and blistering. In cases of child abuse, children are burned intentionally with cigarettes (often mistaken for lesions of impetigo) or other heated objects. At times, children are submerged in scalding water. Usually, both lower extremities are involved.

BULLOUS IMPETIGO

In bullous impetigo, *Staphylococcus aureus* is usually present in pure culture. The bullae are caused by elaboration of a bacterial toxin that acts as a protease to cleave cell adhesion

molecules in the upper epidermis leading to blisters that initially are filled with a clear fluid that rapidly become cloudy. The lesions tend to spread locally. Regional lymph nodes are usually not enlarged. In this setting where bullae are noted, oral antibiotics may prove superior to topical antibiotic therapy.

LABORATORY EVALUATION

If there is no clear idea about what caused the blister, the laboratory tests described next can be helpful.

Gram Stain

The Gram stain of fluid from an intact blister will be positive in impetigo and in a secondarily infected lesion. It will be negative, however, in all other conditions.

Tzanck Smear

Multinucleated giant cells will be present on a Tzanck smear (Fig. 99.7) of material scraped from the base of an intact, freshly opened vesicle caused by herpes simplex, herpes zoster, and varicella.

Rapid Slide Test for Direct Immunofluorescence

Fluorescent-tagged monoclonal antibody is applied to cells scraped from the blister base and can differentiate herpes simplex virus (HSV)-1, HSV-2, or varicella-zoster virus. Results can be available in 1 to 2 hours.

Bacterial or Viral Cultures

Occasionally, cultures help confirm an etiologic diagnosis when Gram stain, Tzanck smears, and direct immunofluorescence (DIF) are negative or indeterminate.

Polymerase Chain Reaction

An alternative or adjunct to traditional culture techniques, polymerase chain reaction techniques, allows for amplification of DNA or RNA present within a specimen and rapid identification of the etiologic pathogen. The technique is useful even when the pathogen present is no longer viable.

Skin Biopsy

For perplexing cases undiagnosed by clinical and/or simple laboratory evaluation, dermatologic consultation and skin biopsy are required.

On histologic examination, many characteristic changes can be found that lead to a definitive diagnosis (Table 67.1). Lichen planus, SLE, TEN, SSSS, and vasculitis are some of the diseases that can be identified by histologic studies.

If the picture on histology is compatible with erythema multiforme, DIF should be considered. DIF will be negative in erythema multiforme but will be positive in bullous pemphigoid [linear immunoglobulin G (IgG) on basement membrane], dermatitis herpetiformis [granular immunoglobin A (IgA) at tips of dermal papillae of uninvolved perilesional skin], and chronic bullous disease of childhood (CBDC) (linear IgA on basement membrane). DIF can be negative in CBDC.

Indirect immunofluorescence can be performed to test for circulating antibodies. Circulating IgG is found in bullous pemphigoid; circulating IgA is found in CBDC.

CHAPTER 68 ■ RESPIRATORY DISTRESS

DEBRA L. WEINER, MD, PHD

Respiratory distress is one of the most common chief complaints of children seeking medical care. It accounts for nearly 10% of all pediatric emergency department visits and 20% of visits of children younger than 2 years. Twenty percent of patients admitted to the hospital and 30% of those admitted to intensive care units are admitted for respiratory distress. Primary respiratory processes account for approximately 5% of deaths in children younger than 15 years and 20% in infants. In addition, respiratory distress contributes substantially to deaths in patients with other primary processes. Respiratory arrest is one of the five leading causes of death in pediatric patients, along with congenital anomalies, trauma, neoplasm, and cardiac disease. Respiratory distress results from interruption of the respiratory or ventilatory pathway. The cause of respiratory distress may be within the respiratory system or within organ systems that control or impact respiration. Respiratory failure is caused by an inability to meet metabolic demands for oxygen (O_2) or by inadequate carbon dioxide (CO_2) elimination. Young children are at particular risk of respiratory distress because of their respiratory anatomy and physiology. Rapid evaluation and aggressive treatment of respiratory distress, as well as anticipation and prevention of impending respiratory distress and failure, are essential to optimize outcome. Respiratory distress is usually reversible, but failure to treat the condition may result in cardiac arrest with long-term neurologic sequelae or death.

PATHOPHYSIOLOGY

Respiration is a complex multisystem process. The primary goals of respiration are to meet metabolic demands for O_2 and to eliminate CO_2. Secondary functions include acid-base buffering, host defense, and hormonal regulation. The upper airway or conducting zone, which includes the nose, nasopharynx, oropharynx, larynx, trachea, major bronchi, and terminal bronchioles, serves as a conduit for air movement. The lower airway, or respiratory zone, consists of the acini and interstitium. Each acinus originates from a terminal bronchiole and includes respiratory bronchioles, alveolar ducts, sacs, and alveoli. The interstitium, which consists of the alveolar walls and interstitial septa, is the fibrous structural framework of the lower airway. Exchange of O_2 and CO_2 between the lungs and the blood occurs at the alveolocapillary membrane and depends on adequate and appropriately matched ventilation and perfusion.

Control of respiration is mediated by central and peripheral neural mechanisms. Respiration is an intrinsic brainstem function of the respiratory centers of the medulla. The dorsal respiratory group produces rhythmic inspiration, whereas the ventral respiratory group controls expiration. Respiration is modulated by impulses within the brain and among the brain, respiratory system, blood, cerebrospinal fluid, and peripheral tissues. In the pons, the apneustic center increases the duration and depth of inspiration, whereas the pneumotaxic center shortens the duration and depth of respiration. Central chemoreceptors in the medulla respond to changes in the pH of cerebrospinal fluid. Peripheral chemoreceptors in the carotid and aortic bodies respond to changes in O_2, CO_2, and pH in arterial blood. In the airways, lungs, and chest wall, stretch, juxtacapillary, and irritant reflex mechanoreceptors respond to lung volume, changes in pulmonary microvasculature, chest wall muscle activity, and environmental irritants. Respiration is further influenced by the cerebellum, which alters respiration with postural change; by the hypothalamus, which controls respiration on a moment-to-moment basis; by the limbic system, which modulates respiration in response to emotion; and by the motor cerebral cortex, which controls volitional respiratory activity, including hyperventilation and hypoventilation and speech. Afferent information is transmitted to the brain primarily by the vagus [cranial nerve (CN) X] from the aortic body and mechanoreceptors, the glossopharyngeal (CN IX) from the carotid body, and the spinal motor neurons from muscle proprioceptors. Efferent impulses are transmitted from the brain via the vagus and spinal nerves to the larynx, trachea, bronchi, bronchioles, and acini; the glossopharyngeal to the pharynx; the hypoglossal (CN XII) to the tongue; and the spinal accessory (CN XI) to accessory muscles.

Impulses are also transmitted via spinal motor neurons in the anterior spinal horn to the cervical nerves (C2 to C4), the phrenic nerve (C3 to C5), and the intercostal nerves (T1 to T12), which innervate accessory muscles, the respiratory diaphragm, and intercostal muscles, respectively. The muscles and bones of the chest wall provide structural support and, along with the muscles of the abdomen, impact lung excursion and thus movement of air in and out of the lung. Cardiovascular and lymphatic drainage maintain the fluid balance of the lung and thus impact gas exchange.

Respiratory distress results from dysfunction or disruption of the respiratory/ventilatory pathway and/or systems that control or modulate respiration.

Respiratory failure is the inability to meet the metabolic demand for O_2 (hypoxia) or the inability to eliminate CO_2 (hypercapnia). Criteria for defining respiratory failure vary widely; one set of criteria is presented in Table 68.1. Hypoxia can be categorized on the basis of mechanism. Hypoxic or arterial hypoxemia is the most common type of hypoxemia. It results from an inability to deliver adequate O_2 to the blood.

TABLE 68.1

CRITERIA FOR RESPIRATORY FAILURE[a]

Clinical	Laboratory
Tachypnea, bradypnea, apnea, irregular respirations	$Pa_{O_2} < 60$ mmHg in 60% O_2[b]
Pulsus paradoxus > 30 mmHg	$Pa_{CO_2} > 60$ mmHg and rising
Decreased or absent breath sounds	pH < 7.3
Stridor, wheeze, grunting	Vital capacity < 15 mL/kg
Severe retractions and use of accessory muscles	Maximum inspiratory pressure ±25 cm H_2O
Cyanosis in 40% O_2[b]	
Depressed or heightened level of consciousness, decreased response to pain	
Weak to absent cough or gag reflex	
Poor muscle tone	

[a]Respiratory failure is likely if two clinical findings and one laboratory finding exist.
[b]Excluding cyanotic heart disease.
[c]Without underlying pulmonary disease.

Most often, this type of hypoxia results from hypoventilation secondary to airway obstruction, central respiratory depression or impairment, neuromuscular or skeletal insufficiency, or restricted lung expansion. Other causes of hypoxemic hypoxia include low atmospheric P_{O_2} (e.g., high altitude), diffusion impairment (e.g., pulmonary edema, pulmonary fibrosis, acute respiratory distress syndrome, O_2 toxicity), anatomic or physiologic shunt (e.g., atelectasis, pneumonia, abnormal pulmonary blood flow), or increased metabolic demand (e.g., exercise, systemic illness). Anemic hypoxia is the result of the blood's inability to deliver adequate O_2 to tissues as a result of decreased hemoglobin oxygen-carrying capacity. It is caused by inadequate red blood cell number (decreased production, increased destruction, loss), low erythrocyte hemoglobin concentration (anemia), abnormal hemoglobin, carboxyhemoglobin, or methemoglobin. Hypokinetic, ischemic, or stagnant hypoxia also results in an inability of the blood to transport O_2 to the tissues. This type of hypoxia is caused by decreased blood flow to a localized area secondary to compromised cardiac output (e.g., cardiac failure), poor tissue perfusion (e.g., shock), sludging (e.g., polycythemia), or obstructed flow (e.g., vascular obstruction). Histotoxic hypoxia results from inability to metabolize O_2 at the tissue level as a result of inactivation of metabolic enzymes by a chemical such as cyanide. Hypercapnia is caused by inadequate alveolar ventilation [e.g., central nervous system (CNS) depression, spinal cord injury, neuromuscular disease, diaphragmatic dysfunction], ventilation-perfusion imbalance with relative hypoventilation (e.g., restrictive airway disease, pulmonary embolism), or increased CO_2 production (e.g., metabolic/endocrine disturbance). Hypercapnia often contributes to respiratory failure as a result of hypoxemia and is less commonly the primary cause.

Infants are at an increased risk of respiratory distress compared with children and adults because of anatomic and physiologic differences (Table 68.2). These differences result in greater risk of airway obstruction, less efficient respiratory effort, limited respiratory reserve, and dysfunction of CNS respiratory control.

DIFFERENTIAL DIAGNOSIS

Establishing a diagnosis for respiratory distress in part depends on localizing the source of the distress to a particular organ system. Respiratory distress may result directly from a disturbance of the upper or lower respiratory system. It may also be caused by inability of the CNS or peripheral nervous system to interpret or process respiratory requirements, or of the musculoskeletal system to perform the work of breathing. Alternatively, disease or dysfunction of other organ systems may indirectly result in respiratory disturbance by compromising respiratory system function or by stimulating compensatory respiratory mechanisms (Tables 68.3 to 68.5). Treatment of the underlying cause is essential for definitive treatment of the respiratory distress.

Respiratory System

Conditions may be congenital or acquired. They may be caused by upper or lower airway obstruction or by disorders of the parenchyma or interstitium. Upper airway obstruction is common in infants and young children in part because of their airway anatomy and physiology (see Chapter 72). Manifestations of upper airway obstruction include nasal flaring, stertor or snoring, gurgling, drooling, dysphagia, aphonia, hoarseness, stridor, retractions, and paradoxical chest/abdominal wall movement. In neonates, the common causes include nasal obstruction, congenital upper airway anomalies (particularly laryngotracheomalacia), and congenital or postintubation subglottic stenosis. Common causes for acquired upper airway obstruction in infants and children include adenotonsillar hypertrophy, peritonsillar abscess, croup, foreign body, retropharyngeal abscess, tracheitis, and airway edema from trauma, thermal or chemical burn, or allergic reaction. *Epiglottitis*, although less common, is one of the most life-threatening causes of respiratory distress and is a true emergency. The incidence of epiglottitis has declined significantly since routine immunization against *Haemophilus influenzae* B, the pathogen that once caused at

TABLE 68.2

ANATOMIC/PHYSIOLOGIC DIFFERENCES IN INFANT/CHILD AND ADULT AIRWAYS

Difference	Consequence
Nose: infants <4 mo obligate nose breathers	Nasal congestion may result in significant respiratory distress
Larynx: higher (C3–C4 vs. C6), funnel shaped, narrowest at cricoid ring, softer, more elastic	More difficult to intubate Collapses more easily, particularly with fixed obstruction (i.e., Bernoulli's principle—as the velocity of flow through a collapsible tube increases, the pressure that holds the tube open decreases)
Trachea: one-third diameter of adult at birth, shorter	Poiseuille's law—resistance varies inversely with fourth power of the radius; 1-mm thickening decreases cross-sectional diameter by 20% in adult and by 80% in child More difficult to intubate/maintain proper depth
Alveoli: elastic fibers less well developed	Alveoli collapse more easily, results in ventilation-perfusion mismatch
Lungs: lower functional residual capacity	Reserve small, therefore limited protection when ventilation is interrupted, Pa_{O_2} decreases more rapidly
Respiratory control apparatus: immature—reflexes that inhibit respiration, particularly Hering-Breuer reflex, which responds to stretch of lung, are very strong; central nervous system processing of information markedly affected by sleep state, cold, drugs, other metabolic derangements	Apnea or inability to respond appropriately to mechanical respiratory obstruction or increased metabolic demand
Chest wall: more compliant; intercostal muscles immature; ribs more horizontal; diaphragm flatter, fatigues; during rapid eye movement sleep, intercostal muscle movements become uncoordinated	Accessory muscle retractions Diaphragm does more work but is less effective

least 75% of cases. Epiglottitis should be suspected in children who have abrupt onset of fever, dysphagia, drooling, muffled voice, labored respirations, and stridor. Children appear toxic and anxious and assume a sniffing position with protruding jaw and extended neck. These children are at risk of abrupt onset of respiratory arrest from obstruction. *Peritonsillar and retropharyngeal abscess* may present with symptoms similar to epiglottitis but have more gradual onset. *Croup* or laryngotracheobronchitis is the most common cause of upper airway obstruction in children 3 months to 3 years of age. Croup causes subglottic narrowing and is characterized by a barky cough, inspiratory stridor, and hoarseness that are worse at night. Viral croup, most often caused by parainfluenza virus, has an insidious onset following several days of upper respiratory infection symptoms with normal temperature or low-grade elevation. Spasmodic or allergic croup has acute onset, usually with wakening during the night, in a child who was well before going to sleep. Children with recurrent or prolonged croup may have an underlying fixed or functional airway abnormality, most commonly subglottic stenosis or hemangioma. Children with chronic stridor, particularly those younger than 2 years, are also likely to have an underlying congenital anomaly. *Tracheitis*, a bacterial infection of the trachea, usually due to *Staphylococcus* or *Streptococcus*, may occur as a primary infection with abrupt onset, high fever similar to epiglottitis or more commonly as a secondary infection in a child with a croup-like illness and is suggested by worsening clinical course. In patients with respiratory failure due to upper airway infection, tracheitis is now more likely to be the etiology than epiglottitis or croup.

Foreign-body aspiration, which has a peak age of occurrence of 1 to 5 years, may cause obstruction of the upper or lower airway and is a leading cause of accidental death in toddlers. A history of abrupt onset of choking or gagging is suggestive. Drooling, dysphagia, and stridor suggest an upper airway foreign body, whereas unilateral wheeze, particularly first-time wheeze with acute onset, suggests lower airway position. Presentation, particularly with lower airway foreign body, may be delayed by days to weeks from time of aspiration.

Other common causes of lower airway obstruction involve inflammation and bronchospasm and include asthma, allergy, and bronchiolitis. Wheeze, most often diffuse, is usually a predominant feature of these conditions (see Chapter 80). *Asthma* may be triggered by infection, exercise, environmental irritants, stress, and/or gastroesophageal reflux. Allergy, usually accompanied by coryza, congestion, mucosal edema, and/or rash, may be in response to environmental exposures, food, or medications. *Bronchiolitis*, most often caused not only by respiratory syncytial virus but also by parainfluenza, influenza, adenovirus, metapneumovirus, and less commonly other viruses, presents with wheeze in children younger than 2 years. These conditions cause airway obstruction by decreasing airway lumen secondary to bronchospasm, edema, or thickening of the wall of the lumen. Lower airway obstruction is also caused by include filling of the airway lumen by excessive secretions (e.g., from inflammation, infection, toxin such as organophosphate) or aspirated fluids and decrease in lumen diameter due to loss of radial traction of the airway wall, as with emphysema and masses.

TABLE 68.3

CAUSES OF RESPIRATORY DISTRESS

Respiratory system
Upper airway obstruction
Nasopharynx (craniofacial anomalies, choanal atresia, adenotonsillar hypertrophy, nasal congestion, foreign body, trauma, mass)
Oropharynx (macroglossia, micrognathia, midface hypoplasia, tonsillitis, peritonsillar abscess, Ludwig's angina, trauma)
Larynx (laryngomalacia, hemangioma, papilloma, webs, cysts, laryngoceles, laryngotracheal cleft, subglottic stenosis, croup, epiglottitis, retropharyngeal abscess, tracheitis, anaphylaxis, angioneurotic edema, thermal or chemical burn, foreign body, vocal cord paralysis, trauma)
Trachea (tracheomalacia, stenosis, tracheoesophageal fistula, foreign body)
Bronchi (bronchomalacia, stenosis, bronchogenic cyst, bronchitis, foreign body)
Lower airway obstruction/acinar/interstitial disease
Bronchioles (asthma, bronchiolitis, allergy, angioneurotic edema, bronchiectasis)
Acini/interstitium
Disorders of lung maturity (transient tachypnea of newborn, respiratory distress syndrome, bronchopulmonary dysplasia, persistent fetal circulation, Wilson-Mikity syndrome)
Congenital malformation (congenital emphysema, cystic adenomatoid malformation, sequestration, pulmonary agenesis/aplasia/hypoplasia, pulmonary cyst)
Aspiration (meconium, foreign body, near drowning, gastroesophageal reflux, vomiting)
Infection (pneumonia; bacterial, atypical bacteria, viral, chlamydial, pertussis, fungal, pneumocystis)
Pulmonary collapse, fluid, mass (atelectasis, edema, hemorrhage, embolism, mass)
Environmental/trauma (high-altitude pulmonary edema, thermal or chemical burn, smoke, carbon monoxide, hydrocarbon, drug-induced pulmonary fibrosis, bronchopulmonary traumatic disruption, pulmonary contusion)

Central nervous system
Structural abnormality (agenesis, hydrocephalus, mass, arteriovascular malformation)
Dysfunction/immaturity (apnea, hyperventilation/hypoventilation)
Infection (meningitis, encephalitis, abscess)
Inherited degenerative disease
Intoxication (alcohol, barbiturates, benzodiazepines, opiates)
Seizure
Trauma (birth asphyxia, hemorrhage)
Spinal cord (congenital anomaly, tetanus, trauma)
Anterior horn (poliomyelitis, transverse myelitis, spinal muscular atrophy)

Peripheral nervous system
Peripheral motor nerve (phrenic nerve injury, Guillain-Barré syndrome, multiple sclerosis, tick paralysis, heavy metal or organophosphate toxicity, porphyria)
Neuromuscular junction (myasthenia gravis, botulism, snake bite, organophosphate toxicity, antibiotics)
Muscle (muscular/myotonic dystrophies, IEM, carnitine deficiency, polymyositis/dermatomyositis, fatigue)

Chest wall/intrathoracic
Air leak (pneumothorax, tension pneumothorax, pneumomediastinum, pneumopericardium)
Space-occupying (esophageal foreign body, pleural effusion, empyema, chylothorax, hemothorax, anomalies great vessels, diaphragmatic hernia, cyst, mass)
Boney and/or muscular deformity or dysfunction (congenital bone/muscle absence, spine deformity, pectus excavatum/carinatum, diaphragmatic hernia, contusion, rib fractures/flail chest, burn)

Cardiovascular
Congenital (structural defect, arrhythmia)
Acquired (myocarditis, myocardial ischemia or infarction, pericardial effusion, pericardial tamponade, aortic dissection or rupture, mass, coronary artery dilation/aneurysm, congestive heart failure)

Gastrointestinal
Distension/pain (necrotizing enterocolitis, mass, obstruction, perforation, laceration, hematoma, contusion, appendicitis, infection, inflammation, ascites)

Metabolic/endocrine
Acidosis (exercise, fever, hypothermia, dehydration, sepsis, shock, IEM, liver disease, renal disease, diabetic ketoacidosis, salicylates)

Hyperammonemia (IEM, liver failure)
Serum chemistry disturbance (hyperkalemia/hypokalemia, hypercalcemia/hypocalcemia, hypophosphatemia, hypermagnesemia/hypomagnesemia)
Respiratory chain disturbance (cyanide)
Endocrine (hyperglycemia/hypoglycemia, hyperthyroidism/hypothyroidism, hyperparathyroidism, adrenal hyperplasia)

Hematologic
Anemia, abnormal hemoglobin (inadequate erythrocyte numbers, decreased production, loss, hemoglobinopathy, methemoglobin, carboxyhemoglobin)
Polycythemia

IEM, inborn error of metabolism.

TABLE 68.4

MOST COMMON CAUSES OF RESPIRATORY DISTRESS

Neonates	Infants/children
Nasal obstruction	Peritonsillar abscess
Congenital airway anomalies	Croup
Transient tachypnea	Tracheitis
Respiratory distress syndrome	Foreign body
Meconium aspiration	Bronchiolitis
Pneumonia	Asthma
Sepsis	Allergy
Congenital heart disease	Pneumonia
	Fever
	Sepsis
	Gastroenteritis/dehydration

Disorders of the alveoli and interstitium involve pus or fluid collection, collapse, and structural or functional abnormality. Alveolar and interstitial disease is characterized by tachypnea, cough, grunting, crackles, rhonchi, wheeze, and decreased and/or asymmetric breath sounds with or without fever. In neonates, transient tachypnea of the newborn and meconium aspiration are common causes. *Pneumonia* is one of the most common causes of lower airway disease in neonates, infants, and children. Findings are more likely to be localized in the setting of bacterial pneumonia, whereas patients with viral and atypical pneumonias, such as *Mycoplasma* infection, *Chlamydia* infection, and pertussis, tend to have diffuse peribronchial, interstitial processes. Severe acute respiratory syndrome (SARS), first seen in November 2002, is a form of atypical pneumonia caused by a coronavirus (SARS-CoV). The most common symptoms of SARS are fever, chills, malaise, myalgias, cough, tachypnea, dyspnea, and hypoxia. Chest x-ray (CXR) films reveal focal infiltrates with progression to general patchy, interstitial infiltrates similar to pneumonia or respiratory distress syndrome. Less commonly, aspiration, hemorrhage, and pulmonary edema cause fluid collection in the acini and interstitium. Atelectasis, or airway collapse, resulting from loss of air from the pulmonary parenchyma, often occurs secondary to other processes, including pneumonia, particularly viral; bronchospasm; and inadequate lung expansion, most often resulting from pain, neuromuscular disease, or inactivity. Structural and/or functional abnormalities include bronchopulmonary dysplasia, hyaline membrane disease or respiratory distress syndrome, bronchiectasis (most commonly seen in cystic fibrosis), congenital or acquired emphysema, and pulmonary fibrosis (usually from radiation and chemotherapy).

Several biological and chemical agents that are potential weapons of terrorism or warfare produce respiratory distress as their most predominant effect. These include the biological agents inhalational anthrax, pneumonic plague, pneumonic tularemia, melioidosis, and the toxins *Staphylococcus* enterotoxin B and ricin, and the chemical agents chlorine and phosgene (see Chapter 7). Respiratory findings include cyanosis, chest pain, cough, hemoptysis, dyspnea, tachypnea, stridor, rales, and/or wheeze. CXR films may reveal infiltrates, pulmonary edema, pleural effusions, widened mediastinum, abscesses, and/or granulomas.

TABLE 68.5

MOST COMMON ACUTE LIFE-THREATENING CAUSES OF RESPIRATORY DISTRESS

Foreign body	Pericardial tamponade
Tension pneumothorax	Epiglottitis

Nervous System

CNS disturbances may result in hypoventilation or hyperventilation, loss of protective airway reflexes, or airway obstruction from loss of pharyngeal tone. These conditions include CNS malformation, immaturity, infection, degenerative disease, seizures, mass, trauma, and intoxication. Focal neurologic deficits, visual disturbances, pupillary abnormalities, papilledema, abnormal muscle tone, and altered level of consciousness suggest CNS processes. Spinal cord trauma and anterior horn cell disease cause bulbar and respiratory muscle dysfunction, which results in airway obstruction and/or hypoventilation. Peripheral neuromuscular (i.e., peripheral nerve, neuromuscular junction, muscle) disorders result in muscle weakness or paralysis. Physical findings that suggest significant chest wall weakness may include hypotonia, hyporeflexia, muscle weakness, weak cry, hoarse voice, cough, gag, shallow or irregular respiratory pattern, and inability to lift the head or extremities (see Chapter 83).

Chest Wall/Thoracic Cavity

Musculoskeletal deformity or disease involving the support structures of the chest may severely restrict lung expansion, limiting normal ventilatory efforts or attempts at compensatory ventilation for respiratory dysfunction and other systemic disturbances.

Intrathoracic conditions that may produce respiratory distress include air leak and space-occupying lesions, including fluid collections and masses. Air leak is most commonly caused by pneumothorax or tension pneumothorax, which may be traumatic or spontaneous. Pneumothorax occurs when air enters the pleural space either by chest wall penetration (open pneumothorax) or by rupture of lung through the visceral pleura (closed pneumothorax) and causes collapse of the lung. With tension pneumothorax, air is able to enter but not egress. Pneumothorax, in addition to nonspecific signs of respiratory distress, is suggested by chest wall hyperexpansion, decreased or absent breath sounds, and hyperresonance on the side of the air leak. Rarely, a patient will have bilateral pneumothoraces. With tension pneumothorax, there is also jugular venous distension (JVD) and deviation of the trachea and mediastinum away from the air leak. Tension pneumothorax decreases venous return and thus cardiac output. It is therefore life threatening and must be relieved immediately by thoracentesis. The most commonly occurring space-occupying lesion is pleural effusion. Pleural effusion, which may be caused by infection, inflammation, ischemia, trauma, malignancy, major organ failure, drug hypersensitivity, or venous or lymphatic obstruction, is suggested on physical examination by decreased breath sounds and a pleural

rub. Mass lesions include congenital or traumatic diaphragmatic hernia, esophageal anomalies, benign or neoplastic masses, and vascular malformations (see Chapter 95).

Cardiovascular

Congenital and acquired heart disease may result in respiratory distress from decreased cardiac output, reduced O_2 saturation, and/or congestive heart failure. Compromised cardiac output, most commonly caused by congenital structural heart defects, cardiac arrhythmias, myocarditis, pericardial effusion, pericardial tamponade, or hypotension, may result in insufficient tissue O_2 delivery to meet metabolic demands. *Pericardial tamponade* causes decreased cardiac output as a result of compromised cardiac filling. Classic physical examination findings of arterial hypotension, JVD, and distant heart sounds, referred to as Beck's triad, are seen in fewer than one-third of patients. Pericardial tamponade may be caused by trauma, infection, inflammation, malignancy, or cardiac surgery. Acute tamponade may be immediately life threatening and must be relieved expeditiously by pericardiocentesis. Cardiac anomalies with right-to-left shunting of deoxygenated blood result in reduced O_2 saturation of blood entering the systemic circulation, hence causing hypoxia with cyanosis. Cardiac defects causing left-to-right shunting result in pulmonary overcirculation, pulmonary venous congestion, and pulmonary edema that directly compromises pulmonary function. In children, congenital heart defects are the most common cause of *congestive heart failure* (CHF). Other cardiac causes of CHF include valvular heart disease, myocardial dysfunction, arrhythmias, ischemia, and infarction. Metabolic disturbances, sepsis, fluid overload, and severe anemia may also result in CHF. Pulmonary manifestations of CHF include tachypnea, increased work of breathing, dyspnea on exertion, orthopnea, cough, wheeze, and bibasilar rales. Other manifestations include poor feeding, failure to thrive, fatigue, tiring with feeds, diaphoresis, edema, tachycardia, weak thready pulses, JVD, displaced point of maximum impulse, cardiac murmur, gallop, rub, cardiomegaly, and hepatosplenomegaly. Vascular causes of respiratory distress include pulmonary embolism, pulmonary hypertension, and pulmonary arteriovenous fistula (see Chapter 82).

Gastrointestinal

Abdominal obstruction, perforation of hollow viscous, laceration of solid organs, hematoma, contusion, appendicitis, infection, inflammation, ascites, or mass may result in impaired diaphragmatic excursion secondary to abdominal distension and/or pain. Prolonged shallow respiration may result in pulmonary hypoventilation. Gastroesophageal reflux or vomiting, particularly in children unable to protect their airway, may result in pulmonary aspiration (see Chapter 93).

Metabolic and Endocrine Disturbances

Metabolic disturbances often manifest as compensatory alterations in respiratory status. Metabolic acidosis results in rapid, deep breathing. Hyperammonemia directly stimulates the respiratory center to produce tachypnea, which results in primary respiratory alkalosis with secondary metabolic acidosis. Metabolic disruption of O_2 metabolism is another cause for respiratory distress. Endocrine disturbances that cause alterations in metabolic rate or chemical imbalances also result in respiratory distress (see Chapters 97 and 98).

Hematologic

Inadequate concentrations of hemoglobin or hemoglobin with decreased oxygen-carrying capacity result in deficient O_2 delivery to tissues. Polycythemia results in sludging of blood and therefore compromised O_2 delivery (see Chapter 87).

EVALUATION AND DECISION

Triage and Stabilization

Every child with significant respiratory distress must be considered to be at potential risk of respiratory collapse. Airway patency, breathing, and circulation should be rapidly assessed and, if compromised, should be established and optimized immediately (Table 68.6). For the child in respiratory arrest, cardiac arrest, if not already present, is imminent.

Cardiorespiratory status should be continuously monitored. A health care provider skilled in airway management and resuscitation should remain with the patient at all times. Evaluation that is stepwise and focused is critical for determining the source and severity of respiratory distress. Anticipation and rapid aggressive management are essential for optimizing outcome. In the child who is alert and otherwise healthy, the position that he or she has naturally assumed is likely to be the one that minimizes respiratory distress and thus should be maintained. A child with significant respiratory distress should be allowed to remain with the parents and should not be agitated. Anxiety increases minute ventilation and adds significantly to the child's O_2 consumption. Any patient believed to have ventilatory compromise should be treated immediately with humidified O_2 at the highest concentration available. Supplemental O_2 provides a small but often crucial margin of safety in ensuring adequate cerebral and myocardial oxygenation. In patients with decreased sensorium or neuromuscular disease, a position to optimize airway patency must be established. Airway devices or assisted ventilation may be necessary. For management of cardiorespiratory arrest, resuscitation efforts must be initiated immediately, as detailed in Chapters 1, 2, and 5.

History

A detailed history usually provides important clues to the cause of respiratory distress, but in a critically ill child, comprehensive detail should not be obtained at the expense of patient care. A brief history can be obtained while emergent treatment is initiated. Details can follow once the child is stabilized. Information obtained by history should include a description of respiratory and other symptoms, onset and duration of symptoms, possible precipitating factors including ill contacts, environmental exposures and recent travel, therapeutic interventions, history of previous similar symptoms, underlying medical conditions,

TABLE 68.6

LIFE-SAVING MANEUVERS TO RELIEVE RESPIRATORY DISTRESS

Maneuvers	Indications	Comments
Heimlich maneuver (abdominal thrusts) for age ≥ 1 yr	Relieve upper airway obstruction caused by foreign body	Contraindicated if conscious patient able to phonate
Back/chest blows for age < 1 yr Manual foreign-body extraction		Remove visible foreign body in the oropharynx, blind sweep contraindicated
Head tilt/chin lift, jaw thrust	Relieve oropharyngeal obstruction	Head tilt/chin lift contraindicated if neck trauma
Nasopharyngeal airway	Relieve nasopharyngeal obstruction	Conscious or unconscious patient Contraindicated if bleeding diathesis, cerebrospinal fluid leak, nasal deformity
Oropharyngeal airway	Relieve obstruction by the tongue	Unconscious patient
Suction	Remove excess secretions, mucous plug	Nose, mouth, and, if intubated, trachea
Bag-valve-mask ventilation	Provide mechanical ventilation, deliver high-concentration oxygen	Self-inflating or anesthesia bag
Endotracheal intubation/assisted ventilation	Control ventilation for depressed central nervous system	Relatively contraindicated if severe midface trauma
	Absent pharyngeal reflexes	If epiglottitis, consider intubation in operating room
	Mechanical support for weak chest wall Artificial airway for obstructed airway Supplemental oxygen for damaged alveoli Control intracranial pressure by hyperventilation Provide tracheopulmonary toilet Provide positive end-expiratory pressure to increase lung volume	Avoid intubation in severe asthma if possible
Needle cricothyroidotomy	Emergent artificial airway required to sustain life, upper airway obstruction cannot otherwise be relieved, tracheostomy cannot be immediately performed	Temporizing measure, tracheostomy to follow immediately
Tracheostomy	Emergent artificial airway required to sustain life, upper airway obstruction cannot be relieved by endotracheal intubation	Should be performed in operating room by experienced physician
Thoracentesis	Evacuation pneumothorax, tension pneumothorax, hemothorax, drainage pleural effusion, empyema	Chest tube placement to follow immediately or performed instead
Thoracostomy	Evacuate, prevent reaccumulation pneumothorax, tension pneumothorax, hemothorax, effusion, empyema	Thoracentesis first if chest tube cannot be placed immediately in life-threatening situation
Pericardiocentesis	Relieve tamponade: effusion, hemopericardium, pneumopericardium	Improve cardiac output
Bronchoscopy	Foreign-body removal	Do not agitate the child before the procedure Esophagoscopy for esophageal foreign body

particularly those that predispose to respiratory compromise, medications, allergies, and immunizations.

Physical Examination

The physical examination should assess the degree of respiratory distress and should identify the site and likely cause of respiratory distress (Figs. 68.1A and 68.1B). Continuous cardiopulmonary monitoring and frequent assessment are important because respiratory status can change instantaneously. General appearance, level of consciousness, vital signs, respiratory rate, respiratory effort, and adequacy of oxygenation and ventilation give immediate information regarding the severity of respiratory distress and possible sites. Heightened level of consciousness, manifesting as restlessness, anxiety, or combativeness, is more likely an early sign of hypoxia, whereas diminished level of consciousness, manifesting as somnolence,

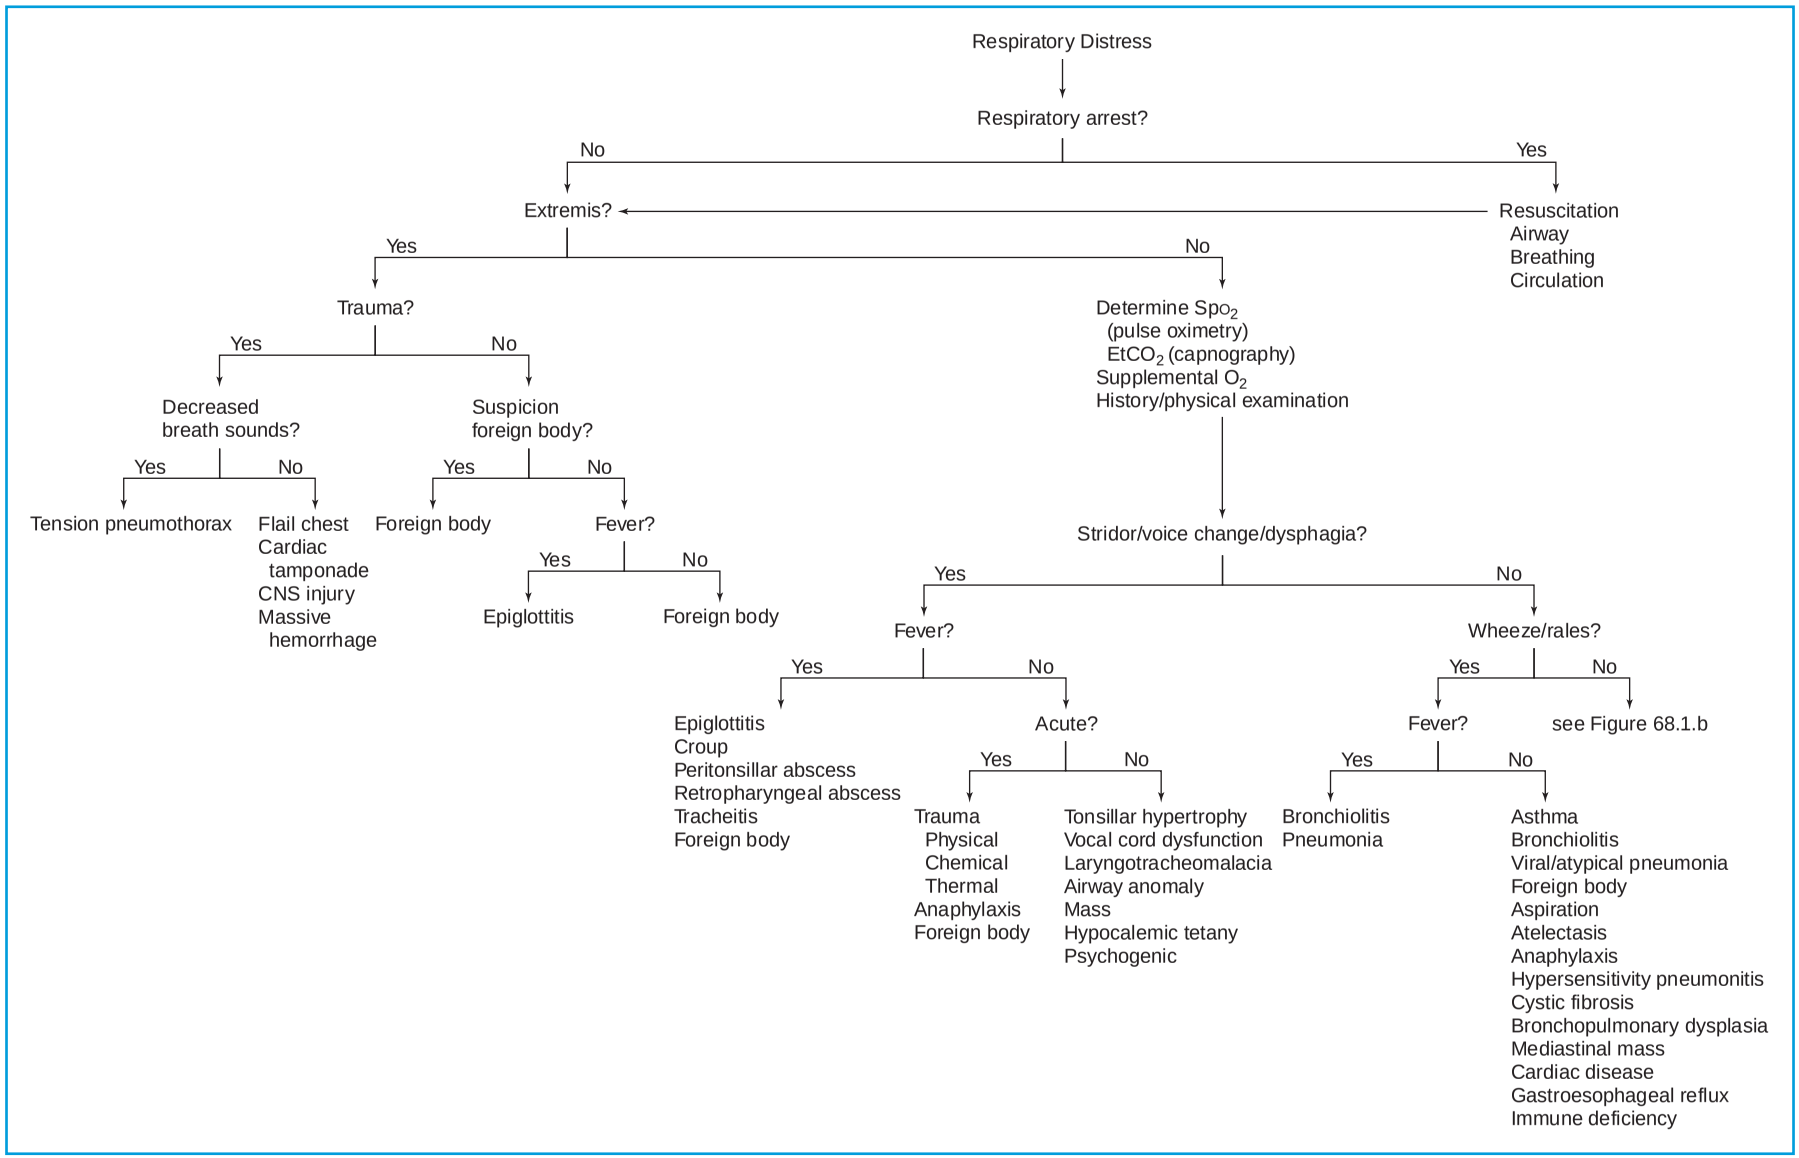

FIGURE 68.1 **A:** Approach to the child with respiratory distress. (*continued*)

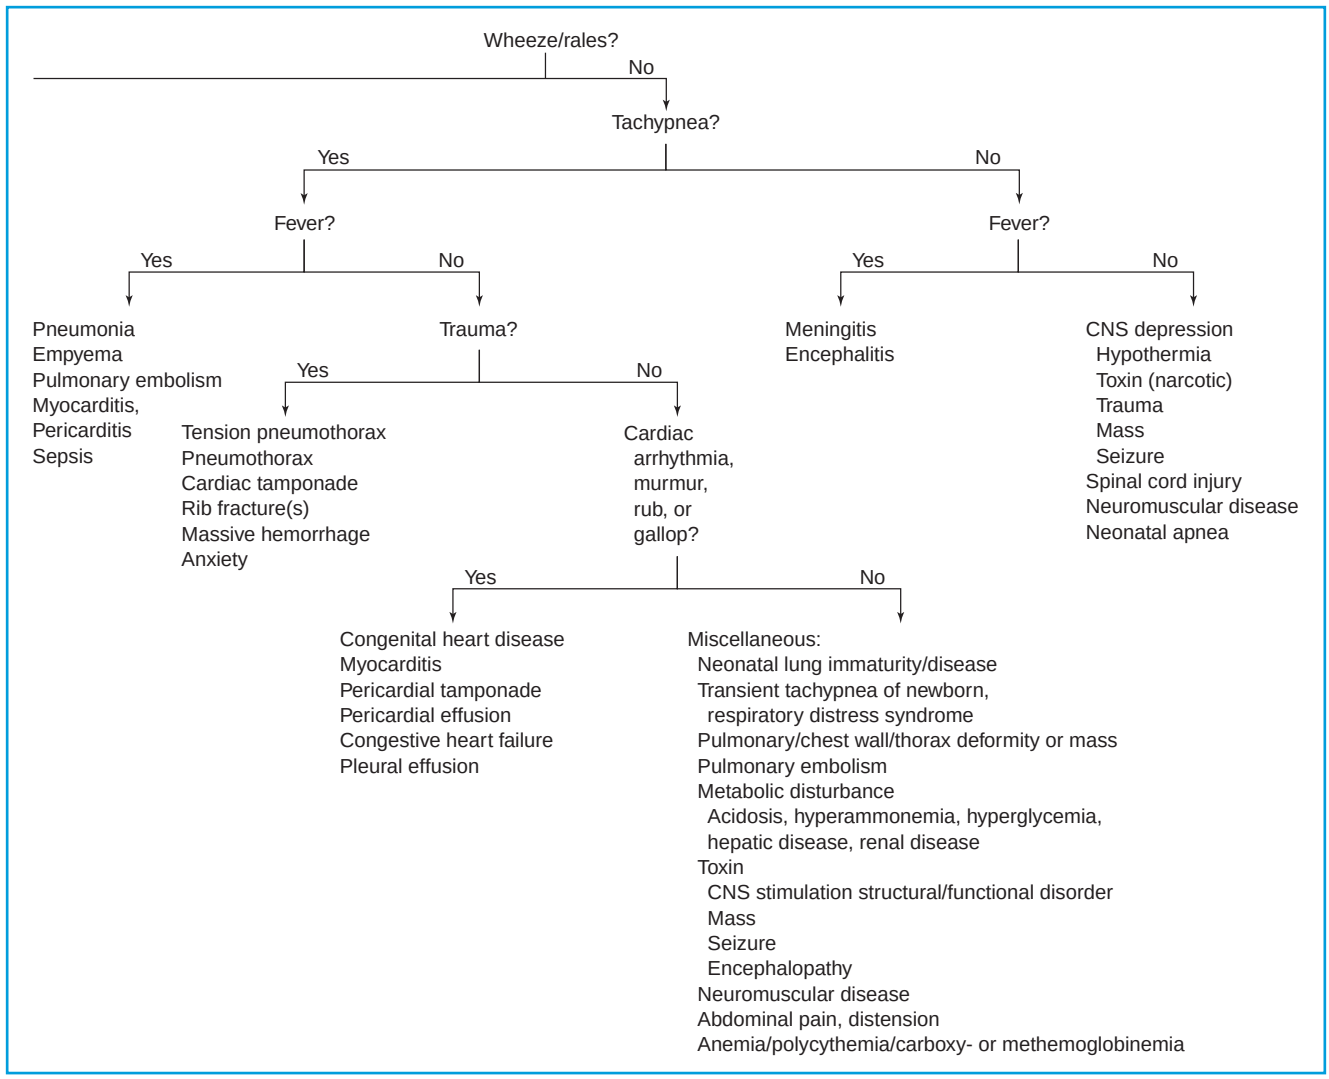

FIGURE 68.1 (*Continued*) **B:** Approach to the child with respiratory distress. SpO_2, percentage oxygen saturation; O_2, oxygen; $EtCO_2$, end tidal carbon dioxide; CNS, central nervous system.

lethargy, stupor, obtundation, or coma, tends to result from hypercarbia or severe hypoxia. The child's posture may suggest the site of the disturbance. Children with upper airway obstruction tend to assume a sniffing position, an upright sitting posture with neck slightly flexed and head extended. For lower airway obstruction, a tripod position, in which the child is sitting up and leaning forward, may be preferred.

TABLE 68.7

NORMAL RESPIRATORY RATES

Age group	Respiratory rate (breaths/min)
Neonates	35–50
Older infants/toddlers	30–40
Elementary school-aged children	20–30
Older children/adolescents	12–20

Vital sign abnormalities provide important clues about the severity of illness and adequacy of compensatory mechanisms. To maintain cardiac output (CO), children are more dependent on increasing heart rate (HR) than on stroke volume (SV) (CO = HR × SV). Tachycardia is one of the early signs of respiratory compromise and is expected because of increased sympathetic tone due to respiratory distress. Bradycardia in a hypoxic child is a late and ominous sign that often signals impending cardiac arrest. Cardiac arrhythmias that compromise cardiac output may result in respiratory distress. Respiratory rate in children varies with age (Table 68.7). Tachypnea is a compensatory mechanism for hypoxia, hypercapnia, and acidosis, and it also occurs with pain, anxiety, and exercise. Although not specific for respiratory distress, tachypnea is one of the findings most consistently present with respiratory distress and is particularly pronounced with lower airway processes. Tachypnea may be the only manifestation of lower respiratory infection in children younger than 6 months. Bradypnea, or decreased respiratory rate, may reflect central respiratory depression, increased

intracranial pressure, diabetic coma, or fatigue of respiratory muscles. It is usually an ominous sign that heralds impending respiratory arrest. Blood pressure is often increased because of anxiety. Pulsus paradoxus, an exaggeration (more than 10 mmHg) of the normal decrease in blood pressure during inspiration, correlates well with degree of airway obstruction. Pulses paradoxus is also caused by compromised venous return because of forces on the pericardium that result in decreased cardiac output, particularly during forced inspiration. Hypotension in a child is a late and extremely worrisome finding. It suggests profound shock, significantly decreased cardiac output, and impending cardiorespiratory arrest. Fever results in an increase in the respiratory rate of approximately 3 breaths per minute for each degree centigrade of temperature elevation above normal, due at least in part to an increase in CO_2 production.

On inspection, in addition to respiratory rate, one should appreciate depth, rhythm, and symmetry of respirations; the use of accessory muscles; and perfusion. Breathing that becomes progressively more rapid and more shallow results from greater air trapping because airway resistance increases in obstructive lower airway disease. Rapid shallow breathing may also result from chest pain or chest wall musculoskeletal dysfunction. Kussmal's respirations (deep, regular, sighing breaths that may be rapid, slow, or normal in rate) are seen with metabolic acidosis, particularly diabetic ketoacidosis. Cheyne-Stokes respirations (respirations with increasing then decreasing depth alternating with periods of apnea) are seen with CNS immaturity in otherwise normal neonates and infants, particularly during sleep, and with inadequate cerebral perfusion, brain injury, increased intracranial pressure, and central narcotic depression. Biot's, or ataxic, respirations (breaths of irregular depth interrupted irregularly by periods of apnea) suggest CNS infection, injury, or drug-induced depression. Asymmetric chest wall movement and/or expansion suggest unilateral chest wall or thoracic cavity pathology. Nasal flaring and supraclavicular, suprasternal, and subcostal retractions of accessory muscles of respiration usually reflect upper airway obstruction but may occur with lower processes (Table 68.8). Intercostal retractions are usually a sign of inadequate tidal volume as a result of lower airway disease. Thoracoabdominal dissociation, also called respiratory alternans or paradoxical breathing, in which the chest collapses on inspiration and the abdomen protrudes, is a common sign of respiratory muscle fatigue. Central cyanosis results from reduced ambient O_2, airway obstruction with impaired oxygenation, alveolar diffusion impairment, cardiac defect with right-to-left shunting, left ventricular heart failure with pulmonary edema, or methemoglobinemia. Cyanosis usually reflects at least 5 g per dL of unsaturated hemoglobin and an O_2 saturation of less than 90%. Cyanosis may not be recognized in severely anemic patients and may be more pronounced in polycythemic patients. Peripheral cyanosis is caused by local vascular changes of the extremities that result in inadequate perfusion or vascular stasis; it is not usually associated with a decrease in systemic O_2 saturation.

Palpation of the chest commonly reveals vibratory rhonchi over the large airways, which suggests fluid in the airway. Tactile fremitus, when increased, suggests bronchopulmonary consolidation or abscess, and when decreased or absent, it suggests bronchial obstruction or space-occupying processes of the pleural cavity. Crepitus on palpation of the chest or neck may reveal subcutaneous emphysema caused by pneumothorax or pneumomediastinum.

Auscultation is particularly useful for localizing the site of respiratory distress (Table 68.8). Stertor, gurgle, dysphonia, aphonia, hoarseness, barky cough, and inspiratory stridor localize the respiratory distress to the upper airway. A lower airway cause is suggested by decreased or asymmetric breath sounds, changes in pitch of breath sounds, expiratory stridor,

TABLE 68.8

LOCALIZATION OF RESPIRATORY DISTRESS BY PHYSICAL EXAMINATION FINDINGS

Flaring: reflexive opening of nares during inspiration with upper airway obstruction
Retractions: inward collapse of chest wall as a result of high negative intrathoracic pressure from increased respiratory effort; supraclavicular, suprasternal, and subcostal retractions reflect upper airway obstruction, intercostal retractions reflect lower airway obstruction or disease
Stertor: snoring with nasal congestion, adenotonsillar hypertrophy, neuromuscular weakness
Gurgle: inspiratory and expiratory bubbling sounds caused by secretions oropharynx, trachea, large bronchi
Aphonia/dysphonia: vocal cord obstruction, dysfunction
Hoarseness: laryngeal obstruction, dysfunction
Barky cough: subglottic, tracheal obstruction
Stridor: abnormal turbulence over airway obstruction; (i) inspiratory: quiet, high pitched from glottic, subglottic region; (ii) expiratory: loud, harsh from carina or below; and (iii) biphasic: loud, harsh from trachea
Grunt: expiration against a closed glottis to maintain expiratory lung volume with lower airway, gastrointestinal process
Wheeze: continuous, musical; (i) obstructed bronchi, bronchioles—polyphonic (variable, pitched, regional differences) expiratory as in asthma; (ii) obstructed central airway—monophonic (low pitched, same in all lung fields) expiratory ± inspiratory as with tracheal foreign body, tracheomalacia
Crackles (rales): discontinuous, usually high-pitched, inspiratory; moist, from thin secretions in (i) bronchi, bronchioles (medium rales), or (ii) alveoli (fine rales)
Rhonchi (coarse rales): discontinuous, usually low-pitched, inspiratory; moist or dry, from exudate, edema, inflammation in larger bronchi
Pleural friction rub: loud, low-pitched, inspiratory ± expiratory, due to pleural inflammation
Bronchophony, egophony, whispered pectoriloquy: alterations in voice sounds as a result of lobar pneumonia, pleural effusion

grunting, and/or adventitial sounds, including crackles, rhonchi, wheeze, rub, bronchophony, egophony, and whispered pectoriloquy. The ratio of inspiratory to expiratory phase of respiration, normally 1:1, is often useful in distinguishing an upper from lower respiratory tract cause of respiratory distress. Respiratory distress from upper airway disease usually results from difficulty of inward air movement. The inspiratory phase is often increased relative to the expiratory phase to between 1:1 and 2:1. Lower airway processes often impede outward air movement and may result in a prolonged expiratory phase with ratios of 1:3 to 1:4. Absence or disappearance of wheeze in a child with continued or worsening respiratory distress may represent severe obstruction and should not be considered reassuring but rather may herald impending respiratory arrest.

Percussion of the chest may reveal either hyperresonance, suggesting air trapping, or dullness, suggesting an area of consolidation, a mass in the lung or pleural space, or pleural fluid. Air trapping is further suggested by depressed position of the diaphragm. Diaphragmatic excursion can be accessed by measuring the difference between the level of dullness on percussion during full inspiration and full expiration. Poor diaphragmatic excursion may reflect diaphragmatic dysfunction.

The remainder of the physical examination should concentrate on the nervous, cardiac, gastrointestinal, renal, skin, metabolic/endocrine, and hematologic systems and may reveal pathology of these organ systems that localizes the underlying source of respiratory distress.

Approach

The approach to the child with respiratory distress (Figs. 68.1A and 68.1B) begins with the assessment of airway patency, oxygenation and ventilation, and, as required, appropriate resuscitation as per Pediatric Advanced Life Support guidelines. Patients in extremis (Fig. 68.1A) most commonly due to airway obstruction, tension pneumothorax, flail chest, or cardiac tamponade require immediate treatment of these conditions. History and physical examination to determine etiology, most commonly foreign body, infection, anaphylaxis, or injury and to guide further evaluation and management should be obtained while providing emergent treatment.

For patients with mild to moderate respiratory distress, allow patients to assume and maintain a position that maximizes their respiratory function. Every effort should be made to avoid agitating the child as this may result in critical airway compromise and increased metabolic demand for O_2. The initial focus of the examination should be on the respiratory and cardiac systems. Assessment begins with the observation of patient position, general appearance, work of breathing, and respiratory sounds that can be appreciated without a stethoscope and is followed by auscultation to assess abnormal cardiopulmonary sounds, oxygenation, and ventilation. The remainder of the examination is performed when the child is sufficiently stable to tolerate the examination.

Nearly all patients with respiratory distress should have their oxygenation level tested by pulse oximetry. Arterial blood gas or capnography, which measures end-tidal carbon dioxide ($EtCO_2$) and CO_2 waveform, and chest radiograph are the tests most likely to be helpful in the determination of respiratory failure and impending failure, particularly because of lower airway processes, and may provide insights into its cause. Measurement of $EtCO_2$ and CO_2 waveform is indicated in all intubated patients to access and monitor endotracheal tube placement and ventilation and is recommended in spontaneously breathing patients to diagnosis upper or lower airway obstruction.

Stridor, altered phonation, and/or dysphagia suggest partial airway obstruction. Children with abnormal auscultatory findings (i.e., wheeze, rales, rhonchi, and/or asymmetric breath sounds) and fever are likely to have pneumonia or bronchiolitis, whereas asthma, bronchiolitis, and foreign-body aspiration are common in afebrile patients.

Patients can be further categorized on the basis of tachypnea (Fig. 68.1B). Children with rapid respirations and fever may have pneumonia, even in the absence of rales; empyema, pulmonary embolism, and encephalitis are also important considerations. Tachypnea without fever points to trauma, cardiac disease, metabolic disturbances, toxic ingestions or exposures, and miscellaneous disorders. Biological and chemical warfare agents may produce tachypnea with or without fever. The identity of the agent is suggested by characteristic onset, progression, and multisystem constellation of symptoms.

Febrile children without tachypnea may have apnea or bradypnea as late manifestations of CNS infection. In afebrile patients, considerations include the myriad causes of CNS depression, spinal cord injury, neuromuscular disease, and neonatal apnea. Diagnostic tests should be used selectively to rule out diagnoses suggested by history and physical examination (Table 68.9).

Treatment

Regardless of the cause of respiratory distress, aggressive treatment must be initiated immediately to rapidly restore oxygenation and ventilation. Airway patency, if inadequate, must be established. In the patient with decreased sensorium, positioning of the airway by chin lift (contraindicated if neck injury is suspected) or jaw thrust may relieve soft-tissue obstruction of the airway. The oral cavity should be cleared of secretions, vomitus, blood, and visible foreign matter. The unconscious patient may benefit from the placement of an oropharyngeal airway or endotracheal intubation. In the alert patient with suspected soft-tissue obstruction of the airway, a nasopharyngeal airway may improve airway patency. Placement of a nasogastric tube to decompress a distended abdomen often improves respiratory effort by allowing full expansion of the lungs. The child in whom airway patency cannot be maintained or adequate ventilation and oxygenation cannot be established likely requires endotracheal intubation.

Indications for intubation directly related to respiratory distress include respiratory failure or impending failure, apnea, airway obstruction, inability to handle secretions, and risk of aspiration.

TABLE 68.9

DIAGNOSTIC STUDIES FOR EVALUATION OF RESPIRATORY DISTRESS

Test	Indications	Comments
Pulse oximetry	Respiratory distress, failure	Measures oxygen saturation Relative contraindication if agitation will worsen distress Not reliable if severe anemia No information about ventilation
Capnography	Respiratory distress, failure Confirm, monitor endotracheal tube placement, ventilatory failure Diagnose, differentiate upper, lower airway obstruction, monitor therapeutic interventions	Measures end-tidal CO_2 ($EtCO_2$), CO_2 waveform Can be used in intubated or nonintubated patients Approximates ABG $PaCO_2$ if cardiovascular status intact; $EtCO_2$ values 2–5 mmHg < $PaCO_2$ Characteristic waveforms for apnea, hypoventilation, obstruction
ABG	Respiratory distress, failure, acidosis, carboxyhemoglobin, methemoglobin	Information about ventilation Most useful for lower airway process Relative contraindication if agitation will worsen distress ABG changes occur late and may not be seen until arrest (A-a) O_2 gradient increase suggests ventilation-perfusion mismatch
CBC count, blood cx, + CSF analysis, cx, mono spot/EBV titer	Infection, allergy	Relative contraindication if agitation or positioning for lumbar puncture will worsen distress
Electrolytes, BUN, CR, glucose, Ca, PO_4, Mg, LFTs, ammonia, TFTs	Metabolic/endocrine disease, metabolic disturbance	Calculate anion gap
PT/PTT	Bleeding/clotting disorder, pulmonary embolism	May be normal
Toxicologic screen blood, urine	Ingestion/intoxication	Central nervous system depressants, neuromuscular blockade, electron transport chain poisons
Nasal, ocular, rectal swab: DFA, PCR, cx	Bronchiolitis, *Chlamydia* infection, pertussis, viral pneumonia	Neonates, infants
Sputum: stains, cx	Bacterial, TB, pneumocystis, fungal	Adolescents
TB skin test	TB	
Radiograph		
Lateral neck radiograph	Tracheitis, abscess, foreign body	Not necessary for the diagnosis of croup Relative contraindication unstable airway Consider portable if unstable
Chest radiograph (AP/lateral)	Lower respiratory disease, foreign body, barotrauma, effusion, mass, chest wall trauma/deformity, cardiac process	
Forced expiratory or bilateral decubitus	Foreign body	Air trapping behind object
	Distinguish effusion from infiltrate	Effusion layers
Unilateral decubitus	Abdominal mass, obstruction, perforation	
AP supine/prone, upright/cross-table lateral		
Fluoroscopy	Upper airway obstruction; structural or functional anatomic, foreign body, paralysis vocal cords, diaphragm	
Laryngoscopy/bronchoscopy	Upper or lower airway obstruction; structural or functional, foreign body	Esophagoscopy for esophageal processes

(continued)

TABLE 68.9

CONTINUED

Test	Indications	Comments
Head CT scan	Central mass, hydrocephalus	
Chest CT scan	Congenital anomaly, mass—tumor, abscess, diaphragmatic hernia	
Abdomen CT scan	Obstruction, mass, appendicitis	
Chest and cardiac US	Pleural or pericardial effusion, tamponade	
Electrocardiogram	Cardiac anomaly, failure, pericarditis	
Thoracentesis, pericardiocentesis cytology, biochemical, cx	Infection, inflammation, oncologic process chest, heart, lymphatics	Also therapeutic Consider ultrasound guidance
Ventilation-perfusion scan	Pulmonary embolism	
Barium swallow	Tracheoesophageal fistula, vascular ring, reflux	
Pulmonary function tests	Central or peripheral nervous system depression of chest wall function, respiratory system disease	Measures lung volume, flow, compliance
Electromyography	Central respiratory drive depressed, neuromuscular disease	Measures muscle activity generated by neural outflow from respiratory centers
Angiography	Vascular anomaly	

ABG, arterial blood gas; CBC count, complete blood cell count; cx, culture; CSF, cerebrospinal fluid; EBV, Epstein-Barr virus; BUN, blood urea nitrogen; CR, creatinine; Ca, calcium; PO_4, phosphate; Mg, magnesium; LFTs, liver function tests; TFTs, thyroid function tests; PT, prothrombin time; PTT, partial thromboplastin time; IFA, immunofluorescence assay; TB, tuberculosis; AP, anteroposterior; CT, computed tomography.

SUMMARY

Respiratory distress is one of the most common chief complaints of children seeking medical care. The causes of respiratory distress are numerous and varied. History and physical examination provide important clues that allow rapid localization of the site of impairment. The underlying cause must be identified and may be within the respiratory system or organ systems that control or impact respiration. Any disorder that causes respiratory distress may be life threatening. Airway and ventilatory problems not only must be recognized but also must be anticipated and addressed aggressively. The underlying cause must also be treated. Patients must be monitored continuously and reassessed frequently. Airway, breathing, and circulation must be established and maintained. Diagnostic evaluation of body fluids, radiologic studies, direct visualization, and specialized tests of organ function must be performed prudently so that respiratory status is not further compromised.

CHAPTER 69 ■ SEIZURES

VINCENT W. CHIANG, MD

Seizures are the most common neurologic disorder in childhood and among the more common symptoms that lead to an emergency department (ED) visit. Studies have shown that 4% to 6% of all children will have at least one seizure in the first 16 years of life. These can range from a self-limited, nonrecurring episode to a prolonged, life-threatening event. The pediatric emergency physician must have a fundamental knowledge of all aspects of seizure management, including initial stabilization, determination of cause (differential diagnosis), appropriate definitive treatment, and patient disposition.

BACKGROUND

A *seizure* is defined as a transient, involuntary alteration of consciousness, behavior, motor activity, sensation, and/or autonomic function caused by an excessive rate and hypersynchrony of discharges from a group of cerebral neurons. A *convulsion* is a seizure with prominent alterations of motor activity. *Epilepsy*, or seizure disorder, is a condition of susceptibility to recurrent seizures.

Seizures may be generalized or partial. Generalized seizures reflect involvement of both cerebral hemispheres. These may be convulsive or nonconvulsive. Consciousness may be impaired and this impairment may be the initial manifestation. Motor involvement is bilateral. Types of generalized seizures include absence (petit mal), myoclonic, tonic, clonic, atonic, and tonic-clonic (grand mal) seizures.

Partial (focal, local) seizures reflect initial involvement limited to one cerebral hemisphere. Partial seizures are further classified on the basis of whether consciousness is impaired. When consciousness is not impaired, the seizure is classified as a simple partial seizure. Simple partial seizures may have motor, somatosensory/sensory, autonomic, or psychic symptoms. When consciousness is impaired, the seizure is classified as a complex partial seizure. Both simple and complex partial seizures may evolve into generalized seizures (e.g., Jacksonian march).

Status epilepticus is the condition of prolonged seizure activity (more than 5 minutes) or persistent, repetitive seizure activity without recovery of consciousness in between episodes.

A postictal (decreased responsiveness) period usually follows the seizure. During this time, the patient may be confused, lethargic, fatigued, or irritable; also, headache, vomiting, and muscle soreness may occur. In general, the length of the postictal period is proportional to the length of the seizure. For brief seizures, there may be few or no postictal symptoms. Transient focal deficits (e.g., Todd's paralysis) may occur during the postictal period, but one must first rule out a focal central nervous system (CNS) deficit.

PATHOPHYSIOLOGY

The underlying abnormality in all seizures is the hypersynchrony of neuronal discharges. Cerebral manifestations include increased blood flow, increased oxygen and glucose consumption, and increased carbon dioxide and lactic acid production. If a patient can maintain appropriate oxygenation and ventilation, the increase in cerebral blood flow is usually sufficient to meet the initial increased metabolic requirements of the brain. Brief seizures rarely produce any lasting effects. However, prolonged seizures may result in permanent neuronal injury.

Systemic alterations may occur with seizures and result from a massive sympathetic discharge, leading to tachycardia, hypertension, and hyperglycemia. Failure of adequate ventilation, especially in patients in whom consciousness is impaired, can lead to hypoxia, hypercarbia, and respiratory acidosis. Patients with impaired consciousness may be unable to protect their airway and are at risk for aspiration. Prolonged skeletal muscle activity can lead to lactic acidosis, rhabdomyolysis, hyperkalemia, hyperthermia, and hypoglycemia.

DIFFERENTIAL DIAGNOSIS

It is important to remember that a seizure does not constitute a diagnosis but is merely a symptom of an underlying pathologic process that requires a thorough investigation (Table 69.1). Often, no underlying condition is "identified," and the diagnosis of idiopathic epilepsy is made. However, it is important not to exclude potentially treatable causes prematurely. For instance, seizures that result from metabolic derangements (e.g., hyponatremia, hypoglycemia) are often refractory to anticonvulsant therapy until the abnormality is corrected. Furthermore, every effort should be made to rule out a potentially life-threatening cause of seizures (e.g., intracranial injury or hemorrhage, meningitis, ingestions) before a less serious diagnosis is accepted.

Although the diagnosis of a seizure is often made in the ED on the basis of the clinical history, other childhood paroxysmal events are often mistaken for seizure activity (Table 69.2). Occasionally, these events are referred to as an apparent life-threatening event (ALTE). An ALTE is not a diagnosis per se but rather any episode that frightens an infant's caregiver (see Chapter 10). Typically, these events involve apnea, color change (cyanosis, erythema, or pallor), marked change in muscle tone (limpness), or choking and gagging. Although a seizure itself may be the cause of an ALTE, the differential diagnosis (as for seizures themselves) of an ALTE is quite broad. Every attempt should be made to differentiate these events from seizures to ensure appropriate diagnosis, correct

TABLE 69.1

ETIOLOGY OF SEIZURES[a]

Infectious	Metabolic
Brain abscess	Hepatic failure
Encephalitis	Hypercarbia
Febrile (nonspecific)	Hyperosmolarity
Meningitis	Hypocalcemia
Parasites (central nervous system)	Hypoglycemia
Syphilis	Hypomagnesemia
Idiopathic	Hyponatremia
Withdrawals	Hypoxia
Alcohol	Inborn errors of metabolism
Anticonvulsants	Pyridoxine deficiency
Hypnotics	Uremia
Toxicologic	Vascular
Anticonvulsant	Cerebrovascular accident
Camphor	Hypertensive encephalopathy
Carbon monoxide	Oncologic
Cocaine	Primary brain tumor
Heavy metals (lead)	Metastatic disease
Hypoglycemic agents	Endocrine
Isoniazid	Addison's disease
Lithium	Hyperthyroidism
Methylxanthines	Hypothyroidism
Pesticides (organophosphates)	Obstetric
Phencyclidine	Eclampsia
Sympathomimetics	Traumatic
Tricyclic antidepressants	Cerebral contusion
Topical anesthetics	Diffuse axonal injury
Degenerative cerebral disease	Intracranial hemorrhage
Hypoxic ischemic injury	Congenital anomalies

[a]Bold type denotes most common causes. Given their nature, virtually all these etiologies are potentially life threatening, except perhaps simple febrile seizures.

TABLE 69.2

DIFFERENTIAL DIAGNOSIS OF PAROXYSMAL EVENTS

Seizure disorders	Movement disorders
Pseudoseizures	Paroxysmal choreoathetosis
Head trauma	Tic disorders
Loss of consciousness	Shudder attacks
Posttraumatic seizures	Benign myoclonus
Syncope	Psychiatric disorders
Hypovolemia	Daydreaming
Hypoxia	Attention-deficit hyperactivity disorder
Reduced cardiac output	Panic attacks
Sleep disorders	Gastrointestinal disorder
Nightmares	Sandifer syndrome (gastroesophageal reflux)
Night terrors	Abdominal migraines
Narcolepsy	Cyclic vomiting
Sleep-apnea hypersomnia	Breath-holding spells
Somnambulism	Pallid, cyanotic
Atypical migraines	Apparent life-threatening event

treatment, and accurate prognosis. Each episode or "spell" should be evaluated by examining the preceding events, the episode itself, and the nature and duration of the postictal impairment. Obviously, a thorough physical examination needs to be performed. If any of these features seem atypical, an alternative diagnosis should be considered.

Syncope, or the transient loss of consciousness that results from inadequate cerebral perfusion or substrate delivery, is the most common alternative diagnosis given to patients who present for the evaluation of a seizure episode (see Chapter 73). Further complicating matters is the fact that a small percentage of patients with syncope exhibit some sort of convulsive movement. Although vasovagal episodes or orthostatic hypotension is the most common causes for syncope, it is important to evaluate these patients for potential underlying cardiac disease.

Pseudoseizures are a movement disorder that resemble seizure activity but have no corresponding abnormal brain electrical activity. The movements can be quite startling, are typically bizarre and thrashing, and are often associated with a great deal of vocalization. There is usually no biting, incontinence, or injury associated with pseudoseizures. There is also rarely a postictal period, and patients often possess a clear mental status after the event. Pseudoseizures also rarely occur during sleep. The diagnosis can often be made upon history and physical examination alone but may also require long-term video and electroencephalographic (EEG) monitoring to confirm the diagnosis. Further complicating the issue is that pseudoseizures are most likely to occur in patients with an underlying seizure disorder.

Breath-holding spells are common, affecting 4% to 5% of all children (see Chapter 131). They typically present between the ages of 6 and 18 months and disappear by 5 years of age. The two types of breath-holding spells—cyanotic and pallid—have common features, including a period of apnea and an alteration in the state of consciousness. Usually, some initiating event (e.g., pain, fear, agitation) triggers the episode. The diagnosis is based on the clinical findings, and the prognosis is excellent.

A variety of movement disorders can mimic seizures. Paroxysmal choreoathetosis is often associated with a positive family history for seizures and exacerbated by intentional movement. Tic disorders can be manifested by twitching, blinking, head shaking, or other repetitive motions. These are usually suppressible and are not associated with any loss of consciousness. Shudder attacks are whole-body tremors similar to essential tremor in adults. Benign myoclonus of infancy can look like infantile spasms but is associated with a completely normal EEG.

Sleep disorders, such as somnambulism, night terrors (preschool-aged children), and narcolepsy (typically in adolescents) can often be diagnosed on the basis of the history alone (see Chapter 131). Infants with gastroesophageal reflux may exhibit torticollis or dystonic posturing (Sandifer syndrome). Atypical migraines and pseudoseizures are often diagnosed after other causes are excluded.

INITIAL STABILIZATION

The first priority in the seizing patient is to address airway, breathing, and circulation (the ABCs; see Chapter 1). An adequate airway is necessary to allow for effective ventilation and

oxygenation. Patients with impaired consciousness as part of their seizure are at risk for obstruction (the tongue, oral secretions, emesis), aspiration (loss of protective reflexes), and hypoventilation. Simple maneuvers such as the jaw thrust or suctioning of the oropharynx may improve the compromised airflow. The use of adjunctive airways (oral or nasopharyngeal) may also help maintain an adequate airway. In patients who are actively seizing, it may be difficult to insert these adjuncts and may cause injury if the intervention is forced. Furthermore, in patients for whom trauma is a possibility, these maneuvers must be undertaken with cervical spine (C-spine) immobilization. In patients in whom the airway remains unstable despite these actions, endotracheal intubation is warranted. When it is necessary to use a muscle relaxant to intubate a seizing patient, one should use the shortest acting agent possible. The presence of motor activity may be the only clinical manifestation of seizure, and a long-acting muscle relaxant will mask the ongoing seizure activity.

The patient's circulatory status must also be closely monitored. Seizures generally cause a massive sympathetic discharge that results in hypertension and tachycardia. Continuous cardiac monitoring and intravenous (IV) access should be obtained. Blood samples, including rapid blood glucose testing, should be acquired at this time in an attempt to establish a diagnosis. Peripheral IV access, which is often difficult in the pediatric age group, may be nearly impossible in the actively seizing patient. Intraosseous and/or central venous access may be required in the patient with prolonged seizures.

Once the respiratory and circulatory functions have been assessed and maintained, efforts should be directed at making a diagnosis and stopping any ongoing seizure activity. As long as adequate ventilation and oxygenation are maintained, long-term sequelae are unlikely to result from a transient seizure. The initial increase in cerebral blood flow compensates for any increase in brain metabolic requirements. Consensus management suggests the initiation of anticonvulsant treatment of anyone who has been seizing for more than 10 minutes. This likely represents all patients who are brought to the ED actively seizing.

EVALUATION AND DECISION

History

As a result of the numerous potential causes of seizures, as well as the large number of events that can be mistaken for a seizure, a focused history is important. The parent or caregiver needs to carefully describe the episode and the preceding events. Was there a warning (aura) that the patient was about to have an event? Was there a loss of consciousness, tongue biting, or incontinence? Did the event involve the entire body or only a portion? How long did the event last? How did the patient act after the event was over?

In addition to the episode itself, the preceding events are also crucial. Was there a history of trauma, toxin exposure or ingestion, fever, or other systemic signs of illness (e.g., headache, ataxia, vomiting, diarrhea)? Does the child have an underlying seizure disorder, history of seizures, or other neurologic problems? Is the child taking any anticonvulsants? If yes, was there a recent change in dose, or were any new medications started or old medications stopped? Is there a chance that the patient could have a subtherapeutic level? Other questions that should be asked include if there was any other significant medical history (including abnormal developmental history), any significant surgical history (including the placement of a ventricular shunt), family history of seizures, other medication use, and travel history to an endemic region (neurocysticercosis is one of the leading worldwide causes of seizures)?

Physical Examination

With the history, a directed physical examination is performed to look for a possible cause of the seizure. Vital signs, including temperature, need to be obtained. An elevated temperature points to a potential infectious cause. The entire body needs to be examined for the evidence of trauma, either as a preceding cause or as a result of falling during the seizure episode. The skin should be examined for rashes or other congenital skin lesions. Dysmorphic features may be associated with other congenital CNS anomalies. Stigmata of underlying hepatic, renal, or endocrinologic disorders should also be noted.

The head should be carefully examined for swelling, deformity, or other signs of trauma. The presence of a ventricular shunt should be noted. The pupils are studied for shape, size, reactivity, and equality. The fundi are examined for the presence of retinal hemorrhages or papilledema. The tympanic membranes are examined for the presence of hemotympanum or for a source of potential infection. The mouth should be examined for the evidence of tongue biting.

The neck is assessed for meningeal irritation. If there is a history or other physical signs of trauma, neck immobilization should be maintained until the C-spine can be "cleared." Examination of the chest, lungs, and abdomen is performed in the usual fashion. The extremities are examined for the evidence of trauma, especially as the result of falling during a seizure.

The neurologic examination may be limited by either ongoing seizure activity or a postictal state and may consist solely of the pupillary examination and an assessment of any asymmetric movements (focality). Any abnormal posturing (decerebrate or decorticate) should be noted and dealt with immediately.

If there is a question of a possible ingestion, the examination is also directed at uncovering a potential toxicologic syndrome (toxidrome) that may suggest a specific class of drugs or toxins that are responsible for the seizure (see Chapter 88). Important variables include temperature, heart rate, blood pressure, pupil size, sweating, flushing, and cyanosis.

As the patient recovers from the seizure episode, periodic reassessment is needed to assess for any underlying neurologic abnormalities.

Diagnostic Approach

Once it has been determined that a seizure may have taken place, the initial diagnostic evaluation (Fig. 69.1) starts with the history and physical examination. Laboratory, radiologic, and other neurodiagnostic testings (e.g., EEG) are other tools that can be a part of the seizure evaluation.

Patients with obvious trauma who are seizing should be treated per advanced trauma life support (ATLS) guidelines (see Chapter 103), with close attention to possible intracranial injury (see Chapter 105).

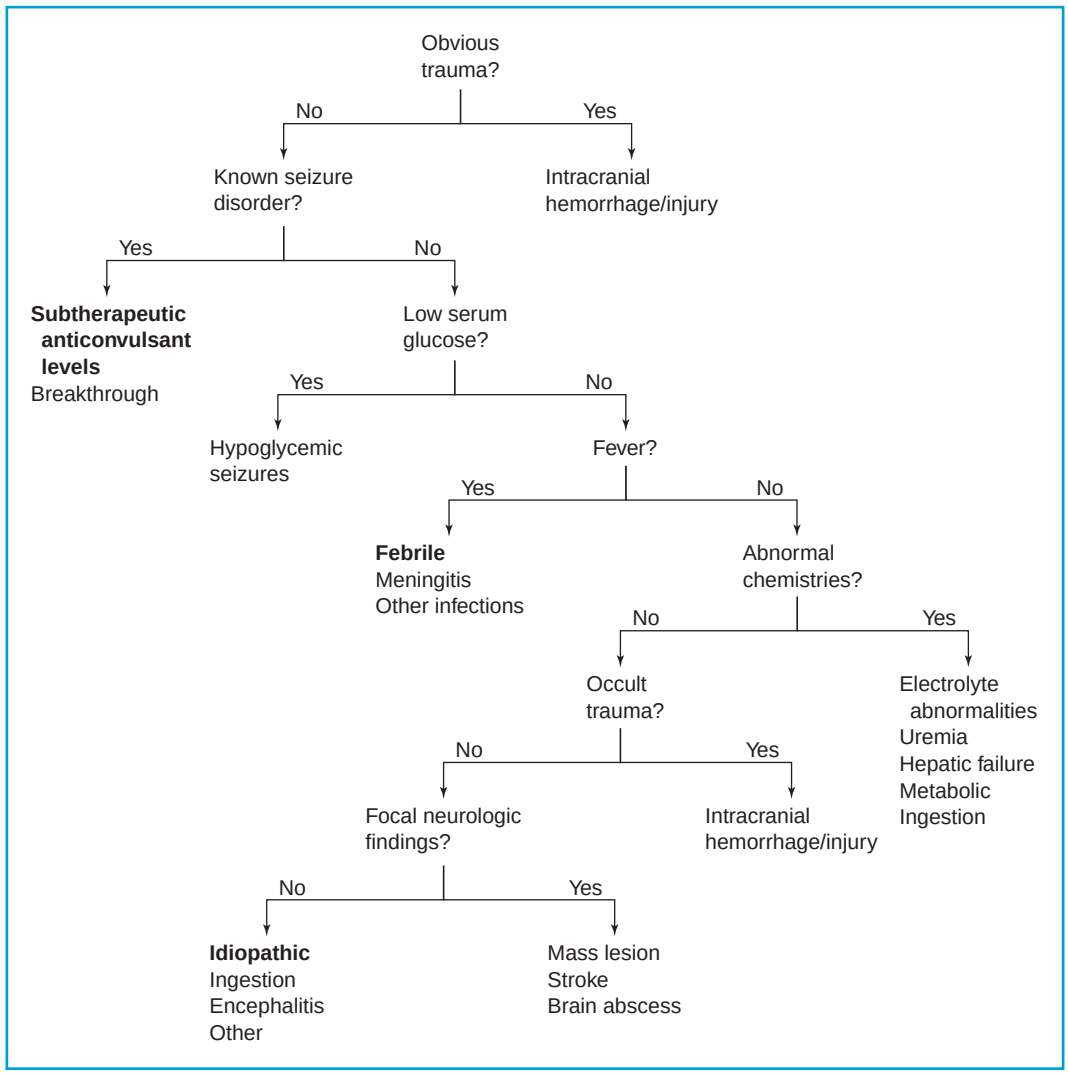

FIGURE 69.1 Diagnostic approach to seizures. The most common causes are in bold type.

Often, patients with a known seizure disorder will present to the ED actively seizing. Patients known or suspected to be taking anticonvulsants should have drug levels evaluated. A subtherapeutic anticonvulsant level is among the most common reasons for patients to present with seizures.

Many different laboratory tests may reveal a cause for a seizure and, as a result, suggest a potential treatment. A rapid glucose reagent strip test should be performed with the initial blood sample. Hypoglycemia is a common problem that can often precipitate seizure activity. If hypoglycemia is documented or a rapid assessment is not available, treatment with 0.25 to 1 g per kg of dextrose is indicated.

A *febrile seizure* is defined as a seizure caused by a fever, but this is a diagnosis of exclusion. Other infectious etiologies that present with a fever and can be the direct cause of a seizure (e.g., meningitis) must first be ruled out (see Chapters 28 and 84). Furthermore, infections not involving the CNS may still be the cause of the seizure through the elaboration of fever. Presence of fever or an elevated white blood cell (WBC) count should direct one to look for a potential infectious cause. Blood cultures should be drawn with the initial samples from patients at risk for bacteremia in an effort to identify a specific pathogen. Urinalysis and chest radiographs can also be used to confirm a source of infection.

A lumbar puncture (LP) with analysis of the cerebrospinal fluid (CSF) is the only way to make the diagnosis of meningitis and should be performed when meningitis is being considered. An elevated CSF protein and CSF WBC count and a low CSF glucose level are all suggestive of CNS infection. CSF cultures, Gram stain, latex studies, and polymerase chain reaction may identify a specific agent. Ideally, CSF cultures should be obtained before antibiotic therapy is initiated. However, in the critically ill or unstable patient, antibiotics should not be withheld until an LP is performed. Furthermore, in cases in which a potential metabolic disease is being considered, CSF lactate, pyruvate, or amino acid level determinations can be used to diagnose a specific disorder. In these cases, it is often helpful to collect an extra tube of CSF to be frozen and used for later analysis. In any patient with suspected elevated intracranial pressure (ICP), an LP should not be performed until head imaging can be done.

Electrolyte abnormalities may also cause seizures, with hyponatremia, hypocalcemia, and hypomagnesemia being

most common. In general, the routine screening for electrolyte abnormalities in a patient with seizure is a low-yield procedure. Unfortunately, seizures caused by electrolyte derangements are often refractory to anticonvulsant therapy and patients will continue to seize until the underlying abnormality is corrected. Serum electrolytes should be measured in all patients with seizure with significant vomiting or diarrhea; patients with underlying renal, hepatic, neoplastic, or endocrinologic disease; patients who are taking medications that may lead to electrolyte disturbances; or patients who have seizures that are refractory to typical anticonvulsant management. One characteristic scenario involves hyponatremic seizures in infants, typically younger than 6 months, after prolonged feedings of dilute formula ("infantile water intoxication"). Other patients may be evaluated on a case-by-case basis. Intravenous calcium, magnesium, and hypertonic (3%) sodium chloride should be used to treat the appropriate abnormal condition. In the case of hyponatremia, once the seizure activity has been stopped, the rate of sodium correction must be titrated to avoid possible central pontine myelinolysis.

Other chemistries can be helpful in identifying specific organ dysfunction either as a cause of the seizure activity or as an assessment of systemic injury. An elevated blood urea nitrogen or creatinine level suggests uremia as a potential cause. Elevated liver function tests (transaminases or coagulation times) can be a reflection of hepatic failure. Metabolic acidosis or hyperammonemia can suggest an underlying metabolic disorder. In patients with prolonged seizures, an arterial or venous blood gas level can help in assessing adequacy of ventilation and a creatine kinase level can identify possible rhabdomyolysis.

Toxicologic screening can also be helpful in the seizing patient because certain ingestions are managed with specific antidotes or treatments. Typically, the clinical scenario is the young child with a possible accidental ingestion or the adolescent after a suicide attempt. In general, the toxicologic screen should be directed at agents known to cause seizures (Table 69.1) or those suggested by a clinical toxidrome.

Radiologic imaging of the patient with seizure generally consists of either a computed tomography (CT) scan or a magnetic resonance imaging (MRI) study in the acute care setting. The following situations should be considered emergent: (i) a patient who has signs or symptoms of elevated ICP, (ii) a patient who has a focal seizure or a persistent focal neurologic deficit, (iii) a patient who has seizures in the setting of head trauma, (iv) a patient who has persistent seizure activity, or (v) a patient who appears ill. Until C-spine injury is ruled out, it is important to maintain C-spine immobilization when head trauma is a concern. Patients with transient generalized seizures in whom a cause of the seizure activity is identified probably do not require any further head imaging studies. Patients with transient generalized seizures in whom no cause is identified and who appear clinically well can have their head imaging performed on a nonemergent basis.

In the past, because of easier availability and lack of a need for sedation for most patients, CT scans were most often the study of choice in the ED for a patient who presented with a seizure. However, given the recent heightened awareness of the risks of ionizing radiation associated with CT scans, patients who do not require emergent imaging may have an MRI study instead. An MRI study also has several other advantages over a CT scan. MRI is better at identifying underlying white matter abnormalities, disorders of brain architecture, lesions in the neurocutaneous syndromes, lesions in the posterior fossa and the brainstem, and small lesions.

EEG is an important diagnostic tool in the evaluation of seizure types, response to treatment, and prognosis. It is rarely indicated in the acute care setting.

Emergency Treatment

Prolonged seizure activity is a true medical emergency. In one series, 88 of 239 patients who had convulsive status epilepticus for more than 1 hour had permanent neurologic sequelae. Thus, following stabilization of the ABCs, further treatment is directed at stopping the seizure activity. Although certain causes of seizures may require a specific treatment, anticonvulsant therapy is initiated simultaneously during the evaluation of the seizing patient (Fig. 69.2). The approach to this subject is detailed in Chapter 83, but some emergency treatment guidelines are reviewed here.

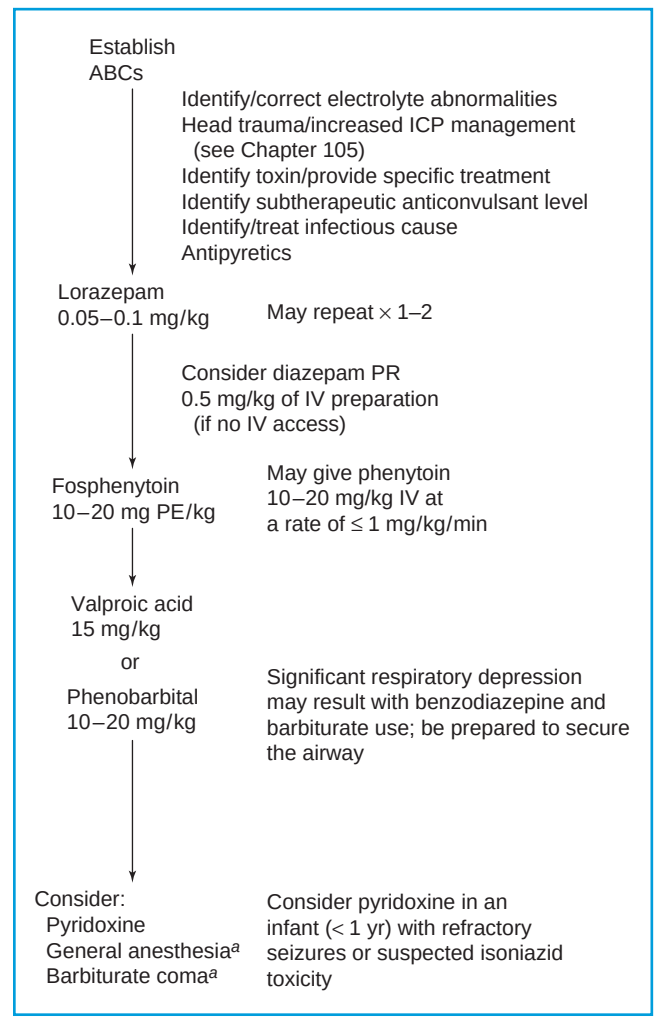

FIGURE 69.2 Management of status epilepticus. [a]Electroencephalogram monitoring and ICU setting required. ABCs, airway, breathing, circulation; ICP, intracranial pressure; PR, per rectum; IV, intravenous; PE, phenytoin equivalent; ICU, intensive care unit.

The benzodiazepines are the initial drug of choice for the treatment of seizures. Lorazepam (Ativan) has a rapid onset of action (less than 5 minutes) and can be given intravenously or intramuscularly. The dose is 0.05 to 0.1 mg per kg, with a maximal dose of 4 mg and can be given over 1 to 2 minutes. Its anticonvulsant effects can last for several hours. It may be repeated at 10- to 15-minute intervals, but its effectiveness decreases with successive doses. The major side effects are respiratory depression and sedation (dose dependent), especially when combined with phenobarbital.

Diazepam (Valium) had been the standard initial treatment of seizures for many years before the development of the newer benzodiazepines. Diazepam is similar to lorazepam, but because of its increased lipid solubility, it has a much shorter half-life. Diazepam has an advantage in that it can be given rectally, which is useful when a patient does not have IV access. More recently, a rectal gel has been introduced in fixed doses of 5, 7.5, 10, 12.5, 15, 17.5, or 20 mg. The IV preparation of the drug may be used alternatively. Recommended rectal dosing for children up to 5 years of age is 0.5 mg per kg.

Phenytoin (Dilantin) is a second-line agent for the treatment of seizures. The dose is 10 to 20 mg per kg as an initial load. It has several limitations as compared with the benzodiazepines. First, peak CNS concentrations may not be reached until 10 to 30 minutes after its infusion is completed and, thus, it is much slower in onset. Furthermore, it must be administered slowly (no faster than 1 mg per kg per minute) because of concerns of cardiac conduction disturbances, which further lengthens its onset of action. It cannot be given in dextrose-containing solutions.

As a result of the limitations in the administration of phenytoin, fosphenytoin (Cerebyx) was created. It is a prodrug whose active metabolite is phenytoin. The drug is dosed as phenytoin equivalents (PE), and the loading dose is 10 to 20 mg PE per kg. The advantages are that it can be given much more rapidly (up to 150 mg PE per minute) and that it may be given in either normal saline or a 5% dextrose-containing solution or intramuscularly.

Phenobarbital (Luminal) is another second-line agent for the treatment of seizures. The loading dose is 10 to 20 mg per kg. Its advantage over phenytoin is that it can be given much more rapidly (100 mg per minute). However, it has an extremely long half-life (up to 120 hours) and a pronounced sedating effect. Furthermore, it can cause significant respiratory depression, especially when given after a benzodiazepine. One must be prepared to intubate a patient who has received both a benzodiazepine and a barbiturate for the treatment of seizures. It is important to remember that if a patient needs to be intubated, a muscle relaxant can mask the motor manifestation of seizure activity. With the introduction of fosphenytoin, phenobarbital should now be considered a third-line agent.

Valproic acid (Depokene) is a commonly used antiepileptic agent and the IV preparation had been used in the past to rapidly attain therapeutic levels. Recently, there have been a few case series demonstrating its effectiveness in treating seizures in children who have been refractory to the first-line agents. As such, many now consider it a third-line agent for the treatment of status epilepticus. It is given intravenously at a dose of 15 mg per kg. It is generally well tolerated and is less sedating than the barbiturates.

Pyridoxine deficiency is an uncommon cause of seizures in newborns. One should consider its use in patients younger than 1 year whose seizure activity is refractory to the other therapies (100 mg). It is also used in the treatment of isoniazid overdose (usual initial dose 70 mg per kg).

If all the described therapies fail, patients may require general anesthesia to abort the seizures. A variety of agents, such as inhalational anesthetics (e.g., halothane, isoflurane) or large doses of short-acting barbiturates (e.g., pentobarbital) or benzodiazepines (e.g., continuous infusion midazolam), can be used. The patient needs both to be intubated (if not already done) and to have continuous EEG monitoring in an intensive care unit. The level of anesthesia should be sufficient to maintain either a flat-line or burst-suppression pattern on the EEG. The anesthesia can be then withdrawn slowly to see if any electrical seizure activity persists.

SPECIAL CONSIDERATIONS

Febrile Seizures

Febrile seizures are the most common convulsive disorder in young children, occurring in 2% to 5% of the population (see Chapter 83). A consensus statement by the National Institutes of Health defines a febrile seizure as a seizure occurring between 6 months and 5 years of age that is associated with a fever [temperature higher than 38°C (100.4°F)] but without the evidence of intracranial infection or other defined cause or neurologic disease.

Febrile seizures can be of any type, but most commonly, they are generalized tonic-clonic seizures. They are usually self-limited and last for only a few minutes. Febrile seizures are classified as simple febrile seizures, which last less than 15 minutes, are generalized, and occur only once during a 24-hour period. In contrast, complex febrile seizures are prolonged, recur within 24 hours, and have a focal onset. Simple febrile seizures (85%) are much more common. There is a family history of febrile seizures in an immediate family member in 25% to 40% of cases. Viral infections are frequently associated with febrile seizures, and more recent studies have shown human herpesvirus as a commonly identified agent.

After the first febrile seizure, approximately 33% of patients will have at least one recurrence and about 9% will have three or more episodes. The younger the patient is at first presentation, the greater the likelihood of recurrence. In addition, recurrences are more likely to recur in patients with lower temperatures on presentation of their first seizure (lower than 40°C) and shorter duration of fever before the seizure (less than 24 hours) and in patients with a family history of febrile seizures. Most recurrences (75%) will also happen within 1 year. The exact risk of developing epilepsy after a febrile seizure is unknown, but most studies indicate that it is less than 5%. Risk factors for developing epilepsy after a febrile seizure include abnormal development before the episode, a family history of afebrile seizures, and a complex first febrile seizure.

The treatment of a patient who presents with a febrile seizure is nearly identical to that for other seizure types. The primary goal is the establishment of a clear airway; secondary efforts are then directed at the termination of the seizure and concurrent lowering of body temperature. However, because

most febrile seizures are brief in duration, the typical patient who presents for the evaluation of a febrile seizure is no longer seizing upon arrival to the ED. In those instances, if the history is consistent with a simple febrile seizure, the patient has no stigmata of a CNS infection, and the patient's neurologic examination is completely "normal" (the patient may be postictal or slightly hyperreflexive), further evaluation for the cause of the seizure is unnecessary. As such, routine laboratory studies are not recommended for the patient with a simple febrile seizure. Furthermore, routine neuroimaging or EEG screening is also not recommended for the patient with a first-time simple febrile seizure. However, the evaluation should focus on the possible cause of the fever.

It is important to note that typical signs of meningitis may be absent in patients younger than 12 to 18 months. Furthermore, seizure may be the first presentation of meningitis. Thus, one should strongly consider an LP in all patients younger than 12 months who present with a simple febrile seizure, and one should maintain a low threshold to perform one in patients 12 to 18 months of age. LP is recommended in patients younger than 18 months with a complex febrile seizure or a concerning physical or neurologic evaluation, including irritability, lethargy, or poor feeding.

Patients who have a simple febrile seizure may be safely discharged to home. Parents should be reassured that febrile seizures are common and that most patients have no further episodes. They need to be cautioned that a recurrence may happen and should be given simple instructions on what to do should another seizure occur. Furthermore, parents should understand that patients with recurrent febrile seizures may still contract meningitis and may require clinical evaluation for this possibility. They can also be instructed on the proper use of antipyretics, even though studies have failed to demonstrate that this is effective in reducing the recurrence rate. Finally, any identified source of the fever should be properly treated.

CHAPTER 70 ■ THE SEPTIC-APPEARING INFANT

STEVEN M. SELBST, MD

A young infant may be brought to the emergency department (ED) because he or she "just doesn't look right" to the parents. Even inexperienced parents whose first baby is just a few weeks old may notice when their child is unusually sleepy, fussy, or not drinking as well as usual. To the physician in the ED, such an infant may appear quite ill with pallor, cyanosis, or ashen color. There may be notable irritability or lethargy, and fever may or may not be present. The infant may be found to have tachypnea, tachycardia, or both. Hypotension or other signs of poor perfusion may also be apparent.

Generally, an ill-appearing infant, such as the one described, will be immediately considered to have sepsis and will be managed reflexively. Although this may be the correct approach in most cases, the physician should remember that several other conditions could produce a septic-appearing infant.

This chapter establishes a differential diagnosis for infants in the first 2 months of life who appear quite ill. An approach to the evaluation and management of such an infant is discussed.

DIFFERENTIAL DIAGNOSIS

Numerous disorders (Table 70.1) may cause an infant to appear septic. The most common of these disorders (Table 70.2) includes certain bacterial infections and viral syndromes. The remaining disorders, although uncommon, demand diagnostic consideration because they are potentially life threatening, yet treatable.

Sepsis

Sepsis (see Chapter 91) should always be considered when the emergency physician is confronted with an ill-appearing infant. The signs and symptoms of sepsis may be subtle. The history may vary, and some infants may seem to be ill for several days whereas others deteriorate rapidly. Likewise, any one or combination of symptoms, such as lethargy, irritability, diarrhea, vomiting, anorexia, or fever, may be a manifestation of sepsis. Fever is generally an unreliable finding in the septic infant; most septic infants younger than 2 months will be hypothermic instead. On physical examination, a septic infant may be pale, ashen, or even cyanotic. The skin is often cool and may be mottled because of poor perfusion. The infant may seem lethargic, obtunded, or irritable. There is often marked tachycardia, with the heart rate approaching 200 beats per minute, and tachypnea may be noted (respiratory rate more than 50 breaths per minute). If disseminated intravascular coagulopathy (DIC) has developed, there may be scattered petechiae or purpura may be evident. If meningitis is also present, a bulging or tense fontanel may be found. Likewise, if the infection has localized elsewhere, there may be otitis media, abdominal rigidity, joint swelling, or tenderness in one extremity or possibly chest findings such as rales. Finally, if the disease process has progressed, the infant may develop shock and may be hypotensive.

The laboratory is often helpful in suggesting a diagnosis of sepsis; however, definitive cultures require time for processing. A complete blood cell (CBC) count may reveal a leukocytosis or left shift. In addition, a coagulation profile may show evidence of DIC, and blood chemistries may reveal hypoglycemia or metabolic acidosis. If localized infection is suspected, aspiration and Gram stain of urine, joint fluid, spinal fluid, or pus from the middle ear may reveal the offending organism. Similarly, a chest radiograph may show a lobar infiltrate if pneumonia is present. A Gram stain of a petechial scraping may also reveal the responsible organism.

Viral Infections

Overwhelming viral infections may mimic sepsis in the young infant. About 25% of infants younger than 1 month with *enteroviral infections* develop a sepsis-like illness. Respiratory distress and hemorrhagic manifestations, including gastrointestinal bleeding and bleeding into the skin, are commonly seen. Seizures often occur, as well as icterus, splenomegaly, congestive heart failure, and abdominal distension. Mortality from enteroviral infections is high among neonates. This infection is indistinguishable from bacterial sepsis, except that bacterial cultures will give negative results, whereas viral isolates from stool and cerebrospinal fluid (CSF), or enterovirus polymerase chain reaction (PCR) of the CSF, may confirm the offending enterovirus.

Epidemics of *respiratory syncytial virus* (RSV) occur in the wintertime, and babies younger than 2 months may present with apnea or respiratory distress with cyanosis. Those born prematurely or with previous respiratory or cardiac disorders are especially susceptible to apnea. These infants often appear septic, but knowledge of illness in the community and a predominance of wheezing on chest examination may lead to the suspicion of RSV bronchiolitis. Still, some infants develop wheezing later in the course and, thus, the initial diagnosis is difficult. A rapid nasal wash test for RSV, if available, will be quickly diagnostic. Culture for RSV requires several days. A CBC count may show a lymphocytosis, but because of stress, a left shift can also be found. Chest radiographs may show diffuse patchy infiltrates and, possibly, lobar atelectasis.

Another viral infection to consider is *herpes simplex*, which usually causes systemic symptoms and encephalitis at 7 to 21 days of life. Neonates present with fever, coma, apnea, fulminant

TABLE 70.1

DIFFERENTIAL DIAGNOSIS OF THE SEPTIC-APPEARING INFANT

Infectious diseases
Bacterial sepsis
Meningitis
Urinary tract infection
Viral infections—enterovirus, respiratory syncytial virus, herpes simplex
Pertussis
Congenital syphilis

Cardiac disease
Congenital heart disease
Supraventricular tachycardia
Myocardial infarction
Pericarditis
Myocarditis
Kawasaki disease

Endocrine disorders
Congenital adrenal hyperplasia

Metabolic disorders
Hyponatremia, hypernatremia
Cystic fibrosis
Inborn errors of metabolism, galactosemia
Hypoglycemia
Drugs/toxins—aspirin, carbon monoxide

Renal disorders
Posterior urethral valves

Hematologic disorders
Severe anemia
Methemoglobinemia

Gastrointestinal disorders
Gastroenteritis with dehydration
Pyloric stenosis
Intussusception
Necrotizing enterocolitis
Appendicitis
Volvulus

Neurologic disease
Infant botulism
Shunt obstruction, infection
Child abuse—intracranial hemorrhage

TABLE 70.2

MOST COMMON DISORDERS THAT MIMIC SEPSIS

Urinary tract infection	Congestive heart failure
Viremia	Gastroenteritis with dehydration

hepatitis, pneumonitis, coagulopathy, and seizures, which are often difficult to control. History of maternal genital herpes should lead to suspicion of systemic herpes infection in the neonate. In most cases, however, the mother is completely asymptomatic. Ocular findings such as conjunctivitis or keratitis may be noted, as well as focal neurologic findings. If vesicular lesions are present on the skin, this infection should be strongly considered. However, they are present in only one-third to one-half of patients. Rapid diagnostic tests are available. PCR is a sensitive method to detect the virus from CSF in infants suspected of herpes encephalitis. Direct fluorescent antibody staining of vesicle scrapings is specific but less sensitive than culture. A Tzanck preparation has low sensitivity and is not recommended as a rapid diagnostic test. An electroencephalogram (EEG) or computed tomography (CT) scan may also be helpful and may reveal abnormalities of the temporal lobe. The diagnosis is confirmed by culture of a skin vesicle, mouth, nasopharynx, eyes, urine, blood, CSF, stool, or rectum.

Pertussis is another infection to consider when evaluating a very ill infant. Apnea, seizures, and death have been reported in this age group. Parents may report respiratory distress, cough, poor feeding, and vomiting (often posttussive). History of exposure to pertussis may be lacking because the infant usually acquires the disease from older children or adults who have only symptoms of a common upper respiratory infection. Physical examination will distinguish the infection from sepsis if the infant has a paroxysmal cough. The characteristic inspiratory "whoop" after a coughing paroxysm (a hallmark in older patients) is uncommon in very young infants. Auscultation of the chest is usually normal; tachypnea and cyanosis may be present. Initial laboratory studies may not identify the condition. The CBC count in young infants may fail to show a marked lymphocytosis as expected in older patients with pertussis. Likewise, the chest radiograph may not show the typical "shaggy right heart border." Atelectasis or pneumonia may be present. Nasopharyngeal culture for *Bordetella pertussis* is confirmatory. PCR technique can reliably identify the condition from nasopharyngeal specimens.

Infants with *congenital syphilis* may present in the first 4 weeks of life with extreme irritability, pallor, jaundice, hepatosplenomegaly, and edema. They may have pneumonia and often have painful limbs. Snuffles and skin lesions are common. Although these infants may appear to be ill on arrival in the ED, their histories reveal that they also have been chronically ill. Certainly, if a history of maternal infection is obtained, the diagnosis should be considered. Laboratory tests will be helpful in that radiographs of the infant's long bones may reveal diffuse periostitis of several bones. A serologic test is needed to confirm the diagnosis.

Cardiac Diseases

In addition to infections, cardiac disease should be considered with a very ill infant. An infant with underlying *congenital heart disease* (CHD), such as ventriculoseptal defect, valvular insufficiency, valvular stenosis, hypoplastic left heart syndrome (HLHS), or coarctation of the aorta, may present with shock or congestive heart failure and clinical findings similar to those of an infant with sepsis. There may be tachycardia and tachypnea, as well as pallor, duskiness, or mottling of the skin. Cyanosis is not always present. There may also be sweating or decreased pulses, and hypotension caused by poor perfusion. However, a careful history and physical examination may help the physician differentiate CHD with heart failure from sepsis. For instance, a chronic history of poor growth and poor feeding may suggest heart disease. Also, the presence of a cardiac murmur may suggest a structural lesion. Moreover, a gallop rhythm, hepatomegaly, neck vein distension, and

peripheral edema may lead one to consider primary cardiac pathology. Intercostal retractions and rales, rhonchi, or wheezing are nonspecific findings and may be present on chest examination in either heart failure or pneumonia. An infant with HLHS or coarctation of the aorta may present with shock toward the end of the first week of life as the patent ductus arteriosus (PDA) closes. In a young baby, difference between upper- and lower-extremity blood pressures suggests coarctation of the aorta. If cardiac output is inadequate, however, pulse differences may not be detected. Normal femoral pulses do not exclude a coarctation because the widely patent ductus arteriosis provides flow to the descending aorta.

Laboratory evaluation is essential in establishing cardiac disease as the cause of an infant's moribund condition. A chest radiograph often shows cardiac enlargement and may show pulmonary vascular engorgement or interstitial pulmonary edema rather than lobar infiltrates (as in pneumonia). The electrocardiogram (EKG) may be helpful in revealing certain congenital heart lesions. For instance, in HLHS, the EKG invariably shows right-axis deviation, with right atrial and ventricular enlargement. The EKG is often a nonspecific indicator of cardiac decompensation; however, an echocardiogram is more helpful. Finally, a complete blood count may be helpful in that the absence of leukocytosis and left shift may make sepsis a less likely consideration. Rarely, an infant with anomalous or obstructed coronary arteries will develop myocardial infarction and appear to be septic initially. Such young infants may have dyspnea, cyanosis, vomiting, pallor, and other signs of heart failure; however, these infants usually have cardiomegaly on chest radiograph. This will prompt the physician to perform an EKG, which usually shows T-wave inversion and deep Q waves in leads I and AVL. Echocardiogram and cardiac catheterization with contrast are needed to confirm the diagnosis.

In addition to CHD, certain *arrhythmias* may cause an infant to appear ill. For instance, a young baby with *supraventricular tachycardia* (SVT) often presents with findings similar to those of a septic infant. This arrhythmia may be idiopathic (50%), associated with CHD (20%), or related to drugs, fever, or infection (20%). Often young infants with SVT go unrecognized at home for 2 days or more because, initially, they have only poor feeding, fussiness, and some rapid breathing. As this condition goes untreated, however, the infants will develop congestive heart failure and may present with all the signs of sepsis, including shock. Because fever can be a precipitating cause of the arrhythmia, the condition is obviously confused with sepsis. However, a careful physical examination will make the diagnosis of SVT obvious. Particularly, the cardiac examination will reveal such extreme tachycardia in the infant that the heart rate cannot even be counted. It is usual for the heart rate to exceed 250 to 300 beats per minute in such infants. With this information, laboratory aids can confirm the diagnosis. An EKG will show regular atrial and ventricular beats with 1:1 conduction, although P waves appear different than sinus P waves and may be difficult to see at all. They are often buried in the T waves. Moreover, a chest radiograph may show cardiomegaly and pulmonary congestion.

Additional cardiac pathologies to consider include *myocarditis* and *pericarditis*. Pericarditis may be caused by bacterial organisms such as *Staphylococcus aureus*; myocarditis usually results from viral infections such as coxsackievirus B. In infants, these often are fulminant infections and the baby with such a condition will appear critically ill, with fever and grunting respirations. A complete physical examination may help the physician distinguish these conditions from sepsis in that signs of heart failure may be seen and unexplained tachycardia is often present. Also, pericarditis may produce neck vein distension and distant heart sounds if a significant pericardial effusion exists. In addition, a friction rub may be present. Laboratory tests may be helpful in that a chest radiograph will show cardiomegaly and a suggestion of effusion if pericarditis is present. The EKG will show generalized T-wave inversion and low-voltage QRS complexes, especially if pericardial fluid is present. Also, ST-T-wave abnormalities may be seen. The echocardiogram will confirm the presence or absence of a pericardial effusion and poor ventricular function in the case of viral myocarditis. The CBC count will not distinguish these infections from sepsis because leukocytosis is common and a left shift may be present.

Kawasaki disease with associated coronary artery aneurysms is very rare in young infants and is associated with a poor prognosis. A baby with Kawasaki disease may present with cyanosis and shock. Usually, history reveals prolonged and unexplained fever, rash, and mucous membrane inflammation. The physical examination may distinguish this illness from sepsis if there is a diffuse, raised, erythematous rash or cracked red lips, swollen hands and feet, conjunctivitis, and cervical lymphadenopathy. However, these classic features, found in older infants and children, may be absent in young babies. Neonates with Kawasaki disease often have an atypical presentation. Routine laboratory studies may not differentiate this condition from sepsis either. A CBC count may reveal leukocytosis and/or thrombocytosis. CSF usually shows a pleocytosis, with a lymphocytic predominance. Sterile pyuria is sometimes noted. In some cases, findings consistent with myocardial ischemia or an arrhythmia may be noted on EKG. Normal findings or nonspecific abnormalities are more common. Coronary artery aneurysms may be discovered with an echocardiogram, making the diagnosis highly likely.

Endocrine Disorders

Certain endocrine disorders can also mimic sepsis. For instance, infants with *congenital adrenal hyperplasia* (CAH) may present in the first few days or weeks of life with a history of vomiting, lethargy, or irritability. On arrival, signs of marked dehydration may be present, with tachycardia and possibly hypothermia. The recent history may be revealing in that such infants may have been poor feeders since birth and the symptoms may be progressive over a few days. The physical examination can be extremely helpful in establishing the diagnosis in females if ambiguous genitalia are noted. The laboratory evaluation is also helpful in that the presence of marked hyponatremia with severe hyperkalemia should make CAH a likely diagnosis. Other nonspecific laboratory findings in this disorder include hypoglycemia, metabolic acidosis, and peaked T waves or arrhythmias on EKG. Specifically, the finding of elevated 17-hydroxyprogesterone and renin with decreased aldosterone and cortisol in the serum confirms the diagnosis of CAH. Treatment with hydrocortisone 100 mg/m^2 (or 2 mg/kg) intravenously should be initiated as soon as the diagnosis is suspected.

Metabolic Disorders

Various metabolic disorders can also look like sepsis and should be considered in the differential diagnosis. Prolonged diarrhea or vomiting can produce *dehydration*, *electrolyte disturbances*, and *acid-base abnormalities* such that an infant will appear quite ill. For instance, young infants with diarrhea may develop marked hyponatremia caused by iatrogenic water intoxication. This is seen when well-meaning parents give excess free water to a young infant or improperly mix concentrated formula, leading to a rapid drop in serum sodium. Such infants may appear extremely lethargic, with slow respirations, hypothermia, and, possibly, seizures that are difficult to control. Likewise, dehydrated infants with *hypernatremia* may be lethargic or irritable, with muscle weakness, seizures, or coma. Infants with persistent vomiting may have hypochloremic alkalosis with hypokalemia, and they may appear weak or have cardiac dysfunction (see Chapters 17 and 78).

A special cause of hyponatremic dehydration to consider is *cystic fibrosis* (see Chapter 99). The history in these cases may not be helpful initially, except that the infant usually gets very ill in hot weather. The mother may report poor intake, poor growth, and increased lethargy. Only with specific questioning might the mother report that the baby's skin tastes "salty" or that the baby had meconium plug syndrome (transient form of distal colonic obstruction secondary to inspissated meconium) as a newborn or prolonged neonatal jaundice. In some cases, pulmonary symptoms such as cough, tachypnea, or pneumonia may have been treated earlier in life. On examination, the dehydrated baby looks much like any other septic infant. However, laboratory tests that show profound hypoelectrolytemia, especially when not accounted for by gastrointestinal losses, should suggest cystic fibrosis. A sweat test or DNA analysis will help confirm the diagnosis.

In addition, rare inborn errors of metabolism such as *inherited urea cycle disorders* may produce vomiting in young infants, who will then present with lethargy, seizures, or coma resulting from metabolic acidosis, hyperammonemia, or hypoglycemia (see Chapter 94). Galactosemia is an important metabolic problem that can cause a young infant to appear septic. Galactosemia is caused by a genetic defect in the metabolism of galactose. Neonates with this enzyme deficiency, who are exposed to galactose, present with vomiting, acidosis, failure to thrive, and jaundice. Some may have hypoglycemia and many will have liver dysfunction with a significant coagulopathy. Many develop urinary tract infections or sepsis due to gram-negative organisms. Inquiry about neonatal screening for galactosemia is important. When considering these conditions, it is essential to evaluate the CBC count, electrolytes, bicarbonate, blood glucose, liver function (including coagulation studies), and, possibly, plasma ammonia levels in young infants with significant symptoms of gastroenteritis, lethargy, or irritability. A urinalysis including ketones is helpful. Collect extra plasma (2 mL) and urine (5 mL) for additional testing. Consider sending a follow-up blood filter paper specimen to the newborn screening laboratory. A rapid bedside test for blood sugar level is recommended for immediate recognition of hypoglycemia. *Hypoglycemia* also can be secondary to sepsis, certain drugs, or alcohol intoxication

Another metabolic problem to consider is that of *toxins* (see Chapter 94). Obviously, young infants are incapable of accidental ingestions, but well-meaning parents may rarely cause salicylism in their attempts to aggressively treat fever with aspirin (despite current Reye's syndrome warnings). Affected infants can then present with vomiting, hyperpnea, hyperpyrexia, or convulsions and coma. In such cases, the history of medication given is crucial because the physical examination will not distinguish this ill baby from the infant with sepsis. The laboratory evaluation may lead to the suspicion of some metabolic problem because abnormalities of sodium, blood sugar, or acid-base balance are often found. Moreover, hypokalemia can be seen in salicylism, as well as abnormal liver function or renal function studies. An elevated salicylate level in the serum confirms the diagnosis of aspirin poisoning, but in chronic poisoning, the aspirin level may be relatively low despite a fatal course.

Carbon monoxide poisoning may present as an unknown intoxication when families are unaware of a defective heating system in the home. The young baby may have a history of sluggishness, poor feeding, and vomiting. A more careful history generally reveals that other family members are also ill with headache, syncope, or flulike symptoms. Their symptoms may improve after leaving the home environment. The classic "cherry red" skin color may be lacking, and physical examination may reveal only lethargy. Elevation of the carboxyhemoglobin level is diagnostic.

Renal Disorders

A young infant may also appear extremely ill because of renal failure or dysplasia. Such renal failure could be caused by *posterior urethral valves* that cause bladder outlet obstruction, especially in males. About one-third of these cases are diagnosed by 1 week of age, but more than half go undetected for the first few months of life. The parents may give a history of vomiting or poor appetite, or they may say that the baby has not grown well or that the infant's abdomen appears swollen. On physical examination, hypertension or an abdominal mass (hydronephrosis) may be detected, as well as urinary ascites. Laboratory tests will elucidate the diagnosis even more. Suprapubic ultrasound may demonstrate the dilated posterior urethra and bladder, strongly suggesting posterior urethral valves. A voiding cystourethrogram should be obtained; this will show a dilated posterior urethra, hypertrophy of the bladder neck, and trabeculated bladder. The serum creatinine and blood urea nitrogen levels may be markedly elevated. Urosepsis is a possible complication of posterior urethral valves.

Hematologic Disorders

It is also important to consider hematologic disorders when confronted with a critically ill infant. Any infant with severe *anemia* caused by aplastic disease, hemolytic process, or blood loss can look quite ill (see Chapters 33 and 91). In addition to anemia, disorders of hemoglobin such as *methemoglobinemia* can cause an infant to appear toxic. Although the chronic forms are uncommon inherited disorders of hemoglobin structure or enzyme deficiency, transient methemoglobinemia in infants is occasionally caused by environmental toxicity from oxidizing agents such as nitrates found in some specimens of well water or oxidant drugs (e.g., topical benzocaine in

teething gels). This intoxication presents in very young infants with cyanosis, poor feeding, failure to thrive, vomiting, diarrhea, and then lethargy. In other patients, the oxidant stress is less obvious. Methemoglobinemia has been described in infants with gastroenteritis and metabolic acidosis. Often, the associated diarrhea is severe, and it has been believed that the infectious agent that causes the diarrhea or the secondary metabolic acidosis may produce an oxidant stress that leads to methemoglobin formation. On examination, such infants have been described as toxic and lethargic, with hypothermia, tachycardia, tachypnea, and hypotension. They often appear mottled, cyanotic, or ashen. One key to the diagnosis of methemoglobinemia is that oxygen administration does not affect the cyanosis, yet no cardiac problem exists. Also, laboratory tests show a profound acidosis (pH 6.9 to 7.2), yet the Pa_{O_2} is normal despite the cyanosis. Leukocytosis and thrombocytosis are present. The blood itself may appear chocolate brown (most easily noted when a drop of blood on filter paper is waved in the air and compared with a normal control), and methemoglobin levels will be elevated up to 65% (normal 0% to 2%). Hemoglobin electrophoresis will be normal (except in rare cases of hemoglobin M), as is the glucose-6-phosphate dehydrogenase assay in most cases. Prerenal azotemia may be noted. With appropriate treatment, the methemoglobin level returns to normal. However, death can occur from methemoglobinemia in infants if not treated promptly.

Gastrointestinal Disorders

Gastrointestinal disorders can cause an infant to appear acutely ill. *Gastroenteritis*, even without electrolyte disturbances, can lead to profound dehydration. In a very young infant with little reserve, this can quickly lead to lethargy and even shock. Bacterial infections such as *Salmonella* may cause sepsis in a young infant, and viral agents may mimic this. A history of bloody diarrhea may suggest this diagnosis. Stool cultures will diagnose bacterial infections, but a few days are needed for isolation. Viral isolation takes even longer. In the ED, a stool smear may reveal polymorphonuclear leukocytes, suggesting bacterial infection. A CBC count with many band forms and a white blood cell (WBC) count in the normal range suggest *Shigella*. Laboratory tests are otherwise not helpful. Fluid resuscitation may improve the infant's appearance and make dehydration the likely diagnosis. However, sepsis often cannot be ruled out in the ED, regardless of laboratory studies and initial therapy.

Also, *pyloric stenosis* causes severe vomiting in the young infant. This is most often seen in male infants 3 to 6 weeks old. An infant with pyloric stenosis may present to the ED with significant dehydration and may be lethargic. Usually, no fever is present. A careful history reveals that vomiting is the predominant feature of the illness, and there may be a positive family history for pyloric stenosis. The physical examination may reveal an abdominal mass, or "olive," in less than half of the cases, which would strengthen the diagnosis of pyloric stenosis. Rarely, a peristaltic wave can be noted to pass over the epigastric area. Electrolytes typically show hypochloremia and hypokalemia, and alkalosis is prominent. Plain radiographs of the abdomen, a barium study, or ultrasound of the upper gastrointestinal tract may be needed to confirm the diagnosis.

Another gastrointestinal disorder to consider is *intussusception*. Although this rarely occurs in infants younger than 5 months, it has been noted in some infants 2 to 3 months old. These infants may present with vomiting, fever, or signs of abdominal pain (e.g., legs drawn up, irritability). The infant may appear to have spasms of pain during which he or she is fretful. This can be followed by apathy and listlessness. Diarrhea may be seen, and if the typical currant jelly stool is noted, the diagnosis of intussusception should be strongly suspected. This is considered a late finding in this condition. On physical examination, an abdominal mass may be palpated or bloody stool found on rectal examination. The laboratory may show nonspecific abnormalities such as leukocytosis and possibly anemia on the CBC count. However, a plain radiograph of the abdomen will likely show the evidence of small bowel obstruction in advanced cases that mimic sepsis and an air-contrast enema will show a filling defect usually near the ileocecal valve. A history of colicky behavior and the physical findings point to a gastrointestinal lesion rather than to sepsis.

Several other unusual but important gastrointestinal disorders have to be considered in infants. *Necrotizing enterocolitis* (NEC) occurs in premature infants in the first few weeks of life and can also occur in term infants, usually within the first 10 days of life. A history of an anoxic episode at birth or other neonatal stresses may suggest NEC. These infants are quite ill, with lethargy, irritability, anorexia, distended abdomen, and bloody stools. Radiographs of the abdomen may be helpful and usually show pneumatosis cystoides intestinalis caused by gas in the intestinal wall. Neonatal *appendicitis* is a rare event, but several cases have been reported to closely mimic sepsis. The mortality for this disorder is close to 80%, and perforation obviously worsens the prognosis. Thus, rapid diagnosis is essential. The most common presenting signs include irritability, vomiting, and abdominal distension on examination. There may also be hypothermia, ashen color, and shock as the condition progresses, as well as edema of the abdominal wall, localized to the right flank, and, possibly, erythema of the skin in that area. The WBC count may be elevated, with a left shift, and there may be a metabolic acidosis, as well as DIC. Abdominal radiographs may show a paucity of gas in the right lower quadrant, evidence of free peritoneal fluid, or a right abdominal wall thickened by edema.

Another gastrointestinal emergency to consider includes *volvulus* secondary to malrotation. About half of infants with this condition present in the first month of life. Neonates with this condition appear very ill and present with bilious vomiting and possibly bloody stools. Physical examination may reveal abdominal distention, signs of peritonitis as intestinal ischemia progresses, and shock. A plain radiograph of the abdomen may give abnormal finding; however, a limited upper gastrointestinal contrast study (designed to visualize the duodenum and proximal jejunum) is imperative for diagnosis. Finally, consider rare diagnoses such as perforation caused by *trauma* from enemas or thermometers, and *Hirschsprung's enterocolitis*.

Neurologic Diseases

Neurologic problems should be considered in the evaluation of a critically ill infant. For instance, an unusual process that produces a sepsis-like picture is *infant botulism*. This illness is

produced by neurotoxins elaborated by *Clostridium botulinum*. An infant with botulism is often lethargic at presentation to the ED, with a weak cry and, possibly, signs of dehydration. These infants are usually afebrile. A thorough history may help distinguish botulism from sepsis. If constipation has preceded the acute illness, botulism should be seriously considered. The disease is also associated with the ingestion of honey, breast-feeding, a recent change in feeding practices, a rural environment, or nearby construction. The parents may note a more gradual progression with this illness. On physical examination, infants with botulism are notably hypotonic and hyporeflexic and may have increased secretions caused by bulbar muscle weakness. Infants with botulism differ from those with sepsis because they are generally well perfused with normal cardiovascular parameters. Also, the presence of a facial droop, ophthalmoplegia, and decreased gag reflex are consistent with botulism, whereas they remain unusual findings with a septic infant. The diagnosis of infant botulism is usually made by clinical findings; however, laboratory evaluation (cultures) should rule out bacterial illness. Moreover, abnormal (decreased) pulmonary function tests, such as the measurement of maximal inspiratory force and vital capacity, lend supportive evidence to the diagnosis of botulism. Finally, specific tests will confirm the diagnosis of botulism. A stool specimen to identify toxins of *C. botulinum* may be diagnostic but requires considerable time for identification. However, electromyography will show decreased muscle action potential with the "staircase" phenomenon in this disease. The WBC count is normal in infants with botulism.

A young baby with a ventriculoperitoneal shunt in place because of hydrocephalus can develop serious complications that cause the baby to appear extremely ill. *Shunt infection* could present with fever and irritability in a young infant. Abdominal pain or tenderness may be found on examination, as well as erythema or pus around the shunt itself. The definitive diagnosis is made by shunt aspiration under sterile conditions, but other causes of fever, such as meningitis, should be ruled out first. *Shunt obstruction* may result in increased intracranial pressure that causes a young infant to present with a history of lethargy or poor feeding. On examination, the baby may have bradycardia, apnea, coma, opisthotonic posturing, bulging fontanel, or cranial nerve VI palsy. The shunt may be found to pump poorly. Laboratory tests such as radiographic evaluation of the shunt may be helpful if it shows a disconnection. Otherwise, a CT scan will demonstrate ventricle size and indicate the adequacy of shunt function.

Child Abuse

Intracranial hemorrhage that results from child abuse (see Chapter xxx) must be considered in the very ill infant. It must be emphasized that the absence of bruises on an infant does not rule out child abuse. Vigorous shaking of an infant, followed by throwing the baby against a soft surface such as a mattress or sofa, can produce subdural or subarachnoid hemorrhages. The history may or may not be helpful in establishing a diagnosis. The parents may note that the child seemed to be in respiratory distress at home; only a few may admit to shaking the infant. Reports that the infant was well and is now suddenly in critical condition should raise suspicion of abuse. On examination, the infant may appear gravely ill with apnea, bradycardia, hypothermia, bradypnea, and possibly, seizures. However, a careful physical examination may suggest abuse rather than sepsis. For instance, bruises may be present elsewhere on the body. More often, no external evidence of trauma is present. Respiratory distress without stridor or lower airway sounds may be apparent, leading to the consideration of a central nervous system cause. The head circumference is often at the 90th percentile, and the fontanel may be full or bulging. Retinal hemorrhages are often found, strongly suggesting trauma or intracranial hemorrhage rather than meningitis. Some neurologic signs may be confused with meningitis, such as nuchal rigidity, irritability or coma, seizures, or posturing. The laboratory is helpful in confirming suspicions of intracranial bleeding. Although the CBC count often shows a leukocytosis and thus is confusing, the spinal fluid from a shaken baby is usually bloody and fails to clear as the fluid is collected. A noncontrast CT scan or magnetic resonance imaging (MRI) usually demonstrates a small posterior, interhemispheric subdural hematoma. Such shaken babies have a high incidence of serious morbidity and mortality.

EVALUATION AND DECISION

Any infant who is critically ill in the first few months of life should initially be presumed to have sepsis. Because such illness is a life-threatening situation that may respond to early treatment, it is imperative to stabilize the child rapidly (Fig. 70.1). After airway, breathing, and circulation have been restored, vascular access should be obtained. Unless another diagnosis is immediately obvious, it is best to give intravenous antibiotics while pursuing alternative diagnoses. If time permits, cultures should be sent to the laboratory before giving antibiotics. Use of prostaglandins should be considered if cardiogenic shock due to PDA closure is suspected.

A complete history should be obtained. It is important to learn of any previous medical problems such as known heart disease or failure to thrive. The time of onset of symptoms, exposure to infection, medications given at home, and specific symptoms noted by the parents must be determined. Next, careful physical examination must be performed because specific findings may lead to a diagnosis other than sepsis (Table 70.3). After the physical examination, a complete laboratory evaluation should be performed. A rapid test for blood sugar level should be obtained promptly as hypoglycemia may be life threatening. All sick infants should have blood culture and urine culture specimens obtained by a urethral catheter or suprapubic bladder tap. A lumbar puncture should also be performed unless physical findings point strongly to a diagnosis other than sepsis or the infant is too ill to tolerate the procedure. A chest radiograph is also essential to look for pulmonary infection and to evaluate the heart size. A CBC count should be obtained; leukocytosis will add support to a suspicion of sepsis but also may be found in various other disorders including viral infections, myocarditis, pericarditis, intracranial bleeds, NEC, appendicitis, intussusception, and methemoglobinemia. Because metabolic problems (disturbances in acid-base balance, electrolytes, blood sugar) can result from sepsis or be the primary problem that mimics sepsis, all sick infants should have chemistries to evaluate serum sodium, potassium, chloride, glucose, and bicarbonate levels.

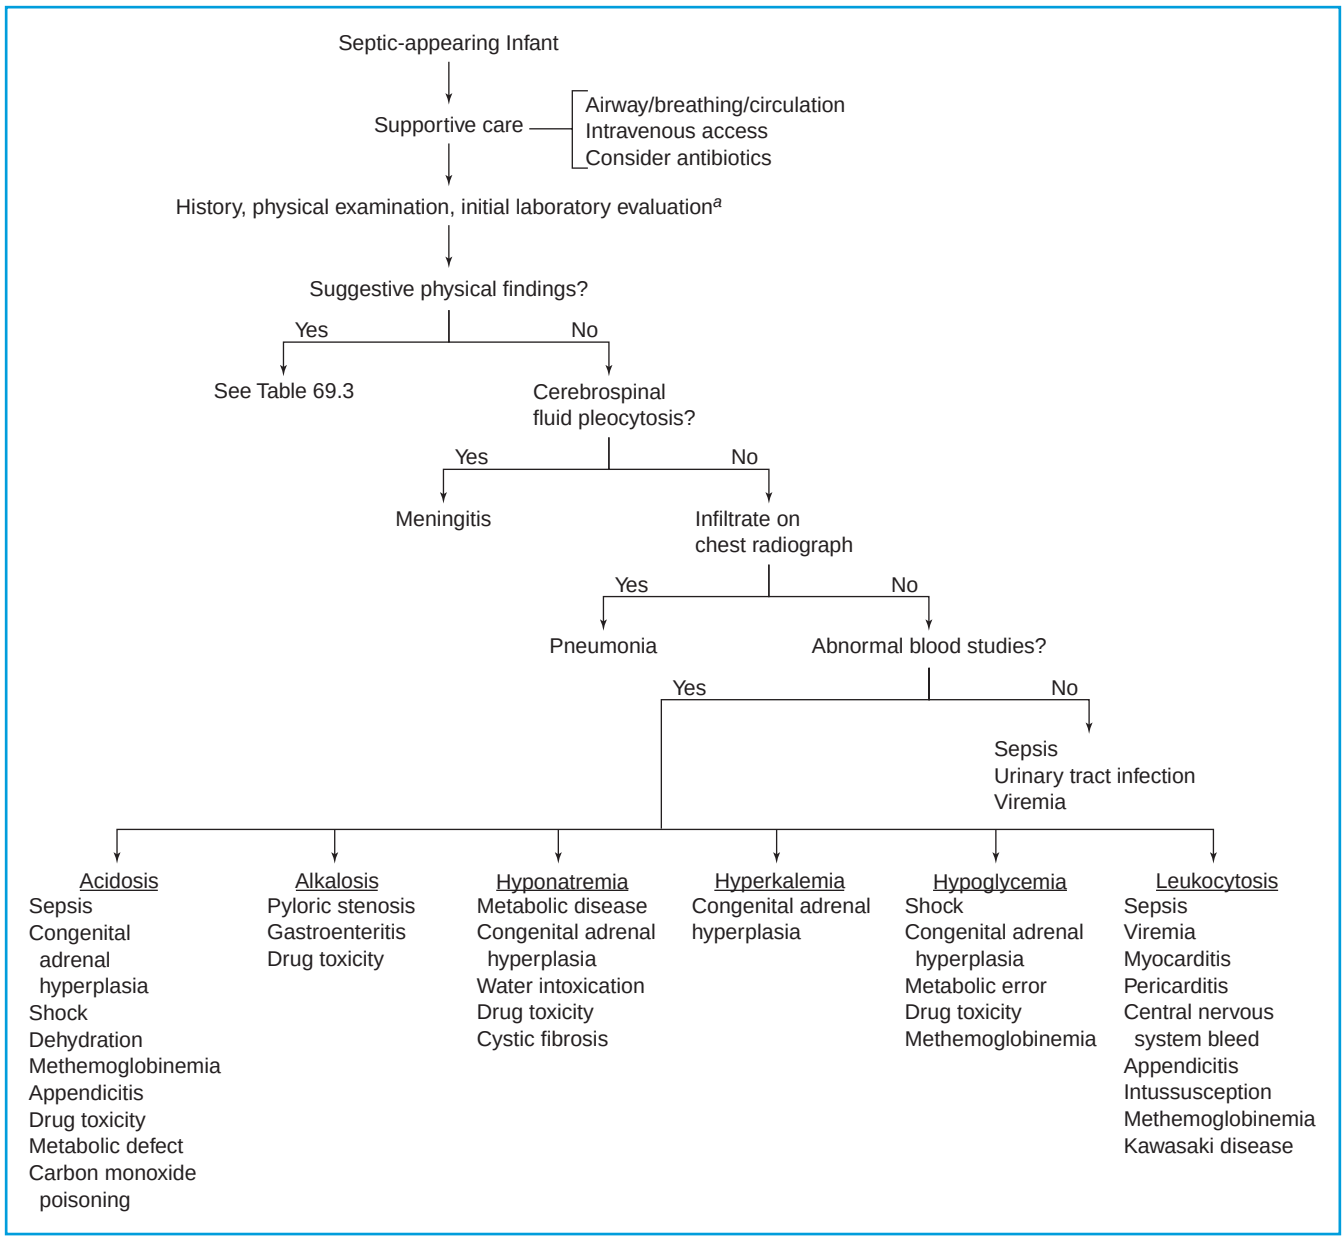

FIGURE 70.1 Initial approach to the septic-appearing child. [a]Initial laboratory evaluation: culture of blood, urine, usually cerebrospinal fluid, chest radiograph, complete blood cell count, urinalysis, electrolytes, glucose, bicarbonate, and maybe arterial blood gas.

If hyponatremia is found, water intoxication, aspirin toxicity, cystic fibrosis, and CAH should be considered. If there is also a marked hyperkalemia, CAH is most likely. If there is hypochloremic alkalosis or alkalosis alone, then pyloric stenosis, aspirin toxicity, or gastroenteritis should be considered. If there is hypoglycemia, it should be considered secondary to poor glucose reserves in an ill infant or related to drug (aspirin) toxicity, inborn errors of metabolism, CAH, or methemoglobinemia. If the serum bicarbonate level is low, this should be confirmed with an arterial blood gas level. Then, if acidosis is present, poor perfusion caused by shock should be considered, as well as dehydration, drug toxicity, methemoglobinemia, appendicitis, CAH, and inborn errors of metabolism, as primary problems.

Finally, if laboratory tests are not revealing for a specific disorder or the patient does not improve quickly as an inpatient receiving antibiotics, stool and CSF isolates for viruses should be considered.

If the physical examination suggests a specific problem, it may be necessary to obtain additional laboratory tests (Table 70.3). For instance, if the examination reveals pallor, cyanosis, or cardiac abnormality (muffled heart sounds, murmur, unexplained tachycardia, or arrhythmia), the physician should consider various cardiac disorders and, possibly, methemoglobinemia. An EKG, arterial blood to measure Pa_{O_2}, and possibly an echocardiogram should then be obtained. If there are unusual neurologic findings, such as a bulging fontanel, a lumbar puncture should be performed to rule out meningitis, as well

TABLE 70.3

APPROACH TO THE SEPTIC-APPEARING INFANT WITH CHARACTERISTIC PHYSICAL FINDINGS

Physical findings	Diagnoses to consider	Specific tests
Cardiovascular abnormalities	Congenital heart disease	Echocardiogram, EKG
	Kawasaki disease	EKG, erythrocyte sedimentation rate
	Supraventricular tachycardia	EKG
	Myocarditis	Echocardiogram, EKG
	Myocardial infarction	EKG
	Methemoglobinemia	Pa_{O_2} methemoglobin level
Neurologic abnormalities	Meningitis	Lumbar puncture
	Infant botulism	Stool for culture, electromyogram
	Child abuse	Long bone films, CT scan, MRI
	Shunt malfunction	Shunt series, CT scan
Skin abnormalities	Child abuse	Long bone films, CT scan, MRI
	Coagulopathy	Coagulation profile
	Herpes simplex	PCR, electroencephalogram, CT scan
Genitalia abnormalities	Congenital adrenal hyperplasia	Blood for 17-hydroxyprogesterone, renin, aldosterone, cortisol
Pulmonary abnormalities	Pertussis	PCR
	Pneumonia	Chest radiograph
	Bronchiolitis	Respiratory syncytial virus tests
	Metabolic acidosis	Arterial blood gas
Renal abnormalities (abdominal mass)	Posterior urethral valves	Abdominal, renal ultrasound, voiding cystourethrogram
		Blood urea nitrogen, creatinine

EKG, electrocardiogram; CT, computed tomography; MRI, magnetic resonance imaging; PCR, polymerase chain reaction; EEG, electroencephalogram.

as blood studies mentioned previously. The presence of seizures should prompt a CT scan, EEG, and culture and treatment of herpes simplex. Also, if marked hypotonia is present, an electromyogram may help diagnose botulism. Retinal hemorrhages may suggest an intracranial bleed and, thus, a noncontrast CT scan, MRI, and lumbar puncture would be valuable studies. Likewise, if there were abdominal distension, rigidity, mass, or bloody stools, this would indicate a gastrointestinal emergency. In such cases, abdominal radiographs, ultrasound, or air-contrast studies would be important diagnostic aids, but a workup for sepsis may still be indicated.

Furthermore, if the physical examination reveals bruises or purpura, further evaluation for child abuse, coagulopathy, and sepsis should be considered. In addition, long bone radiographs, coagulation profile (including platelet count), and Gram stain of the purpura may then be desirable. If vesicular lesions are seen on the skin, a PCR and culture for herpes should be obtained. If ambiguous genitalia are noted, blood should be drawn for 17-hydroxyprogesterone, renin, aldosterone, and cortisol levels to rule out CAH (see Chapter xx). Finally, if wheezing is detected on chest examination, a nasopharyngeal swab should be sent for rapid detection of RSV or for the culture of RSV.

CHAPTER 71 ■ SORE THROAT

GARY R. FLEISHER, MD

Sore throat refers to any painful sensation localized to the pharynx or the surrounding areas. Because children, particularly those of preschool age, cannot define their symptoms as precisely as adults, the physician who evaluates a child with a sore throat must first define the exact nature of the complaint. Occasionally, young patients with dysphagia (see Chapter 52), which results from disease in the area of the esophagus or with difficulty swallowing because of a neuromuscular disorder, will verbalize these feelings as a sore throat. Careful questioning usually suffices to distinguish between these complaints.

Although a sore throat is less likely to portend a life-threatening disorder than dysphagia or the inability to swallow, this complaint should not be dismissed without a thorough evaluation. Most children with sore throats have self-limiting or easily treated pharyngeal infections, but a few have serious disorders such as retropharyngeal or lateral pharyngeal abscesses. Even if the reason for the complaint of sore throat is believed to be an infectious pharyngitis, several different organisms may be responsible. Symptomatic therapy, antibiotics, antiinflammatory drugs, or surgical intervention may be appropriate at times. Most children experience no adverse consequences from misdiagnosis and inappropriate therapy, but a few may develop local extension of infection or sepsis, chronically debilitating illnesses such as rheumatic fever, or life-threatening airway obstruction.

DIFFERENTIAL DIAGNOSIS

Infectious Pharyngitis

Infection is the most common cause of sore throat and is usually caused by respiratory viruses including adenoviruses, coxsackievirus A (various serotypes), or parainfluenza virus (see Chapter 92; Tables 71.1 to 71.3). Several of the respiratory viruses produce easily identifiable syndromes, including hand-foot-mouth disease (coxsackievirus) and pharyngoconjunctival fever (adenovirus). These viral infections are closely followed in frequency by bacterial infections caused by group A streptococci (*Streptococcus pyogenes*). In the winter months during streptococcal outbreaks, as many as 30% to 50% of episodes of pharyngitis may be caused by *S. pyogenes* in school-aged children. The only other common infectious agent in pharyngitis is the Epstein-Barr virus, which causes infectious mononucleosis. Although infectious mononucleosis is not often seen in children younger than 5 years (Fig. 71.1), it cannot be considered rare even during these early years of life. More commonly, however, it affects the adolescent. An additional consideration in adolescents with an infectious mononucleosis-like syndrome is human immunodeficiency virus (HIV), which does not commonly cause significant pharyngeal inflammation.

Other organisms produce pharyngitis only rarely; these include *Neisseria gonorrhoeae*, *Corynebacterium diphtheriae*, *Francisella tularensis*, and other bacteria. *N. gonorrhoeae* may cause inflammation and exudate but more often remains quiescent, being diagnosed only by culture. Diphtheria is a life-threatening but seldom encountered cause of infectious pharyngitis, characterized by a thick membrane and marked cervical adenopathy. Oropharyngeal tularemia is rare and should be entertained only in endemic areas among children who have an exudative pharyngitis that cannot be categorized by standard diagnostic testing and/or persists despite antibiotic therapy. Although unusual, mixed anaerobic infections should be considered in the ill-appearing adolescent with a severe pharyngitis because these organisms occasionally lead to sepsis (Lemierre's disease). Other pathogens—group C and G streptococci, *Arcanobacterium haemolyticum*, *Mycoplasma pneumoniae*, and *Chlamydia pneumoniae*—have been implicated as agents of pharyngitis in adults, but in childhood, their roles remain unproved and their frequency is unknown. Of these, *A. haemolyticum* is the most frequent, having been isolated from 0.5% to 2.0% of adolescents with pharyngitis, often in association with a maculopapular rash.

Irritative Pharyngitis/Foreign Body

Drying of the pharynx may irritate the mucosa, leading to a complaint of sore throat. This condition occurs most commonly during the winter months, particularly after a night's sleep in a house with forced hot-air heating. Occasionally, a foreign object such as a fishbone may become embedded in the pharynx.

Herpetic Stomatitis

Stomatitis caused by herpes simplex virus is usually confined to the anterior buccal mucosa but may extend to the anterior tonsillar pillars occasionally and involve the upper esophagitis in immunocompetent patients on rare occasions. Particularly, in these more extensive cases, the child may complain of a sore throat.

Peritonsillar Abscess

A peritonsillar abscess may complicate a previously diagnosed infectious pharyngitis or may be the initial source of a child's

TABLE 71.1

DIFFERENTIAL DIAGNOSIS OF SORE THROAT IN THE IMMUNOCOMPETENT HOST

Infectious pharyngitis
- Respiratory viruses
- Group A streptococci
- Epstein-Barr virus (infectious mononucleosis)
- Human immunodeficiency virus
- *Neisseria gonorrhoeae*
- Anaerobic bacteria
- Group C and G streptococci
- *Arcanobacterium haemolyticum*
- *Mycoplasma pneumoniae* (unconfirmed)
- *Chlamydia pneumoniae* (unconfirmed)
- *Francisella tularensis*
- *Corynebacterium diphtheriae* (diphtheria)

Other causes
- Herpetic stomatitis
- Irritative pharyngitis
- Foreign body
- Peritonsillar abscess
- Retropharyngeal and lateral pharyngeal abscesses
- Epiglottitis
- Kawasaki disease
- Stevens-Johnson syndrome
- Chemical exposure
- Psychogenic pain
- Referred pain

discomfort. This disease is most common in older children and adolescents. The diagnosis is evident from visual inspection, augmented occasionally by careful palpation. These abscesses produce a bulge in the posterior aspect of the soft palate, deviate the uvula to the contralateral side of the pharynx, and have a fluctuant quality on palpation.

Retropharyngeal and Lateral Pharyngeal Abscesses

Retropharyngeal abscess is an uncommon cause of sore throat, usually occurring in children younger than 4 years. Although most children with this disorder appear toxic and have respiratory distress, a few complain of sore throat and dysphagia without other manifestations early in the course. Occasional infants and young children may also manifest torticollis. A soft-tissue radiographic examination of the lateral neck demonstrates the lesion readily in most cases, whereas direct visualization is often impossible. Unfortunately, even limited

- Diphtheria
- Peritonsillar abscess
- Lemierre's syndrome

flexion of the neck during the radiograph may cause a buckling of the retropharyngeal tissues that resembles a purulent collection. The physician must insist on a radiograph with the neck fully extended before hazarding an interpretation. If the diagnosis remains uncertain despite adequate radiographs, a computed tomography (CT) scan should be obtained.

Lateral pharyngeal abscesses manifest in a fashion similar to retropharyngeal infections but occur less often. High fever is a common symptom, and both trismus and swelling below the mandible may be seen. To confirm the diagnosis, a CT scan is appropriate.

Epiglottitis

The incidence of epiglottitis, a well-appreciated cause of life-threatening upper airway infection, has declined significantly since the introduction of vaccination against *Haemophilus influenzae* type b. This disease manifests with a toxic appearance, high fever, stridor, and drooling. In every reported series of cases, sore throat appears on the list of symptoms. Although rarely this may be the primary complaint in a child, other more striking findings almost always predominate. Epiglottitis

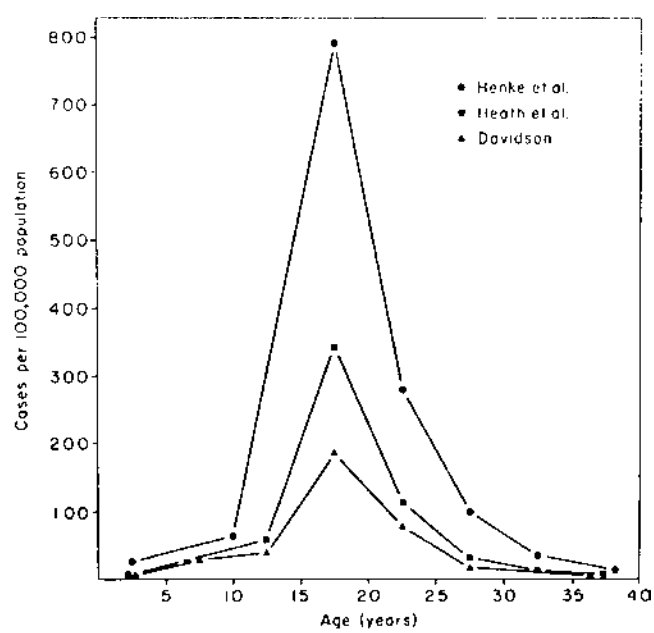

FIGURE 71.1 Incidence by age of infectious mononucleosis in three large studies.

should be excluded easily as a diagnosis in the patient with a sore throat who is without stridor and appears relatively well.

Kawasaki Disease

Kawasaki disease is characterized by high fever along with at least four of the five following findings: (i) conjunctivitis, (ii) mucositis, (iii) peripheral erythema and/or edema, (iv) truncal rash, and (v) cervical adenopathy (see Chapter 101). The mucositis most commonly involves the lips, but occasionally pharyngitis may be a prominent feature. Other systemic inflammatory conditions (Behçet's syndrome) may involve the pharynx as well.

Stevens-Johnson Syndrome

Stevens-Johnson syndrome, a disease of unknown etiology but presumed to be immune mediated, is characterized by vesicular and ulcerative lesions of the mucosa, including the pharynx, the genitalia, and the conjunctivae. In addition, children with this condition may have a diffuse rash, often characterized by target lesions or vesicles and bullae. Usually self-limited, an occasional case may lead to dehydration or progress to involve the pulmonary system.

Chemical Exposure

Certain ingestions, such as paraquat and various alkalis, may produce a chemical injury to the mucosa of the pharynx (see Chapter 102). Usually, these findings occur in the setting of a known ingestion and are accompanied by lesions of the oral mucosa.

Referred Pain

Occasionally, pain from the inflammation of extrapharyngeal structures is described as arising in the pharynx. Examples include dental abscesses, cervical adenitis, and, occasionally, otitis media.

Psychogenic Pharyngitis

Some children who complain of a sore throat have no organic explanation for their complaint after a thorough history and physical examination and a throat culture. In these cases, the physician should consider the possibility of anxiety, at times associated with frequent or difficult (globus hystericus) swallowing.

Pharyngitis in the Immunosuppressed Host

Immunosuppressed hosts may develop pharyngitis from any of the previously discussed causes. In addition, these patients exhibit a particular susceptibility to infections with fungal organisms such as *Candida albicans*.

EVALUATION AND DECISION

The history and physical examination should focus on findings seen with systemic illnesses causing pharyngitis and the appearance of the oral cavity. A medical history of an immunosuppressive disorder or missed immunizations raises the specter of unusual infections. A sudden onset is most characteristic of epiglottitis.

Fever, either historical or measured, points to an infection or, less commonly, Kawasaki disease. Toxicity and/or respiratory distress occur with infections leading to respiratory obstruction, such as peritonsillar, retropharyngeal, and lateral pharyngeal abscesses; epiglottitis; diphtheria; and infectious mononucleosis with severe tonsillar hypertrophy. Conjunctivitis suggests pharyngoconjunctival fever (adenovirus), Kawasaki disease, or Stevens-Johnson syndrome; generalized adenopathy occurs with infectious mononucleosis and HIV; and a rash is seen with scarlet fever (group A streptococci), Kawasaki disease, infectious mononucleosis, particularly after the administration of amoxicillin, and rarely with A. *hemolyticum* in adolescents.

The tendency of most clinicians is to assume that one of the common organisms is the cause of pharyngitis in the child with a sore throat. Before settling on infectious pharyngitis, however, the emergency physician should first at least briefly consider several more serious disorders (Fig. 71.2). Conditions

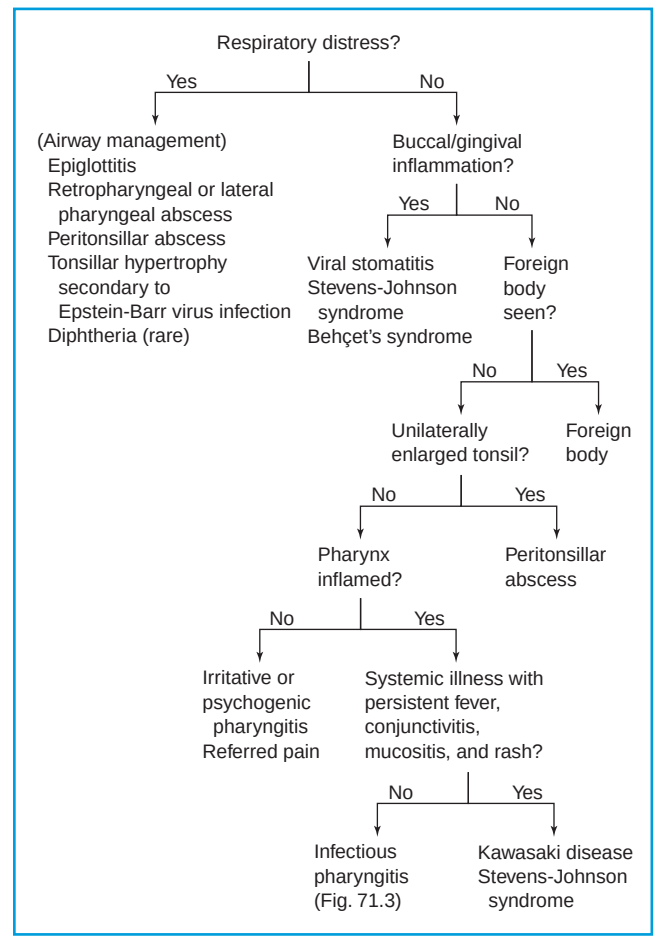

FIGURE 71.2 Diagnostic approach to the child with sore throat.

that have immediate life-threatening potential include epiglottitis, retropharyngeal and lateral pharyngeal abscesses, peritonsillar abscess, severe tonsillar hypertrophy (usually as an exaggerated manifestation of infectious mononucleosis), and diphtheria. Generally, stridor and signs of respiratory distress accompany the complaint of sore throat in epiglottitis and retropharyngeal abscess. Drooling and voice changes are common in children with these two conditions, as well as in patients with peritonsillar abscess and severe infectious tonsillar hypertrophy. In cases of epiglottitis or retropharyngeal abscess that are not clinically obvious, a lateral neck radiograph, obtained under appropriate supervision, is confirmatory. Peritonsillar abscess and tonsillar hypertrophy are diagnosed by visual examination of the pharynx. Diphtheria is rarely a consideration except in unimmunized children, particularly those from underdeveloped nations.

The next phase of the evaluation of the child with a complaint of sore throat hinges on a careful physical examination, particularly of the pharynx (Fig. 71.2). The appearance of vesicles on the buccal mucosa anterior to the tonsillar pillars points to a herpetic stomatitis or noninfectious syndromes such as Behçet's or Stevens-Johnson syndrome (erythema multiforme). Uncommonly, a small, pointed foreign body, most commonly a fishbone, becomes lodged in the mucosal folds of the tonsils or pharynx; usually, the history suggests the diagnosis, but an unanticipated sighting may occur in the younger child. Significant asymmetry of the tonsils indicates a peritonsillar cellulitis or, if extensive, an abscess. Clinically, the diagnosis of an abscess is reserved for the tonsil that protrudes beyond the midline, causing the uvula to deviate to the uninvolved side. Kawasaki disease produces a systemic syndrome with a prolonged fever and other characteristic findings that are usually more prominent than the pharyngeal involvement.

The remaining organic diagnoses, once those already discussed have been eliminated by history, physical examination, and occasionally imaging, include referred pain, irritative pharyngitis, and infectious pharyngitis. Sources of referred pain (otitis media, dental abscess, and cervical adenitis) are usually identified during the examination. Irritative pharyngitis, seen most commonly during the winter among older children who live in homes with forced hot-air heating, produces minimal or no pharyngeal inflammation. It often is transient, appearing on arising and resolving by midday.

Infectious pharyngitis (Fig. 71.3) evokes a spectrum of inflammatory responses that range from minimal injection of the mucosa to beefy erythema with exudation and edema formation. The three relatively common causes are streptococci, respiratory viruses, and infectious mononucleosis (Fig. 71.3). In a few cases, a viral pharyngitis that results from coxsackievirus infection will be self-evident on the basis of vesicular formation in the posterior pharynx or involvement of the extremities (hand-foot-mouth syndrome). Such patients require only symptomatic therapy. A small number of additional patients will have signs of infectious mononucleosis: large, mildly tender posterior cervical lymph nodes; diffuse lymphadenopathy; and/or hepatosplenomegaly. In these children, the physician should obtain a white blood cell count with differential and a slide test for heterophil antibody (e.g., "monospot," see Fig. 71.4) in an effort to confirm the clinical diagnosis, thereby guiding therapy and discussion of prognosis. Some children, especially those younger than 5 years, will

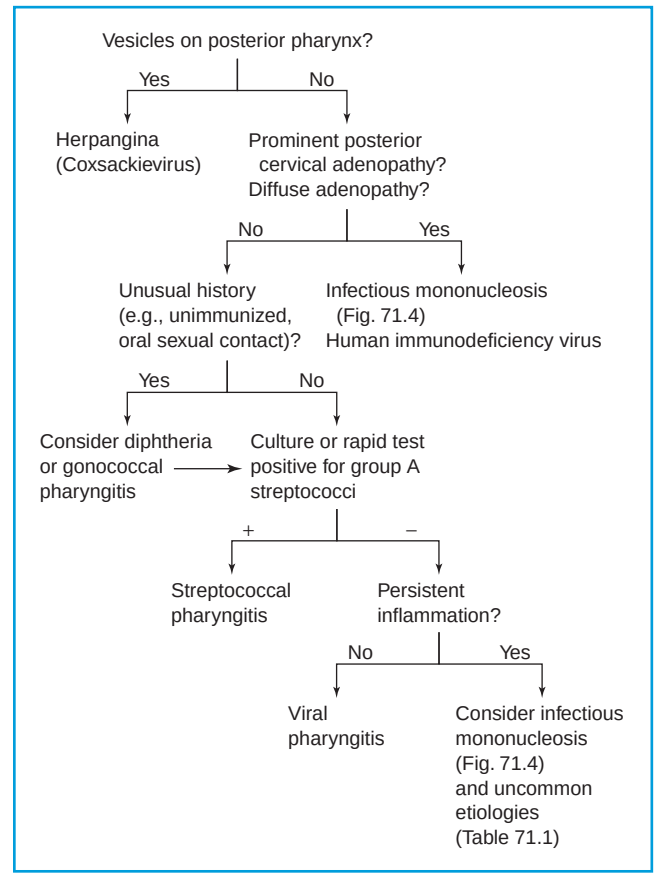

FIGURE 71.3 Diagnostic approach to infectious pharyngitis in the immunocompetent child.

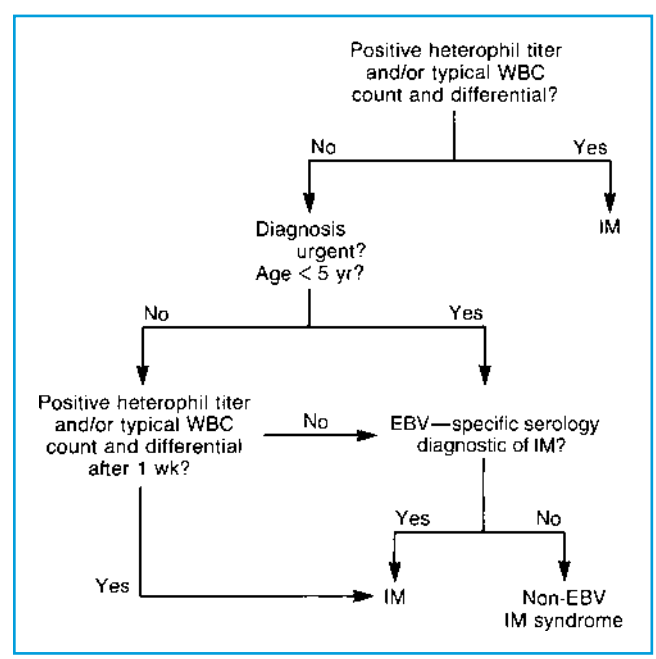

FIGURE 71.4 Diagnostic approach when findings are clinically suggestive for mononucleosis. WBC, white blood cell; IM, infectious mononucleosis; EBV, Epstein-Barr virus.

not have the characteristic lymphocytosis or heterophil antibody response and will require repeated testing or specific serologic assays for antibodies to Epstein-Barr virus. In the rare child with an unusual history, the physician must pursue diagnoses such as gonococcal pharyngitis (sexual abuse, oral sex) or diphtheria (immigration from an underdeveloped nation, lack of immunization).

Ultimately, most children will have a mildly to moderately inflamed pharynx but no specific etiologic diagnosis based solely on the history and physical examination. Although certain symptoms and signs favor streptococcal infection, none is conclusive. Thus, obtaining a rapid test (latex agglutination or optical immunoassay) for group A streptococci, followed by a culture, if negative, is prudent. Rapid tests are most helpful when a positive result is obtained because specificity of the tests is high; however, a negative test result does not exclude streptococcal infection reliably, although some authorities would be satisfied with a negative optical immunoassay alone. With the more recent reported rise in the incidence of rheumatic fever, the accurate diagnosis of streptococcal pharyngitis assumes increasing importance. Generally, symptomatic therapy suffices in the patient with a negative rapid test, although the physician may elect to initiate therapy, usually with a penicillin (penicillin V or amoxicillin) but occasionally with a cephalosporin or macrolide, while awaiting the results of the throat culture in selected cases with highly suggestive clinical features.

CHAPTER 72 ■ STRIDOR

HOLLY E. PERRY, MD

Stridor, although a relatively common occurrence, can be frightening to both children and parents. The presence of stridor necessitates a complete and careful evaluation to determine the cause of this worrisome and occasionally life-threatening symptom. This chapter presents the causes of stridor and provides the emergency practitioner with guidelines for initial evaluation and management.

PATHOPHYSIOLOGY

Stridor is an externally audible sound associated with respiration. It is produced by turbulent airflow through large airways. It occurs when a normal respiratory volume of air moves through narrowed airways, which results in the normal laminar flow becoming turbulent. Stridor thus signifies partial airway obstruction.

The level of obstruction can be inferred from several characteristics of stridor: associated phase of respiration, pitch, and length of respiratory phase. Inspiratory stridor occurs with obstruction of the extrathoracic trachea, biphasic stridor when both extrathoracic and intrathoracic tracheas are involved, and expiratory stridor when only the intrathoracic trachea is involved. The pitch of the stridor also helps determine the location of the obstruction. Laryngeal and subglottic obstructions are associated with high-pitched stridor. In contrast, obstruction of the nares and nasopharynx results in lower pitched snoring or snorting sounds also called stertor. Because the passage of saliva and the flow of air are impeded in pharyngeal obstruction, these patients often have a gurgling quality of breathing. Finally, the relative length of inspiratory and expiratory phases may be helpful. Laryngeal obstruction results in an increased inspiratory phase, whereas expiration tends to be prolonged in bronchial obstruction. Both inspiratory and expiratory phases are increased in patients with tracheal obstruction.

DIFFERENTIAL DIAGNOSIS

Stridor may occur in a wide variety of disease processes affecting the large airways from the level of the nares to the bronchi but most often arises with disorders of the larynx and trachea (Table 72.1). For the purposes of differential diagnosis, it is helpful to categorize the common causes of stridor as chronic or acute in onset and to further divide acute onset into febrile and afebrile causes (Table 72.2). Life-threatening causes of stridor must be considered early during the evaluation process (Table 72.3).

Stridor with Acute Onset in the Febrile Child

Laryngotracheitis (croup) is by far the most common cause of stridor in the febrile child. Other diagnoses that should be considered include bacterial tracheitis (see Chapter 92), epiglottitis, retropharyngeal abscess, and laryngeal diphtheria in the unimmunized child. Although less common than croup, these diseases have a greater potential for life-threatening airway compromise.

Croup typically affects children between 7 and 36 months of age but is seen throughout childhood. The illness begins with upper respiratory tract symptoms and fever, usually ranging from 38°C to 39°C (100.4°F to 102.2°F). Within 12 to 48 hours, a barky, "seal-like" cough and inspiratory stridor are noted. Supraclavicular and subcostal retractions may be present. Symptoms are aggravated by crying and ameliorated by nebulized epinephrine. Most children appear only mildly or moderately ill.

Bacterial tracheitis presents in a variety of ways but may closely resemble croup. However, affected patients generally appear toxic, tend to be older, and do not respond as well to nebulized epinephrine. Dysphagia is common, and drooling may be present. The verbal child may complain of anterior neck pain or a painful cough.

Epiglottitis is an infection of the supraglottic structures. It may be divided into disease caused by *Haemophilus influenzae* or that caused by a number of other pathogens including *Staphylococcus aureus*, *Streptococcus pneumoniae*, and β-hemolytic streptococci. The incidence of epiglottis due to *H. influenzae* has plummeted to as low 0.02 per 100,000 in Western countries, following the introduction of the conjugate vaccine. Patients with *H. influenzae* epiglottitis typically are febrile, drooling, and appear toxic. Respiratory distress and a tripod stance (upright position, neck extended, and mouth open) are characteristic symptoms. Sudden airway compromise may occur and is frequently precipitated by the manipulation of the oropharynx.

In contrast, epiglottitis caused by pathogens other than *H. influenzae* has a slower onset, is much more common in adults, and is almost universally associated with difficulty swallowing or sore throat. Importantly, the risk of airway compromise is less than with epiglottitis caused by *H. influenzae*. However, any child with epiglottitis should be managed as if he or she has disease caused by *H. influenzae* and should have the airway inspected under controlled conditions.

A retropharyngeal abscess is another possible cause of stridor, although respiratory distress does not dominate the clinical presentation. More commonly, patients have fever, limitation of neck movement, agitation, or lethargy.

TABLE 72.1

CAUSES OF STRIDOR BY ANATOMIC LOCATION

Nose and pharynx
Congenital anomalies
- Lingual thyroid
- Choanal atresia
- Craniofacial anomalies (Apert's and Down's syndromes; Pierre Robin sequence)
- Cysts (dermoid, thyroglossal)
- Macroglossia (Beckwith's syndrome)
- Encephalocele

Inflammatory
- Abscess (parapharyngeal, retropharyngeal, peritonsillar)
- Allergic polyps
- Adenotonsillar enlargement (acute infection, infectious mononucleosis)

Neoplasm (benign, malignant)
Adenotonsillar hyperplasia
Foreign body
Neurologic syndromes with poor tongue/pharyngeal muscle tone

Larynx
Congenital anomalies
- Laryngomalacia
- Web, cyst, laryngocele
- Cartilage dystrophy
- Subglottic stenosis
- Cleft larynx

Inflammatory
- Croup
- Epiglottitis
- Tracheitis
- Angioneurotic edema
- Miscellaneous: tuberculosis, fungal infection, diphtheria, sarcoidosis

Vocal cord paralysis (multiple causes)
Neoplasm
- Subglottic hemangioma
- Laryngeal papilloma
- Cystic hygroma (neck)
- Malignant (e.g., rhabdomyosarcoma)

Laryngospasm (hypocalcemic tetany)

Trachea and bronchi
Congenital
- Vascular anomalies
- Webs, cysts
- Tracheal stenosis
- Tracheoesophageal fistula

Neoplasm
- Tracheal
- Compression by adjacent structure (thyroid, thymus, esophagus)

Foreign body (tracheal or esophageal)

Physical examination may reveal midline fullness of the oropharynx.

Stridor with Acute Onset in the Afebrile Child

A foreign body in either the trachea or the esophagus may produce stridor. There may be a history of choking on food or a small object. Physical examination varies, depending on the location of the foreign body.

Both ingestion and inhalation of caustic or thermally damaging substances may result in injury to the airway or hypopharynx. Symptoms of airway compromise may be delayed for as long as 6 hours. Blind finger sweeps have also been reported rarely to result in stridor. Other causes to consider include spasmodic croup, angioneurotic edema, and trauma (see Chapter 112).

TABLE 72.2

COMMON CAUSES OF STRIDOR

Acute, febrile
Croup
Tracheitis
Epiglottitis
Retropharyngeal abscess

Acute, afebrile
Foreign body
Caustic or thermal injury to airway
Spasmodic croup
Angioneurotic edema

Chronic
Laryngomalacia
Vascular anomalies
Adenotonsillar hyperplasia

Chronic Stridor

The differential diagnosis is determined by the age at onset. Stridor noted shortly after birth is most likely caused by a structural defect. This type of stridor tends to slowly worsen and is severe only when the infant is stressed, such as during crying. Laryngomalacia is the most common cause of congenital stridor accounting for up to 75% of chronic stridor in children younger than 1 year. Stridor associated with laryngomalacia is positional and is worsened by placing the infant in the supine position. It frequently disappears when the child cries. Other congenital causes of stridor include laryngeal webs, laryngeal diverticula, vocal cord paralysis, sub-

TABLE 72.3

LIFE-THREATENING CAUSES OF STRIDOR

Usually febrile

Angioneurotic edema
Neck trauma
Neoplasm (compressing trachea)
Thermal or caustic injury

glottic stenosis, tracheomalacia, and vascular anomalies such as a double aortic arch or a vascular sling. Stridor in infants has also been reported to be associated with gastroesophageal reflux.

Stridor in older children may be caused by papillomas or neoplastic processes. Patients with papillomas generally present between 2 and 4 years of age with complaints of hoarseness and stridor. Neoplastic processes causing tracheal compression can also lead to stridor in the older child.

Psychogenic stridor, also called functional stridor, is an uncommon cause of stridor in the older child. Cases have been reported in adolescents, with the youngest age being 10 years. Adolescent girls are diagnosed three times more often with this condition than are adolescent boys. More than 50% of patients meet diagnostic criteria for a psychiatric disorder. Characteristically, stridor improves when the patient is unaware that he or she is being observed, and it may clear with cough. The diagnosis can only be confirmed by direct laryngoscopy in the symptomatic patient when the vocal cords are noted to be adducted during inspiration.

EVALUATION AND DECISION

The first priority is to ensure that the airway is adequate by assessing the level of consciousness, color, perfusion, air entry, breath sounds, and work of breathing, including respiratory rate, nasal flaring, and retractions. Resuscitative measures should be instituted as necessary (see Chapter 5). The child may then be evaluated systematically. In the child with acute onset of stridor, history should focus on associated symptoms such as fever, duration of illness, drooling, rhinorrhea, and history of choking (Fig. 72.1). Immunization status should be verified, particularly *H. influenzae* vaccination. In the case of a child with chronic stridor, important historical points include age at onset and progression of stridor, as well as ameliorating and aggravating factors.

Physical examination should include careful inspection of the nares and oropharynx, with particular attention to increased secretions, drooling, visible mass, and abnormal phonation. Quality of the voice or cry should be noted as normal, hoarse (croup, vocal cord paralysis, papilloma), weak (neuromuscular disorder), or aphonic (laryngeal obstruction by a foreign body). Regional findings such as adenopathy, neck masses, meningismus, trauma, or bruising should also be sought. Position of comfort should be noted. Children with airway obstruction at the level of the larynx and above usually hyperextend the neck and lean forward ("sniffing" position) in an effort to straighten their upper airway and maximize air entry. This posture does not help relieve more distal obstruction. Finally, response to therapies, such as nebulized racemic epinephrine, should be noted.

Emergency management of the child with stridor depends on its severity and its likely cause. Oxygen, nebulized epinephrine, corticosteroids, laryngoscopy, intubation, and even emergency cricothyroidotomy or tracheostomy all have specific roles in the emergency department (ED) management of stridor, depending on its cause (see Chapters 110 and 123).

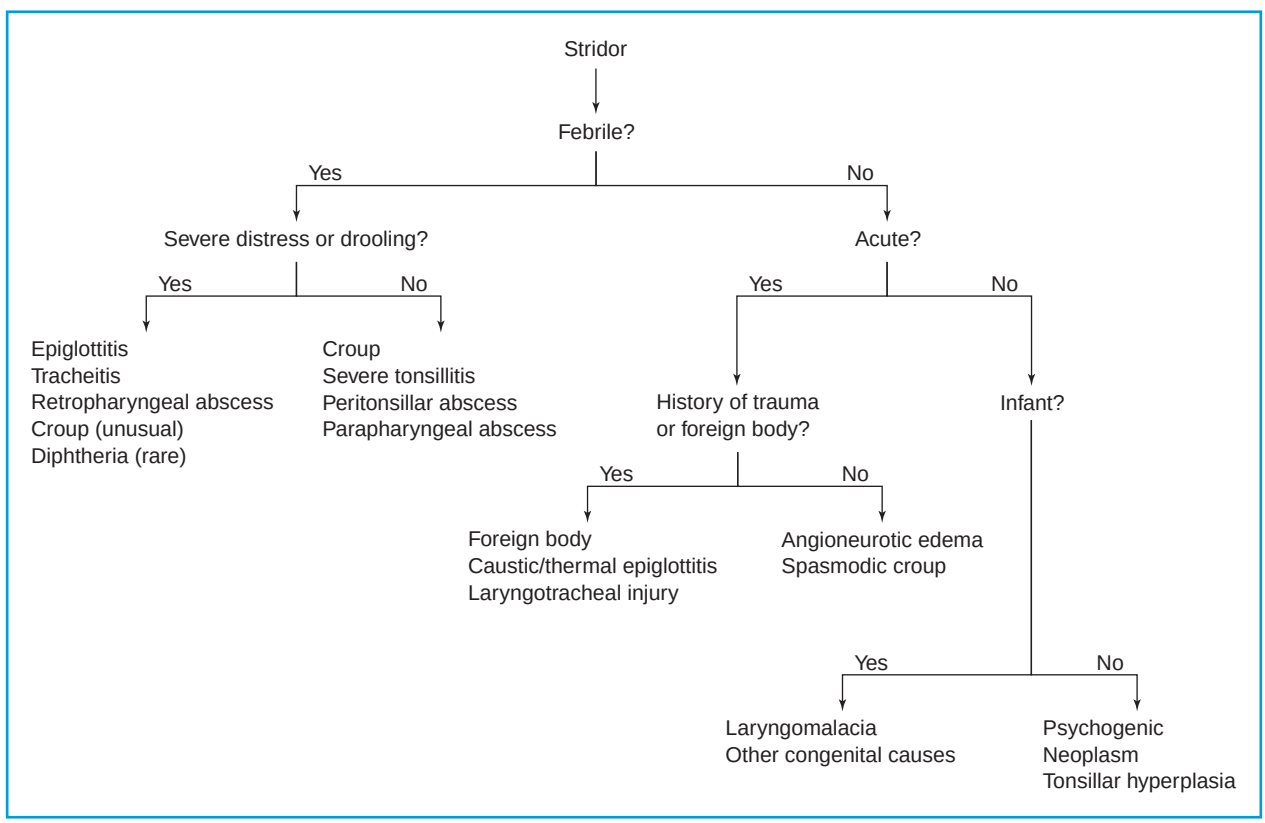

FIGURE 72.1 Diagnostic approach to stridor.

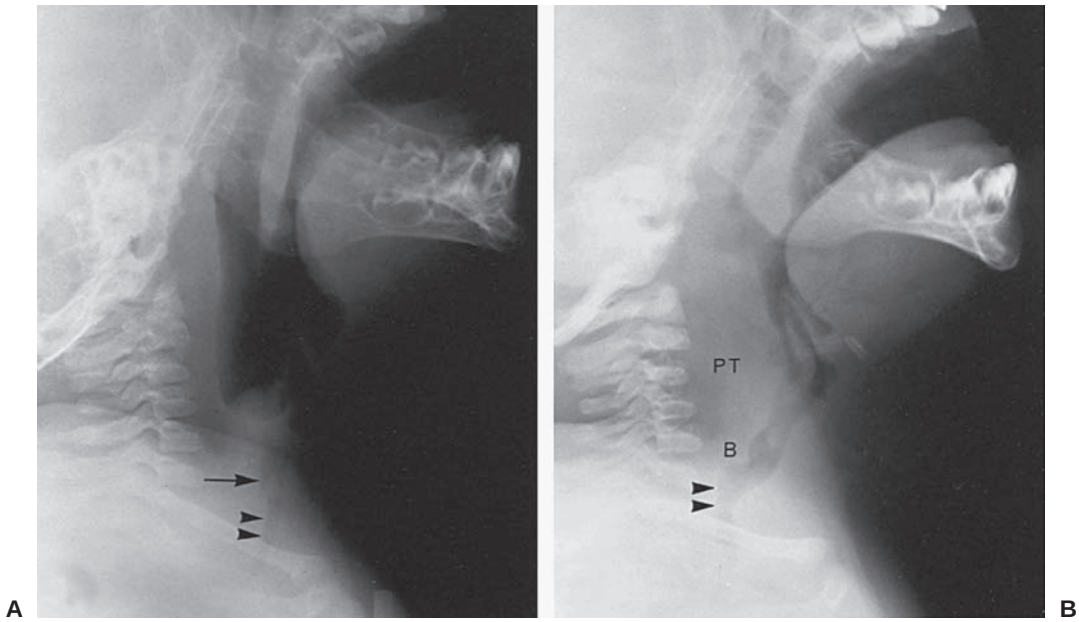

FIGURE 72.2 Inspiratory (**A**) and expiratory (**B**) lateral neck radiographs of a child with upper airway obstruction secondary to a granuloma *(arrow)* in the upper trachea. Note ballooning of the pharynx during inspiration (**A**) and narrowing of the trachea *(arrowheads)* below the level of obstruction. On expiration (**B**), note the normal pharyngeal lumen and dilation *(arrowheads)* of the trachea distal to the obstruction. The "bunching up" of the pharyngeal tissues *(PT)* and the buckling of the trachea *(B)* are normal findings on expiratory films.

Febrile Child

In the febrile child with stridor, the onset is generally acute and the most common cause is croup. Other diagnostic possibilities that should be considered include bacterial tracheitis, epiglottitis, and retropharyngeal abscess. The child whose clinical picture is consistent with mild to moderate croup needs no further evaluation. Although, history and physical examination are the most important diagnostic tools, anteroposterior and lateral neck radiographs may add some useful information and should be considered for the ill-appearing child or one who does not respond as anticipated to treatment. If epiglottitis is strongly suspected, a lateral neck radiograph should be obtained in the ED or the child should be taken to the operating room to have direct visualization of the epiglottis under controlled conditions.

Airway radiographs must be interpreted with care because they are affected by positioning, crying, swallowing, and the phase of respiration. To properly interpret the prevertebral space, the lateral neck radiograph must be taken with the patient's head extended and during inspiration. Normal tracheal buckling, which is seen during expiration in a young child, may be misinterpreted as tracheal mass lesion or deviation from an extrinsic mass (Fig. 72.2). Abnormal findings on a lateral neck radiograph include swollen epiglottis or aryepiglottic folds (epiglottitis), irregular tracheal borders or stranding across the trachea (tracheitis), and increased prevertebral width (retropharyngeal abscess). In children, the preverterbral space should be less than 75% the width of the body of C4 (cervical vertebra). Radiographic findings consistent with croup are a narrowed subglottic area on anteroposterior view (the "steeple sign") and ballooning of the hypopharynx, best appreciated on the lateral view.

Afebrile Child

In the afebrile child with acute onset of stridor, the duration of stridor, the likelihood of foreign-body aspiration, and the child's age are all key elements to consider. Emergent otolaryngologic or surgical consultation should be obtained in a child with an evidence of airway obstruction if either aspirated foreign body or trauma is a likely cause of stridor. Angioneurotic edema, an autosomal-dominant trait, is characterized by rapid onset of swelling without discoloration, urticaria, or pain. Symptoms may occur in affected patients as young as 2 years of age but usually are not severe until adolescence; they may be precipitated by trauma, emotional stress, or menses. Determination of the C_1-esterase inhibitor level should be considered if angioneurotic edema is suspected.

A child with chronic stridor generally does not require an extensive evaluation in the ED unless significant respiratory distress is present. The infant with chronic stridor who is otherwise well should be referred back to the private pediatrician or to an otolaryngologist. Once a neoplastic cause is deemed unlikely, the older child with chronic stridor should be referred to otolaryngology for evaluation, including direct visualization of the vocal cords.

CHAPTER 73 ■ SYNCOPE

CARLOS A. DELGADO, MD, FAAP

From the Greek *synkoptein*, meaning "to cut short," syncope is defined as the temporary loss of consciousness and postural tone, resulting from an abrupt, transient, and diffuse reversible disturbance of cerebral function. Often, the terms *fainting* or *blackout* spells are used. Pathophysiologically, syncope can be explained as a sudden reduction in delivery of substrates such as O_2 or glucose to the brain. Most transient altered consciousness events in children include seizures, syncopes, or hysteric episodes ("fits, faints, or fakes"), and the approach to diagnosis of syncope is to exclude the other two.

Syncope during childhood is generally a benign, brief, isolated event, followed by a complete recovery without sequelae, although in few instances, it can represent potentially life-threatening causes. A thorough, detailed history and physical examination, with attention to clues provided by the premonitory signs and symptoms, are usually sufficient to provide the cause of syncope in most cases. All syncopal events associated with exercise or exertion must be considered dangerous. An overall incidence in the pediatric population of 0.1% to 0.5% has been reported. Syncope occurs predominantly in teenagers, with a peak incidence occurring between 15 and 19 years of age. Females were evaluated more commonly than males. It is estimated that at least 50% of all individuals will have a least one syncopal episode during their adolescence. Syncopal events account for 1% to 3% of all emergency department visits, and, in this setting, the patient has usually regained consciousness by the time of initial assessment by a physician.

DIFFERENTIAL DIAGNOSIS

Pathophysiologically, all causes of transient and abrupt onset of alterations of consciousness can be best categorized into three broad groups (Table 73.1): (i) true syncope reflecting any mechanism that causes a transient decrease in substrate delivery to the brain (e.g., O_2, glucose, blood); (ii) all seizures; and (iii) hysterical pseudoloss of consciousness. Most children and adolescents who faint have orthostatic syncope, vasovagal episodes, or breath-holding spells (Table 73.2). This is in marked contrast to adults, who often have cardiovascular disease. Studies report additional diagnoses in "fainting" children including migraines (11%), seizures (8%), and cardiac causes (6%).

The goal in evaluating syncopal episodes must be to accurately identify the occasional warning signs of serious pathology from the common benign events. The causes of true syncope may be classified into three etiologic categories: *autonomic* (vasovagal), *cardiovascular*, and *metabolic*. Table 73.3 provides a list of the major causes of syncope and conditions that mimic it.

Vasovagal Syncope

Vasovagal syncope is also called neurocardiogenic syncope, vasodepressor syncope, or fainting spell. It is by far the most common cause of fainting in children and adolescents and accounts for more than 50% of cases of childhood syncope.

The pathophysiologic mechanism of vasovagal syncope is similar to an exaggerated Bezold-Jarisch reflex. This reflex is responsible for maintaining blood pressure during orthostatic stress. In patients prone to syncope, the cascade of events begins with a decrease in systemic venous return and, therefore, decreased preload after prolonged upright posture. Enhanced or compensatory sympathetic activity causes an elevation of circulating catecholamines (particularly epinephrine), which increase left ventricular contractility in a relatively empty ventricle. In response, a negative feedback loop via vagal afferents results in sympathetic withdrawal (*hypotensive vasodepressor response*) and augmented vagal tone (*the bradycardic cardioinhibitory response*). The factors that trigger this abnormal response are still unclear. It is probable that a combination of abnormal catecholamine response to orthostatic or other stress, exaggerated ventricular contraction, diminished ventricular volume from venous pooling in the upright position, and enhanced sensitivity of ventricular mechanoreceptors are all involved in the clinical predisposition to recurrent vasovagal syncope.

Most episodes occur while the patient is standing or during a rapid change from a supine or sitting position to standing. Syncope represents a cascade of signs and symptoms that begin with a brief prodrome or presyncopal phase. This progresses to a brief and sudden stage of unconsciousness that typically lasts 1 to 2 minutes and ends with arousal to a previous level of consciousness within a short period.

A syncopal episode may be triggered by a wide array of emotional events such as pain, fear, and anxiety that increase circulatory catecholamines in response to a real or perceived threat. The prodromal symptoms may include light-headedness, dizziness, nausea, shortness of breath, diaphoresis, pallor, and visual changes. Physical conditions such as anemia, dehydration, exertion, hunger, pregnancy, and/or concurrent illness can predispose to a syncopal event. Other factors include confinement to enclosed or poorly ventilated spaces and environmental heat. The patient may remain nauseated, pale, and diaphoretic for several hours after the syncopal episode.

A full syncope can be avoided if the patient recognizes the prodromal symptoms and assumes a supine or Trendelenburg position. Prognostically, vasovagal syncope is considered a benign illness. A prophylactic approach is taken to prevent symptoms of presyncope or near-syncope. Patient education

2. Seizures
3. Hysterical pseudoloss of consciousness

must be geared toward rapid symptom recognition, allowing the patient to assume a recumbent position and abort a potential syncopal event. Other preventative measures may include avoiding dehydration and using salt-enriched diets during athletic activity or environmental stress.

Several other related forms of autonomic syncope are orthostatic hypotensive syncope and situational syncope related to micturition, defecation, coughing, and swallowing. Orthostatic hypotensive syncope is associated with an excessive and prolonged fall in blood pressure level on assuming the erect posture from a recumbent position. An unusual and uncommon condition, micturition syncope, follows rapid bladder decompression, in which reduced cardiac return is associated with both postural effects and splanchnic vascular stasis. Hair-pulling syncope has been described in girls. Underlying medical conditions such as anemia or pregnancy may exacerbate the tendency toward any of these vasovagal events.

Another common, usually benign, pediatric variant of vasovagal syncope is that of breath-holding spells, which occur in two forms (see Chapter 131). *Pallid* breath-holding spells result from vagally mediated cardiac inhibition. *Cyanotic* breath-holding spells involve interplay between hyperventilation, Valsalva maneuver, expiratory apnea, and intrinsic pulmonary mechanisms. In pallid breath-holding spells, an inconsequential injury induced by a sudden emotional stimulus such as pain, fright, or anger provokes one or two short cries, followed by pallor and sudden loss of consciousness. In cyanotic breath holding spells, the event occurs as a reflexive response a stressor and is characterized by an initial shrill cry; forced expiration and apnea ensues and progresses to cyanosis and brief loss of consciousness. These spells typically occur in children between 6 months and 5 years of age.

Cardiac Syncope

Syncope caused by significant cardiac or vascular pathology occurs far less often than autonomic syncope. It is suspected when fainting occurs in any of the following situations: a patient with known heart disease, sudden fainting, fainting during exercise, incontinence during fainting, injury during the event, family history of sudden cardiac death, and/or an abnormal heart rhythm on the electrocardiogram (EKG) at presentation. It does not follow the stimuli typical of vasovagal syncope. Hypercyanotic spells, usually associated with tetralogy of Fallot, can occur with any heart defect associated with intracardiac right-to-left shunting. An increase in obstruction to pulmonary blood flow or a fall in systemic vascular resistance can precipitate such a spell. The most common arrhythmia causing syncope with an apparently structurally

TABLE 73.3

CLASSIFICATION OF SYNCOPAL EPISODES

I. Syncope
  A. Autonomic
    1. Vasovagal syndrome
    2. Excessive vagal tone—athletes
    3. Volume depletion (orthostatic)—hemorrhage or anemia, dehydration, diuretic abuse
    4. Reflex
      a. Breath-holding spells
      b. Situational—cough, micturition
    5. Pregnancy
  B. Cardiovascular
    1. Structural heart disease
      a. Tetralogy of Fallot
      b. Hypertrophic cardiomyopathy
      c. Valvular aortic stenosis
      d. Primary pulmonary hypertension
      e. Eisenmenger's syndrome
      f. Atrial myxoma
      g. Dilated cardiomyopathy
      h. Pericarditis with tamponade
    2. Tachyarrhythmias
      a. Long QT syndromes
        (1) Congenital
        (2) Acquired, including drug/toxin induced (antiarrhythmics, arsenic, tricyclic antidepressants, phenothiazines, antihistaminics, cisapride)
      b. Supraventricular tachycardia—idiopathic, Wolff-Parkinson-White syndrome, many drugs and toxins (Chapter 74, Table 74.4)
      c. Ventricular tachycardia
    3. Bradyarrhythmias
      a. Atrioventricular block
      b. Sinus node disease
    4. Vascular
      a. Vertebrobasilar insufficiency
  C. Metabolic
    1. Transient hypoglycemia, hypoxia, hyperammonemia, carbon monoxide poisoning
II. Conditions that mimic syncope
  A. Psychological
    1. Hysteric faints
    2. Malingering
    3. Hyperventilation
    4. Panic disorder
    5. Munchausen syndrome by proxy
  B. Neurologic
    1. Seizures
    2. Migraines

normal heart is supraventricular tachycardia (SVT), especially in the context of Wolff-Parkinson-White (WPW) syndrome. Arrhythmias occur more often in structurally abnormal hearts. Many drugs and toxins may also induce arrhythmias (Chapter 74, Table 74.4).

Prolonged QT syndrome is estimated to be present in 1 of every 5,000 individuals, and approximately one-third of those newly diagnosed have been previously asymptomatic. It is estimated that long QT syndrome may be responsible for as many as 3,000 otherwise unexplained deaths in children and young adults each year in the United States. The diagnosis is made by documenting the prolongation of the corrected QT interval (QTc; by more than 0.45 seconds) by Bazett's formula. The prolongation of QTc results from an extended refractory period of the ventricular myocardium, which places it at risk for "torsade de pointes," a malignant form of ventricular tachycardia (VT; see Chapter 84). This form of VT will impede adequate blood flow to the brain, causing sudden loss of consciousness. Prolonged QT syndrome can be congenital or acquired. Syncope occurs secondary to paroxysmal episodes of rapid VT. Of the congenital forms, the rare Jervell and Lange-Nielsen syndrome is associated with autosomal-recessive deafness. The Romano-Ward syndrome is now being recognized with increasing frequency and is associated with an autosomal-dominant trait in families with normal hearing. More recent work has identified the genetic basis of the congenital forms of long QT syndrome and relates them to at least a dozen distinct heritable arrhythmia syndromes, several disease-susceptibility autosomal-dominant genes, and hundreds of implicated mutations coding for abnormal myocardial K^+ and Na^+ ion channels and, in some cases, inner ear endolymph proteins. The altered ion channel function produces a prolongation of the action potential and cardiac repolarization and propensity to torsade de pointes VT. Long QT syndromes often present as syncope on exercise or exertion and can also masquerade as a seizure. In acquired forms, QTc will be prolonged as a result of electrolyte abnormalities (hypokalemia, hypocalcemia), increased intracranial pressure, or medication use or overdose. Drug exposure may be intentional or accidental. A thorough history should include the types of medications available in the home, possible environmental exposures such as carbon monoxide poisoning, and illicit drug use. Numerous medications including some antibiotics, antiarrhythmics, antihistamines, and psychotropics may prolong QTc. In addition, other drugs such as erythromycin, trimethoprim-sulfamethoxazole, and ketoconazole may prolong QTc themselves or, if taken concomitantly with some of the former classes of medications, may inhibit hepatic metabolism of the latter and thus exacerbate QTc prolongation (Chapter 82, Table 82.17).

Episodic, complete heart block accompanied by syncope may occur in children and adolescents with baseline abnormalities of cardiac conduction. Children who have undergone surgical repair of ventricular defects, such as in tetralogy of Fallot, are also at risk.

Hypertrophic cardiomyopathy (IHSS), is associated with recurrent syncope and is a disease that presents with a thickened left ventricular myocardium, resulting in subaortic stenosis that causes obstruction to ventricular outflow. Patients with severe aortic valvular stenosis present with the classic triad of syncopal episodes, anginal chest pain, and dyspnea on exertion.

Noncardiac Syncope and Disorders that Mimic Syncope

Metabolic causes of syncope include hypoglycemia, which is often associated with pallor, dizziness, and diaphoresis and is unrelated to position. Seizures may occur and unconsciousness may be prolonged, and patients will often require the administration of glucose for recovery. Hypoglycemia may be a component of other childhood disorders that include diabetes mellitus, ketotic hypoglycemia, hepatic enzyme deficiencies, and drug or toxin ingestion, especially ethanol and oral hypoglycemics. Other metabolic causes of syncope include hypoxia alone or in association with mild to moderate carbon monoxide poisoning, which is notorious for producing syncope. Recovery occurs when the child is removed from the offending environment. Hyperammonemia may rarely cause syncope by direct cytotoxic central nervous system effect.

Hyperventilation, associated with high anxiety and emotional events during which the patient will complain of shortness of breath, tachypnea, chest pain, paresthesias, and lightheadedness, may result in syncope. This results from cerebral vasoconstriction in response to self-induced hypocapnia.

Loss of consciousness often occurs with generalized seizures, which may be difficult to distinguish from vasovagal syncope if the event was not witnessed. Seizures are likely to be preceded by an aura, followed by a prolonged postictal state. Both neonatal and complex partial seizures may be subtle and particularly difficult to differentiate from syncope (Table 73.4; see Chapter 69).

Basilar artery migraine may cause syncope. It is usually preceded by an aura, followed by severe occipital headache. It should be considered in patients with syncope and paroxysmal headaches, especially with family history of migraine. Narcolepsy should be considered in the differential diagnosis in adolescents. These episodes characterized by irresistible sleep attacks may last seconds to minutes. In the severe form of cataplexy, the patient experiences sudden loss of muscle tone brought about by intense emotion or physical activity.

Syncope-like events caused by hysteria are common in the adolescent patient. Characteristic features of the clinical event are helpful in differentiating hysteria from organic causes of true syncope. Hysterical "syncope" may be associated with hyperventilation, usually occurs in the presence of an audience, and lacks true loss of consciousness. No overt or objective prodromal symptoms such as hypotension or bradycardia are recognized. It may occur when the patient is in the supine position, which is virtually unreported with vasovagal syncope. There may be a peculiar fluttering of the eyes behind half-closed eyelids. The patient usually describes the event in a calm and indifferent manner and vividly recalls the event, suggesting a lack of complete loss of consciousness. The association of the onset of hysterical syncope and sexual molestation or sexual abuse has also been observed. The presence of a psychiatric disorder is associated with an increased incidence of recurrent events. These patients tend to be anxious and more prone to panic disorders and avoidance-oriented coping strategies.

TABLE 73.4

DIFFERENTIATING SYNCOPE FROM OTHER "SPELLS"

	Syncope, vasovagal	Metabolic (e.g., hypoxia, hypoglycemia)	Seizure	Breath-holding
Period of unconsciousness	Usually seconds	Variable	Minutes or longer	Seconds
Prodrome	Fright, pain, "feels faint"	Confusion, altered mental status, ↑ heart rate, diaphoresis	Occasional aura	Pain, fright → vigorous → cry apnea → LOC
Incontinence	Absent	Absent	May be present	Absent
Confusion on awakening	Absent or mild	Mild	Marked	Absent
Tonic-clonic movements	Occasionally present, if LOC is prolonged	May occur	Commonly present	Rare, may see 1–2 beats
Electroencephalogram	Normal	Normal	Often abnormal	Normal

LOC, loss of consciousness.

Drug or toxin exposure may be accidental or intentional and, in addition to precipitating arrhythmias as previously noted, may occasionally cause an acute, transient loss of consciousness or gradual altered mental status changes leading to syncope rather than the typical prolonged alterations in consciousness. Such an effect may be more characteristic of carbon monoxide poisoning or volatile inhalant abuse (e.g., see Chapter 88). Antihypertensives, β-blockers, diuretics, antiarrhythmics, and drugs that decrease cardiac output such as barbiturates, tricyclic antidepressants, and phenothiazines may cause syncope. Substances of abuse such as alcohol, sedative-hypnotics, and opiates can cause alterations in consciousness that mimic syncope but are usually more prolonged. Anaphylactic reactions characterized by hypotension, pallor, asthenia, nausea, vomiting, and profuse sweating may also mimic syncope.

EVALUATION AND DECISION

In the era of rising health care costs and cost containment, one must be mindful of the utility and expense of diagnostic studies used to evaluate syncope. Extensive and expensive testing is usually unnecessary. A thorough history and physical examination will often suggest the diagnosis. One should pay attention to the airway, respiratory effort, and hemodynamic stability. Vital signs including orthostatic blood pressure and pulse oximetry measurements must be documented and reviewed. In most cases, a complementary EKG screen is useful to rule out symptomatic arrhythmias or long QT syndrome. This approach, emphasizing evaluation of the clinical features of the syncopal episode, supplemented by EKG, is outlined in Fig. 73.1.

The primary goal in evaluating a syncopal child or adolescent is to identify conditions that are associated with a risk of serious injury or are life threatening. Table 73.5 highlights clinical features of syncope that suggest such conditions and thus indicate hospitalization.

A thorough history is the most important part of the evaluation. Parents and relatives often contribute important information to the cause of the syncopal event. A prodromal sign or symptom precedes a typical vasovagal spell. Most occur while standing. Stressful situations, emotional upset, and mild physical trauma can trigger such an event.

Syncope occurring during intense physical activity may identify those patients who have potentially fatal conditions. These patients' symptoms may also suggest vagal tone and/or volume depletion caused by dehydration and heat stress. A detailed evaluation should be considered for patients who have syncope during exercise or have a family history of sudden death, myocardial disease, or arrhythmias. A history of palpitations before syncope should alert the physician to the possibility of tachyarrhythmias. Palpitations are also reported in hyperventilation episodes. History is sought regarding medication use, recent food intake, and intercurrent illnesses for consideration of additional causes of nonvasovagal syncope. A medical history or family history of cardiac or neurodevelopmental disorders is important to elicit possible cardiac or neurologic causes of syncope. If there are no suggestive historical features of either vasovagal or the more worrisome causes of syncope, it may be prudent to cautiously consider some psychological assessment questions, particularly in well-appearing adolescents.

TABLE 73.5

CLINICAL FEATURES OF SYNCOPE REQUIRING HOSPITALIZATION

- Presence of cardiovascular disease or abnormal cardiovascular examination—congestive heart failure, arrhythmias
- Abnormal electrocardiogram—prolonged QT interval, tachyarrhythmias, atrioventricular or severe bundle branch blocks
- Chest pain with syncope
- Cyanotic spells
- Apnea or bradycardic spells requiring vigorous stimulation
- Abnormal neurologic findings—focal signs, status epilepticus, signs of meningeal irritation
- Acute toxic ingestions
- Orthostatic hypotension resistant to fluid therapy

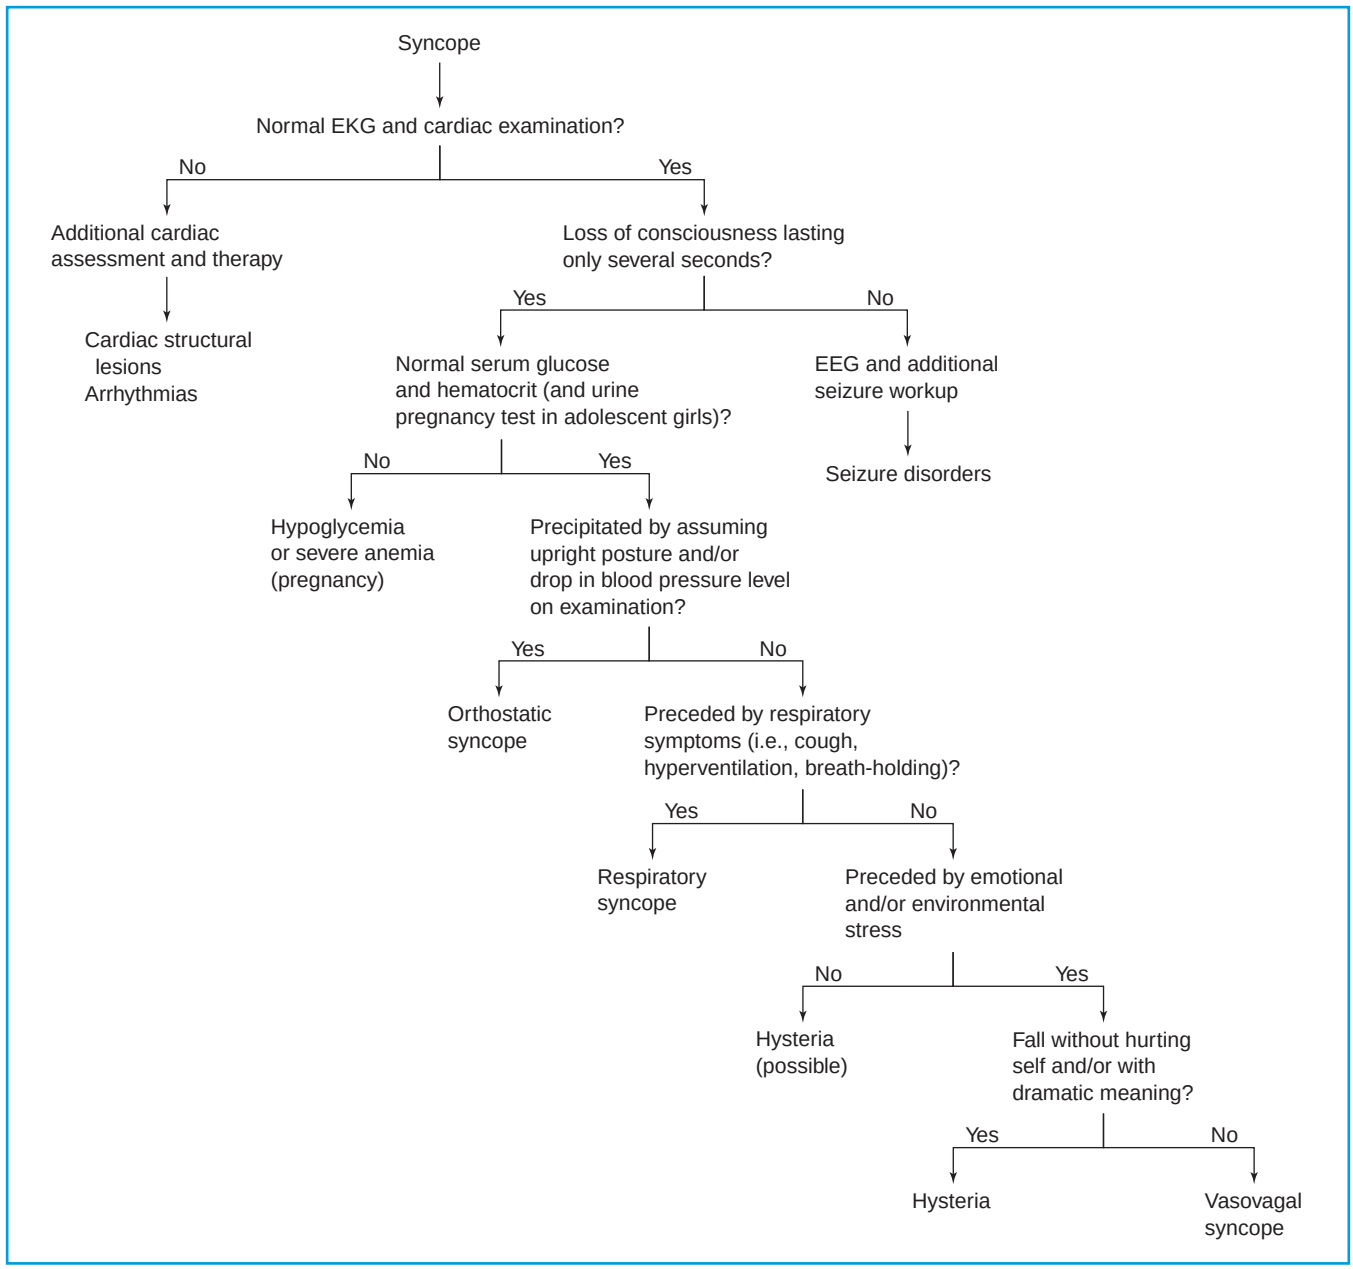

FIGURE 73.1 The diagnostic approach to syncope. EKG, electrocardiogram; EEG, electroencephalogram.

On physical examination, heart rate and blood pressure should be measured first while the patient is supine and then standing. In orthostatic hypotension caused by autonomic dysfunction, dehydration, or blood loss, the patient will have an abnormal decrease in systolic blood pressure (more than 20 mmHg) or an abnormal increase in heart rate with this change in posture. The presence of orthostatic vital signs is confirmatory, but even if normal, the vital signs should not trump the history and clinical findings. Palpation of an abnormal apical impulse or peripheral pulses may suggest a structural heart disease. On auscultation, a loud systolic ejection murmur in the midsternum and upper sternum is present in severe aortic stenosis or IHSS. In addition, the diastolic murmur of a rare left atrial myxoma may be heard. A fourth heart sound may be present in hypertrophic cardiomyopathy. The general physical examination should include a careful neurologic examination, auscultation for cervical and carotid bruits, an assessment of hydration status, and consideration of the presence of any toxidrome.

Routine Laboratory Testing

The emergency physician must assess the cardiac status of all children who present with a history of a syncopal episode. While in the emergency department, the patient should be placed on a continuous cardiac monitor for the evaluation of heart rate, rhythm, and conduction intervals, unless an obvious noncardiac cause is revealed by the clinical examination. An

EKG should be included with all initial evaluations for syncope. The rhythm strip would assess the presence of any arrhythmias (SVT, atrioventricular block, sick sinus syndrome, or prolonged QT interval). Particular attention should be paid to the QT interval and T-wave morphology for the evidence of long QT syndrome (see Chapter 82). The QTc must be calculated. Voltage criteria to determine ventricular hypertrophy in evaluating obstructive outflow lesions and evidence of preexcitation in WPW syndrome should be sought. The EKG is also helpful in recognizing cardiac ectopy and conduction disturbances, as well as hypertrophic cardiomyopathies and myocarditis.

Serum laboratory tests, if indicated, may include a complete blood cell count, serum glucose, and carboxyhemoglobin determinations. Toxicology screens should be performed in patients suspected of ingestion or illicit drug use. In teenage girls, pregnancy should be ruled out.

Specialized Testing

Several nonemergent studies or devices may contribute to the diagnostic evaluation in selected patients. An *echocardiogram* may be a helpful diagnostic test for recognition of hypertrophic cardiomyopathy or obstructive disease. *Holter monitoring* is expensive and rarely diagnostic in children and, thus, is often not included in an initial workup. *Event recorders*, however, are similar in size and appearance and have replaced Holter monitors in many medical centers for the evaluation of children with syncope. A digitally recorded rhythm strip can be transmitted via a telephone line to a receiving and recording device. *Implantable loop recorders* have been used in high-risk patients when conventional diagnostic testing has been inconclusive. Finally, *electroencephalogram* (*EEG*) is indicated if a seizure disorder is suspected and may help distinguish epilepsy from simple or convulsive syncope. Immediately after a vasovagal syncopal episode, the EEG findings may reflect cerebral hypoperfusion.

The utility of the *head-upright tilt table test* (HUTT) in pediatric patients is controversial for the diagnosis of vasovagal syncope. It has not been shown to be a sensitive or specific test in children and adolescents. It is expensive, invasive, and the results are not likely to change management. If performed early in the evaluation, it may provide a definite diagnosis and will therefore reduce the need for further testing by demonstrating the physiologic response leading to syncope. It has emerged as a laboratory method for provoking episodes of neurally mediated (vasodepressor) syncope in susceptible individuals. Children, usually pubertal girls with a positive response to HUTT, often have had syncope in special circumstances (e.g., prolonged standing, anxiety, and fright) and experienced a prodrome such as pallor, lightheadedness, and nausea. Children with recurrent unexplained syncope may be referred to appropriate specialists (e.g., a neurologist or an otorhinolaryngologist) for such testing.

THERAPY

Any therapeutic approach to the child with syncope should be individualized on the basis of several issues including the likely pathologic process, frequency and nature of symptoms, likelihood of recurrence, and risk of adverse outcomes.

TABLE 73.6

INDICATIONS FOR SUBSPECIALIST REFERRAL OR CONSULTATION

Atypical episodes
Recurrent episodes or episodes not resolved with conventional therapy
Exertional syncope
Syncope associated with chest pain, arrhythmias, or palpitations
Syncope associated with abnormal cardiac history, examination, or electrocardiogram
Family history of sudden death
Seizures
A focal neurologic examination or neurologic abnormality

If the diagnosis of vasovagal syncope is made, reassurance and education with regard to the benign prognosis of the process are required. Parental and patient education involves learning to identify and avoid precipitating situations. The patient is instructed to recognize prodromal symptoms and then to assume a seated or supine position and elevate his or her feet to avoid loss of consciousness. Other simple prophylactic measures include drinking plenty of fluids and avoiding dehydration, taking salt-enriched diets during periods of intense physical activity, and, rarely, using mineralocorticoids (*fludrocortisone*) to induce salt and water retention. These measures, if the diagnosis of syncope is correct, will work 95% of the time. If the patient does not respond to salt, water, and fludrocortisones, he or she should be referred to a cardiologist.

The patient can be discharged with home observation instructions that have been explained to the parents or guardians. Follow-up visits with their primary care physician should be arranged and encouraged.

If these measures are unsuccessful, medical management for severe vasovagal events can be directed at breaking the cycle of events that lead to syncope. Pharmacologic therapy with β-adrenergic blockers (atenolol or propanolol), which decrease the mechanical stimulation of the cardiac mechanoreceptors, may be indicated. *Disopyramide* may be an option, acting as an anticholinergic, negative inotropic, and vasoconstrictive agent.

Transdermal scopolamine has been reported to be effective presumably by reducing the vagal tone associated with these episodes. More recently, *sertraline* has been shown to be successful in decreasing the frequency of syncope. Midodrine, a peripheral α-stimulating agent, is also effective in adult patients with recurrent neurocardiogenic syncope refractory to other forms of therapy. Pacemaker implantation or implantable cardioverter-defibrillators for vasovagal syncope are reserved for the rare refractory case that has failed aggressive pharmacologic measures.

Table 73.6 offers guidelines regarding which patients require referral to pediatric subspecialists, such as a cardiologist or neurologist.

CHAPTER 74 ■ TACHYCARDIA

JAMES F. WILEY II, MD, MPH

Fast heart rate or tachycardia is a common sign in children receiving emergency care. It may be noticed on initial evaluation by the emergency provider or may be raised as a concern by the caregiver who notes a rapid heart rate while holding the child or observes rapid jugular venous pulsations, increased apical heart rate, or pulse rate. The definition of tachycardia varies by age [callout to the table of normal vital signs in Appendix C, "Resting Heart Rate"]. In infants and young children, the higher resting heart rate, relative to older children adolescents and adults, reflects higher tissue oxygen utilization and metabolic rate. In most instances, the underlying cause for tachycardia in children is benign. However, children with a life-threatening etiology for their tachycardia require prompt recognition and treatment.

PATHOPHYSIOLOGY

Cardiac muscle has intrinsic automaticity that allows it to beat without any external stimulus. Under normal circumstances, the heartbeat is initiated by an electrical impulse in the sinoatrial (SA) node and travels through the atria to the atrioventricular (AV) node. From there, the electrical impulse is propagated in a coordinated fashion via the His-Purkinje conduction system to the ventricles.

Resting heart rate typically reflects a balance of input from the vagus nerve (cranial nerve X) and the thoracic sympathetic ganglion (levels T1 to T4). Vagal stimulation results in slowing of the heart rate mediated by cholinergic receptors and has a greater impact on resting heart rate than on the sympathetic nervous system. Thus, medications with anticholinergic receptor effects (e.g., antihistamines, atropine) may cause tachycardia. Sympathetic stimulation results in increased heart rate and force of contraction primarily through the β_1-adrenergic receptors. These receptors may also be stimulated by circulating endogenous substances (e.g., epinephrine, increased carbon dioxide tension, hypoxemia) and by exogenous agents (e.g., sympathomimetic drugs).

Life-threatening cardiac tachyarrhythmias [e.g., supraventricular tachycardia (SVT), ventricular tachycardia] arise from various mechanisms that disrupt normal electrical conduction in the heart. The pathophysiology of these arrhythmias is discussed separately (see Chapter 84).

DIFFERENTIAL DIAGNOSIS

Many conditions may produce tachycardia (Table 74.1). Most tachycardic children exhibit sinus tachycardia without significant cardiac pathology (Table 74.2). However, life-threatening conditions frequently come to medical attention because of fast heart rate and may reflect cardiac and noncardiac origins (Table 74.3).

Sinus Tachycardia

Fever, pain, and emotional arousal (e.g., crying, anxiety) are the most frequent causes of sinus tachycardia in children. Sympathetic stimulation from other conditions such as hypoxemia, hypoglycemia, hypercarbia, anemia, and excess circulating catecholamines (e.g., hyperthyroidism, pheochromocytoma) also increase SA node firing rate (see Table 74.2). In addition, exogenous sympathomimetic or anticholinergic substances may cause sinus tachycardia. Over-the-counter medications that contain antihistamines or pseudoephedrine, "energy" drinks and diet pills that have high concentrations of caffeine, and commonly abused drugs (cocaine, amphetamines) are frequently implicated (see Table 59.4).

Shock is a life-threatening cause of sinus tachycardia that requires rapid recognition and reversal to prevent permanent organ damage or death (see Chapter 3). Circulatory shock may result from intravascular volume loss, inadequate cardiac contractility, a marked drop in systemic vascular resistance, or a combination of these mechanisms. Physical findings help differentiate the different forms of shock (hypovolemic, cardiogenic, septic, and distributive) and identify the underlying cause (Fig. 74.1).

Life-threatening Tachyarrhythmias

SVT represents the most common tachyarrhythmia of childhood (see Chapter 84). The typical heart rate in infants with SVT exceeds 220 beats per minute, whereas older children usually have a heart rate in excess of 180 beats per minute. Infants and children with SVT demonstrate a spectrum of physical signs including no symptoms, palpitations, chest pain, tachypnea (often with feeding in infants), diaphoresis, and severe cardiogenic shock.

The most common form of SVT involves an accessory AV pathway. Additional etiologies include drug exposure, congenital heart disease, and Wolff-Parkinson-White syndrome. Sympathomimetics in cough and cold preparations are the most common drugs to incite SVT in children. As of 2008, the US Food and Drug Administration recommends that over-the-counter cough and cold preparations should not be used in children younger than 2 years. Unregulated dietary supplements such as ephedra (and its congeners, often advertised as "ephedra-free" products) and high-caffeine energy drinks also

have the potential to precipitate SVT. Cardiac lesions associated with SVT include Ebstein's anomaly, repaired dextrotransposition of the great arteries, and single-ventricle lesions status post-Fontan operation.

Ventricular tachycardia (monomorphic or polymorphic/torsades de pointes) and atrial flutter rarely occur in children (see Chapter 84). Congenital heart disease, electrolyte disturbance (especially hyperkalemia, hypocalcemia, and hypomagnesemia), genetic predisposition (long QT syndromes), or poisoning accounts for most cases of ventricular tachycardia in children. Atrial flutter usually arises from an intraatrial reentry circuit. Most children with atrial flutter have congenital heart disease. Although rare, atrial flutter carries a significant risk of sudden death if not controlled by medications or surgical intervention.

Other Cardiac Causes

Cardiac inflammation associated with viral myocarditis, acute rheumatic fever, or Kawasaki syndrome frequently presents with sinus tachycardia (see Chapter 84). Patients with these conditions, especially myocarditis, are also at risk for life-threatening arrhythmias, myocardial ischemia, congestive heart failure, and/or cardiogenic shock. For patients with pericardial effusion, sinus tachycardia is a physiologic response to impaired cardiac outflow in order to maintain cardiac output (see Chapter 84). Pericardial effusion with tamponade may complicate pericarditis, blunt chest trauma, or recent cardiac surgery and results in decreased cardiac output with significant impairment of systemic circulation. In this setting, pericardiocentesis or surgical pericardiotomy is life saving [see Chapter 135, Fig. 9.1, Illustrated techniques of pediatric emergency procedures].

EVALUATION AND DECISION

The child with tachycardia requires rapid assessment for the presence of hypoxia, hypoglycemia, an existing life-threatening arrhythmia, or shock (see Fig. 74.2). Respiratory distress with cyanosis or low pulse oximetry (less than 90%) demands immediate provision of supplemental oxygen and further management of airway and breathing (see Chapter 5). Hypoglycemia typically presents with altered mental status, diaphoresis, and/or hypertension and can be confirmed by measuring rapid blood glucose level. If an arrhythmia is suggested by an extremely rapid heart rate or a concerning tracing on the bedside cardiac monitor, a 12-lead electrocardiogram (EKG) and rhythm strip is necessary to confirm this impression and to guide further treatment (see Chapter 84). Children with congenital heart disease or a family history of sudden death are at increased risk for a life-threatening tachyarrhythmia. Consultation with a pediatric cardiologist and emergent echocardiography are warranted. In patients with shock, additional history and physical findings help guide the clinician

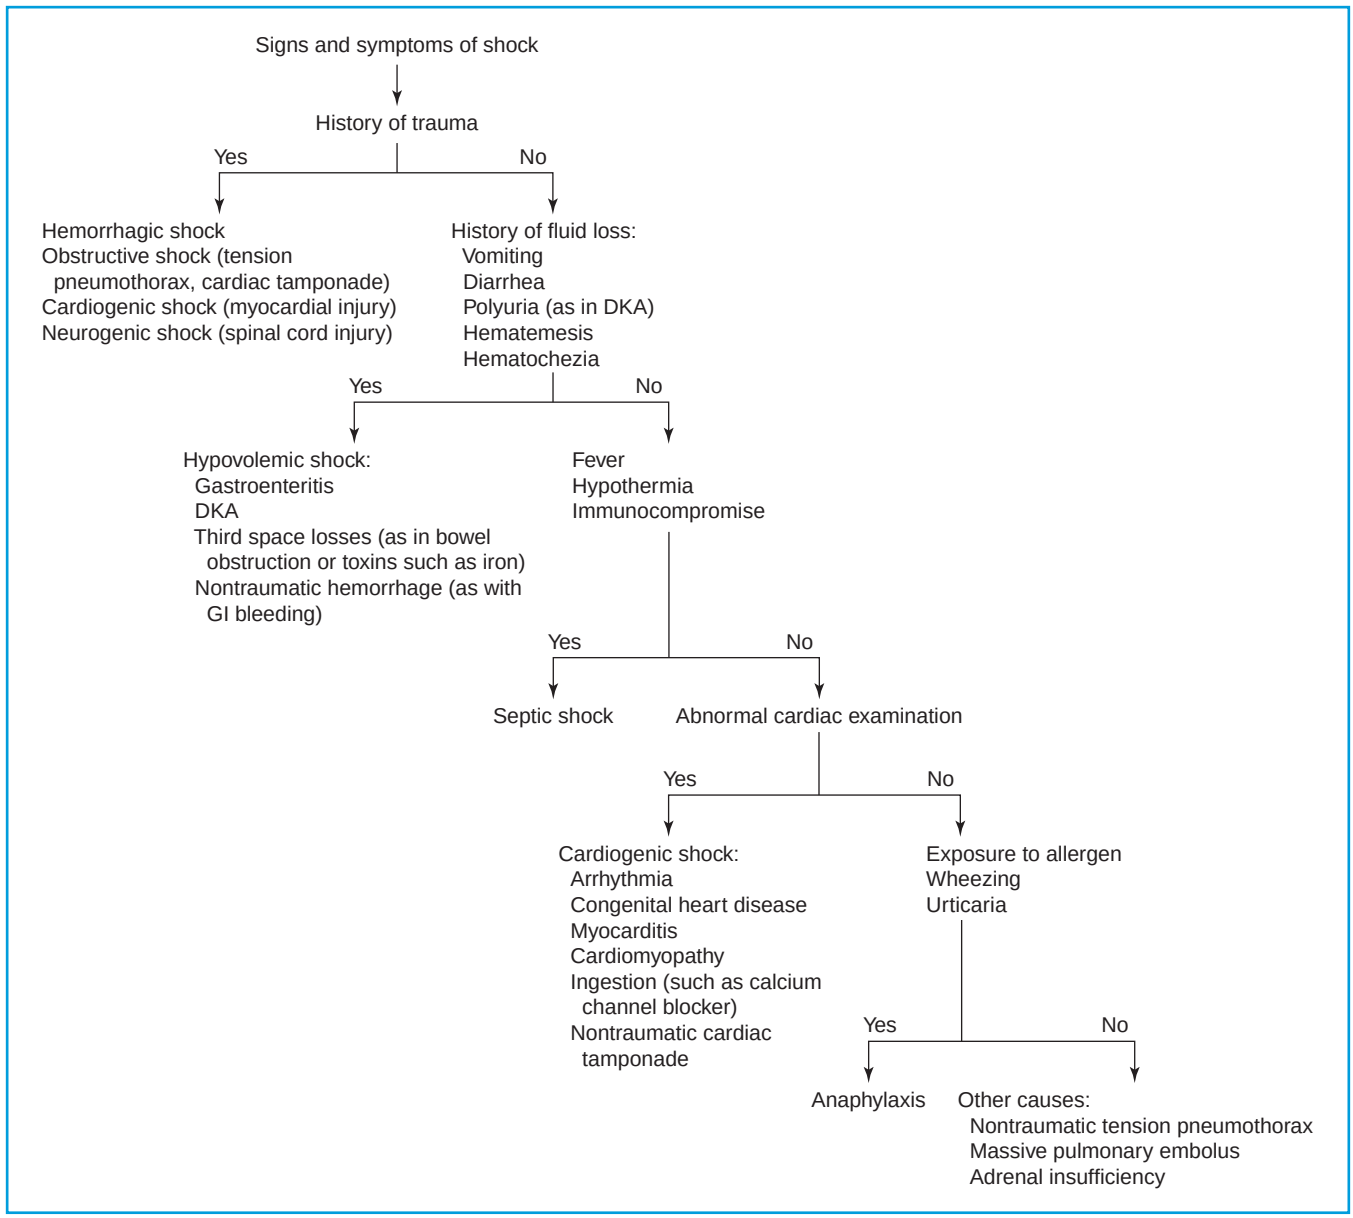

FIGURE 74.1 Approach to the classification of undifferentiated shock in children. DKA, diabetic ketoacidosis; GI, gastrointestinal. (Reproduced with permission from Waltzman, M. Initial evaluation of shock in children. In: UpToDate, Basow, DS (Ed), UpToDate, Waltham, MA, 2009.)

(see Fig. 74.1). Although the etiology may not be initially apparent, rapid treatment is imperative (see Fig. 3.3).

Children with fever and sinus tachycardia typically have a self-limited febrile illness. However, fever is also present in patients with cardiac pathology, including myocarditis, pericardial effusion, Kawasaki syndrome, and acute rheumatic fever, as well as in rare patients with thyroid storm. Myocarditis describes inflammation of the muscle wall of the heart. Multiple organisms can cause this pathology, with the most common identified agent being coxsackievirus. Clinical features of this disease are fever, tachycardia out of proportion to the activity or degree of fever, pallor, cyanosis, respiratory distress secondary to pulmonary edema, muffled heart sounds with gallop, and hepatomegaly caused by passive congestion of the liver (see Chapter 59). A child with tachycardia and clinical findings suggestive of myocarditis requires emergent supportive care (see Chapter 3), echocardiography, and admission to a unit capable of intensive monitoring and rapid treatment of cardiac arrhythmias and hemodynamic instability.

Pericardial effusion may occur after blunt chest trauma, viral infection, or as a component of inflammatory diseases such as systemic lupus erythematosus. Small effusions may be detected as a friction rub. Large effusions often cause cardiogenic shock and may lead to muffling of heart sounds and EKG changes, such as low-voltage or T-wave flattening with "strain" pattern in leads V1 through V6, but are nonspecific. Pericardial effusions are best identified using ultrasound. Patients with evidence of significant circulatory impairment should undergo a pericardial drainage procedure (e.g., placement of a pericardial catheter percutaneously under ultrasound guidance, pericardial window procedure).

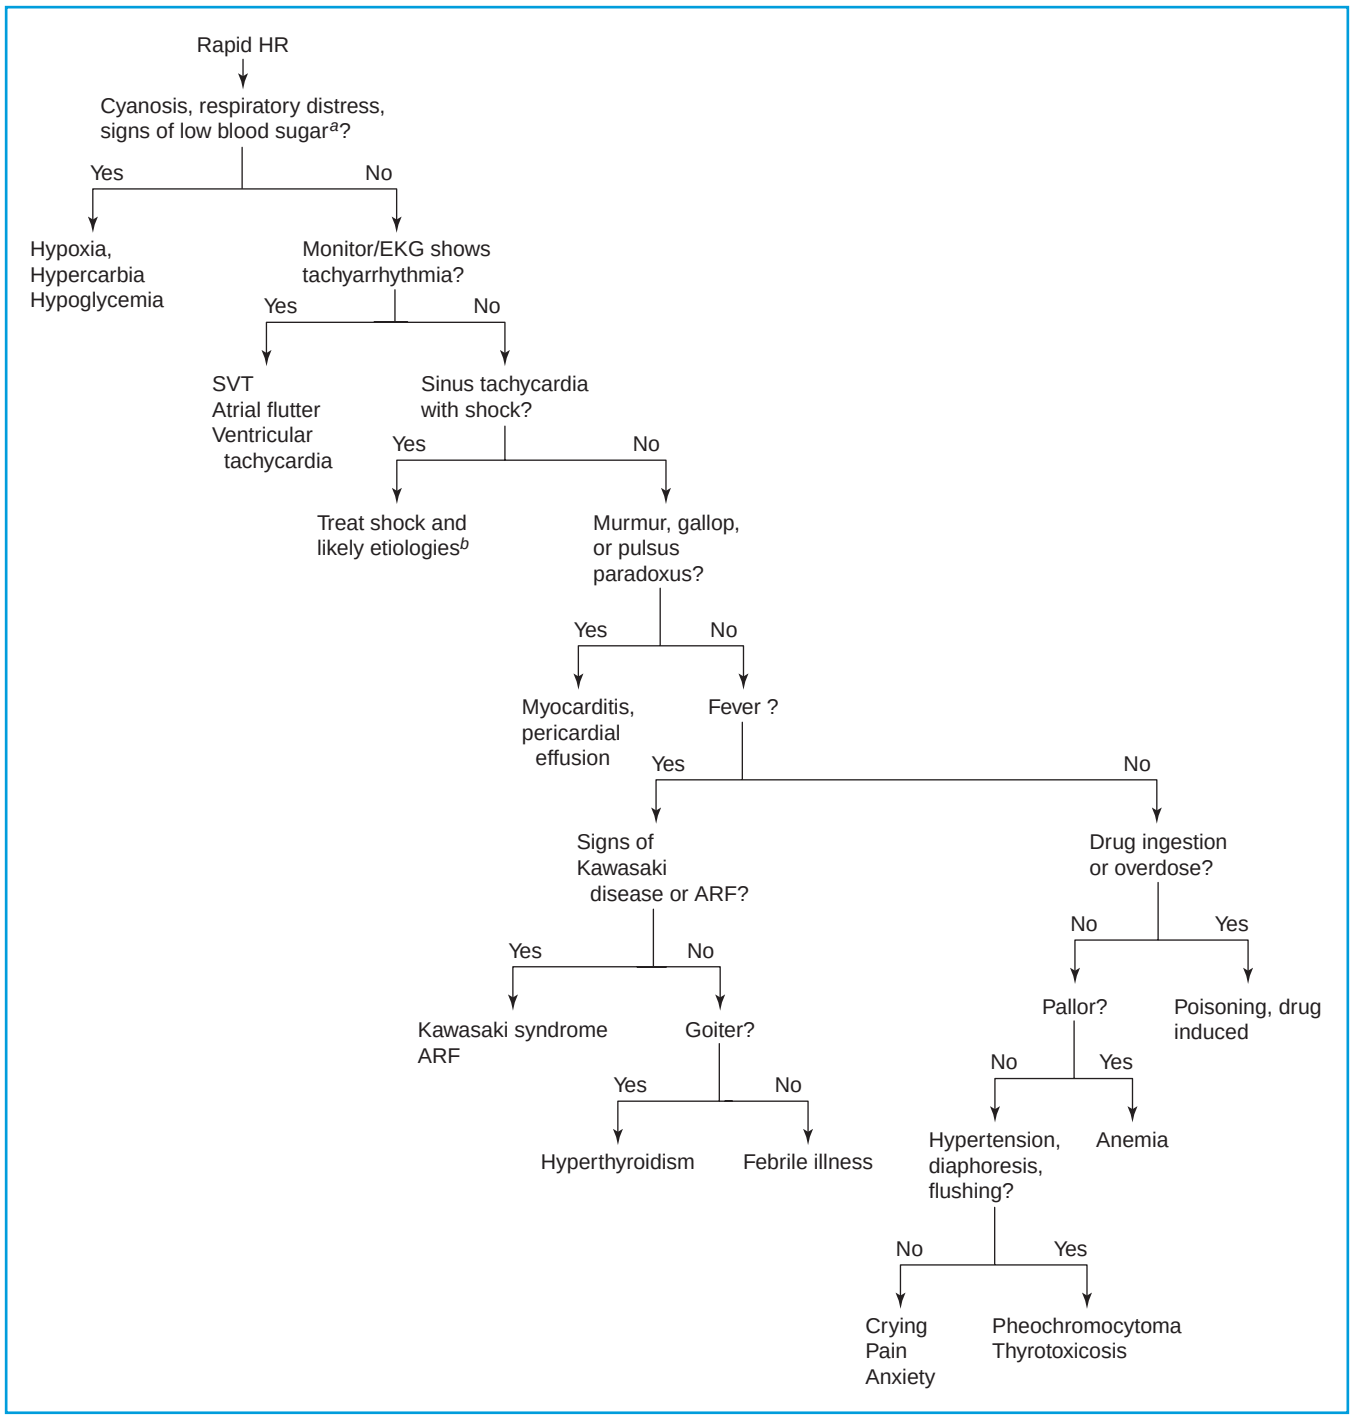

FIGURE 74.2 A diagnostic approach to tachycardia. HR, heart rate; SVT, supraventricular tachycardia; EKG, electrocardiogram; ARF, acute rheumatic fever. [a]Altered mental status, diaphoresis, hypertension. [b]See Fig. 74.1.

Acute rheumatic fever follows pharyngeal streptococcal infection and is an inflammatory disease that targets the heart, vessels, joints, skin, and central nervous system (CNS). Diagnosis and management of acute rheumatic fever are discussed separately (see Chapter 84). Clinical criteria for Kawasaki disease consist of prolonged high fever, conjunctivitis with perilimbic sparing, strawberry tongue, painful swelling of the hands and feet, rash, and lymphadenopathy. Early recognition and treatment of Kawasaki disease with intravenous γ-globulin is necessary to prevent the development of coronary artery aneurysms with potential for myocardial ischemia (see Chapter 101).

Patients with thyroid storm may have marked sinus tachycardia, fever, goiter, and CNS stimulation (agitation, delirium, psychosis, seizures) accompanied by congestive heart failure (see Chapter 86). Trauma, thyroid infection, thyroid surgery, and acute iodine load are frequent precipitants. Rapid recognition and institution of therapy to treat adrenergic symptoms

(β-adrenergic blockers), block hormone synthesis (methimazole), prevent peripheral conversion of T4 to T3 (iodinated radiocontrast agents), and prevent thyroid hormone release (iodine) are necessary to prevent mortality.

Crying, pain, or anxiety is the most frequent cause of sinus tachycardia in afebrile children. Drug ingestion, poisoning, and anemia are important additional considerations (see Table 59.4). Rarely, sinus tachycardia may herald the presence of hyperthyroidism or pheochromocytoma, a catecholamine-secreting tumor that causes extreme hypertension, diaphoresis, and flushing (see Chapter 86).

CHAPTER 75 ■ URINARY FREQUENCY IN CHILDHOOD

ROBERT G. BOLTE, MD

Urinary frequency is a symptom of several commonly encountered, clinical pediatric problems such as urinary tract infection (UTI), urethritis, vulvovaginitis, diabetes mellitus (DM), drug side effect (with caffeine, theophylline, and diuretics), or psychogenic stress. Moreover, urinary frequency may suggest underlying disease processes with life-threatening potential such as diabetic ketoacidosis, diabetes insipidus (DI), or congenital adrenal hyperplasia that require emergent diagnosis and management. Therefore, an organized approach in the emergency department (ED) evaluation of this symptom is important for any clinician providing acute care to children.

Urinary frequency (pollakiuria) is defined as an increase in the number of voids per day. It is a symptom distinct from polyuria (excretion of excessive amounts of urine). Although the two symptoms can be related, most children who present to the ED with frequency have a normal daily urine output, although the individual voids are frequent and small. Frequency is also distinct from *enuresis*, which is defined as inappropriate urination at an age when bladder control should be achieved.

PATHOPHYSIOLOGY

More than 90% of newborns void during the first day of life. Infants void between 6 and 30 times each day. Over the next 2 years, the number of voidings per day decreases by about half, whereas the volume of urine produced increases fourfold. Children between 3 and 5 years of ages average 8 to 14 voids per day. By 5 years of age, the number of voids decreases to 6 to 12 times per day. Adolescents average 4 to 6 voids per day. In the school-aged population, urinary frequency is usually defined as voiding more often than every 2 hours.

Normal bladder mucosa is both pressure sensitive and pain sensitive. An uncomfortable sensation is produced when urine volume approaches the age-dependent capacity of the bladder. Voiding is initiated by relaxation of the striated muscles of the urinary sphincter. There is an associated contraction of the smooth muscle of the bladder, resulting in bladder emptying. This mechanism is mediated by sacral nerves II to IV. Uncontrolled, "uninhibited" bladder contractions are the normal mechanism for infant and toddler voiding. Uninhibited (parasympathetic-mediated) bladder contractions do not normally occur after toilet training. By 5 years of age, 90% of children have achieved direct voluntary mastery of the voiding reflex and exhibit the adult pattern of urinary control.

Urinary frequency may be caused by reduced bladder capacity, polyuria, or psychological stress. The urinary volume per voiding will be low if frequency is related to reduced bladder capacity or psychological stress. Moreover, there will not be associated polydipsia. If frequency is secondary to polyuria, the urine volume per voiding will be normal or high, and there usually is associated polydipsia (see Chapter 60).

A reduced bladder capacity may also be secondary to inflammation of the bladder, changes in the bladder wall induced by distal obstruction, or extrinsic masses pressing on the bladder. When the bladder is inflamed, its pain/pressure sensitivity threshold is markedly decreased, so less stimuli are necessary to initiate the urge to void.

Distal infravesical obstruction leads to bladder muscle hypertrophy because of the increased effort needed to empty the bladder. This hypertrophied muscle has a higher resting tone, so smaller than normal urine volumes are necessary to initiate the desire to void. A decrease in the size and force of the urinary stream and/or straining to urinate may be noted. Eventually, the bladder muscle fatigues and cannot empty the bladder effectively. This decompensated bladder has an increased residual urine volume with a resultant decrease in the functional bladder capacity. This large, hypotonic bladder contracts poorly, resulting in small, frequent voids.

Extrinsic extravesical masses that impinge on the bladder may cause frequency by mechanically interfering with normal bladder expansion. Extrinsic masses may also stimulate frequent voiding by causing an irritable focus in the bladder wall.

Normal pediatric values for urine output are useful in determining the presence of polyuria. The traditional definition of polyuria is a urinary output of more than 900 mL per m^2 per day. An infant/toddler up to 2 years of age rarely exceeds 500 mL per day. Children 3 to 5 years of age void up to 700 mL per day. Children 5 to 8 years of age have an approximate maximum volume of 1,000 mL per day. Children 8 to 14 years of age void up to 1,400 mL per day. When polyuria is the cause of urinary frequency, the urine volume per void generally is more than 2 mL per kg.

Polyuria with dilute urine is classically associated with a decreased production of antidiuretic hormone or with impaired renal responsiveness to circulating antidiuretic hormone. Polyuria with dilute urine can also be seen when the stimulus for antidiuretic hormone release is absent (e.g., chronic water overloading). In all these situations, the specific gravity of urine seldom is greater than 1.005 and urine osmolality rarely exceeds 200 mOsm per kg. This contrasts with a normal urinary concentrating ability, which is confirmed by a specific gravity of greater than 1.020.

Polyuria with isotonic or slightly hypertonic urine occurs with an osmotic or solute diuresis. Unlike a water diuresis, there are increases in both urine flow rate and solute excretion. The urine osmolality is never lower than 300 mOsm per kg. However, the specific gravity of urine is variable, ranging from 1.010 when the solute is primarily electrolytes and urea (e.g.,

renal failure, administration of diuretics) to as high as 1.045 when the solute mass is large (e.g., DM, intravenous contrast agents).

Psychogenic/emotional stress may also induce urinary frequency. Cystometric studies have documented significant anxiety-related increases in intravesical pressure, usually accompanied by a desire to void.

DIFFERENTIAL DIAGNOSIS

A differential diagnosis of urinary frequency is outlined in Table 75.1. In-depth discussions of many of these subjects can be found in other chapters of this textbook (in particular, see Chapters 27, 34, 53, 60, 86, 92, 100, 124). The following discussion highlights selected topics in the differential diagnosis.

Frequency is often associated with UTIs; therefore, this diagnosis must always receive significant consideration in the differential, particularly in the febrile Caucasian female patient younger than 2 years (see Chapters 27 and 92). Accurate diagnosis of pediatric UTI is important to ensure both appropriate initial treatment and follow-up evaluation.

The term *urethral syndrome* refers to an entity that can be seen in female adolescents, characterized by acute onset of frequency and dysuria with "insignificant" bacterial counts (less than 10^5 per mL). Pyuria is generally, but not absolutely, present. Vaginitis is a common cause of the urethral syndrome. *Chlamydia trachomatis* is also a relatively common etiology. The urethral syndrome can also occasionally be associated with *Neisseria gonorrhoeae*. There is evidence to support the causal relationship of low-level bacteriuria and symptomatic disease. Therefore, in the context of the urethral syndrome, after all other causes have been excluded, "significant" bacteriuria may be considered as 10^2 *Enterobacteriaceae* or more per mL.

Irritative vulvovaginitis (e.g., secondary to poor hygiene or bubble baths) is a relatively common cause of frequency, usually associated with dysuria but not with pyuria. Frequency may be secondary to urethral trauma secondary to straddle injuries, catheterization, masturbation, or sexual abuse. Pinworms (*Enterobius vermicularis*) may occasionally cause frequency in young females. Children with pinworm infestation may or may not present with perineal itching. Pyuria and dysuria are usually absent.

Frequency may be a presenting symptom of a pelvic mass pressing on the bladder, such as appendicitis, appendiceal abscess, or ovarian torsion. There is obvious potential for significant morbidity. Associated abdominal pain, by history and examination, should be present. Pyuria, microscopic hematuria, and proteinuria (but generally not bacteriuria) may also be present.

Frequency may be secondary to a partial distal urethral obstruction. The urinary stream in the male infant or child who presents with posterior urethral valves is usually nonforceful and nonsustained. Straining to urinate may also be noted. A lower abdominal mass (enlarged bladder) may be palpable.

A neurogenic bladder associated with a spinal cord lesion (e.g., tethered cord) may present with urinary frequency. There may be associated lumbosacral abnormalities (hairy patches, cutaneous dimples or tracts, lipoma, or bony irregularities). Decreased anal tone, as well as lower-extremity weakness or reflex abnormalities, may be noted. An enlarged bladder may be palpable.

Extraordinary urinary frequency syndrome[a]
Water intoxication[b]
Psychogenic water drinking
Munchausen syndrome by proxy

[a]Relatively common causes of frequency.
[b]Emergent/life-threatening causes of frequency.

It is well recognized that in children with urinary tract dysfunction, an association with constipation is often present. Large fecal masses may restrict maximal bladder capacity or directly produce symptoms of frequency by stimulating uninhibited bladder contractions. Resolution of the fecal accumulation decreases frequency symptoms.

Pregnancy should always be considered as a cause of frequent urination in the adolescent female. A lower abdominal mass may be palpable. To state the obvious, adolescent sexual histories are notoriously unreliable.

Uninhibited bladder contractions ("unstable bladder" syndrome) occur involuntarily in children who have failed to gain complete voluntary control over the voiding reflex. This appears to represent a delay in nervous system maturation. A child who attempts to maintain continence must constrict the voluntary urinary sphincter tightly. If the sphincter is relatively weak, urinary frequency associated with urgency and enuresis may result. Females may exhibit the so-called "curtsey" sign, so named because the child squats and attempts to prevent leakage by compressing the perineum with the heel of one foot. This maneuver will usually prevent major incontinence but generally small amounts of urine leakage occur. A history of recurrent UTIs is associated with the presence of this maneuver. If performed, a screening ultrasound examination would reveal normal (minimal) residual urine volumes. With maturity, spontaneous resolution of uninhibited contractions occurs in most cases. In children with significant mental retardation or behavioral disorders, the infantile pattern of spontaneous bladder contraction may persist. Unstable bladder syndrome may also develop in otherwise normal children who have undergone normal toilet training. If symptoms are persistent, a trial of extended-release oxybutynin, behavioral therapy, and/or biofeedback techniques after urologic consultation may be warranted.

Anatomic anomalies of the urogenital tract may result in a chronic leakage of urine. Ectopic ureter would be an example of such an anatomic defect.

Uncontrolled DM is a potentially life-threatening condition that can present with frequent urination. Polyuria results from a glucose-induced osmotic diuresis. At initial presentation, polydipsia, polyphagia, Kussmaul respirations, lethargy, and/or weight loss may also be noted.

In chronic renal failure and in certain diseases of the renal parenchyma (e.g., renal tubular acidosis, Fanconi's syndrome, and Bartter's syndrome), the renal tubules lose their ability to concentrate urine. This leads to polyuria and frequency with large volumes of relatively dilute urine. A concentration defect may also occur with sickle cell disease or trait and may be evident as early as 6 months of age.

Hypercalciuria has been reported as a significant noninfectious cause of the "frequency-dysuria syndrome" in pediatric patients. Onset of symptoms generally ranges from 2 to 14 years of age. Occasionally, hypercalciuria can present in early infancy, where irritability is a hallmark symptom. Symptoms often spontaneously resolve within 2 months. There may be a positive family history of calcium urolithiasis. Dysuria may or may not be present. Hematuria (generally microscopic) and/or crystalluria are often seen. However, the urinalysis may be normal. If the diagnosis is suspected and symptoms persist, studies of urinary calcium excretion and urologic consultation should be considered. A spot urinary calcium-creatinine ratio of 0.2 or more denotes hypercalciuria. Voiding dysfunction in the majority of patients with hypercalciuria responds to behavioral therapy and anticholinergics, with only a small minority of patients requiring treatment with thiazides.

The salt-losing form of congenital adrenal hyperplasia is a life threatening, although a relatively rare, cause of frequency. Excessive urinary excretion of sodium leads to severe water loss and marked dehydration with associated hyperkalemia and hyponatremia. However, at initial presentation (usually in the first 2 months of life), urinary frequency as a symptom is generally not appreciated. Female infants may exhibit virilization of the external genitalia. Male infants may demonstrate increased pigmentation of the external genitalia and/or a relatively enlarged phallus.

Diabetes insipidus is an uncommon, although life-threatening, cause of frequency in the ED. It is clinically characterized by polyuria (with resultant frequency) and polydipsia. It is caused by an inability of the kidneys to concentrate urine. This is related to a deficiency in the hypothalamic production of antidiuretic hormone (central DI) or a renal unresponsiveness to antidiuretic hormone (nephrogenic DI). Some causes of central DI (e.g., septooptic dysplasia) present in the neonatal period. However, most causes of central DI are acquired (e.g., head injury, brain tumors) and therefore can present at any age. The most common type of nephrogenic DI in childhood is the X-linked recessive type, which presents in males during early infancy. If fluids are not accessible or if the thirst sensation is impaired, hypernatremic dehydration develops. If DI is suspected, oral fluids should not be limited. The child should be admitted to the hospital for evaluation and treatment under strict medical supervision.

Drugs are a relatively common cause of frequency in childhood. Methylxanthines (caffeine, theophylline) and ethanol inhibit the production of antidiuretic hormone. Lithium, chronic hypokalemia, hypercalcemia, and vitamin D are also associated with urinary frequency, interfering with renal responsiveness to antidiuretic hormone. Diuretic agents may cause urinary frequency. These agents represent only a few of the many drugs that can cause urinary frequency as a side effect. Therefore, a detailed pharmacology history should be obtained in the child who presents with urinary frequency.

Frequency may result from polyuria secondary to water intoxication. Absence of nocturia and enuresis in the presence of polyuria would suggest an excessive fluid intake. The serum sodium and osmolality would generally be decreased. Psychogenic water drinking is an extremely unusual diagnosis in young children but may present in adolescence. Water intoxication secondary to Munchausen syndrome by proxy, an unusual presentation of abuse in the younger child, is also a consideration.

The "extraordinary urinary frequency syndrome" probably represents a relatively common cause of urinary frequency in pediatric primary care settings. Average age of onset is about 6 years (with a range of about 2 to 11 years). Daytime frequency occurs as often as every 5 minutes. Dysuria is not present. Nocturia is present in about half the cases but usually occurs only about one to two times per night. Polydipsia and polyuria are absent. The physical examination is normal. The urinalysis and serum electrolytes are also normal. If the diagnosis of "extraordinary urinary frequency syndrome" is likely, reassurance and follow-up are indicated. Initial radiologic

evaluation and pharmacologic therapy are generally unnecessary. Left untreated, frequent voiding often resolves spontaneously within about 2 months, although in some children, the duration of symptoms can be markedly longer. The etiology is unclear but often has a psychogenic component, with an apparent "trigger" (school problems, parental death, sibling illness, etc.) identifiable in about 40% of cases. Parekh et al. reported a 21% rate of hypercalciuria (positive spot urinary calcium-creatinine ratio) in their series of 38 pediatric patients with this syndrome. More extensive urologic and possibly psychological evaluation is warranted if isolated urinary frequency persists for more than 2 months. After consultation, a trial of extended-release oxybutynin, behavior modification, and/or biofeedback techniques are therapeutic considerations.

As an isolated symptom, frequency would be an atypical presentation of pediatric sexual abuse. However, urinary frequency may be seen in association with pertinent history or physical findings (e.g., vulvovaginal venereal infection or genital trauma), which would be suggestive of sexual abuse.

EVALUATION AND DECISION

The primary role of the emergency physician in evaluating the child with urinary frequency is to exclude significant underlying pathology that may result in morbidity and to identify treatable conditions. When confronted with a child whose chief complaint is frequent urination, it should initially be determined whether the criteria for true urinary frequency have been met (see the "Pathophysiology" section above for age-related normal values). Additional history should then focus on symptoms related to the infection of the urinary tract. Are associated symptoms of dysuria, fever, or flank pain also present? Is there a history of UTIs? Questions specifically related to DM should also be included (polyuria, polydipsia, polyphagia, weight loss, family history). The presence or absence of nocturia and enuresis are also important historical points. The urine volume per voiding should be determined (large vs. small). Generally, the presence of polyuria (copious volumes of dilute urine) is obvious from the history. The onset and duration of the symptoms and the quality of the urinary stream should be documented.

In addition, other historical features may be pertinent. For example, are there symptoms to suggest central DI (polydipsia, nocturia, central nervous system abnormalities)? Is there a history of poor growth, suggesting renal disease? Is there a family history of sickle cell disease or trait? Is the child taking any medication or drug (including caffeinated beverages) associated with frequency? Is there a history of chronic constipation, vulvovaginal infection/trauma, or pruritis ani? Are there

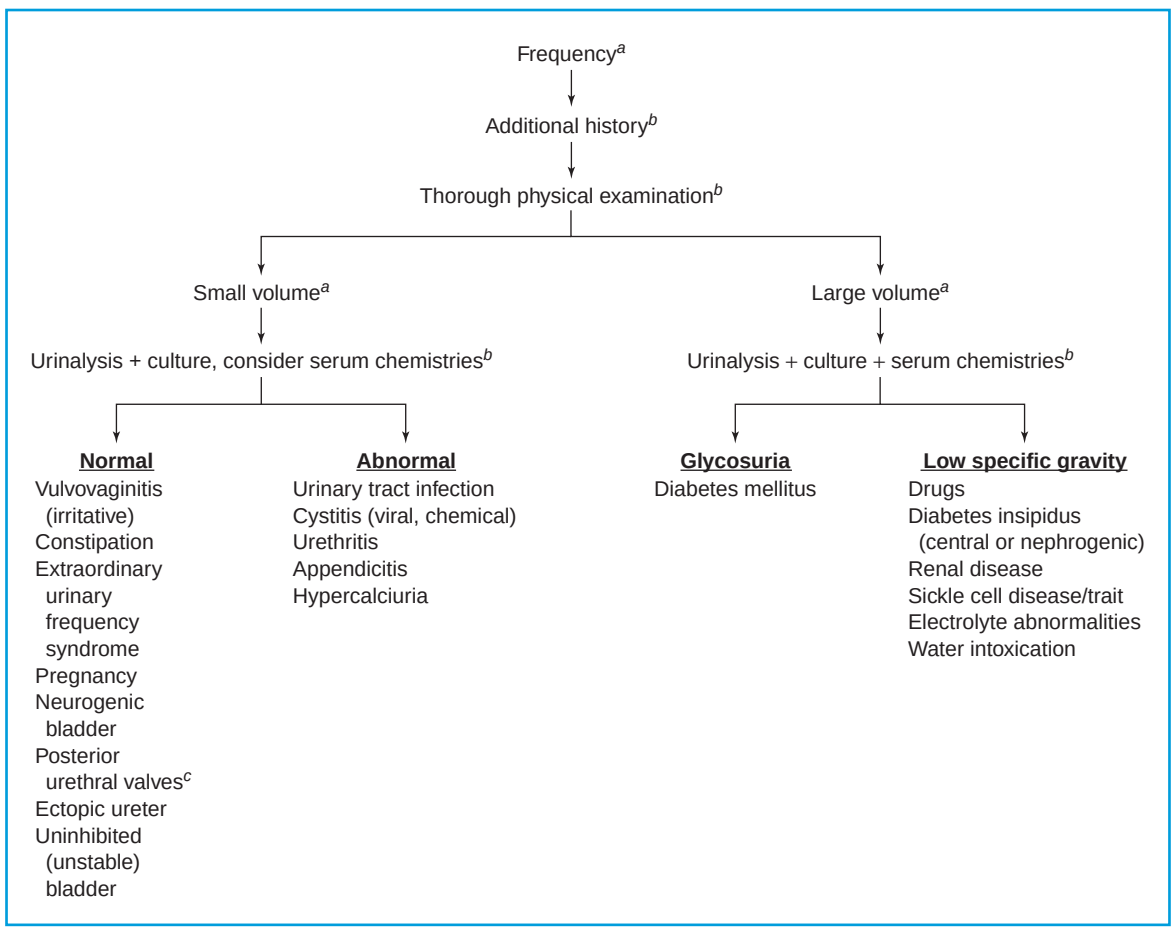

FIGURE 75.1 Evaluation of urinary frequency. [a]Refer to the "Pathophysiology" section for age-related normal values. [b]Refer to the "Evaluation and Decision" section. [c]Renal function tests may be abnormal.

symptoms of abdominal pain, suggesting the possibility of acute appendicitis or appendiceal abscess? In young male patients, what is the quality of the urinary stream? In an adolescent female patient, when was her last menstrual period? Is there a family history of urolithiasis or renal disease?

A complete physical examination should be performed, including an accurate blood pressure measurement. The child's growth parameters should be plotted, and the blood pressure should be compared with age-specific normal values to screen for hypertension (see Chapter 34). The abdomen should be palpated carefully for the presence of abdominal masses and/or tenderness. Percussion of the flanks should be performed. The lumbosacral area should be examined closely for anomalies (hairy patches, dimples, tracts, etc.). Special attention should be focused on the function of sacral nerves II to IV (anal wink and sphincter tone). Unless the diagnosis is readily apparent, a rectal examination should be performed, noting tone, tenderness, masses, and the quality and quantity of stool in the rectal vault. The external genitalia should always be thoroughly examined, meticulously searching for signs of infection, trauma, or anatomic abnormalities. Signs of virilization (in the female) or hyperpigmentation (in the male) should be evaluated. A thorough neurologic examination with careful attention to the retinal fundi and visual fields is warranted.

The laboratory evaluation is fairly straightforward. A urinalysis (including specific gravity) and urine culture should be performed in all cases. Caution should be exercised in interpreting pyuria and/or bacteriuria from a "bag" or "midstream" urine specimens in the infant or toddler. If a UTI is a significant differential consideration, then a catheterized specimen should be the standard in all children still wearing diapers. If a UTI is confirmed, additional elective radiologic evaluation should be considered. Glycosuria obviously suggests the diagnosis of DM.

If the diagnosis is not apparent at this point, serum chemistries (including electrolytes, glucose, blood urea nitrogen, creatinine, and calcium) should be obtained. A sickle cell preparation should also be considered in the African-American child, and a pregnancy test should be performed in the adolescent female patient. This workup is generally sufficient for those children who do not have both daytime and nighttime symptoms or anatomic and/or neurologic abnormalities.

In the child with progressive or worrisome urologic symptoms or signs (e.g., nocturia, persistent dysuria, poor urinary stream, straining to urinate, growth failure, hypertension, fixed low urinary specific gravity), urologic and/or nephrologic consultations are recommended. Additional studies may include a screening ultrasonogram of the urinary tract and abdomen, a voiding cystourethrogram, urinary calcium studies, and possible urodynamic investigation. If the presence of polyuria is in doubt, a 24-hour urine collection may be necessary to establish the diagnosis. If a neurogenic bladder (related to a spinal cord lesion such as a tethered cord) or a brain tumor is suspected, emergent radiologic evaluation with neurosurgical consultation is indicated.

A simplified schematic approach to the evaluation of the child with urinary frequency is outlined in Fig. 75.1.

CHAPTER 76 ■ VAGINAL BLEEDING

JAN E. PARADISE, MD

Vaginal bleeding can be either a normal event or a sign of disease and, when pathologic, can indicate variously a local genital tract disorder, systemic endocrinologic or hematologic disease, or a complication of pregnancy. During childhood, vaginal bleeding is abnormal after the first week or so of life and before menarche. After menarche, abnormal vaginal bleeding must be differentiated from menstruation and, in turn, menstrual bleeding must be categorized as either normal or excessive. *Menstruation* is defined as the spontaneous, periodic shedding of endometrial tissue and blood.

Menstrual patterns during the first 2 years after menarche vary, but it is possible to set outside limits. Ninety-five percent of young adolescents' menstrual periods are between 2 and 8 days long. A duration of 10 days or more is abnormal. An occasional interval of less than 21 days from the first day of one menstrual period to the first day of the next is normal for teenagers, but several short cycles in a row are abnormal. Whether the quantity of a patient's menstrual bleeding is normal can be difficult to determine historically. However, it is uncommon for adolescents to soak more than six to eight perineal pads or tampons a day. Normal menstrual bleeding never produces an acute fall in hemoglobin or hematocrit. Because the relative prevalence of disorders that produce vaginal bleeding correlates more closely with patients' hormonal status than with their chronologic age, the diagnostic approach outlined in this chapter is presented in two sections divided according to patients' menarcheal status (Table 76.1).

VAGINAL BLEEDING BEFORE NORMAL MENARCHE (FIG. 76.1)

Evaluation and Decision

During the patient's general physical examination, the emergency physician should be particularly alert for signs of hormonal stimulation (i.e., breast development, pubic hair growth, a dull pink vaginal mucosa, or physiologic leukorrhea). For the initial examination of the genitalia, an infant or a child should be placed in a frog-leg position either on the parent's lap or on the examining table (Fig. 90.2A). The physician then separates and applies gentle outward traction to the child's labia majora, inspecting the introitus for a bleeding site. A vaginal speculum should not be used. If the vulva is normal, the child should next be placed in the knee-chest position for examination of her vagina (Fig. 90.2B). In this position, the girl is encouraged to relax her abdominal muscles while the examiner gently separates her labia and buttocks. As air enters the vaginal vault, it falls open. The physician can then use an otoscope light to look for a bleeding site or a foreign body. If no bleeding site or foreign body is seen, the child is returned to the supine position and a vaginal specimen for culture is obtained, using either a soft plastic medicine dropper or a cotton-tipped swab moistened with nonbacteriostatic saline solution. Finally, if the interior of the vagina could not be seen well but the examiner suspects a foreign body or trauma, vaginal examination under sedation or general anesthesia should be considered.

Vulvar Bleeding

The vulva consists of several structures: the labia majora, the labia minora, the clitoris, and the vaginal introitus. A premenarcheal girl with the complaint of vaginal bleeding whose vulva looks abnormal may have a vaginal disorder, a vulvar disorder, or both.

Trauma to the vulva often produces lacerations, ecchymoses, or both. Even a minor vulvar injury should alert the emergency physician to the possibility of concurrent, potentially serious vaginal or rectal injuries. Vulvar lacerations do not usually bleed excessively, but hematomas can extend widely through the tissue planes, forming large, painful masses that occasionally produce enough pressure to cause necrosis of the overlying vulvar skin. Because minor periurethral injuries can produce urethral spasm that leads to acute urinary retention, the injured child's ability to void should be checked. The possibility of sexual assault must be considered in the management of every child with a genital injury.

Urethral prolapse (see Chapter 90) is probably the most common cause of apparent vaginal bleeding during childhood. Some patients with urethral prolapse complain of dysuria or urinary frequency, but most have bleeding as their only symptom. A prolapse is diagnosed by its characteristic doughnut shape (Fig. 90.5). The ring of protruding urethral mucosa above the introitus is swollen and dark red with a central dimple that indicates the meatus. When the child is supine, the prolapse is often large enough to cover the vaginal introitus and appears to protrude from the vagina. Bleeding comes from the ischemic mucosa. Urethral prolapse is sometimes mistaken for a malignant tumor, which is a rare cause of vaginal bleeding. If the diagnosis is in doubt, one may safely catheterize the bladder through the prolapse to obtain urine. Some patients with small prolapses whose urethral tissue is still pink will improve with the use of sitz baths alone for several days. However, if the prolapsed tissue looks dark or necrotic at the time of the patient's examination, or if sitz baths are not effective, elective surgical excision of the prolapsed tissue will be needed within a few days after diagnosis.

TABLE 76.1

DIFFERENTIAL DIAGNOSIS OF VAGINAL BLEEDING

I. At any time
  A. Trauma
  B. Tumor
II. Before normal menarche
  A. Hormonal
    1. Neonatal bleeding
    2. Exogenous estrogen
    3. Precocious puberty
  B. Nonhormonal
    1. Urethral prolapse
    2. Genital warts
    3. Lichen sclerosus
    4. Infectious vaginitis
    5. Foreign body
III. After menarche
  A. Bleeding diathesis
  B. Pelvic infection
  C. Endocrinologic problem
    1. Midcycle spotting
    2. Dysfunctional uterine bleeding
      a. Hormonal contraception
      b. Axis immaturity
      c. Polycystic ovary syndrome
      d. Hypothyroidism
      e. Ovarian cyst
  D. Ectopic pregnancy
  E. Spontaneous abortion
  F. Placenta previa
  G. Abruptio placentae

Genital warts, like a urethral prolapse, can be recognized by inspection (Fig. 90.12) and can produce bleeding when they are located on the mucosal surface of the introitus or just inside the hymenal ring. Because the presence of such warts in a child indicates that sexual contact may have occurred, the child should be screened for other sexually transmitted infections and consideration should be given to reporting the case to the state child protective services agency (see Chapter 132). Topical podophyllin can produce systemic toxicity if a large amount is absorbed. Accordingly, to select an appropriate treatment for bleeding genital warts, a gynecologist or other knowledgeable clinician should be consulted.

Vulvar inflammation can be seen in some patients with vaginal bleeding resulting from bacterial or fungal vulvovaginitis (see also Chapter 77). Infections caused by *Shigella* species, group A hemolytic streptococci, *Neisseria gonorrhoeae*, and *Candida albicans* produce vaginal bleeding or bloody discharge in varying proportions of cases. A few children with rectal *Enterobius vermicularis* (pinworm) infestations scratch so vigorously that they excoriate the perineal area and cause bleeding. Pinworm ova can often be discovered by low-power microscopic examination of perianal material that is collected with clear cellophane tape and then attached to a glass slide.

Although bleeding per se is not common, ecchymoses, fissures, and telangiectasias are frequent clinical manifestations of lichen sclerosus (Fig. 76.2), an uncommon, chronic, idiopathic skin disorder that most often affects the vulva. In this condition, white, flat-topped papules gradually coalesce to form atrophic plaques that involve the vulvar and perianal skin in a symmetric hourglass pattern. Topical treatment with ultrapotent steroids or an immunomodulator is helpful in most cases.

VAGINAL BLEEDING WITHOUT SIGNS OF HORMONAL STIMULATION

Trauma, infection, and foreign bodies are the most common causes of vaginal bleeding during childhood. Vaginal bleeding after trauma indicates a potential emergency. A penetrating narrow object can damage the rectum, bladder, or abdominal viscera without producing much external evidence of injury. Because vaginal lacerations do not always produce a great deal

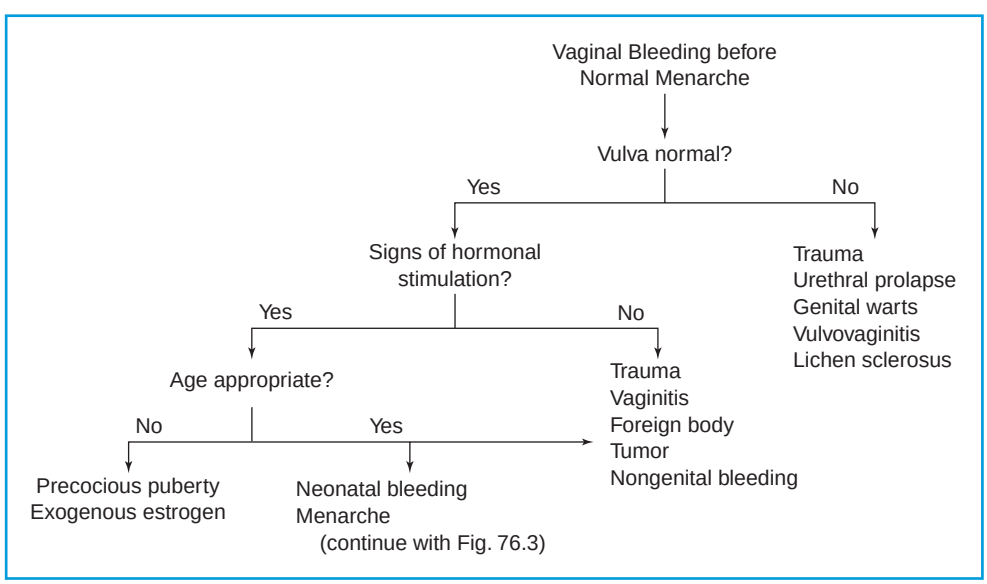

FIGURE 76.1 Diagnostic approach to vaginal bleeding before normal menarche.

FIGURE 76.2 Figure-of-eight pattern of vulvar and perianal hypopigmentation in a 10-year-old girl with lichen sclerosus.

of bleeding or pain, the emergency physician cannot rely on the severity of the patient's symptoms to indicate the extent of the injury. When a child sustains a genital injury, the physician must consider the possibility that it was inflicted during a sexual assault.

If the clinician knows or suspects that trauma has occurred, the girl's abdomen should be evaluated carefully. Lower quadrant tenderness may provide a clue to intraabdominal injury. The vulva is inspected for bruises, and a rectal examination is performed to identify any lacerations. A general principle of management is that patients with penetrating genital injuries, even apparently minor ones, should undergo careful vaginal examination. This is likely to require procedural sedation or general anesthesia, particularly in young children. Laboratory evaluation of the child with vaginal trauma should include a baseline hemoglobin determination and a urinalysis to screen for hematuria that might indicate urethral or bladder injury.

About half of all patients with *Shigella* vaginitis have bleeding that may be more noticeable than any associated discharge. Most patients do not have concurrent diarrhea. Vaginal infections with group A streptococci, *N gonorrhoeae*, and *C albicans* also cause bleeding in some cases. A vaginal culture will provide the diagnosis and guide the selection of an appropriate antibiotic. The manifestations and treatment of vaginal infections in children are discussed in more detail in Chapters 77 and 90.

Although a chronic, foul-smelling discharge is generally considered the hallmark of a vaginal foreign body, many girls have intermittent scanty vaginal bleeding alone or with an unimpressive discharge. Direct inspection of the vaginal vault using the knee-chest position (Fig. 90.2B) usually allows the examiner to find a foreign body easily. If a foreign body is strongly suspected but cannot be seen using the knee-chest position, the patient should receive a rectal examination and either gentle vaginal lavage (using saline solution, a 50-mL syringe with the plunger discarded, a red rubber catheter, and gravity) or an examination under procedural sedation or anesthesia. Because the most common foreign body—toilet paper—is not radiopaque, pelvic roentgenography is not often likely to be helpful and should be avoided.

Occasionally, a prepubertal patient with a history of bleeding has no abnormalities and no bleeding at the time of the examination. This history should not be dismissed lightly because most parents are good observers, but the patient's urine and stool should also be checked for blood. Vaginal foreign body, genital trauma, and inapparent hormonal stimulation (see the following text) are also in the differential diagnosis.

VAGINAL BLEEDING WITH SIGNS OF HORMONAL STIMULATION

During the first 2 to 3 weeks of life and late in puberty, hormonal fluctuations produce physiologic endometrial bleeding. Before female infants are born, high levels of placental estrogen stimulate growth of both the uterine endometrium and the breast tissue. As this hormonal support wanes after birth, some infants have an endometrial slough that results in a few days of light vaginal bleeding. The bleeding will stop spontaneously and requires no treatment except reassurance for the parents.

Occasionally, an adolescent girl is brought to the emergency department (ED) by her parents to confirm their belief that she is having her first menstrual period. About 65% of girls are in sexual maturity stage 4 (Tanner stage 4) for breast development when menarche occurs (Table 76.2). Of the remaining girls, about 25% are in breast development stage 3 and 10% are in stage 5. If the adolescent's chronological age and degree of pubertal development are consonant with this expected pattern of maturation, no further evaluation is necessary.

If a girl younger than about 10 years has bleeding that is cyclic or is associated with breast development (thelarche), pubic hair growth (adrenarche), or accelerated linear growth, the various causes of precocious puberty must be considered in the differential diagnosis. Such a patient and her parents should be questioned about possible exposure to exogenous feminizing hormones (e.g., creams or medications containing estrogen). The possibility that a girl early in puberty simply has a nonendocrinologic disorder (e.g., foreign body, trauma) must also be considered. If the patient does appear to have precocious puberty, she should be checked in particular for café-au-lait spots (McCune-Albright syndrome) and an abdominal mass (endocrinologically active ovarian tumor or cyst) and should be referred to a pediatrician or pediatric endocrinologist for subsequent evaluation and follow-up.

TABLE 76.2

MEDIAN AGE AT ENTRY TO EACH STAGE OF BREAST DEVELOPMENT DURING PUBERTY IN US GIRLS, BY ETHNICITY[a]

Sexual maturity stage	Description of stage	Median age at entry to pubertal stage (yr)		
		Non-Hispanic blacks (n = 788)	Mexican-Americans (n = 763)	Non-Hispanic whites (n = 594)
2	Breast buds; areolar elevation	9.5	9.8	10.4
3	More growth; no separation of contours	10.8	11.4	11.8
4	Areola projects beyond breast contour	12.2	13.1	13.3
5	Mature breast	13.9	14.7	15.5

ABNORMAL BLEEDING AFTER MENARCHE

Evaluation and Decision

For postmenarcheal adolescents, the first discrimination the emergency physician must make is between those patients whose menstrual bleeding is heavier, more prolonged, or more frequent than they would like but is nevertheless normal, and those patients whose bleeding falls outside the limits presented at the beginning of this chapter. After that, patients with abnormal bleeding will be divided for evaluation and management into two groups: patients who are pregnant and those who are not. For all patients, historical points will include the adolescent's age at menarche, her usual menstrual pattern, and the date of onset of her most recent normal menstrual period. Because anovulatory bleeding is nearly always painless, the presence of dysmenorrhea argues against a diagnosis of anovulatory dysfunctional uterine bleeding (DUB). Other pertinent historical details include the presence or absence of trauma, fainting or dizziness, fever, easy bruising, and excessive bleeding at other sites. While the patient is alone, and after assuring her of confidentiality, the patient should be asked whether she has experienced sexual intercourse. Sexually experienced patients should be asked whether they have ever had a sexually transmitted infection or been pregnant. Current and recent methods of contraception should also be ascertained.

The patient's pulse and blood pressure are noted and checked for orthostatic change. After a routine general examination, a complete pelvic examination is performed for patients who are either not pregnant or within the first trimester of pregnancy. A speculum examination is not necessary for virginal adolescent patients who have not been injured, but a bimanual examination should generally be carried out because teenagers are not always candid about their sexual activity. If it is more comfortable, bimanual rectoabdominal palpation with the patient in the lithotomy position can be substituted, or the examiner can place one finger intravaginally instead of two.

A urine pregnancy test should be obtained early in the evaluation of most postmenarcheal adolescents presenting to the ED because of vaginal bleeding. For the occasional parent who finds it difficult to understand the rationale for this test for his or her daughter, it may be helpful to point out that the medical consequences of failing to diagnose pregnancy can be substantial. A pregnancy test should be obtained even if the patient with an episode of abnormal bleeding says she has had regular menstrual periods, because about 25% of patients with ectopic pregnancies do not report having missed a menstrual period.

BLEEDING IN THE PREGNANT PATIENT (FIG. 76.3)

Bleeding During Late Pregnancy

If the patient is 20 weeks pregnant or more by history or abdominal examination, potential causes of bleeding that must be identified urgently are placenta previa, premature separation of the placenta (abruptio placentae), and a bloody show during labor. Placenta previa occurs in about 1 of 200 pregnancies and abruption in about 1 in 100. However, the risk of both of these pregnancy complications is lower in adolescents than in older women. An obstetrician should be consulted at the earliest opportunity regarding further ED management of the pregnant patient with second- or third-trimester bleeding.

Because digital vaginal examination of a patient with placenta previa can provoke uncontrollable hemorrhage, the emergency care of a patient with vaginal bleeding after the 20th week of pregnancy starts with the management of potential hypovolemic shock (see Chapter 3) rather than with an examination to determine the anatomic site of bleeding. Thus, the patient's vital signs are recorded, the fetal heart rate is monitored, and a large-bore intravenous catheter is inserted. The patient with an apparently normal initial blood pressure is followed carefully nonetheless because her baseline pressure during pregnancy may have been elevated. Initial laboratory evaluation should include determinations of the blood type and antibody screen, hematocrit, platelet count, fibrinogen level, and coagulation studies to screen for disseminated intravascular coagulation, which may be present in moderate and severe abruption. If the patient continues to bleed while in

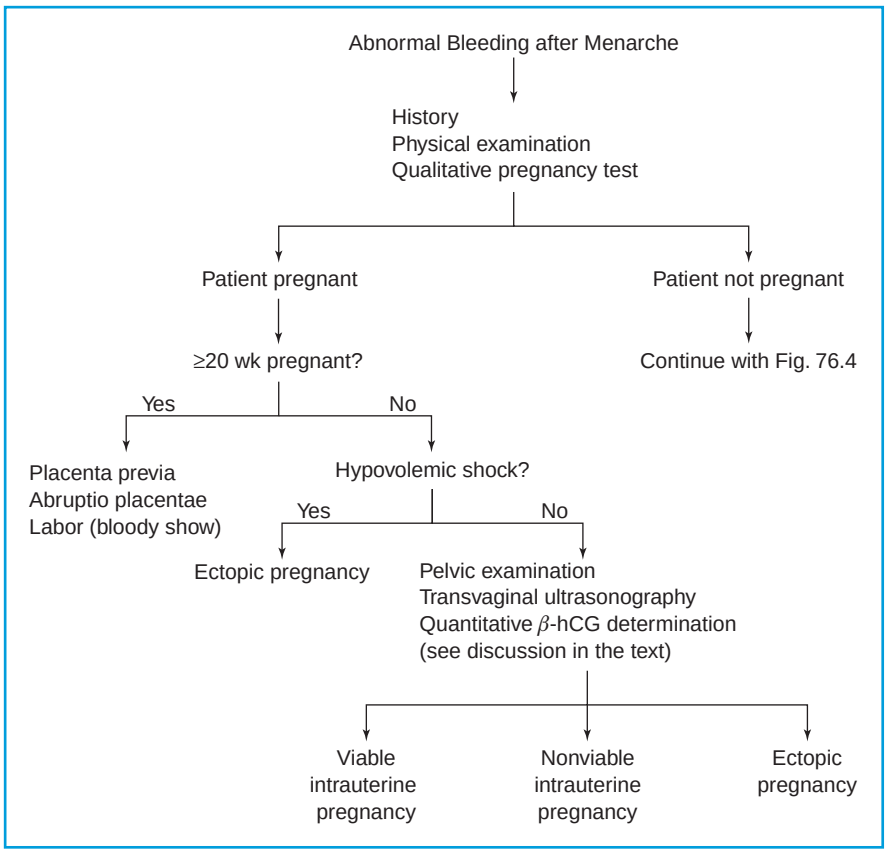

FIGURE 76.3 Diagnostic approach to abnormal uterine bleeding after menarche—pregnant patients. β-hCG, β-human chorionic gonadotropin.

the ED, volume replacement is initiated. If the patient is stable and the fetus is in no distress, the goal of subsequent investigation is to determine the location of the placenta and to identify the cause of the bleeding if it is not placenta previa.

Bleeding during Early Pregnancy

Although the ED physician should be able to recognize and begin managing complications of early pregnancy, an obstetrician should be consulted about any pregnant adolescent who has vaginal bleeding.

Bleeding with Shock

If the patient with vaginal bleeding is in the first or second trimester of pregnancy and has shock or early signs of cardiovascular instability (pallor, perspiration, vomiting), ruptured ectopic pregnancy must be ruled out. In this case, the treatment of shock and diagnostic measures should be undertaken simultaneously. Pelvic examination is performed and obstetric consultation should be obtained rapidly. Emergency laparoscopy or laparotomy may be necessary for critically ill patients. If the patient is relatively stable, transabdominal or transvaginal ultrasonography may help to clarify the diagnosis.

Bleeding without Shock

Among adults in the first trimester of pregnancy presenting to an ED with abdominal pain or vaginal bleeding, approximately 60% have normal pregnancies, 30% have nonviable intrauterine pregnancies, and 10% have ectopic pregnancies. Corresponding data for adolescents are not known, but the risk of ectopic pregnancy is lower among adolescents than among older women. Apart from older age, the factors that convey the highest risk for ectopic pregnancy (e.g., prior tubal surgery, previous ectopic pregnancy) are rare in adolescents. But, in any case, most patients with ectopic pregnancy do not have any of these risk factors.

The standard terminology for spontaneous abortion includes threatened, incomplete, and complete abortions. Three less common but more complex manifestations of abortion deserve special consideration by the ED physician. *Septic abortion* is diagnosed if signs of infection, usually fever, disproportionately severe pelvic pain, and leukocytosis, are present during a spontaneous or induced abortion. After an induced abortion, persistent or heavy bleeding can indicate *retained products of conception* that will require removal. In a *missed abortion*, the embryo is not expelled from the uterus within 4 weeks of its death. Dark bleeding is often seen. The patient's symptoms of pregnancy may have regressed, the uterus is smaller than it should be according to her menstrual history, and disseminated intravascular coagulation can occur.

In a pregnant patient with abdominal pain or vaginal bleeding in the first trimester, symptoms that favor an intrauterine pregnancy (either normal or abnormal) include mild pain, pain located in the midline, and uterine size greater than 8 weeks. Sharp pain, lateralized pain, and pain of moderate to severe intensity favor ectopic pregnancy. On examination, the diagnosis of incomplete miscarriage is straightforward if the internal cervical os is open or tissue fragments are visible. Examination

findings that favor ectopic pregnancy include cervical motion tenderness, lateral pelvic tenderness, and signs of peritoneal irritation. The amount of bleeding and the presence of an adnexal mass on examination are nondiagnostic. If products of conception are not visible, then no constellation of symptoms and signs can accurately distinguish intrauterine from ectopic pregnancy, and diagnostic testing will be crucial.

To identify the cause of bleeding in a pregnant adolescent, a quantitative β-human chorionic gonadotropin (β-hCG) level and findings on transvaginal ultrasonography must be correlated. A single β-hCG level can establish the diagnosis of pregnancy but not its location. Transvaginal ultrasonography can establish that a pregnancy is intrauterine but does not always predict its viability. Clinical assessment of the patient relies on the observation that a normal intrauterine pregnancy should be visible on transabdominal ultrasound when the β-hCG level reaches about 6,000 mIU per mL at the sixth or seventh gestational week (4 to 5 weeks after conception) and should be visible on transvaginal ultrasound when the level reaches between 1,000 to 2,000 mIU per mL at approximately the fifth week of gestation (3 weeks after conception). This so-called "discriminatory threshold" will vary to some extent with operator skill and ultrasound sensitivity. In addition, it should be remembered that β-hCG levels for any given gestational age are higher in twin pregnancies.

Failure to visualize a gestational sac on transvaginal ultrasound in a patient whose β-hCG level exceeds 3,000 mIU per mL strongly suggests a nonviable pregnancy but does not identify its location. Among patients with vaginal bleeding, no intrauterine gestational sac on transvaginal sonography, and a β-hCG level of 2,000 mIU per mL or higher, about 40% will miscarry, about 55% have ectopic pregnancies, and only about 5% have normal intrauterine pregnancies. Because vaginal bleeding is uncommon very early in the course of normal pregnancy, and because ectopic pregnancies produce lower than normal amounts of β-hCG, the likelihood of ectopic pregnancy is increased in symptomatic patients whose β-hCG levels are less than 1,500 mIU per mL.

Sonographic signs suggestive of ectopic pregnancy include a solid or complex adnexal mass, a pelvic mass, particulate fluid in the fallopian tube, an endometrial pseudogestational sac, and cul-de-sac fluid that is either moderate to large in volume or echogenic.

An obstetrician should direct the management of pregnant patients with vaginal bleeding and indeterminate results on transvaginal ultrasonography. Ordinarily, the patient will require either admission to the hospital or close outpatient follow-up. The obstetrician will evaluate serial quantitations of β-hCG. In a normal pregnancy, between days 5 and 42 after conception and above an initial level of 100 mIU per mL, the β-hCG level doubles approximately every 2 days. A decline in β-hCG levels on serial measurement or an increase of less than 66% in 48 hours suggests a nonviable fetus but cannot differentiate intrauterine from extrauterine pregnancy.

Serum progesterone measurement can predict a pregnancy's outcome. Approximately 90% of patients with vaginal bleeding whose progesterone concentrations are higher than 20 ng per mL have normal pregnancies. At a progesterone level below 5 ng per mL, only about 0.16% of pregnancies will be viable. However, because a progesterone level cannot indicate whether a nonviable pregnancy is intrauterine or ectopic, many experts feel that, for ED management, it does not add appreciably to the information afforded by transvaginal ultrasound combined with a β-hCG level.

BLEEDING IN THE NONPREGNANT ADOLESCENT PATIENT (FIG. 76.4)

Vaginal or Cervical Bleeding

On pelvic examination, only a few patients will prove to have vaginal or cervical bleeding. Patients with bleeding from significant vulvar, vaginal, or cervical lacerations should be referred to a gynecologist. The evaluation and management of victims of sexual assault are discussed in detail in Chapters 90 and 132. Hymenal tears produced by coitus rarely require treatment beyond reassurance for the patient. Bleeding genital warts should not be treated with topical podophyllin because toxic amounts of the resin can be absorbed systemically (see Chapter 90). Malignant genital tract tumors are a rare cause of vaginal bleeding during adolescence.

Patients are unlikely to be aware of cervical friability or bleeding caused by infection. On examination, however, punctate cervical hemorrhages (a strawberry cervix) can be seen in about 3% of women with trichomonal vaginitis. Cervical bleeding after swabbing and mucopurulent discharge are common manifestations of cervicitis caused by *Chlamydia trachomatis* and *Neisseria gonorrhea*. Cervical lesions resulting from herpes simplex virus infection may also cause a small amount of bleeding.

Undiagnosed Uterine Bleeding

Most adolescents with vaginal bleeding are not pregnant, and their bleeding is uterine in origin. For these patients, the history, physical examination, and selected laboratory investigations will lead the emergency physician to consider as more or less likely each of three main categories of disease: hematologic problems, pelvic infection, and endocrinologic problems.

The patient should receive a complete blood cell count to screen for anemia and thrombocytopenia. The most common hematologic cause of excessive menstrual bleeding is thrombocytopenia (caused by, for example, idiopathic thrombocytopenic purpura, hematologic malignancy, or chemotherapeutic agents). Clotting factor disorders produce menometrorrhagia much less frequently than does thrombocytopenia, but von Willebrand's disease should be considered in the differential diagnosis.

If the nonpregnant patient with abnormal uterine bleeding also has pelvic pain or tenderness, then pelvic inflammatory disease is a likely possibility. Abnormal bleeding occurs in nearly one-third of patients with pelvic inflammatory disease, generally as a result of endometritis. Pelvic inflammatory disease is discussed in detail in Chapter 90. Every sexually active patient with abnormal vaginal bleeding should be screened for *N. gonorrhoeae* and *C. trachomatis* genital tract infections.

Endocrinologic phenomena—whether physiologic, pharmacologic, or pathologic—are the most common causes of abnormal uterine bleeding in nonpregnant adolescents. During physiologically normal menstrual cycles, the occasional adolescent has spotty bleeding for 24 hours or less in association with the

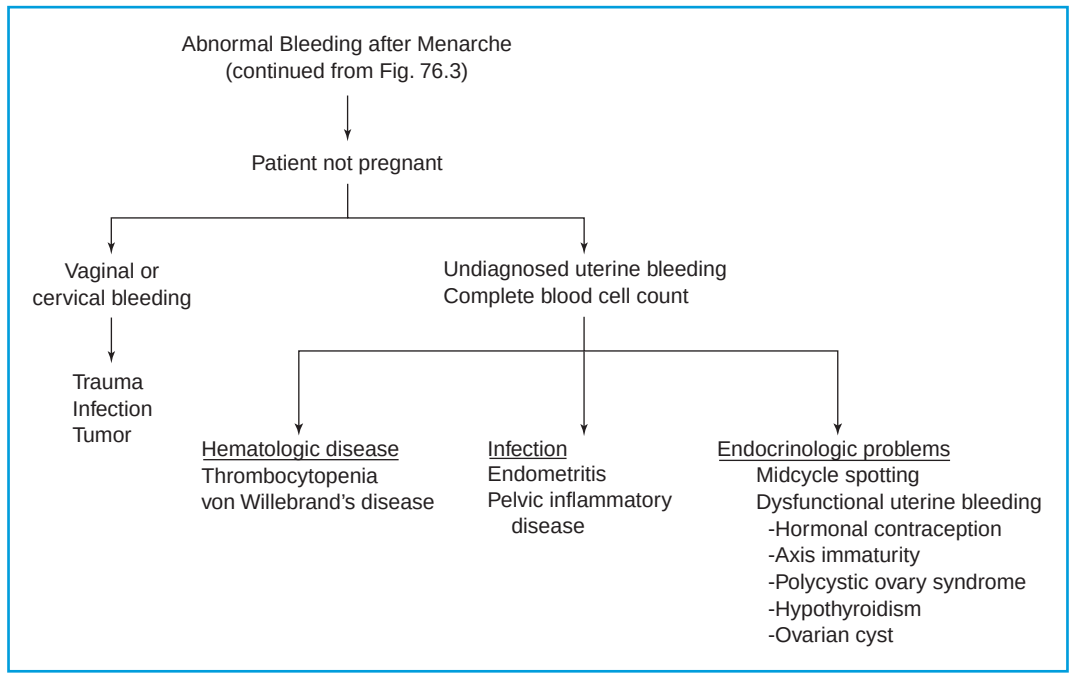

FIGURE 76.4 Diagnostic approach to abnormal uterine bleeding after menarche—nonpregnant patients.

transient decline in estrogen level that occurs at midcycle. The unilateral pain of mittelschmerz can accompany this brief bleeding episode.

Hormonal contraception is a common, pharmacologic cause of irregular menstrual bleeding. Of women who use birth control pills containing 35 μg or less of estrogen, 5% to 10% will have breakthrough intermenstrual spotting or bleeding, especially during the first 3 months of contraceptive pill use. Breakthrough bleeding is also a common side effect of progestin-only contraceptive pills, injectable medroxyprogesterone, and long-acting progestin implants. Many patients using birth control pills experience estrogen withdrawal bleeding if they forget to take one or several pills.

Abnormal uterine bleeding unassociated with either pregnancy or hormonal contraception nearly always indicates lack of regular ovulation and is commonly termed DUB. In adolescents with DUB, the most common underlying causes of anovulation are functional immaturity of the hypothalamic-pituitary-ovarian axis and polycystic ovary syndrome (see Chapter 47). Hypothyroidism should be considered if the patient has other symptoms or signs of thyroid dysfunction. A functioning ovarian cyst is a less common cause of DUB but should be considered especially in the teenager with abnormal uterine bleeding and an adnexal mass or tenderness. The management of DUB is detailed in Chapter 90.

CHAPTER 77 ■ VAGINAL DISCHARGE

JAN E. PARADISE, MD

Infants older than 1 month and prepubertal girls do not normally have visible vaginal secretions. Consequently, any visible vaginal discharge in a female child is abnormal. However, vaginal discharge in neonates and pubertal girls may be either normal or abnormal, because during these times estrogen, either maternal or endogenous, stimulates growth of the vaginal epithelium and secretion of mucus by the paracervical glands. The resulting vaginal discharge consists of desquamated epithelial cells and mucus, is not irritating, and requires no treatment. It is known as physiologic leukorrhea. A vaginal discharge that persists beyond the neonatal period, that occurs during childhood, or that is accompanied by discomfort in a pubertal patient is abnormal and needs to be investigated.

EVALUATION AND DECISION

General Considerations

Although the complaint of vaginal discharge is common among both children and adolescents, this symptom is neither sensitive nor specific as an indicator of actual lower genital tract disease. On the one hand, as noted in the definition given above, an asymptomatic vaginal discharge during the first several weeks of life or after the onset of puberty is normal. This physiologic leukorrhea nevertheless may prompt an emergency department (ED) visit by a girl in early puberty concerned about the unexpected change in her body's function. On the other hand, among prepubertal girls, the complaint of vaginal discharge, irritation, itching, or dysuria can indicate a urologic, gastrointestinal (GI), dermatologic, or gynecologic disorder. Thus, the emergency physician must routinely review GI and dermatologic as well as genitourinary symptoms when evaluating a girl with the complaint of vaginal discharge. In addition, every child with genital complaints (and her parents) should be asked directly about the possibility that she has experienced sexual contact (see Chapter 132). Although physicians are sometimes reluctant to raise this question, many parents will have considered it already, and some will have asked their daughters before the visit to the doctor.

The physical examination and cultures of any vaginal discharge visible on examination are the emergency physician's best guides to the proper management of an infant or child with the complaint of vaginal discharge. For examination of the external genitalia, infants and children should be placed in the frog-leg position either on the parent's lap or on an examining table (see Fig. 90.2A). The genital mucosa of infants and children is normally reddish rather than dull pink, because the epithelium is relatively thin in the absence of estrogenic stimulation. This appearance of the introitus should not be mistaken for inflammation. Children should be examined next in the knee–chest position to check for the presence of a foreign body (Fig. 90.2B). If the examiner sees a vaginal discharge when the child is in either position, a specimen should be collected for culture after the child has returned to the supine position. A soft plastic medicine dropper and a bladder catheter attached to a 3-mL syringe with butterfly tubing are fairly comfortable methods for aspirating vaginal secretions. If a girl's secretions are minimal, the dropper or catheter can be used instead to instill and then withdraw nonbacteriostatic saline washings for culture. Alternatively, the physician can obtain secretions with a cotton-tipped swab moistened with nonbacteriostatic saline solution, but this method is usually less comfortable for the patient.

If a postpubertal girl with vaginal discharge or other lower genital tract complaints has never had sexual intercourse, a speculum examination is not necessary for her evaluation. Either the frog-leg or the lithotomy position may be used for inspection of the girl's external genitalia and for the collection of specimens for microscopic examination, culture, or both.

For sexually active adolescents who complain of vaginal discharge, the extent of the physical examination should depend on the clinician's initial examination and judgment about differential diagnosis. Because sexually transmitted infections are particularly prevalent in adolescents who seek ED care, every patient should be screened for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* infection. In most circumstances this will involve a nucleic acid amplification test of a sample of either urine or cervical secretions. If the external genitalia are normal on examination, speculum examination should be done to look further for the discharge. If there is the slightest suspicion of pelvic inflammatory disease on the basis of history or abdominal examination, then bimanual pelvic examination must be performed. Throughout the evaluation, the clinician should keep in mind the possibility that the patient may have more than one condition. In particular, bacterial vaginosis (BV) commonly coexists with gonococcal, chlamydial, and trichomonal infections.

The patient's age and hormonal status should be considered first in the differential diagnosis of vaginal discharge (Fig. 77.1). For a more detailed discussion of the specific vaginal infections to be mentioned in this section, the reader is referred to Chapter 90.

Infancy and Childhood

Physiologic leukorrhea is a normal vaginal discharge common among female infants during the first 2 to 3 weeks of life. It is clear or white, slippery when fresh, and sticky when dried. Some

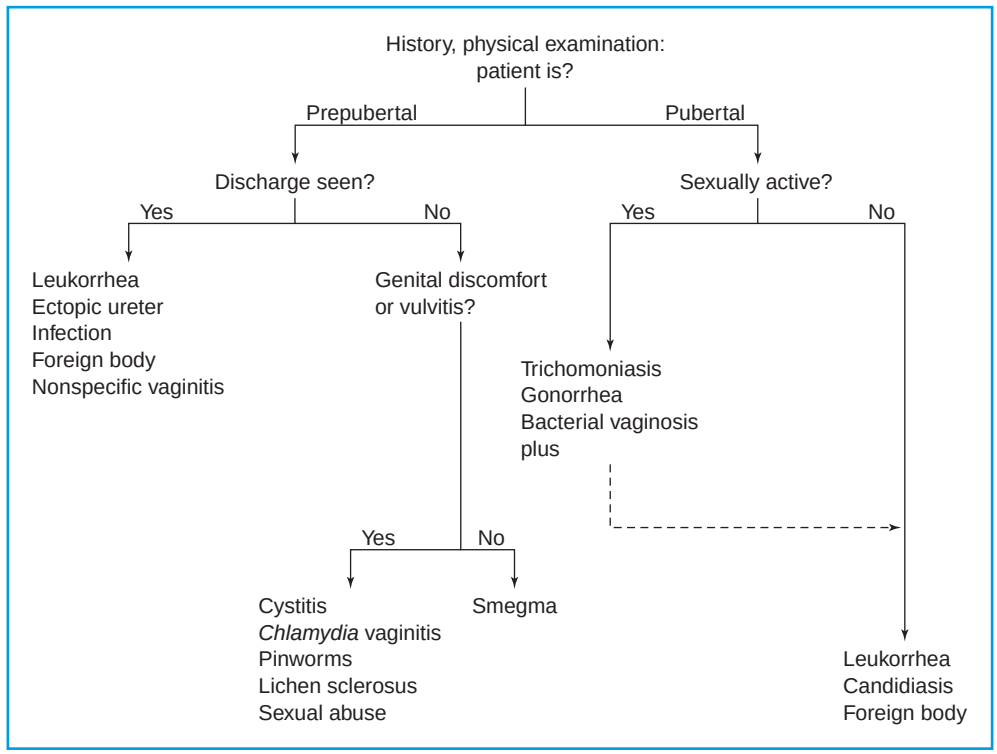

FIGURE 77.1 A diagnostic approach for vaginal discharge.

neonates have associated withdrawal bleeding when maternal estrogenic stimulation of the uterine endometrium wanes.

After exposure to an infected contact, trichomonal vaginitis develops only if the vulvar tissues are estrogenized. Accordingly, this disease occurs exclusively in vaginally delivered infants and in postpubertal children. Trichomonal vaginitis should be suspected if a vaginally delivered infant's discharge is copious or persists beyond the neonatal period. Infected infants may be irritable and have a whitish or yellowish thin discharge. If trichomonal vaginitis is identified in a postpubertal but premenarcheal girl or in a girl who denies consensual sexual contact, the likelihood of sexual abuse is high (see Chapter 132).

Rarely, infants have purulent discharge associated with a congenital malformation of the genitourinary tract (e.g., ectopic ureter). A malformation should be suspected if an infant's discharge is accompanied by systemic signs (fever, vomiting, poor appetite) or if a child with chronic discharge also has had recurrent urinary tract infections (UTIs).

Among older infants and children, a visible vaginal discharge is most likely to indicate a bacterial infection. Routine culture for the bacteria discussed below should be performed. Nonculture diagnostic methods such as nucleic acid amplification tests are not currently approved and should not be used in prepubertal children. Because gonorrhea and shigella are relatively common causes of vaginal discharge in prepubertal girls, because both infections must be reported to state public health departments (http://www.cdc.gov/epo/dphsi/nndsshis.htm) and, most importantly, because the medicolegal implications of diagnosing gonorrhea in a child are serious, ***girls with vaginitis should not be treated with antibiotics until final results of all bacterial cultures are known. In particular, prepubertal girls with vaginitis should not be treated presumptively on the basis of findings on microscopy or gram stain.*** During the wait for culture results, girls may benefit from sitz baths, and their parents can be counseled that proper treatment depends on proper diagnosis.

Gonococcal infection of the vagina typically produces a whitish to greenish purulent discharge. Bloody discharge occurs in half the cases of Shigella vaginitis and is common in vaginitis caused by group A β-hemolytic streptococci. Chlamydial infections are nearly always asymptomatic but can produce dysuria, genital discomfort, or a scant mucoid vaginal discharge. Vaginal culture for *C. trachomatis* should be reserved for symptomatic children with histories of sexual abuse and for those whose routine bacterial cultures already have proved negative, because the prevalence of infection in unselected populations is very low. Other less common causes of vaginal discharge in childhood include nontypable *Hemophilus influenzae* and *Yersinia enterocolitica*. Candidal infections in prepubertal children generally produce perineal dermatitis rather than the vaginal discharge and vulvar inflammation typically seen after the onset of puberty.

An intermittently bloody, foul-smelling vaginal discharge is the classic complaint of the patient with a vaginal foreign body. Small wads of toilet paper, the most common foreign bodies, are usually easy to see just inside the vaginal vault on knee–chest examination (see Fig. 90.2B). The emergency physician must have a high index of suspicion for this diagnosis if the child's vagina cannot be inspected satisfactorily while in the knee–chest position, because intravaginal toilet paper cannot be palpated rectally. Rigid foreign bodies—pencil erasers, pins, beads, nuts—are more likely to be palpable during rectal examination but are uncommon. Gentle vaginal lavage with saline solution

can be used to flush out bits of toilet paper. Small round objects sometimes can be removed if the examiner places a finger in the rectum and then applies gentle outward pressure. However, if an object is large or sharp or if simpler maneuvers fail, then visualization and removal of a foreign body under procedural sedation or general anesthesia will be required.

If examination of the patient discloses vulvar inflammation, excoriation, or hypopigmentation but little or no vaginal discharge, lichen sclerosus, candidiasis, and other dermatologic disorders should be considered in the differential diagnosis. Lichen sclerosus is a chronic, idiopathic dermatitis characterized by atrophy, telangiectasias, and hypopigmentation of the perineal skin, often in a figure-of-eight pattern (Fig. 76.2). Because severe cases can resemble genital trauma, the physician should take care not to confuse the two. Perineal excoriation or inflammation secondary to pinworm infestation, varicella, or any generalized dermatitis also can be misinterpreted as primary vulvovaginal disease.

Some girls with complaints of vaginal discharge or discomfort will have no abnormality on genital examination. In these cases, diagnostic possibilities include poor perineal hygiene, smegma, masturbatory behavior, sexual abuse, Chlamydia vaginitis, and UTI. Girls with poor perineal hygiene will respond well to frequent sitz baths. Genital smegma occurs in girls as well as in boys and sometimes is mistaken by parents for a pathologic discharge. It consists of desquamated epithelial cells, is thick, yellow or white, sticky, and is located characteristically in the interlabial folds and around the clitoral prepuce. Somatic genital discomfort is the presenting complaint of a small number of children who have been sexually abused but are not injured or infected. The task of differentiating abused children from those who display age-appropriate masturbation or genital curiosity can be difficult and often requires consultation with a specialist in child mental health or sexual abuse assessment. The possibility of UTI also should be pursued in girls with genital symptoms but normal physical examinations.

Children with vaginal discharge that cannot be ascribed to any of the conditions just discussed are generally considered to have nonspecific vaginitis. This condition has been attributed to poor perineal hygiene and mechanical or chemical irritants. Accordingly, sitz baths, careful wiping anteroposteriorly after defecation, and the avoidance of presumed irritants (e.g., tight or nylon underwear) are recommended for its treatment. These measures will produce improvement in a majority of patients with nonspecific vaginitis but should not be recommended until after examination has been performed and appropriate cultures have been obtained.

Adolescence

With the onset of puberty, girls' rising estrogen level promotes the discharge of vaginal mucus and cells. This physiologic leukorrhea persists throughout the reproductive years but is most likely to arouse the concern of girls who are starting puberty and are therefore unaccustomed to its presence. On microscopic examination, the discharge shows only abundant epithelial cells. Culture of a specimen is not necessary.

Postpubertal girls with genital itching or dysuria as a prominent symptom are likely to have candidal vulvovaginitis, regardless of whether a predisposing factor such as recent antibiotic treatment or diabetes mellitus is present. A white, cheesy vulvovaginal discharge is associated classically with candidiasis, but only about 84% of patients with such a discharge actually have vulvovaginal candidiasis (positive predictive value 84%). Conversely, about 78% of patients with vulvovaginal candidiasis do not have a characteristic discharge. Many patients instead have predominantly vulvar inflammation with fissuring, erythema, or excoriations, but no notable change in vaginal secretions.

BV, previously termed nonspecific vaginitis, Gardnerella vaginitis, Haemophilus vaginalis vaginitis, and Corynebacterium vaginitis, is a syndrome characterized by a shift in the vaginal ecosystem from the normally abundant, hydrogen peroxide–producing lactobacilli to a relative overgrowth of anaerobic bacteria. The etiology is not known. BV is the most common cause of abnormal vaginal discharge among both virginal and sexually active women, although it occurs somewhat more frequently in women who are sexually experienced. The symptoms classically ascribed to BV are a thin vaginal discharge and abnormal vaginal odor. However, the negative and positive predictive values of these symptoms are very low. In one large study, the proportion of women complaining of abnormal vaginal discharge was about 40% in both those with and without BV. Although women with BV complain of vaginal odor significantly more often than those without, most women do not report odor, and the magnitude of the difference is small (about 25% of women with and 18% of women without BV). Furthermore, physical examination findings correlate poorly with symptoms. Accordingly, laboratory evaluation is necessary for accurate diagnosis of this condition.

While vulvovaginal candidiasis and BV are common in adolescents regardless of whether they have had sexual intercourse, trichomonal vaginitis is a sexually transmitted infection. It is characterized by an increased volume of vaginal discharge associated in some cases with mild pruritus. The discharge is frothy in about 25% of cases.

If an adolescent with the symptom of vaginal discharge does not have Candidiasis, BV, or trichomoniasis, other diagnostic possibilities include cervicitis, physical irritants, and a vaginal foreign body. Gonococcal cervicitis or endometritis can produce a noticeable vaginal discharge although the majority of infected adolescent girls have no lower genital tract symptoms. A pathologic discharge in a girl with gonococcal cervicitis is most likely to be caused by concomitant trichomoniasis or BV. Physical irritants, either mechanical or chemical, should also be considered in the differential diagnosis for patients with only vaginal erythema on examination and only polymorphonucleocytes or no abnormality on microscopic examination of the vaginal discharge. A forgotten tampon, the most common intravaginal foreign body, is a rare cause of vaginitis in adolescents.

Laboratory Evaluation of Adolescents

Three maneuvers—measurement of the pH of vaginal discharge and microscopic examination of the discharge suspended in 0.5 cc or less of saline solution and in 10% potassium hydroxide—are needed to provide a diagnosis for adolescent patients with vaginitis. To avoid contamination by cervical discharge, specimens should be obtained by swabbing

the lateral vaginal wall. Indicator paper should be applied directly to undiluted discharge to measure pH since blood, seminal fluid, lubricating jelly, and saline can falsely elevate the measurement. A commercially available nucleic acid hybridization test for the presence of *Candida* species, *Gardnerella vaginalis* and *Trichomonas vaginalis* is quite sensitive and has good specificity in symptomatic patients. However, if this test is used, it must be correlated with the patient's clinical findings since *Candida* species are present in approximately 10% to 20% and *G. vaginalis* is present in about 20% to 33% of normal women without vaginitis.

Fungal hyphae (see Figure 90.8) are seen on microscopic examination in at most about half of patients with symptomatic candidiasis. Therefore, if a mechanical or physical irritant cannot be identified and if no alternative diagnosis is identified on microscopy, it is reasonable to recommend empirical antifungal treatment for patients with vulvovaginal pruritus or burning and a vaginal pH less than 5.

BV is diagnosed when three of four conditions are present (Amsel criteria): discharge is thin, homogeneous, and whitish grey; vaginal pH is above 4.5; a fishy odor is produced when potassium hydroxide is added to the discharge; and at least 20% of epithelial cells are clue cells. Of these four criteria, the appearance of the discharge has the lowest predictive value. Clue cells are squamous epithelial cells studded with coccobacilli that give the cytoplasm a granular appearance and make the cell edges look shaggy and indistinct (Fig. 90.9). On Gram stain, long gram-positive rods (lactobacilli) are scarce, and short gram-negative and gram-variable coccobacilli (*Gardnerella, Prevotella, Mobiluncus* spp.) are abundant, but Gram stain is not necessary for clinical diagnosis.

Trichomoniasis is easily diagnosed if motile flagellates are seen on microscopic examination (Fig. 90.7). Culture and nucleic acid amplification tests to detect *T. vaginalis* have been studied because microscopy is negative in 20% to 50% of infected women, presumably because they have lower numbers of organisms present. However, the former methods are not widely used in clinical practice. Wet mount preparations should be inspected for trichomonads immediately after they are obtained. Among specimens that initially show moving trichomonads, flagellate motion becomes undetectable—and the test accordingly falsely negative—in one-fifth within 10 minutes and in one-third within 30 minutes.

Management

It is routine to recommend out-patient follow-up for a patient after an ED visit. However, for a number of reasons, follow-up is especially important for adolescents with vaginal discharge. The sensitivity of microscopy for diagnosing vulvovaginal candidiasis and trichomoniasis is low, and a confident diagnosis may not have been made in the ED. For patients with ED diagnoses of sexually transmitted infections, follow-up is crucial to identify treatment failures and reinfections, to address the patient's need for contraception, and to pursue other preventive health measures including partner treatment, Papanicolaou screening, and HIV screening.

CHAPTER 78 ■ VOMITING

MOLLY (MARTHA W.) STEVENS, MD, MSCE, AND FRED M. HENRETIG, MD

Vomiting is defined as the forceful, coordinated act of expelling gastric contents through the mouth. Vomiting may be caused by a number of problems in diverse organ systems. Although it often represents a transient response to a self-limited infectious, chemical, or psychological insult, it also may portend serious infections, metabolic disturbances, or diseases in gastrointestinal (GI), neurologic, or other major organ systems. Thus, an orderly approach to diagnosis is crucial.

Vomiting is a highly complex act, involving coordinated closure of gastric pylorus and glottis; relaxation of stomach, cardioesophageal junction, and esophagus; and vigorous diaphragmatic and abdominal wall muscular contraction. A series of interconnected coordinating centers in the medulla have been identified, with varying responsiveness to afferent signals from diverse areas of the body, including nocireceptors, chemoreceptors, and mechanoreceptors in the pelvic and abdominal viscera and peritoneum, genitourinary system, pharynx, labyrinth, and heart. The chemoreceptor trigger zone in the floor of the fourth ventricle contains chemoreceptors that monitor both blood and cerebrospinal fluid and is probably the key center initiating the emetic response to drugs (especially cytotoxic chemotherapeutic agents) and metabolic aberrations. More recent therapeutic advances arise from an evolving understanding of neurotransmitter activity in the central nervous system (CNS), GI tract, and other sites. Serotonin (5-hydroxytryptamine) receptors are prevalent in the CNS and gut and participate in the induction of emesis. Use of serotonin receptor antagonists (such as ondansetron and granisetron) has proven to be successful in decreasing or preventing emesis associated with many chemotherapeutic and radiotherapeutic cancer treatments, in emetogenic poisonings, and most recently, in children with viral gastroenteritis.

A related complaint, also often heard in the emergency department (ED), is that of young infants who "spit up." This refers to the nonforceful reflux of milk into the mouth, which often accompanies eructation. Such nonforceful regurgitation of gastric or esophageal contents is most often physiologic and of little consequence, although it occasionally represents a significant disturbance in esophageal function.

It is convenient to attempt to organize the many diverse causes of regurgitation and vomiting into age-related categories (Table 78.1). Although overlap is considerable, the most common and serious entities tend to fall into such groupings.

EVALUATION AND DECISION

General Approach

A brief perusal of the long list of causes for vomiting in Table 78.1 serves to emphasize the need for an orderly approach to the differential diagnosis of this symptom. The approach advocated here focuses on three key clinical features: child's *age*, evidence of *obstruction*, and signs or symptoms of *extraabdominal organ system disease*. Other important points to consider include *appearance* of the vomitus, *overall degree of illness* (including the presence and severity of dehydration or electrolyte imbalance), and *associated GI symptoms*.

History

The history should focus on the key elements already listed. The patient's age is often critical because certain important entities (especially those that cause intestinal obstruction) are seen exclusively in neonates, older infants, or children beyond the first year of life. Evidence of obstruction, including symptoms of abdominal pain, obstipation, nausea, and increasing abdominal girth, is sought in addition to vomiting. Other associated GI symptoms may include diarrhea, anorexia, flatulence, and frequent eructation with reflux. The suspicion of significant extraabdominal organ system disease is raised by neurologic symptoms such as severe headache, stiff neck, blurred vision or diplopia, clumsiness, personality or school performance change, or persistent lethargy or irritability; by genitourinary symptoms such as flank pain, dysuria, urgency and frequency, or amenorrhea; by common infectious complaints such as fever, sore throat, or rash; or by respiratory complaints such as cough, increased work of breathing, or chest pain (Tables 78.2 and 78.3).

The appearance of the vomitus (by history and inspection when a specimen is available) is often helpful in establishing the site of pathology. Undigested food or milk should suggest reflux from the esophagus or stomach caused by lesions such as esophageal atresia (in the neonate), gastroesophageal (GE) reflux, or pyloric stenosis. Bilious vomitus suggests obstruction distal to the ampulla of Vater, although it occasionally is seen with prolonged vomiting of any cause when the pylorus is relaxed. Fecal material in the vomitus is seen with obstruction of the lower bowel. Hematemesis usually reflects a bleeding site in the upper GI tract; its evaluation is detailed in Chapter 29.

Physical Examination

The physical examination is directed first toward evaluating the overall degree of toxicity. Does the baby look septic? Is there the inconsolable irritability of meningitis? Are there signs of life-threatening dehydration or concern for symptomatic hypoglycemia? Does the child exhibit the bent-over posture, apprehensive look, and pained avoidance of unnecessary

TABLE 78.1

VOMITING AND REGURGITATION: PRINCIPAL CAUSES BY USUAL AGE OF ONSET AND ETIOLOGY

Newborn (Birth to 2 wk)
- Normal variations
- Gastroesophageal reflux (± hiatal hernia)
- Esophageal stenosis, atresia
- Infantile achalasia
- Obstructive intestinal anomalies
  - Intestinal stenosis, atresia
  - Malrotation of bowel (± midgut volvulus)
  - Meconium ileus (cystic fibrosis)
  - Meconium plug
  - Hirschsprung's disease
  - Imperforate anus
  - Enteric duplications
- Other gastrointestinal causes
  - Necrotizing enterocolitis
  - Cow's milk allergy
  - Lactobezoar
  - Gastrointestinal perforation with secondary peritonitis
- Neurologic
  - Subdural hematoma
  - Hydrocephalus
  - Cerebral edema
  - Kernicterus
- Renal
  - Obstructive uropathy
  - Renal insufficiency
- Infectious
  - Meningitis
  - Sepsis
- Metabolic
  - Inborn errors of urea cycle; amino acid, organic acid, and carbohydrate metabolism (phenylketonuria, galactosemia)
  - Congenital adrenal hyperplasia

Older Infant (2 wk to 12 mo)
- Normal variations
- Gastroesophageal reflux
- Acquired esophageal disorders (corrosive esophagitis ± stricture, foreign bodies, retroesophageal abscess)
- Rumination
- Gastrointestinal obstruction
  - Bezoars, foreign bodies
  - Pyloric stenosis
  - Malrotation (with or without volvulus)
  - Enteric duplications
  - Meckel's diverticulum (complications of)
  - Intussusception
  - Ascariasis
  - Incarcerated hernia
  - Hirschsprung's disease
- Other gastrointestinal causes
  - Gastroenteritis
  - Celiac disease
  - Peritonitis
  - Paralytic ileus
- Neurologic
  - Brain tumors
  - Other intracranial mass lesions
  - Cerebral edema
  - Hydrocephalus
- Renal
  - Obstructive uropathy
  - Renal insufficiency
- Infectious
  - Meningitis
  - Sepsis
  - Urinary tract infection
  - Otitis media
  - Pertussis
  - Hepatitis
- Metabolic
  - Metabolic acidosis (inborn errors of amino acid and organic acid metabolism, renal tubular acidosis)
  - Galactosemia
  - Fructose intolerance
  - Adrenal insufficiency
- Drug overdose
  - Aspirin
  - Theophylline
  - Digoxin
- Respiratory (posttussive)
  - Reactive airways disease
  - Respiratory infection
  - Foreign body (FB)

Older Child (Older than 12 mo)
- Gastrointestinal obstruction
  - Acquired esophageal strictures
  - Foreign bodies, bezoars
  - Peptic ulcer disease
  - Posttraumatic intramural hematoma
  - Malrotation (with or without volvulus)
  - Meckel's diverticulum (complications of)
  - Meconium ileus equivalent (cystic fibrosis)
  - Ascariasis
  - Incarcerated hernia
  - Adhesions (postsurgical, peritonitis)
  - Intussusception
  - Hirschsprung's disease
  - Superior mesenteric artery syndrome
- Other gastrointestinal causes
  - Gastroenteritis, gastritis, duodenitis
  - Gastroesophageal reflux
  - Appendicitis
  - Peptic ulcer disease
  - Pancreatitis
  - Peritonitis
  - Paralytic ileus
  - Crohn's disease
- Neurologic
  - Brain tumors
  - Other intracranial mass lesions
  - Cerebral edema
  - Migraine
  - Motion sickness
  - Postconcussion syndrome
  - Seizures
- Renal
  - Obstructive uropathy
  - Renal insufficiency/renal tubular acidosis
- Infectious
  - Meningitis
  - Urinary tract infection
  - Hepatitis
  - Upper respiratory infection (postnasal mucous drip)
- Metabolic
  - Diabetic ketoacidosis
  - Reye's syndrome
  - Adrenal insufficiency
  - Inborn error of metabolism (urea cycle or fatty acid oxidation defect; acute, intermittent porphyria)
- Toxins and drugs
  - Aspirin
  - Ipecac
  - Theophylline
  - Digoxin
  - Iron
  - Lead (chronic)
- Respiratory (posttussive)
  - Asthma exacerbation
  - Infectious respiratory disease
  - FB
- Other
  - Pregnancy
  - Psychogenic
  - Cyclic vomiting

movement typical of peritoneal irritation in appendicitis? Next, attention is aimed at the abdomen. Are there signs of obstruction such as ill-defined tenderness, distension, high-pitched bowel sounds (or absent sounds in ileus), or visible peristalsis? A complete physical examination must include a search for signs of neurologic, infectious, toxic/metabolic, and genitourinary causes, as well as an evaluation of hydration status (see Chapter 17).

The diverse nature of causes for vomiting makes a "routine" laboratory or radiologic screen impossible. The history and physical examination must guide the approach in individual patients. Some well-defined clinical pictures demand urgent

TABLE 78.2

LIFE-THREATENING CAUSES OF VOMITING

Newborn (Birth to 2 wk)
Anatomic anomalies—esophageal stenosis/atresia; intestinal obstructions (Table 78.1), especially malrotation and volvulus; Hirschsprung's disease
Other gastrointestinal (GI) causes
Necrotizing enterocolitis
Peritonitis
Neurologic—kernicterus, mass lesions, hydrocephalus
Renal—obstructive anomalies, uremia
Infectious—sepsis, meningitis
Metabolism—inborn errors, especially congenital adrenal hyperplasia

Older Infant (2 wk to 12 mo)
Gastroesophageal reflux, severe
Esophageal disorders
Rumination
Intestinal obstruction (Table 78.1), especially pyloric stenosis, intussusception, incarcerated hernia, malrotation with volvulus
Other GI causes, especially gastroenteritis (with dehydration)
Neurologic—mass lesions, hydrocephalus
Renal—obstruction, uremia
Infectious—sepsis, meningitis, pertussis
Metabolic—inborn errors
Drugs—aspirin, theophylline, digoxin

Older Child (Older than 12 mo)
GI obstruction, especially intussusception (Table 78.1)
Other GI causes, especially appendicitis, peptic ulcer disease
Neurologic—mass lesions
Renal—uremia
Infectious—meningitis, sepsis
Metabolic—diabetic ketoacidosis, Reye's syndrome, adrenal insufficiency, inborn errors of metabolism
Toxins, drugs—aspirin, ipecac, theophylline, digoxin, iron, lead

TABLE 78.3

COMMON CAUSES OF VOMITING

Newborn (Birth to 2 wk)
Normal variations ("spitting up")
Gastroesophageal reflux
Gastrointestinal (GI) obstruction—congenital anomalies
Necrotizing enterocolitis (premature birth)
Infectious—meningitis, sepsis

Older Infant (2 wk to 12 mo)
Normal variations
Gastroesophageal reflux
Gastrointestinal (GI) obstruction—especially pyloric stenosis, intussusception, incarcerated hernia
Gastroenteritis
Infectious—sepsis, meningitis, urinary tract infection, otitis media
Posttussive—reactive airways disease, respiratory infection, foreign body
Drug overdose—aspirin, theophylline

Older Child (Older than 12 mo)
GI obstruction—incarcerated hernia, intussusception
Other GI causes—gastroenteritis, gastroesophageal reflux, appendicitis
Infectious—meningitis, urinary tract infection
Posttussive—asthma, infection, foreign body
Metabolic—diabetic ketoacidosis
Toxins/drugs—aspirin, theophylline, iron, lead
Pregnancy

radiologic workup. For example, abdominal pain and bilious vomiting in a child requires supine and upright plain films, as well as a limited upper GI series for evaluation of congenital obstructive anomalies such as malrotation, or a child with paroxysms of colicky abdominal pain and grossly bloody stools requires immediate flat and upright abdominal films, and usually a contrast (air or barium) enema for the likely diagnosis and reduction of intussusception. Other situations require no imaging studies (e.g., a typical case of viral gastroenteritis or a classic history for pyloric stenosis with definite palpation of the pyloric tumor). In many cases, body fluid cultures or serum chemical analyses are essential for making a diagnosis (e.g., meningitis, aspirin toxicity, Reye's syndrome, pregnancy) or for guiding management (e.g., degree of metabolic derangement in pyloric stenosis, diabetic ketoacidosis). For most straightforward, common illnesses (e.g., gastroenteritis, cold with posttussive emesis), laboratory investigation is unwarranted.

APPROACH TO CHILDREN BY AGE GROUPS

With these introductory concepts in mind, we can approach the differential diagnosis of the principal causes of vomiting on an age-related basis. An algorithm for such an approach that uses the key clinical features previously outlined is illustrated in Figure 78.1.

Neonates

A careful history should focus on the perinatal events, onset and duration of vomiting, nature of the vomitus, associated GI symptoms, and the presence of symptoms referable to other organ systems. Newborn babies with the onset of vomiting in the first days of life should always be suspect for one of the common *congenital GI anomalies* that cause obstruction, such as esophageal or intestinal atresia or web, malrotation, meconium ileus, or Hirschsprung's disease. If the vomiting is bilious, bright yellow, or green, an urgent surgical consultation is required. In most cases, a serious and possibly life-threatening mechanical obstruction may be the cause of bilious vomiting. All patients in whom the possibility of GI obstruction is entertained must have immediate flat and upright abdominal films. Other clinical features, such as toxicity, dehydration, and lethargy, usually attest to the length of time of the obstruction and its severity. Except for the later presentations of malrotation, most neonates with a congenital basis for their bowel obstruction will present during their initial nursery stay. Therefore, it is uncommon to see such babies for the first time in the ED. Neonates or infants with malrotation and volvulus may present with abdominal pain (crying, drawing up their knees, poor feeding), with evidence of obstruction (bilious emesis), or an acute abdomen (abdominal distension or rigidity). The diagnosis of malrotation is confirmed by the abnormal

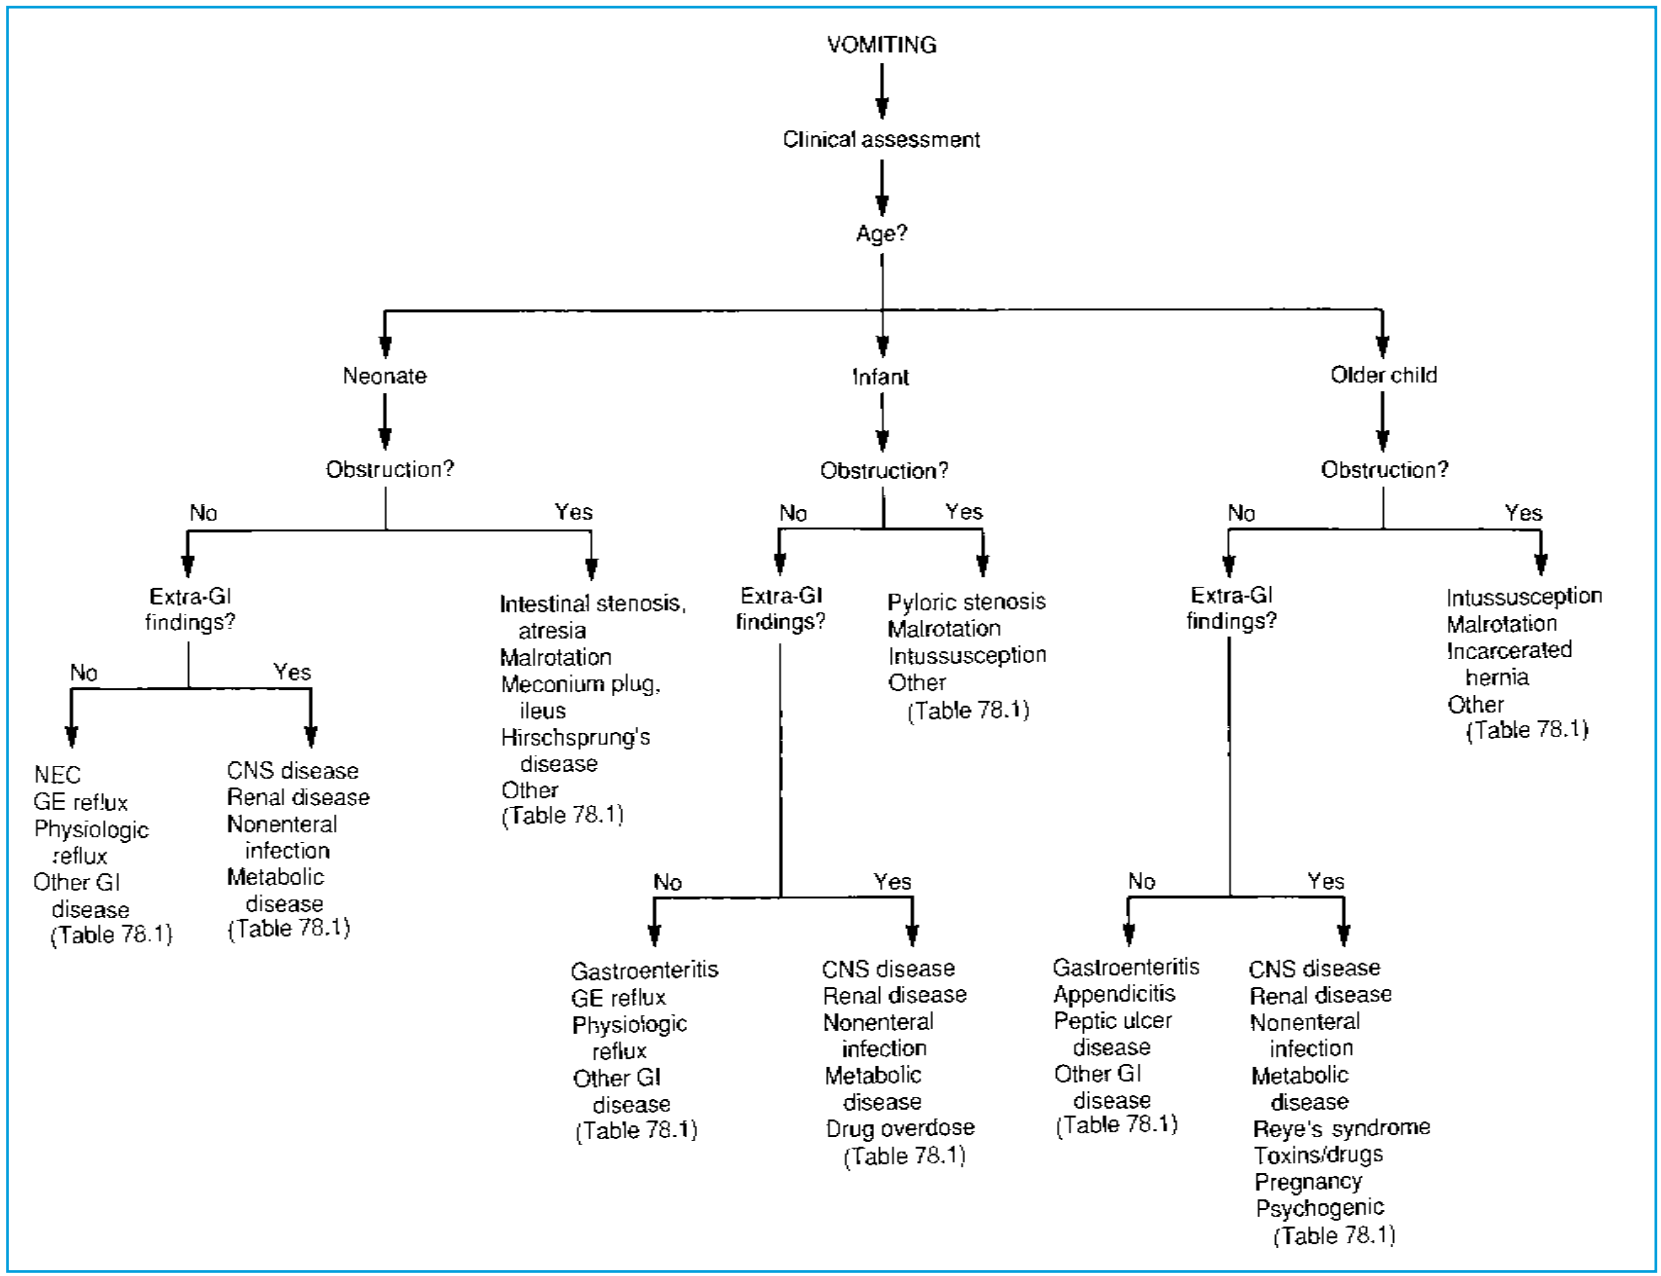

FIGURE 78.1 Differential diagnosis of vomiting. GI, gastrointestinal; NEC, necrotizing enterocolitis; GE, gastroesophageal; CNS, central nervous system.

radiographic location of the duodenal–jejunal junction (upper GI series) and/or the cecum (contrast enema).

Other serious causes of neonatal vomiting that may present to the ED include *infection*, such as meningitis, sepsis, pyelonephritis, or necrotizing enterocolitis (it should be noted that such serious infections are often not accompanied by fever in the neonate); *increased intracranial pressure* (ICP) related to cerebral edema, subdural hematoma, or hydrocephalus; *metabolic acidosis* or *hyperammonemia* caused by the rare inborn errors of amino acid and organic acid metabolism; and *renal insufficiency* or *obstruction*. Such infants usually appear ill, with associated lethargy and irritability; sometimes fever, a full fontanel, a diminished urinary stream, an abdominal mass, or respiratory signs will suggest the correct cause. Obviously, any ill neonate with vomiting, even in the absence of obstruction, also requires hospitalization and prompt evaluation for sepsis and neurologic, renal, and metabolic disease.

Commonly, however, a young infant in the first 2 to 4 weeks of life who appears entirely well is brought to the ED with the complaint of persistent vomiting. The birth history and perinatal course are unremarkable. The baby has gained weight appropriately (usually 5 to 7 oz per week after the first week of life), is vigorous, and has an entirely normal physical examination. Usually, a close description of the "vomiting" (or even better, a trial feeding in the ED) reveals the problem to be *physiologic regurgitation* or *reflux*; so-called spitting up. This is a common (nearly 20% of infants reflux) and insignificant problem, probably representing some normal variation in the developmental maturation of the lower esophageal sphincter (LES). These infants do not exhibit forceful abdominal contractions but rather reflux milk effortlessly into their mouths, which dribbles out, usually when prone, and often with a burp. The degree of reflux may be increased by improper feeding techniques, such as failure to burp the baby, using nipples with holes that are too small, bottle propping, or overfeeding. Observation of a feeding trial and emphasis on good technique suffices for initial management of such babies. Like all newborns, they should be referred for ongoing pediatric care. Most babies outgrow such regurgitation by 6 to 9 months of age, and 95% have resolution of symptoms by 12 months.

Other infants who regurgitate easily may not be managed so easily. Their course may have more significant symptoms of pain, arching, and high volume and frequency of regurgitation, or it may be complicated by distal esophagitis or gastritis, failure to thrive, esophageal–peptic strictures, pulmonary disease, or rarely, apnea or near sudden infant death syndrome, or SIDS, event. Such infants are diagnosed as having *gastroesophageal reflux disease* (GERD), a more severe or pathologic degree of LES dysfunction that is much less common (1:500). Several imaging and physiologic studies may be used to confirm the diagnosis and to correlate a patient's signs and symptoms with episodes of reflux. A 24-hour intraesophageal pH probe is the most sensitive diagnostic test for GE reflux. Based on the patient's history, evaluation of delayed gastric emptying can be done by GE scintiscan, or by an upper GI series to rule out an anatomic cause for the delay. Endoscopy is used to assess suspected complications (esophagitis or stricture); esophageal manometry is primarily a research tool in this disease. Infants with GE reflux should be followed closely by a pediatrician. In uncomplicated GE reflux, reassurance, postural management, and dietary measures are usually adequate. For more severe symptoms or with complications, additional medical management includes the use of histamine H_2 antagonists (ranitidine or famotidine) or gastric acid secretion inhibition with a proton pump inhibitor (omeprazole or lansoprazole). The use of prokinetic drugs has become limited, due to the recall of cisapride for pediatric use (due to the risk of severe cardiac arrhythmias) and the adverse effects of the alternatives, metoclopramide and erythromycin (pyloric stenosis) (dystonic reactions and agitation). GERD that is resistant to vigorous medical therapy (continues to cause serious complications) may be considered for surgical fundoplication (see Chapters 89 and 121).

Older Infant

Infants who present with vomiting after the first few weeks of life may still have intestinal obstruction, but the underlying causes are somewhat different than in the neonate. The important lesions responsible for mechanical obstructions in this age group include congenital hypertrophic pyloric stenosis (HPS), malrotation, intussusception, incarcerated hernia, enteric duplications, and complications of Meckel's diverticulum. Occasionally, other anomalies that might be expected to present in the neonate, such as Hirschsprung's disease, will appear only after several weeks or months of life. In all cases, these conditions have physical findings suggestive of intestinal obstruction and are often specific for the level of obstruction. Having a high index of suspicion for both common and uncommon forms of intestinal obstruction is important to making a timely diagnosis.

The typical infant with *pyloric stenosis* (see Chapter 121) typically appears in the ED at 3 to 6 weeks of age (95% present by 3 months; rarely after 20 weeks) with a chief compliant of projectile vomiting during or shortly after a feeding. The vomiting in pyloric stenosis is typically crescendo in nature, with increasing frequency and severity over days to weeks. In contrast, vomiting caused by GE reflux tends to be relatively consistent over time; in malrotation, vomiting is sudden in onset and can be episodic. The vomitus is nonbilious, reflecting obstruction at the pylorus, and usually voluminous, nearly the entire content of the feeding. The infant may become constipated if vomiting has been of sufficient duration. On examination, an olive-size mass may be palpated (most easily after vomiting has occurred) in the right upper quadrant to the right of the midline and just above the umbilicus. Peristaltic waves may be visualized, moving from left upper to right upper quadrants, again indicating obstruction at the pylorus. Unless the infant is significantly dehydrated, the child is usually vigorous and active, although irritable because of hunger. These infants often develop hypochloremic, hypokalemic metabolic alkalosis, which should be corrected before surgery (see Chapter 100).

The diagnosis of pyloric stenosis is clinical, based on the classic history of projectile, nonbilious emesis, and examination with hyperperistalsis and palpation of a pyloric mass or "olive." Imaging studies [ultrasound (US) or upper GI series] are not necessary if the history and examination are conclusive. In more recent years, however, earlier presentations have resulted in a greater number of infants evaluated before the development of the diagnostic clinical hallmarks, and consequently, an increased reliance on imaging studies to confirm the diagnosis. Early diagnosis has been beneficial with a decrease in the proportion of patients with alkalosis, shortened hospital

stay, and decreased morbidity. US has become the diagnostic modality of choice with characteristic findings in HPS of a thickened pyloric wall (greater than 3 mm) with a lengthened canal (greater than 15 mm). However, some centers have found upper GI series to be more cost-effective because of greater operator experience with the procedure, and therefore, fewer repeat studies, as well as the ability to provide information on other origins of nonbilious vomiting. Endoscopy has more recently been recommended as an adjunct test for complicated cases in which clinical examination, US, and/or upper GI series were inconclusive. Surgical pylorotomy, the standard treatment for HPS, is scheduled as soon as dehydration and metabolic derangements (if present) have been corrected. Medical management with intravenous or oral atropine has been successful in a more recent reinvestigation. Still, a larger, well-controlled trial and cost analysis would be necessary before its use is recommended in place of surgical correction.

Between 2 months and about 5 to 6 years of age, the most common cause of obstruction is *intussusception* (see Chapter 121). Most children develop this disorder between 3 months and 2 years of age; the average was 16 months old in a more recent large series. Early symptoms usually include paroxysms of colicky abdominal pain and vomiting, suggesting a GI illness. Initially, the infant may appear relatively well between attacks, but some children will fall asleep or seem prostrate at these times. Stools may be initially normal, then become positive for occult blood. Within 6 to 12 hours of onset, dark maroon blood may be passed per rectum; this blood is often mixed with mucus earning the descriptive label of "current jelly" stool. However, some infants with intussusception may present primarily with lethargy and decreased responsiveness, without striking GI symptoms (so-called neurologic or painless intussusception). Examination of the abdomen usually reveals a somewhat tender, sausage-shaped mass on the right side. The mass may be more easily appreciated by bimanual rectal and abdominal examination, and a test for occult blood may be positive in the absence of gross blood.

Recommendations for the diagnosis and treatment of suspected intussusception include supine and right-side up decubitus radiographs (decubitus to look for abnormal air-fluid levels, free air, or mass at the hepatic flexure region; supine for signs of obstruction such as dilated bowel loops, paucity of gas, or mass effect). US can also be used if experienced personnel are available. Reduction is attempted by contrast (air or liquid) enema if perforation (free air on radiograph or peritonitis) or shock is not evident. More recent success rates for reduction in pediatric centers using air- or liquid-contrast enemas have improved to the range of 80% to 90%, with some centers reporting their increased success with repeated attempts after short intervals (45 to 60 minutes). Open reduction with laparotomy is reserved for patients with perforation or shock at initial diagnosis or when enema reduction is unsuccessful.

Other important causes of obstruction in the older infant include incarcerated inguinal hernia, volvulus, Hirschsprung's disease, or complications related to Meckel's diverticulum. The presence of an incarcerated hernia will be apparent on examination. Volvulus of the bowel is virtually always associated with bilious vomiting. A good clue to the diagnosis of Hirschsprung's disease is asking, "Has your child ever had a normal (unstimulated) bowel movement?" (see Chapters 13 and 121). The obstructive complications of Meckel's diverticulum include intussusception and volvulus and have similar presentations of these types of obstruction related to other causes.

The principal nonobstructive causes of vomiting in the older infant include GI, neurologic, renal, infectious, and metabolic disorders. Nonobstructive GI disturbances are probably the most common cause for vomiting in this age group. *Viral gastroenteritis*, although usually appearing predominantly as diarrhea associated with vomiting, often begins with a prodromal phase of vomiting alone (see Chapter 92). Physical findings are usually limited to ill-defined and inconsistent abdominal pain and signs of a variable degree of dehydration. Vomiting in older infants is also caused at times by persistent GE reflux, as well as by abdominal disorders uncommon in infancy, such as peptic ulcer disease or appendicitis. Occasionally, vomiting is seen in paralytic ileus related to infection (pneumonia, peritonitis) or electrolyte disorders.

Neurologic causes of vomiting in infancy also include *mass lesions* such as tumor, abscess, and intracranial hematoma (see Chapter 96), as well as *meningitis* and *encephalitis*. There may be evidence of increased ICP: increasing head circumference, bulging fontanel, and split sutures (papilledema is rarely noted during infancy). However, some brainstem tumors cause protracted vomiting by direct effect on the vomiting center without an accompanying increased ICP. Again, it is to be emphasized that meningismus is rarely seen with meningitis in infancy and that signs of increased ICP occur late (see Chapter 92). Early findings include fever, vomiting, lethargy, and irritability, especially the paradoxic irritability of increased crying with parental fondling.

Infections outside the GI and neurologic systems may cause vomiting in infants and, occasionally, in older children. Some of the more important infections are *otitis media* (OM), *urinary tract infection* (UTI), *respiratory infections*, and *viral hepatitis*. Positive physical findings on otoscopic examination are seen in OM, along with mild irritability, and often, fever (see Chapter 92). UTIs may be surprisingly devoid of localizing signs and symptoms in preschool children (see Chapter 124); nonspecific GI complaints, including vomiting and abdominal pain, fever, irritability, and anorexia, may be the only presenting symptoms. Urinalysis and culture provide the specific diagnosis. Vomiting also is a common event after the paroxysms of coughing seen in infants with pertussis (see Chapter 92). It is a common symptom in the prodromal phase of infectious hepatitis, usually preceding the onset of jaundice (see Chapter 89). Abnormal liver function tests substantiate this latter diagnosis.

Renal and *metabolic disorders* also cause vomiting in the older infant. Renal failure, renal tubular acidosis, or rarely, diabetic ketoacidosis may be seen in this age group. Hypoadrenalism, hepatic failure, Reye's syndrome, and inborn errors of metabolism such as galactosemia and fructose intolerance also may present in infancy and may have vomiting as a prominent symptom in an ill-appearing infant.

Occasionally, parental overzealous use of over-the-counter or prescribed drugs in infants will lead to *intoxication*. Drugs that often produce vomiting in excessive doses include aspirin, theophylline, and digoxin; all these intoxications are easily verified by associated signs and symptoms and specific drug levels. The problem of accidental ingestion is discussed later.

An additional rare cause of regurgitation or vomiting in infants, with onset usually at 6 to 12 months of age, is *rumination* (see Chapter 131). This severe psychiatric disorder of

infancy, related to abnormal maternal–infant relationship, may progress to severe failure to thrive and to death. These infants seem to self-induce the reflux, often by gagging themselves, and often appear to partially rechew and reswallow their vomitus.

Older Child

Many of the causes of intestinal obstruction and other important GI diseases described in neonates and older infants, such as volvulus associated with malrotation, Hirschsprung's disease, a meconium ileus "equivalent" in the child with cystic fibrosis, and an incarcerated hernia, may occasionally first appear in the older child. Older children with malrotation and/or volvulus will often have a previous episodic history of vomiting or intermittent colicky abdominal pain. In addition, older children are often subjected to blunt abdominal trauma; persistent vomiting after such injury may reflect obstruction related to a duodenal intramural hematoma or ileus secondary to pancreatitis. Older children with a prior history of intraabdominal surgery may present with obstruction from adhesions as a late complication. Gastroenteritis, as in infants, continues to be the most common cause of vomiting in the older child seen in the ED. Two entities that usually occur in older children, appendicitis and peptic ulcers, are discussed here, although they occur rarely in infancy as well.

Appendicitis (see Chapter 121) in a preadolescent child classically begins with periumbilical, crampy abdominal pain and anorexia, often followed by vomiting. Then the pain shifts to the right lower quadrant and fever may develop. Younger children may deviate from this pattern by exhibiting less specific symptoms early in their illness and a more rapid progression to perforation and generalized peritonitis. As peritoneal irritation becomes well established, the child attempts to minimize any motion to the abdomen. Physical examination usually reveals localized involuntary right lower quadrant guarding and tenderness that, when mild, may be easier to elicit by asking the child to cough or to hop on one foot. In addition, there may be rebound and referred rebound tenderness along with a tender fullness high on the right during rectal examination. Atypical positions of the appendix (e.g., retrocecal, retroileal, pelvic) will be reflected in atypical areas of maximal tenderness, as well as in confusing symptoms such as diarrhea or dysuria (caused by appendiceal inflammation adjacent to colon or ureter/bladder). Pertinent laboratory findings often include leukocytosis with a left shift in the differential count, but a normal white blood cell count in an afebrile patient does not rule out appendicitis. The urinalysis is usually normal. Occasionally, in an atypical patient, abdominal radiographs may be helpful in showing a right lower quadrant fecalith, localized obstruction, a mass effect with a paucity of gas or isolated air–fluid levels in the right lower quadrant, or lumbar spine scoliosis. Appendicitis is a clinical diagnosis, but when the differential diagnosis is difficult or in early or equivocal cases (approximately one-third of patients with appendicitis have been reported to have atypical clinical findings), imaging studies can be helpful. US and computed tomography (CT) have become the modalities of choice in most centers for children in whom clinical diagnosis is not straightforward, but there is a great amount of variability in their utilization. The advantages of US include lower cost, absence of ionizing radiation, and the ability to assess vascularity. It can be particularly helpful in distinguishing tuboovarian pathology or renal pathology from appendicitis. CT scan has become the imaging study of choice in adults; more recent studies show excellent sensitivity of right lower quadrant CT with rectal contrast. In children, findings of higher diagnostic accuracy with CT than US probably reflect less operator dependency. In the case of appendicitis with complications such as perforation or abscess, CT has been noted to offer better delineation of disease extent.

Vomiting as a symptom of *peptic ulcer disease* in children is usually seen in association with abdominal pain (see Chapter 93). In young children, the pain is often nonspecific and not easily related to meals. In adolescents, the pattern becomes more classically related to food or antacids, and may cause nighttime awakening and weight loss. There may be hematemesis and/or melena. The abdominal examination may be normal or reveal mild to moderate epigastric tenderness. A strong clinical suspicion of peptic ulcer disease should be confirmed with an upper GI series or endoscopy. Other inflammatory lesions of the upper GI tract (gastritis, duodenitis, and Crohn's disease) can also cause persistent vomiting.

Genitourinary causes of vomiting in the older child include UTI and obstructive urologic disease. An important additional concern in adolescent girls is early *pregnancy* (see Chapter 48). It is common for such patients to visit the ED with the chief complaint of persistent vomiting (not necessarily only in the morning) for several weeks, and often sexual activity and/or amenorrhea is initially denied. Physical findings at this stage of pregnancy may be subtle. Thus, prolonged vomiting in a postmenarchal girl should be pursued with the appropriate urine or serum gonadotropin assays (see Chapters 47 and 90).

The important extra-GI infectious diseases of the older child that cause vomiting have been discussed for the most part under the neonatal and infantile headings of this chapter. Serious infections localize symptoms more readily in this older age group. Meningitis is usually accompanied by meningismus after the age of 2 years. Lower urinary infections tend to present with dysuria, frequency, and urgency as children approach school age, and pyelonephritis with fever and lower back pain or tenderness. The toddler or school-age child also may vomit with pharyngeal irritation (pharyngitis, postnasal mucous drip) or have posttussive emesis with persistent or severe cough caused by asthma, respiratory infection, or respiratory foreign body.

Neurologic disease that causes vomiting in the older child again represents (primarily) with lesions that cause increased ICP or direct irritation of the medullary vomiting center; they usually lead to papilledema and/or abnormal neurologic findings on examination. One important exception is childhood *migraine* (see Chapter 96). Preadolescent children do not usually present with the classic migraine picture with aura, hemicranial headache, and scotomas. More often, they complain of rare but severe, poorly localized headaches accompanied by nausea and vomiting and followed by sleep. The physical examination between attacks is usually normal. Another common but minor form of vomiting on a neurologic basis (caused by labyrinthine stimulation) would be the propensity to motion sickness.

Metabolic aberrations, including hepatic, renal, and adrenal failure, may cause vomiting in the older child (as well as during infancy). *Ketoacidosis* presenting for the first time

in an as yet undiagnosed diabetic occurs more commonly in older children, especially at school entrance age and later as adolescence begins (see Chapter 86). Vomiting may be the chief complaint of such children, although careful questioning usually uncovers a preceding 3- to 4-week history of polyuria, polyphagia, polydipsia, and at times, weight loss. A fruity breath odor, dehydration, hyperpnea, and varying degrees of altered sensorium are typically present, and a urinalysis and serum glucose determination confirm the diagnosis of diabetic ketoacidosis.

The other important, but now increasingly rare, cause of vomiting is *Reye's syndrome* (see Chapter 89). It is characterized by an acute metabolic encephalopathy and liver disease that presents, typically after a preceding viral illness, with severe recurrent vomiting progressing to varying stages of encephalopathy. Abnormal laboratory data in Reye's syndrome include elevated serum transaminase and ammonia, prolonged prothrombin time, and often, hypoglycemia; bilirubin is usually normal. It has been emphasized that the differential in cases meeting the criteria for Reye's syndrome include Reye's-like syndromes: inherited metabolic disorders and viral and toxic diseases. Because of the substantial morbidity and mortality of Reye's syndrome in the past, the recommendations for the substitution of acetaminophen for aspirin for antipyresis in childhood viral illnesses will most likely continue in the United States until the debate over the association of aspirin in the etiology of these syndromes is settled.

In the discussion regarding older infants, mention was made of occasional inadvertent drug overdose by parents, causing intoxication-related vomiting. In children 1 to 4 years of age, *accidental ingestion* is a common problem. Acute poisonings that cause vomiting as a prominent symptom include aspirin, theophylline, digoxin, and iron sulfate (see Chapter 102). Chronic *lead poisoning* also occurs in this pica-prone age group. Early symptoms of lead intoxication are vomiting, colicky abdominal pain, anorexia, constipation, and irritability. Tragically, many such youngsters have been diagnosed as having nonspecific gastroenteritis syndromes initially, only to return days to weeks later with frank encephalopathy, and ultimately, severe neurologic sequelae. The history of pica and lead paint exposure (peeling paint chips, especially in homes dating back to the 1940s and 1950s) should be sought in every toddler with persistent vomiting. The diagnosis of plumbism can be confirmed with elevated blood levels of lead and erythrocyte protoporphyrins (see Chapter 102).

Cyclic vomiting syndrome is described in a consensus statement as a disorder with recurrent, time-limited episodes of vomiting. It is a diagnosis of exclusion, characterized by an absence of positive laboratory, radiographic, and endoscopic testing. It is often managed by a pediatric gastroenterologist after a prolonged course of primary care and ER visits for disabling nausea and dehydration. The etiology and pathogenesis are unknown, but links with pediatric migraines have been made and postulated mechanisms include episodic dysautonomia, mitochondrial DNA mutations, and/or a heightened hypothalamic stress response.

Finally, the school-age child or adolescent may vomit on a *psychological* basis. Acutely, brief episodes of vomiting may occur with any emotionally disturbing event. Children with school phobia or other significant psychiatric problems may vomit persistently. Adolescents are at risk for self-induced vomiting in the context of the anorexia nervosa and bulimia syndromes (see Chapters 130 and 133). Before the physician attributes the vomiting to a psychological cause, however, a careful history, general examination, and complete neurologic examination are necessary to minimize the likelihood of missing any organic origin. An assessment of disturbed family dynamics, history of emotional disorders, or evidence of depression and/or anxiety during the ED interview may corroborate the suspicion of vomiting on a psychological basis and may warrant a psychiatric referral.

CHAPTER 79 ■ WEAKNESS

NICHOLAS TSAROUHAS, MD, AND JOANNE M. DECKER,† MD

Weakness is defined as an inability to generate normal voluntary force in a muscle or normal voluntary torque about a joint. Although often associated, *hypotonia* is not always synonymous with weakness. Neurologists define hypotonia as decreased resistance to "passive" motion. Not all hypotonic patients are weak; for example, a patient with Down Syndrome may have normal strength (i.e., not weak), yet have decreased tone on physical examination.

PATHOPHYSIOLOGY

Weakness is a reflection of a disease process that may involve any component of the motor neuron unit. These diseases are classically categorized as upper or lower motor unit disorders (Table 79.1). Upper motor neuron disease affects structures extending from the motor strip of the cerebral cortex, through the corticospinal tracts of the spinal cord, to (but not including) the anterior horn cell. Although upper motor neuron disease is generally characterized by increased deep tendon reflexes (DTRs) and spasticity, early in the clinical course there may be flaccid paralysis. Lower motor neuron disease may involve the anterior horn cell, the peripheral nerves, the *neuromuscular junction* (NMJ), or the muscle fibers. In general, it is associated with hyporeflexia, fasciculations, muscle atrophy, weakness, and hypotonia.

DIFFERENTIAL DIAGNOSIS

The *cerebral cortex* can be damaged by *cerebrovascular accidents* (CVAs), which include *cerebral infarctions* and *hemorrhages*. CVAs, while rare (2.1 to 13.1 per 100,000 children per year), cause some of the most catastrophic cases of weakness (Table 79.2). These children usually present with sudden weakness that is most commonly unilateral or asymmetric.

Cerebral hemorrhage is usually due to a *ruptured arteriovenous malformation* (AVM) but may also be caused by a *ruptured aneurysm*. Most AVMs are asymptomatic until rupture, but some children do complain of periodic "migraine-like" headaches. *Brain tumor hemorrhage* may also present acutely as weakness, severe headache, and vomiting.

Cerebral infarctions usually occur in the setting of predisposing factors, which include sickle cell disease, homocystinuria, and hypercoagulable states from antithrombin III, protein C and S deficiencies, and factor V Leiden mutations. Other more common hypercoagulable states include pregnancy, malignancy, infections, or severe dehydration. Substance abuse with cocaine or amphetamines has also been associated with cerebral infarction. *Embolic* causes should be considered in patients with congenital heart disease, mitral valve prolapse, or a history of rheumatic fever.

Transient ischemic attacks (TIAs) often present with resolving weakness. TIAs are defined as transient neurologic deficits referable to a cerebral artery territory in a child whose MRI shows no acute ischemia, but whose history/work-up suggests cerebrovascular disease. Transient focal deficits are common after the cessation of a seizure. This *Todd's postictal paralysis* almost always resolves within minutes to hours after a seizure has ended. It is most important to ensure an intracranial hemorrhage or other mass lesion is not the cause of the focal weakness, however. A head computed tomography (CT) scan is indicated in cases of prolonged postictal paralysis, especially if the mental status remains impaired, or if other focal deficits persist.

Traumatic injuries may seriously damage or compress the spinal cord. *Spinal cord concussion* is defined as a transitory disturbance in spinal cord function secondary to a direct blow to the back. Symptoms may include flaccid paraplegia or quadriplegia, a sensory level at the site of injury, loss of tendon reflexes, and urinary retention. Recovery usually begins within a few hours and is usually complete within a week. *Spinal epidural hematoma* may cause spinal cord compression as the hematoma expands. Emergent magnetic resonance imaging (MRI) scanning is indicated when an epidural hematoma is suspected. Other traumatic injuries include vertebral body compression fractures, dislocations, and spinal cord transections.

Another serious cause of spinal cord compression is *epidural abscess*, which is usually caused by hematogenous spread of bacteria, most commonly *Staphylococcus aureus*, or by direct spread from an adjacent carbuncle or vertebral osteomyelitis. Patients commonly present with fever and back pain, but also headache, vomiting, stiff neck, and bowel and bladder dysfunction. Point tenderness may be elicited over the affected area. The diagnosis is confirmed by MRI, which helps also to distinguish the abscess from a *vertebral discitis*. Similarly, spinal cord tumors are another important cause of spinal cord compression.

Transverse myelitis is an acute demyelinating disorder of the spinal cord. It is frequently attributed to a preceding viral infection, but also may be immune mediated. It presents as an acute episode of fever and back pain at the level of cord involvement. Leg paresthesias and weakness evolve rapidly over the course of 2 days. Asymmetric leg weakness is common. Tendon reflexes may be increased or reduced. Bowel and bladder continence are often lost. The level of myelitis is usually thoracic and is demarcated by a sensory loss. MRI of the spine is required to exclude cord compression.

†Deceased.

Anatomic anomalies of the spine and spinal cord associated with weakness also include the *atlantoaxial dislocations* associated with Klippel-Feil and Down Syndrome. Patients with *Chiari malformations/myelomeningoceles* also have weakness (as well as other deficits). In the growing child, a *tethered spinal cord* may cause weakness and neurologic deficits as the tether causes the spinal cord to stretch. Clumsiness may be the presenting symptom of leg weakness. Bladder control problems are also common.

Juvenile amyotrophic lateral sclerosis (ALS) is a rare hereditary disorder involving upper and lower motor neurons. Similar to "adult" ALS, or Lou Gehrig's disease, it causes spasticity and muscular atrophy. The course is progressive and is ultimately fatal.

Anterior horn cell disease affects the most proximal component of the lower motor neuron unit. Because these diseases affect the motor neurons, sensory function is normal. Reflexes are generally lost early in the course of the disease. Ultimately, muscle atrophy and fasciculations develop. Cranial nerve nuclei are often affected as well.

Poliomyelitis is the classic example of an anterior horn cell disease. Poliovirus is a neurotropic inhabitant of the intestinal tract that produces paralytic diseases by destroying the motor neurons of the brainstem and spinal cord. Initial symptoms include fever, sore throat, and malaise. There appears to be a transient improvement, then fever recurs, with headache, vomiting, and meningeal signs. Extremity and back pain often lead to weakness and paralysis. Usually the weakness is asymmetric, with one limb most affected. Bulbar involvement may lead to compromise of respiratory, autonomic, and circulatory centers of the brainstem, as well as weakness of the muscles of respiration and swallowing.

Fortunately, widespread immunization has virtually eradicated polio from the United States.

A peculiar entity that mimics poliomyelitis is idiopathic *postasthmatic amyotrophy*, or Hopkins syndrome. It presents as a sudden onset of weakness, generally 1 to 2 weeks after an acute asthma attack. Like polio, prognosis is poor, with all patients left with some degree of permanent paralysis.

The three pediatric types of *spinal muscular atrophy* (SMA) comprise a group of autosomal recessive genetic disorders in which the anterior horn cells in the spinal cord and motor nuclei of the brainstem are progressively lost. There is widespread muscle denervation and atrophy. The weakness in SMA may present from birth to adulthood. The weakness is usually a symmetric, progressive, proximal weakness. Cardiac and smooth muscle is usually spared. Bulbar involvement becomes evident as the disease progresses. Late in the course, atrophy and fasciculations of the tongue are seen. DTRs are reduced or absent. There is no sensory loss, intellectual retardation, or sphincter disturbance.

Spinal muscular atrophy I (acute infantile SMA, or Werdnig-Hoffman disease) is the most severe form of SMA. The weakness and severe generalized hypotonia begin before 6 months of age. These patients can never sit alone. Death often occurs by 4 years of age, usually from overwhelming pneumonia. *Spinal muscular atrophy II* (chronic infantile SMA) usually has its onset of weakness between 6 and 18 months. These patients can sit alone, but can never walk. In this "intermediate" SMA, survival to adulthood is expected. *Spinal muscular atrophy III* (mild juvenile SMA, or Kugelberg-Welander disease) usually presents with weakness after 18 months. Many present in late childhood or adolescence. This is the mildest form of the SMAs, as these patients can walk without support.

Neuropathies (primary disorders of the axon or its myelin sheath) usually present as progressive symmetric distal weakness. Weakness and sensory loss may move in a "glove and stocking" fashion. Tendon reflexes are usually lost early. Dysesthesias ("pins and needles" or burning sensations) usually occur in acquired conditions.

Guillain-Barré syndrome (GBS; acute inflammatory demyelinating polyradiculoneuropathy) is the classic acquired immunologic neuropathic disorder. It is the most common cause of acute motor paralysis in children. GBS occurs when activated immune mechanisms, induced by an antecedent viral infection, trigger inflammation and demyelination (see Chapter 96). Many viruses have been implicated including adenovirus, Epstein-Barr virus, cytomegalovirus, human immunodeficiency virus, varicella-zoster virus, measles virus, Rubulavirus (mumps), and vaccinia virus. *Mycoplasma pneumoniae* and *Campylobacter jejuni* infections, as well as some vaccines (i.e. swine flu 1976), have also been implicated.

The most common complaint is weakness, but patients also present with leg and back pain, and in younger children, an abnormal gait. The weakness is usually symmetric and may be ascending or descending. There is often a sensory loss, as well as loss of position and vibratory sense. DTRs are diminished or absent in the weak muscles. Bowel and bladder incontinence, autonomic dysfunction (hypotension), and cardiac dysrhythmias also occur.

Respiratory paralysis occurs in 20% to 30%. Cranial nerve involvement is seen in 30% to 40% of patients, usually manifested by facial weakness or ocular paresis. The Miller Fisher variant of GBS includes the triad of ataxia, areflexia, and ophthalmoplegia. Symptoms of GBS may progress for days to weeks.

Required clinical criteria for diagnosis include a progressive motor weakness of more than one limb and areflexia. Examination of the cerebrospinal fluid demonstrates an elevated protein without pleocytosis (albuminocytologic dissociation). Important diseases to consider in the differential diagnosis include acute cerebellar ataxia, transverse myelitis, toxic neuropathy, tick paralysis, botulism, myasthenia gravis (MG), and acute viral myositis. A chronic form of GBS, chronic inflammatory demyelinating polyradiculoneuropathy, also exists.

Birth trauma may produce traction injuries to the nerve roots causing a restricted pattern of focal weakness. *Erb's palsy*, a proximal (C5/C6) brachial plexus palsy, is the most common brachial plexus injury. These infants assume the "waiter's tip" posture: arm adducted, humerus internally rotated, elbow extended, forearm pronated, wrist flexed. A *Klumpke's palsy*, an injury to the lower trunk (C8/T1) of the plexus, is much rarer. Flaccid weakness of the arms and legs may result from excessive traction on the spinal cord during a difficult delivery.

Heavy metals, such as lead, mercury, arsenic, and thallium, are known neuropathic toxins. Lead, in particular, may cause a distal motor weakness with foot and wrist drop. Drug-induced neuropathies occur with drugs of abuse, as well as pharmacologic medicines. Several antimicrobials (isoniazid, nitrofurantoin, and zidovudine), as well as antineoplastics (vincristine, vinblastine, cytosine arabinoside, and cisplatin), are known to cause paresthesias and muscle weakness. The seas also harbor deadly neurotoxins. Ciguatera and paralytic shellfish poisoning are caused when toxin-elaborating dinoflagellates are ingested by fish or shellfish, which are then eaten by unsuspecting humans. Cone snail stings, blue-ringed octopus bites, sea snake bites, and puffer fish ingestion may also result in life-threatening paralysis.

Acute intermittent porphyria is an autosomal dominant inborn error of metabolism that usually presents after puberty with severe abdominal pain and is accompanied by central and peripheral neuropathies. Motor weakness is more common than sensory symptoms, and the proximal muscles are more affected than the distal musculature. Autonomic dysfunction and mental status changes also occur. Many medications, such as griseofulvin, barbiturates, sulfonamides, and estrogens, are known to trigger attacks. Alcohol has also been implicated in initiating these attacks.

Diseases of the NMJ can be recognized by their cranial nerve abnormalities and autonomic dysfunction. Importantly, sensory function is unaffected. In botulism, *Clostridium botulinum*, a gram-positive anaerobe, produces several potent neurotoxins that prevent presynaptic release of acetylcholine at the NMJ, resulting in descending flaccid paralysis. Preformed toxin may be ingested from improperly home-canned foods or any incompletely cooked food. Botulinum spores are also found in the soils of some areas of the United States, particularly in eastern Pennsylvania and California. There are three distinct clinical presentations of natural disease: infant botulism, classic botulism, and wound botulism (see Chapter 96). In addition, the potential use of botulinum toxin as a weapon of bioterrorism has been described (see Chapter 7).

In *infant botulism*, the bacterial spores are ingested, and then they germinate and colonize in the intestinal tract, leading to in vivo toxin production. Infant botulism has been linked to

TABLE 79.3

ingestion of honey, which has a high rate of contamination by the spores. The spores are also found in soil; consequently, construction sites and rural farming areas have been associated with a higher risk of disease. Peak incidence is between 2 and 3 months of age, but it may be seen in infants up to 9 months old. Despite the similarity in age of presentation of infant botulism and SIDS, no conclusive link has been confirmed. Infant botulism is one of the more common causes of generalized weakness seen in young infants (Table 79.3).

Infant botulism commonly presents with a history of constipation, lethargy, and feeding difficulties. On physical examination, the infants are hypotonic with generalized muscle weakness and a noticeably weak cry. There may be reduced facial expressions, pooling of oral secretions, a decreased gag reflex, ptosis, and dilated pupils that respond poorly to light. A progressive bulbar and descending skeletal muscle weakness ensues, with loss of tendon reflexes over the next several days. Sensory examination is normal. While this subacute presentation is most common, a "sepsis-like" or catastrophic presentation is also possible.

Classic botulism, which is usually seen in older children and adults, is caused by eating food contaminated by the preformed botulinum exotoxin. Even tiny amounts of toxin can produce severe paralysis. Symptoms develop 12 to 36 hours after ingestion of the toxin. These may include nausea and vomiting, followed by blurred vision, diplopia, ptosis, photophobia, and then dysphagia and dysarthria from sequential involvement of cranial nerves. A descending skeletal muscle paralysis follows in many patients—without any sensory involvement.

In *wound botulism*, a wound is contaminated with soil containing the spores of *C. botulinum*. Subsequent production of botulinum toxin results in muscle weakness and bulbar dysfunction 4 to 14 days after the wound has been infected. The severe muscular spasms of generalized *tetanus* ("lockjaw"), caused by *Clostridium tetani*, may initially be confused with botulism, because both are associated with an infected wound. Wound botulism presents similarly to classic botulism, except that no gastrointestinal symptoms are associated.

A less common disorder of the NMJ is juvenile *myasthenia gravis*, which occurs as a result of an antibody-mediated autoimmune reaction against the postsynaptic acetylcholine receptors in skeletal muscle. The sine qua non of MG is muscle weakness provoked by activity and relieved by rest. There is weakness and fatigability of ocular, bulbar, and extremity striated muscles. Most patients present with ptosis. Sensory examination and DTRs are normal.

Ten percent to 15% of babies born to mothers with MG develop *transient neonatal myasthenia*, which is caused by a transient impairment of neuromuscular transmission secondary to the passive transfer of antibodies versus acetylcholine receptors. These babies may present with weak suck or cry, ptosis, dysphagia, generalized weakness, or respiratory distress in the first few hours or days of life. The condition usually resolves in the first few weeks, but occasionally the symptoms may take months to disappear.

Familial infantile myasthenia, or congenital myasthenia, should not be confused with transient neonatal myasthenia. Familial infantile myasthenia is not autoimmune, and these infants are not born to mothers with MG. The defect may be a presynaptic defect in acetylcholine synthesis or release, a synaptic acetylcholinesterase deficiency, or a postsynaptic defect in the acetylcholine receptor. Children with this type of myasthenia also exhibit respiratory muscle weakness, feeding difficulties, ptosis, hypotonia, and limb fatigability.

Paralyzing toxins may also be elaborated by animal life, a dramatic example being *tick paralysis*. This is a toxin-mediated paralysis transmitted from the bite of one of several species of ticks in North America. The dog tick, *Dermacentor variabilis*, and the Rocky Mountain wood tick, *Dermacentor andersoni*, among others, elaborate a salivary gland toxin that most likely acts at the NMJ to induce a rapid, profound, generalized, flaccid weakness. The tick exposure often precedes the paralysis by 5 to 10 days. Although patients may complain of paresthesias, the sensory examination is usually normal. DTRs are absent or decreased. The clinical syndrome is very similar to GBS. Removal of the tick results in dramatic resolution of symptoms.

Organophosphates, which are used in commercial insecticides, inhibit acetylcholinesterases at the NMJ. This leads to the prolonged attachment of acetylcholine at the postsynaptic receptor. Severe muscle cramps and life-threatening weakness ensues. Similarly, children treated with neuromuscular blockers for long periods of time may have exaggerated weakness and remain flaccid for days or weeks after the drugs are discontinued.

Myopathies are primary disorders of muscle fibers. Proximal weakness is the usual presenting feature, and sensory function is normal. *Muscular dystrophy* (MD) is a progressive inherited myopathy caused by defects in structural muscle proteins. These defects result in muscle degeneration and loss of strength. In the two main MDs, Duchenne and Becker, there is a reduction of the structural protein dystrophin. Although MD primarily affects striated skeletal muscle, striated cardiac muscle may also be involved. Four obligatory criteria must be met to diagnose MD: a primary myopathy (not neurogenic), genetic, progressive, and myofiber degeneration.

Duchenne muscular dystrophy (DMD) is an X-linked recessive disorder that presents before the age of 5 years as gait disturbance, frequent falling, waddling gait (hip girdle weakness), and difficulty rising from the floor. The classic "Gower's sign" is commonly seen. Gower's sign denotes using the hands and arms to push up off the floor and then "walking" up the thighs with the arms to straighten into the erect position (because of hip muscle weakness). Boys with DMD often have low-normal intellectual ability. Proximal muscles are weaker than the distal muscles. These children have large, rubbery, hypertrophic calf muscles. Their muscles are generally not

tender. DTRs are present early, but disappear later. Sensory examination is normal. Lab evaluation early in life demonstrates a creatine kinase (CK) that may range from 10 to 10,000 times normal. Death occurs from progressive respiratory insufficiency or infection, dysrhythmia secondary to cardiomyopathy, or congestive heart failure.

Becker muscular dystrophy is also an X-linked recessive MD, but its onset is usually later in childhood, often after age 5 years. Unlike DMD, ambulation is usually maintained into adulthood. Cardiac involvement is rare, and these patients have a normal intelligence. The outlook for survival is good in these children.

Myotonic dystrophy is an autosomal dominant, multisystem disorder that presents from infancy to adolescence with myotonia and distal muscle weakness. Its classic feature, myotonia, is defined as a disturbance in muscle relaxation after contraction. It causes an inability to quickly relax a contracted muscle or release an object. Unlike MG, this myotonia is worsened by rest. A characteristic facial weakness, the "Cheshire cat smile," is an inability for a child to relax a smile.

Dermatomyositis is a systemic angiopathy that is manifested by intravascular occlusion and infarction in muscles, connective tissue, skin, the gastrointestinal tract, and small nerves. It is caused by antibody or immune complex–mediated immune response against a vascular endothelial component. Patients commonly present with fever, anorexia, and fatigue. Later, the rash develops. Of note, the dermatitis usually precedes the myositis. The characteristic "heliotrope" rash is a violaceous discoloration and edema of periorbital and malar areas. Over time, the rash spreads to the extensor surfaces of the joints. Papular, erythematous, scaly lesions over the knuckles are referred to as the "Gottron sign." Arthralgias and cardiac complications are common. *Polymyositis*, a similar disorder, is rare in children.

Infectious processes of the muscle may also present with weakness. *Pyomyositis* is caused by multifocal abscesses associated with a bacterial infection of the muscle. Causative agents include *S. aureus*, streptococci, *Escherichia coli, Yersinia,* and *Legionella* species. Although most common in immunocompromised patients, it can also occur in normal hosts. Clinical presentation includes muscle pain, tenderness, and fever.

Viral myositis is one of the more common causes of acute weakness seen in children (Table 79.4) and commonly follows influenza or some other viral respiratory illness. Several days of prodromal constitutional symptoms lead to severe symmetric muscle pain and generalized weakness. On examination, the muscles are exquisitely tender to palpation. *Myoglobinuria* (positive urinary "dipstick" for heme, in the absence of red blood cells) and *Rhabdomyolysis* (markedly elevated serum creatinine kinase) sometimes complicate viral myositis. Viral myositis resolves with rest, adequate hydration, and analgesics.

TABLE 79.4

COMMON CAUSES OF ACUTE WEAKNESS IN CHILDREN

Viral myositis
Guillain-Barré syndrome
Medications/toxins
Tumors
Seizures

Trichinosis is the most common parasitic disease of skeletal muscle. It occurs when *Trichinella spiralis* is ingested in inadequately cooked meat (usually pork). Most patients are asymptomatic, but some develop constitutional symptoms (fever, headache, abdominal pain, and diarrhea) along with myalgias and generalized weakness. Cysticercosis and toxoplasmosis may have similar presentations.

Myopathies may also be caused by various metabolic abnormalities. Hyponatremia, hypocalcemia, and hypochloremia are frequently associated with weakness. High, low, or normal potassium levels have been described with distinct familial syndromes that present with weakness. These autosomal dominant *periodic paralysis syndromes* may present from infancy to adolescence. Attacks of weakness may be precipitated by rest–shortly after exercise. Mild attacks last for less than an hour, whereas severe attacks can cause flaccid paralysis for many hours. During attacks, the serum potassium is high or low, and electrocardiogram changes sometimes occur.

Rhabdomyolysis and myoglobinuria may occur from excessive physical exertion, prolonged seizures, viral syndromes, toxic exposures, and envenomations. Along with weakness and muscle tenderness, patients present with dark or tea-colored urine that tests positive for heme on dipstick, with few or no red blood cells seen on urinalysis. The serum CK is very elevated. Myoglobinuria may lead to renal insufficiency or failure. Uremia may also lead to muscle weakness.

Inborn errors of metabolism, such as defects in glycogen metabolism (acid maltase deficiency, or Pompe disease), and disorders of lipid or mitochondrial metabolism may also cause weakness. Hyperthyroidism/hypothyroidism, hyperparathyroidism/hypoparathyroidism, and hyperadrenalism/hypoadrenalism are just a few of the endocrinologic causes of myopathies. Even exogenous steroid use has been implicated in myopathies. Corticosteroids are commonly associated with a usually mild, proximal, "steroid myopathy" 4 to 14 days after therapy is started.

Critical illness neuromuscular disease is the term given to patients who develop weakness or paralysis during the course of sepsis or multisystem organ failure, or when exposed to steroids or neuromuscular blocking drugs. This may manifest as a polyneuropathy, or as an acute myopathy. It is an unusual entity that has been best described in adults.

Several disorders are difficult to classify in the conventional neuroanatomic and pathophysiologic manners. *Benign congenital hypotonia* is the term given to an infant with generalized hypotonia but without major weakness. Biopsy, electromyogram, and all other studies are normal. Most children spontaneously improve. Alternating hemiplegia and acute hemiplegic migraine are poorly understood disorders that present with acute onset hemiplegia. Acute hemiplegic migraine may be associated with CVAs later in life.

Finally, patients with weakness secondary to a conversion disorder demonstrate a striking lack of concern for their impairment. They may complain of severe pain without concomitant sympathetic signs. Their examination is often illogical both anatomically and physiologically. Patients with a

"paralyzed leg" who are suspected to have a conversion disorder should be tested for the presence of the "Hoover sign." With the patient supine, the patient is asked to raise the "paralyzed" leg. The contralateral (unaffected) leg should push down on the bed (on top of the examiner's hand) to strain to raise the weak "paralyzed" leg. A positive "Hoover sign" demonstrates no volitional effort on the patient's behalf to actually try to raise the leg. This may indicate malingering.

In summary, there are a wide range of diagnostic possibilities for the child presenting with weakness. Although the neuroanatomic classification system followed above is most helpful pathophysiologically, an easy-to-remember mnemonic, which represents the major disease processes categorized by type of pathologic injury, might also be useful to the clinician. This mnemonic is VITAMINS (Table 79.5), with *V* representing *v*ascular events; *I* *i*nfectious, *i*mmunologic, and *i*nflammatory diseases; *T* *t*rauma and *t*oxins; *A* *a*natomic conditions; *M* *m*yopathies and *m*etabolic disturbances; *I* *i*diopathic disorders; *N* *n*europathies and *n*eoplasia; and *S* seizures.

EVALUATION AND DECISION

The diagnostic evaluation, of course, always starts with a complete history. The acuity and severity of weakness onset are critical features in guiding one's diagnostic approach (Fig. 79.1). A history of a severe or sudden deterioration (Fig. 79.2) should lead one to consider catastrophic processes such as cerebral infarctions, ruptured AVMs, or hemorrhaging brain tumors. After appropriate stabilization, emergent imaging (CT/MRI) and subspecialty consultation (neurology/neurosurgery) is mandatory. Patients with transient, less fulminant presentations may be experiencing a TIA or Todd's postictal paralysis.

A history of spinal cord trauma is commonly associated with minor concussions, but more severe edema and hematomas may rapidly lead to paralysis. Similarly, vertebral column fracture/dislocations may also be devastating. Birth trauma is usually obvious and may present with findings ranging from subtle limb weakness (Erb's palsy) to complete quadriplegia from a spinal column distraction injury.

Other conditions are manifested by less sudden, but still relatively acute onset, over hours to days (Fig. 79.3). Constipation and feeding difficulties, followed over a day or two by facial and extremity weakness in an infant strongly implicate infant botulism. A recent tick bite coupled with an acute progression of paralysis makes tick paralysis the likely diagnosis. A descending paralysis in a patient with a skin wound could be a case of wound botulism, whereas ingestion of improperly prepared or undercooked foods would suggest classic botulism or trichinosis. Fish ingestion with concomitant vomiting and other gastrointestinal symptoms might implicate ciguatera or paralytic shellfish poisoning.

A thorough history of medication use or toxin exposure is always important. Many pharmacologic medications have weakness and paresthesias as an adverse effect. Certain drugs can trigger an attack of acute intermittent porphyria. Drugs of abuse, as well as heavy metals, are associated with both weakness and mental status changes. A mild steroid myopathy is quite common, whereas a rare postasthmatic amyotrophy has

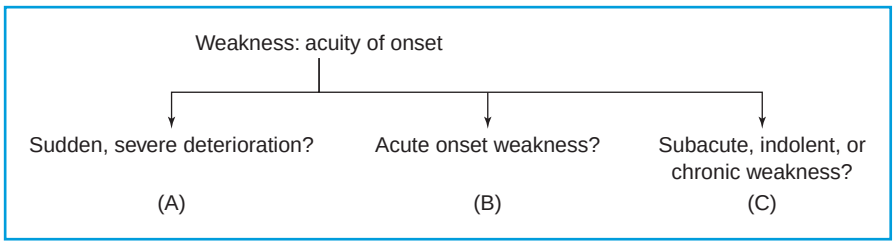

FIGURE 79.1 Diagnostic approach to weakness.

been described in asthmatics irrespective of steroid use. Critical illness neuromuscular disease may occur in the context of steroid use, but should be considered in all severely ill children who require intensive care.

Patients who develop delayed onset of weakness after a prolonged seizure might have rhabdomyolysis with resultant myoglobinuria. Rhabdomyolysis (CK levels greater than 5 times normal, or greater than 1000 IU/L) may also occur after viral syndromes, strenuous physical activity, heat stroke, cocaine abuse, sympathomimetic overdoses, neuroleptic malignant syndrome, and serotonin syndrome. These patients may have a history of dark or tea-colored urine. Urinary heme dipsticks of lesser than 2+ have a lower risk of going on to acute renal failure.

Weakness that is worse after activity (and better with rest) should suggest MG. Patients with hypokalemic/hyperkalemic periodic paralysis, however, have their attacks initiated by rest shortly after exercise. Similarly, the weakness of myotonic dystrophy is worsened by rest. Patients with autoimmune disorders are more prone to myasthenic syndromes and dermatomyositis.

A history (or recent history) of fever suggests infectious (abscess, pyomyositis, viral myositis) and inflammatory (dermatomyositis) disorders. Headache is usually associated with viral processes such as myositis, but may also herald an AVM, an acute hemiplegic migraine, or brain tumor (the latter, especially if associated with emesis upon awakening or cranial nerve palsies). Back pain is common with GBS, an epidural abscess, and transverse myelitis. Abdominal pain should prompt consideration of food poisoning, such as botulism, but is also characteristic of acute intermittent porphyria.

A subacute, indolent, and/or chronic course of muscle weakness (Fig. 79.4) suggests neuropathies and myopathies. This weakness is almost always first noticed in the legs because parents will report clumsiness or gait disturbance as their initial concern. Furthermore, many neuromuscular disorders affect the legs before the arms. Although the history commonly revolves around the child's ability to walk, run, play, and climb stairs, questions should also be directed toward activities of daily living such as hair combing, buttoning, coloring, and writing. The physical examination starts with observation of the child's ability to walk, run, sit, and stand. The classic "Gower's sign" of MD denotes proximal pelvic weakness as the child adopts the prone position before standing and uses his hands to "walk" up his thighs. Toe walking and heel walking assess for gastrocnemius muscle and anterior compartment muscle weakness, respectively. Muscle strength of all the major muscle groups should be carefully assessed and documented (Table 79.6).

To further test the arm muscles, have the child suspend himself above the floor in the "push-up" position. In general, myopathies such as MD present with proximal greater than distal muscle weakness, in contradistinction to neuropathies where the opposite is usually true. Although most disorders have symmetric muscle weakness (GBS, MD, SMA, botulism), some diseases are commonly associated with asymmetric muscle weakness (transverse myelitis, polio). A novel bedside measure of bulbar muscle fatigue has been dubbed the "Slurp" test. Children are given a 4-oz cup of water with a flex straw and are encouraged to drink the water as quickly as possible until the "slurping" sound at the end. This test, which has been used in children with MG, has been shown to

be valuable for identifying patients with bulbar muscle compromise and for monitoring these children during times of decompensation.

Inspection of the muscles should be carried out for the atrophy and fasciculations common in lower motor neuron diseases, such as SMA. Hypertrophy and large "doughy" muscles suggest the muscular dystrophies. Muscle tenderness suggests inflammation or infection, such as would be found with a bacterial pyomyositis or a viral myositis. Focal tenderness of the back may be a clue to an epidural abscess or transverse

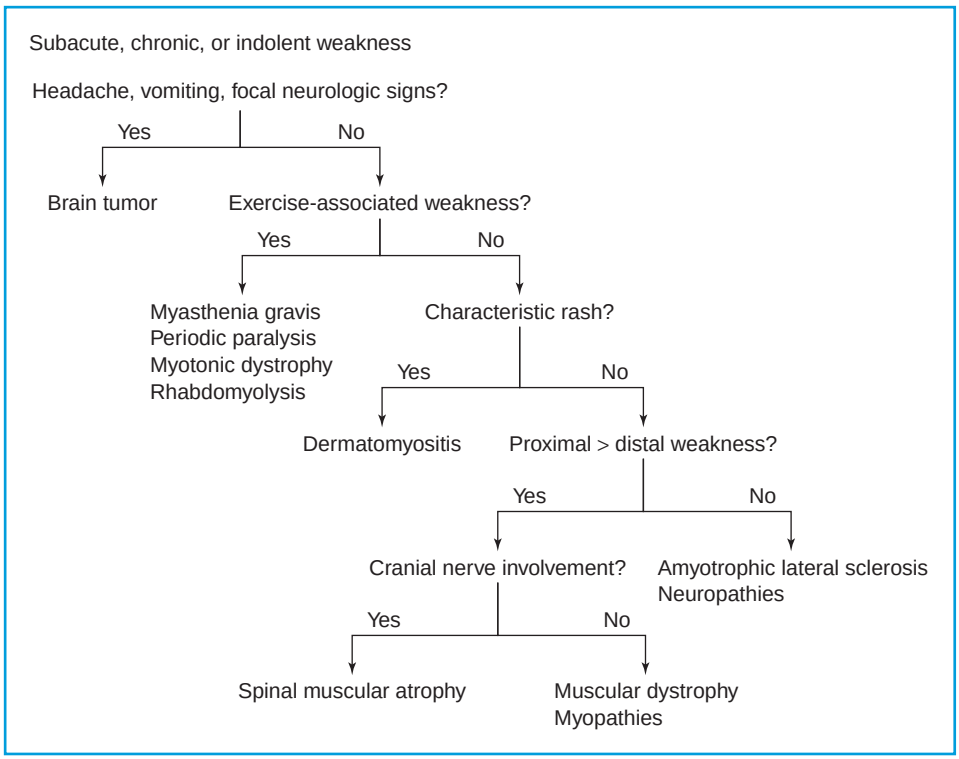

FIGURE 79.4 Approach to subacute, indolent, or chronic weakness.

myelitis. Myotonic muscles that fail to fully relax would implicate myotonic dystrophy.

After the general muscle examination, the neurologic examination continues with the assessment of the cranial nerves. Diseases where cranial nerve involvement is most notable include GBS, SMA, MG, and infant botulism. Ptosis is common to both MG and infant botulism, while multiple prominent cranial nerve palsies are most often seen with infant botulism. Sensory involvement is usually seen in GBS and transverse myelitis, whereas MG, MD, SMA, and botulism usually spare the senses. The DTRs are diminished in GBS, MD, botulism, and tick paralysis, whereas the DTRs are normal in MG.

The rest of the physical examination also yields important clues. Meningismus suggests polio, or an epidural hemorrhage or abscess. An abnormal cardiac examination may be present in GBS, MD, dermatomyositis, periodic paralysis, uremia, and acid maltase deficiency (Pompe's disease). The characteristic heliotrope rash is the hallmark of dermatomyositis. Finally, when the examination is illogical or does not correspond to anatomic or physiologic principles, one should consider a conversion disorder or malingering.

In conclusion, weakness can be a vexing presenting complaint. The differential diagnosis is extensive and the disease processes complex. Although Figure 79.1 outlines a diagnostic approach, as always in emergency medicine, therapeutics should precede diagnostics when the patient is in existing or impending crisis. Patients with acute neurologic, respiratory, or circulatory compromise should have meticulous attention paid to their stabilization first. Trauma patients require adequate cervical spine immobilization to prevent further injury. Once the patient is stable, a careful history and physical will usually narrow the diagnostic field. Furthermore, select diagnostic laboratory and imaging studies may often assist in the search for the definitive diagnosis. Finally, subspecialty consultation and inpatient hospitalization are often indicated for these challenging patients.

CHAPTER 80 ■ WHEEZING

VINCENT J. WANG, MD

Wheezes are whistling or musical adventitial sounds that are the hallmark of lower airway constriction and/or obstruction. Whereas rales or crackles are discontinuous or intermittent popping noises, wheezes are continuous sounds most frequently heard during expiration. The most common diseases causing wheezing in children are bronchiolitis and asthma, but the differential diagnosis is broad, and the causes are often multifactorial. An episode of wheezing may occur at least once in 20% of infants younger than 1 year of age, and in almost 50% of children younger than 6 years of age, but less than 15% of children will develop asthma. This chapter presents an organized approach to the diagnosis of conditions associated with wheezing in children beyond the newborn period.

PATHOPHYSIOLOGY

Obstruction to air flow is the common denominator in all conditions that produce wheezing. Wheezing usually results from obstruction of the intrathoracic lower airways (bronchioles) and less commonly by narrowing of the trachea or bronchi. Obstruction of the lower airway passages may be anatomic or physiologic and is the result of extrinsic airway compression or intrinsic airway narrowing. Intrinsic airway narrowing may be caused by bronchial or bronchiolar constriction, inflammation, and/or intraluminal airway blockage. It may also be caused by a combination of these factors simultaneously, as in asthma. When wheezing is audible during the inspiration and expiration phases of respiration, wheezing is more likely to be caused by extrinsic airway compression. In contrast, when wheezing is predominantly expiratory, intrinsic airway narrowing is more likely to be the cause. Table 80.1 provides a pathophysiologic classification of conditions that cause wheezing in children. Some of the diagnoses overlap, however.

DIFFERENTIAL DIAGNOSIS

Table 80.2 lists the life-threatening causes of wheezing, and Table 80.3 outlines the relative prevalence of conditions that may present acutely with wheezing, divided into age groups.

Common Conditions

Bronchiolitis is an acute viral infection of the lower respiratory tract caused predominantly by respiratory syncytial virus (RSV). Other causes include human metapneumovirus, parainfluenza virus, adenovirus, influenza virus, coronavirus, and rhinovirus. Occurring primarily in epidemics between November and March, bronchiolitis primarily affects infants 2 to 12 months of age but may occur in children as old as 2 to 3 years of age. Older children and adults usually have minor upper respiratory symptoms, but may also present with wheezing. Proliferation of cells and submucosal edema lead to obstruction of the bronchioles. Rhinorrhea and a low-grade fever typically accompany a prominent staccato-like cough and a variable degree of respiratory distress. The concurrence of respiratory symptoms in other family members is common. Degree of severity is multifactorial, with factors such as maternal smoking, prematurity, congenital heart disease, reactive airway disease, and others contributing to the individual patient's response to the viral infection.

Asthma is a chronic inflammatory disorder of the airways, characterized clinically by *recurrent* exacerbations involving symptoms of coughing and/or wheezing. Acute asthma attacks are usually triggered by respiratory infections, allergens, and irritants such as cigarette smoke or particulate air pollution. Patients with asthma have a higher incidence of associated atopic diseases, which include allergic rhinitis, conjunctivitis, and atopic dermatitis. Immediate family members are also more likely to be affected by asthma and atopic disease. Although many hesitate to make the diagnosis of asthma in a child younger than 2 years of age, many asthmatics had had their first episode of wheezing before this age. However, 60% of those that wheeze before 3 years of age will not wheeze by school age. In addition, it is unknown if bronchiolitis predisposes patients to develop asthma, or if the response to bronchiolitis is different for a patient who is allergy prone. Also, bronchiolitis may occur in patients who have asthma.

Less Common Conditions

Other infectious causes of wheezing include viral or bacterial pneumonia. Most cases are preceded by several days of upper respiratory tract symptoms and fever. Physical examination will usually reveal tachypnea, retractions, rales, and/or wheezes. Auscultatory findings are often localized rather than diffuse. The most common causes of pneumonia are viral, with RSV being most common, followed by human metapneumovirus, parainfluenza virus, influenza virus, and adenoviruses. Bacterial causes include *Streptococcus pneumoniae, Mycoplasma pneumoniae, Chlamydia pneumoniae,* group A *Streptococcus,* and *Staphylococcus aureus*. *S. pneumoniae* has been the most common bacterial agent, but the incidence has decreased since the widespread utilization of the conjugate pneumococcal vaccine.

Bronchitis
Histoplasmosis

Miscellaneous Causes
Laryngeal cleft (chronic aspiration)
Pulmonary edema (congenital heart disease, congenital heart failure, hypoalbuminemia, nephrotic syndrome, pneumonia, acute respiratory distress syndrome, inhaled toxic agents, sepsis, drowing/near-drowning, uremia, lymphatic insufficiency, pancreatitis, pulmonary embolism)
Immunodeficiency (severe combined immune deficiency, combined IgA and IgG2 deficiency, B-cell deficiency)
Cystic fibrosis
Immotile cilia syndrome
Psychogenic wheezing

BPD, bronchopulmonary dysplasia; CLD, chronic lung disease; TEF, tracheoesophageal fistula; GE, gastroesophageal.

Pulmonary aspiration is a less common cause of wheezing that occurs in several fairly characteristic clinical circumstances. In otherwise healthy children, the abrupt onset of respiratory distress, associated with an episode of coughing, choking, or gagging, suggests the pulmonary aspiration of a foreign object (see Chapter 28). Foreign-body aspiration is typically seen in toddlers, although older infants may aspirate solid food particles or small objects placed within their reach. Rarely, an older child may also aspirate food particles or other objects. The aspiration of a small object or food substance may not be witnessed, and thus, may go unrecognized for weeks or months until persistent lower respiratory symptoms trigger a search for an underlying cause. In these circumstances, persistent cough, wheezing, and sometimes recurrent fever is associated with an area of consolidation and/or collapse on radiograph. These symptoms fail to resolve despite seemingly appropriate medical therapy for presumed asthma and/or pneumonia.

Recurrent aspiration of food or gastric contents is usually seen in infants younger than 1 year of age, or in older patients with severe developmental delay or neuromuscular disease. Disordered swallowing and esophageal motility, and gastroesophageal (GE) reflux, typically contribute in varying degrees to the recurrent aspiration that occurs in these patients. Repeated aspiration is also seen in children with tracheostomies and in children with structural anomalies of the tracheolaryngeal complex or an H-type tracheoesophageal fistula. Patients with chronic recurrent aspiration may develop wheezing and respiratory distress in the absence of a well-defined episode of choking or severe coughing because many such patients have depressed cough reflexes or experience "microaspiration." Fever often accompanies pulmonary aspiration, reflecting associated chemical inflammation or infection of the tracheobronchial tree.

TABLE 80.2

LIFE-THREATENING CAUSES OF WHEEZING

Asthma
Bronchiolitis
Foreign-body aspiration
Pulmonary hemorrhage
Mediastinal tumor
Congestive heart failure
Chemical pneumonitis
Anaphylaxis

Wheezing attributable to an allergic reaction or anaphylaxis (rare) is also of sudden onset and may be accompanied by one or more other clinical findings that include urticaria, angioedema, stridor, and hypotension. When wheezing is the only finding, an allergic reaction or anaphylaxis may be suspected when the onset of respiratory difficulty is associated with Hymenoptera envenomation, medication, food ingestion, or another allergic precipitant. This type of wheezing typically responds promptly to epinephrine administration and/or to bronchodilator therapy.

Transient wheezing may also occur with smoking and air pollutant exposures. Adult patients who smoke cigarettes may present with wheezing. In extension, adolescents who smoke may also wheeze. Wheezing and bronchiolitis have also been associated with passive smoke exposure, and has been shown to increase with increased maternal smoking. Air pollution containing particulate matter less than or equal to 10 microns in diameter, nitrogen dioxide, nitrogen oxide, and carbon monoxide have been associated with wheezing, as well as exacerbation of other causes of wheezing.

Infants and young children with a history of prematurity, assisted ventilatory support, oxygen dependence, and chronic

TABLE 80.3

radiographic changes for a variety of conditions occurring in the newborn period may have wheezing caused by bronchopulmonary dysplasia (BPD). Patients without a history of prematurity may also have chronic lung disease (CLD). CLD is the common term referring to infants and children who develop chronic respiratory problems beginning in the neonatal period. This condition is the childhood equivalent of chronic obstructive pulmonary disease and represents a pathophysiologic continuum that includes varying degrees of structural damage and airway inflammation. Although gradual improvement in lung function occurs during infancy and early childhood, bronchial hyperactivity and recurrent episodes of wheezing may persist until later in childhood. Other coexisting problems associated with prematurity such as brain damage, tracheostomy dependence, and GE reflux may complicate the respiratory pathophysiology in patients with BPD or CLD.

Even though the diagnosis of bronchitis is more commonly associated with adult patients, children may develop a nonspecific bronchial inflammation associated with various viral agents. The pathophysiology is similar to bronchiolitis and may be preceded by upper respiratory symptoms. Cough is usually prominent and may be followed by wheezing.

Rare Conditions

Cardiovascular abnormalities are one of many uncommon causes of wheezing in children. Small airway edema in the setting of congestive heart failure or airway impingement by enlarged cardiovascular structures are the usual pathophysiologic mechanism. Most cardiac conditions are associated with other abnormal physical findings, including cyanosis, murmurs, abnormal pulses, poor perfusion, or signs consistent with congestive heart failure. A congenital vascular ring or sling may cause wheezing secondary to extrinsic airway compression. Abnormal cardiac physical findings are generally absent in patients with a vascular ring/sling, although concomitant esophageal compression may result in dysphagia. A right-sided aortic arch is associated with this anomaly.

In addition to respiratory tract involvement, patients with cystic fibrosis (see Chapter 99) will often exhibit steatorrhea and failure to thrive because of pancreatic insufficiency and malabsorption. Cystic fibrosis may be included on the state's newborn screening examination, but testing is not universal, and the screening test does not have 100% sensitivity. Similar to the respiratory tract presentation of cystic fibrosis, patients with the immotile cilia syndrome also develop repeated sinusitis and otitis media, often in association with situs inversus viscerum and bronchiectasis (Kartagener's syndrome).

Wheezing may result from pulmonary edema, which may be caused by congenital heart disease and congestive heart failure. However, pulmonary edema may also be caused by other disease processes, such as pneumonia, acute respiratory distress syndrome, and hypoalbuminemic states, such as nephrotic syndrome and liver failure. Hydrocarbon aspiration, leading to a chemical pneumonitis, may also cause pulmonary edema.

Children with various defects in host defense mechanisms often present with recurrent wheezing and bacterial

pulmonary infections. Children with cell-mediated or humoral immune deficiency syndromes can have opportunistic infections or repeated extrapulmonary infections, including meningitis, otitis media, otitis externa, furunculosis, and mucocutaneous candidiasis.

Other uncommon causes of wheezing include extrinsic tracheobronchial compression by an enlarged lymph node or tumor (see Chapter 97). Mediastinal or hilar lymph node enlargement may be the result of leukemia, lymphoma, histoplasmosis, sarcoidosis, or a mycobacterial or fungal infection. Mediastinal tumors that are most likely to produce pulmonary symptomatology include neuroblastoma, pheochromocytoma, ganglioneuroma, thymoma, teratoma, or thyroid carcinoma. The oncologic causes may also metastasize to the lungs and cause extrinsic compression of the airways.

Congenital structural anomalies of the respiratory tract, including bronchogenic cysts, cystic malformations of the lung, congenital lobar emphysema, intrinsic stenosis, and webs, are among the rarest causes of wheezing in children. Respiratory symptoms typically begin in the neonatal period or early infancy. The predominant clinical features will be determined by the site of abnormality within the tracheobronchial tree. Stridor and a croupy cough are typical of laryngotracheal constriction, whereas wheezing and recurrent pneumonia are more characteristic of bronchial narrowing. Respiratory findings generally worsen with intercurrent respiratory infection and may accentuate with crying and activity. Some diagnoses are discovered only with persistence of symptoms, necessitating radiographic evaluation.

Bronchiectasis is the common end result of various causes leading to this irreversible bronchial dilatation. The most common cause is cystic fibrosis, but bronchiectasis may also be caused by immotile cilia syndrome, immune deficiency syndromes, congenital causes, and infection (measles, pertussis, and tuberculosis). Cough is prominent, accompanied by purulent sputum production.

Occasionally, an adolescent patient may present with moderate to severe respiratory distress that is unresponsive to beta agonist therapy. Consideration should be given to precipitating factors and the diagnosis of psychogenic wheezing. These patients may generate wheezing noises in their larynx.

Other rare conditions are listed in Table 80.3.

TABLE 80.4

MAJOR CAUSES OF WHEEZING WITH ASSOCIATED CLINICAL FEATURES

Causes	Associated clinical features
Bronchiolitis	Age <3 yr. Upper respiratory symptoms November through March occurrence Concurrent upper respiratory symptoms in close contacts
Asthma	Recurrent episodes Family history of asthma History of atopy Upper respiratory symptoms Environmental trigger (weather change, etc.)
Pneumonia	Upper respiratory symptoms Fever Unilateral wheezing/rales/decreased breath sounds
Foreign-body aspiration	Age >6 mo Choking episode associated with onset of symptoms Abrupt onset or prolonged symptoms despite appropriate therapy Unilateral wheezing or decreased breath sounds Developmental delay, mental retardation History of tracheal surgery/tracheostomy Swallowing disorder, gastroesophageal reflux
Anaphylaxis	Sudden onset Accompanying urticaria, angioedema, stridor, or hypotension New exposure or Hymenoptera envenomation
Congestive heart failure/cardiac disease	History of failure to thrive Heart murmur, hepatomegaly, poor perfusion Cardiomegaly
Cystic fibrosis	History of failure to thrive Recurrent respiratory tract infections Steatorrhea

EVALUATION AND DECISION

History

Thorough history-taking is the key to arriving at an accurate diagnosis in a child with wheezing. In particular, consideration of the age at onset, course and pattern of illness, and associated clinical features provide a useful framework for approaching a differential diagnosis (Figs. 80.1 and 80.2).

In patients with respiratory distress, a focused history pertaining to life-threatening causes of wheezing (Table 80.2) may be necessary based on an abbreviated version of the aforementioned figures. Such a battery of questions may resemble the following: (i) How acutely did the symptoms present? (ii) Has this occurred before? (iii) Does anyone in the family have asthma? (iv) Are there concurrent upper respiratory symptoms? (v) Was the patient choking or did he or she become cyanotic? (vi) Is there any history of cardiac disease or failure to thrive? Table 80.4 reviews salient features of common disorders that cause wheezing.

The onset of wheezing in the neonatal period is associated with congenital structural airway anomalies, although a history of prematurity, mechanical ventilation, and oxygen dependence is more suggestive of BPD or CLD. The *first episode* of wheezing in an otherwise healthy infant in association with cold symptoms indicates bronchiolitis, especially if the episode occurs between November and March. Recurrent episodes of wheezing precipitated by colds and a variety of other triggers are the hallmark of asthma. However, recurrent

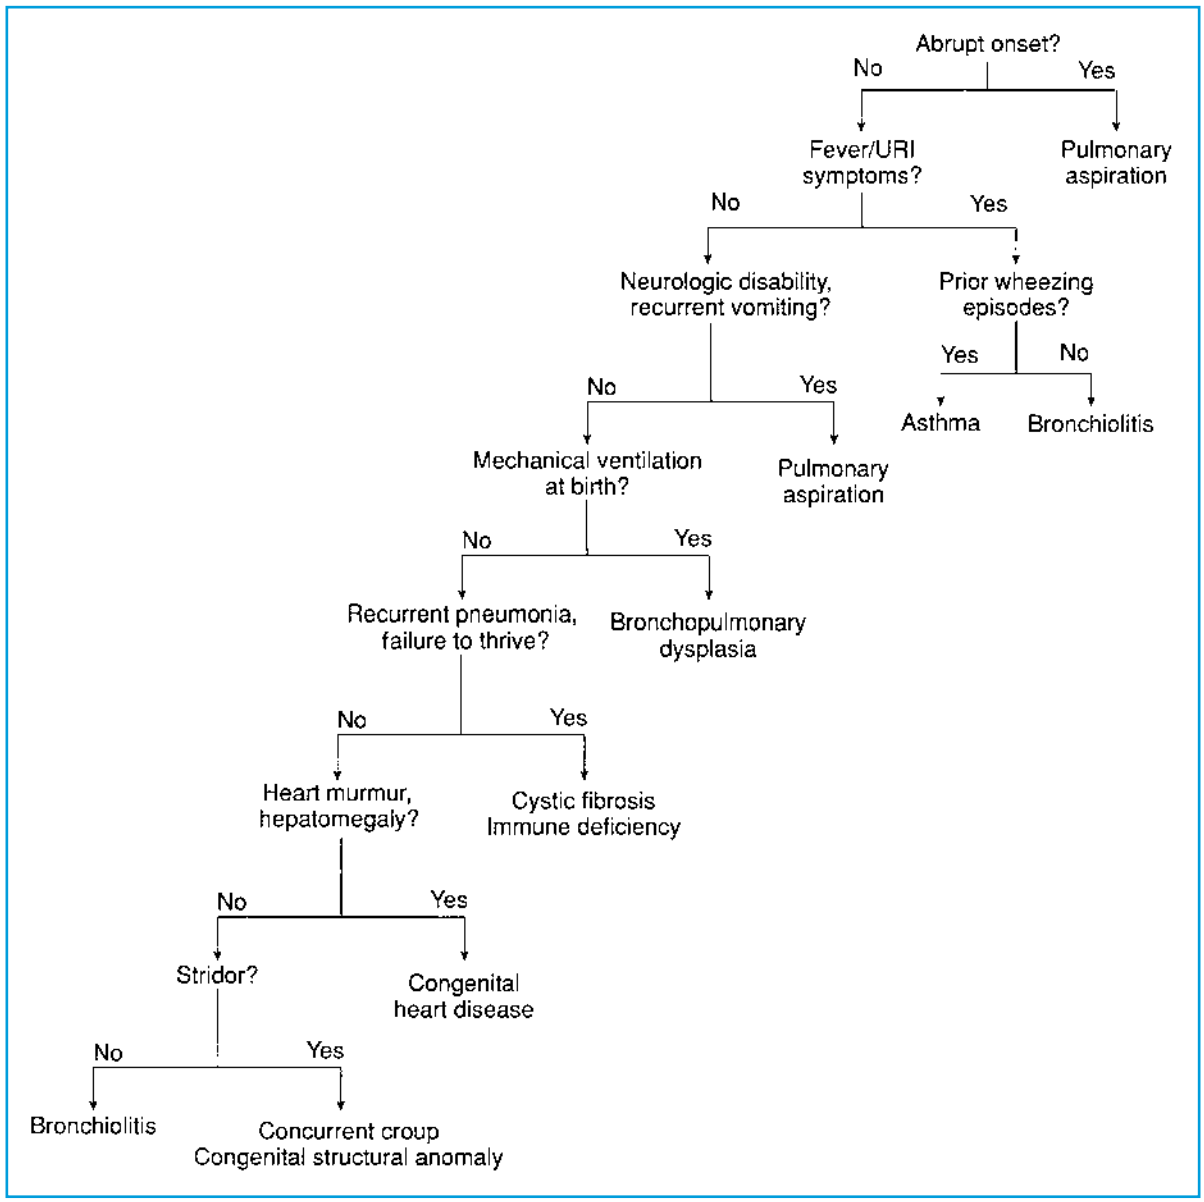

FIGURE 80.1 Approach to wheezing in children younger than 1 year. URI, upper respiratory infection.

wheezing beginning in infancy, or "difficult to control asthma" at any age, should lead to a consideration of cystic fibrosis, GE reflux, recurrent pulmonary aspiration, a retained airway foreign body, immune deficiency, and other diagnoses. Persistent wheezing at any age suggests mechanical airway obstruction from a variety of causes, including congenital airway narrowing, pulmonary foreign body, and compression by a mediastinal tumor. The sudden onset of wheezing is characteristic of pulmonary aspiration, an allergic reaction, or anaphylaxis.

As indicated previously, the diagnosis of a chronic wheezing disorder, such as asthma, relies on the identification of recurrent episodes of obstructive lower airway disease. Subtle manifestations of asthma are often misinterpreted as episodes of bronchitis, pneumonia, or bronchiolitis. Accordingly, it is often useful to ask if the child has ever had any of these or other "breathing problems," or has ever been treated with a "breathing medicine." In a large longitudinal study from Tucson, major risk factors for asthma included eczema or a parental history of asthma, and minor risk factors included wheezing between viral illnesses, nonviral rhinitis, and eosinophilia.

Cough as a salient feature in patients with obstructive lower airway disease cannot be overemphasized (see Chapter 14). In fact, in many patients with asthma, recurrent cough may be the predominant presenting clinical feature and wheezing may be absent despite careful lung auscultation because it is characteristic of cough variant asthma. Further inquiry might reveal that a patient usually experiences severe or persistent bouts of coughing in association with colds or that coughing is the cause of recurrent nighttime awakening.

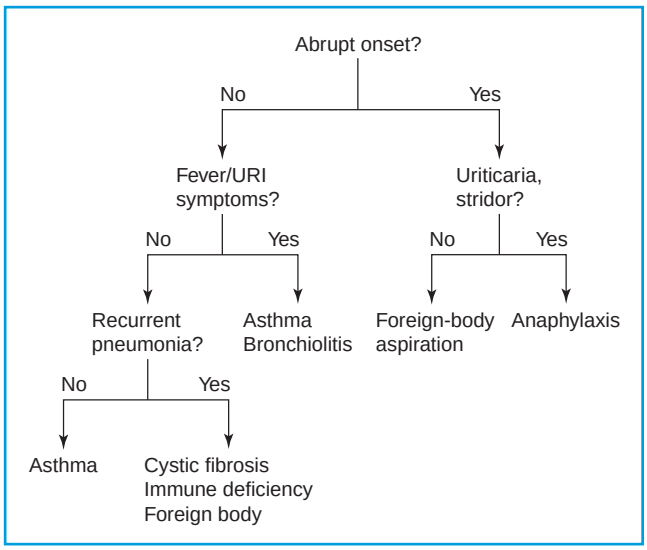

FIGURE 80.2 Approach to wheezing in children 1 year or older. URI, upper respiratory infection.

Physical Examination

Wheezing must be distinguished from other causes of "noisy breathing" in children, including the stridor of upper airway obstruction (see Chapter 72), the stertor of nasal congestion, and audible rhonchi. Because of the dynamic flexibility of airway structures, these clinical features of airway obstruction vary in accordance with the respiratory phase. Accordingly, upper airway collapse and stridor are worse on inspiration, whereas lower airway narrowing and wheezing are accentuated on expiration. Moreover, sounds originating in the upper airway passages (e.g., stridor, stertor) are transmitted with uniform quality and intensity across both lung fields. In contrast, wheezes tend to be polyphonic in pitch and distributed somewhat unevenly in intensity and location. This auscultatory asymmetry reflects the variation in airway narrowing that typically occurs from one lung segment to another. Conversely, wheezes consistently limited to a single lung field suggest a localized obstructive process, such as a foreign body, pneumonia, or an extrinsic mass lesion.

The intensity of wheezes and their pitch and duration are a function of the degree of airway narrowing and the velocity of airflow at the site(s) of obstruction. In patients with minimal airway obstruction, wheezing may be difficult to detect. When such instances are suspected, forced exhalation may reveal low-pitched wheezes limited to the end of expiration. Subtle wheezes can be accentuated further by combining forced exhalation with simultaneous manual compression applied by the examiner in the anteroposterior dimension of the chest (so-called "squeezing the wheeze").

As airway narrowing and minute ventilation increase, wheezes become louder and higher pitched. However, as airway obstruction becomes progressively more severe, airflow and wheezes will diminish proportionately. A "quiet chest" in the face of significant respiratory distress may indicate respiratory failure. Conversely, in patients with reversible bronchospasm, air exchange and wheezes are often noted to increase in response to bronchodilator therapy.

The clinical evaluation of a patient with obstructive lower airway disease will invariably reveal a prominent cough. To the experienced clinician or parent, this cough will usually be perceived as having a characteristic whistling or "wheezy" quality that is distinct from the "seal-like" barky cough of croup. Physical examination of the wheezing child may also reveal inspiratory and expiratory crackles, which are far more often attributable to subsegmental atelectasis than to an associated pneumonia and parenchymal consolidation.

Auscultation of the neck may be used to determine the source of wheezing. Wheezing heard only in the chest, and not the neck, is more likely to be associated with intrathoracic airway obstruction, whereas wheezing heard over the neck, but not in the chest, is more likely associated with upper airway causes of wheezing, such as psychogenic wheezing.

DIAGNOSTIC TESTS

Only a limited number of diagnostic modalities are needed to support the emergency department (ED) evaluation of the wheezing child. Many other necessary investigations can be performed as part of a subsequent inpatient or outpatient workup. The primary measurement that should accompany any patient with respiratory complaints is pulse oximetry, which measures oxygenation. Indeed, many would consider this a standard measurement with vital signs. Noninvasive end-tidal carbon dioxide measurements may also be made to assess ventilation. A chest radiograph may assist in identifying disease complications such as pneumonia, atelectasis, pneumothorax, or pneumomediastinum. A chest radiograph may also help diagnose heart disease, mediastinal masses, and radiopaque foreign bodies of the airway and esophagus. Varying degrees of hyperaeration, bronchiolar thickening, and subsegmental atelectasis are the most common radiographic findings in patients with bronchiolitis or asthma. When bronchiolitis or asthma are suspected, a chest radiograph can usually be avoided if the patient is afebrile and has little to no respiratory distress. The available data do not support the utility of obtaining a chest radiograph for all patients with their first episode of wheezing.

When bronchiolitis is a suspected cause of wheezing, no further diagnostic testing is required. But in cases of uncertainty, it may be helpful to identify RSV in nasopharyngeal secretions by performing a rapid immunoassay while the patient is in the ED. The diagnosis of asthma can be supported by demonstrating improvement in clinical response or peak flow measurements after bronchodilator treatment. Other patients with asthma may benefit from formal pulmonary function evaluation or bronchial challenge testing performed at a later time.

Patients suspected of having aspirated oropharyngeal or gastric contents should have plain radiographs taken of the chest. Nonspecific findings consistent with lower airway obstruction generally precede the appearance of infiltrates. Patients believed to have recurring episodes of pulmonary aspiration subsequently should have further testing to identify swallowing dysfunction, GE reflux, or actual tracheobronchial soiling. Such inpatient or outpatient tests might include a barium esophagram, esophageal pH monitoring, esophageal

endoscopy and biopsy, or radionuclide scintigraphy. Fiberoptic bronchoscopy may be required to diagnose patients with a tracheoesophageal fistula.

An immediate and aggressive workup is always justified in patients suspected of having an airway foreign body (see Chapter 28) on the basis of acute and sudden symptomatology. In this setting, chest radiographs are usually normal, although occasionally they can demonstrate a radiopaque object, the faint outline of a radiolucent foreign body, segmental atelectasis, or a focal area of hyperinflation. Patients with a persistent lower airway foreign body are more likely to show focal collapse and consolidation that is evident on standard chest roentgenograms. Bilateral decubitus views, inspiratory and expiratory radiographs, or airway fluoroscopy may be used to provide additional diagnostic information. Bronchoscopy is the procedure of choice both from a diagnostic and therapeutic perspective when a foreign body is strongly suspected.

The diagnosis of BPD or CLD is established on the basis of chronic respiratory symptoms superimposed on a background of neonatal lung disease. Nevertheless, a chest radiograph characteristically shows hyperexpansion and streaky or patchy infiltrates, punctuated by areas of alternating local hyperaeration and atelectasis. Comparison to previous radiographs is often helpful in distinguishing chronic changes from acute processes.

Newborn screening could identify most children with cystic fibrosis, but screening is dependent on the state standards. Nevertheless, infants with recurrent wheezing and those with failure to thrive associated with chronic diarrhea should be referred for sweat chloride or DNA testing.

A patient suspected of having congenital or acquired heart disease should have an electrocardiogram and a chest radiograph performed in the ED. Definitive diagnosis generally requires echocardiography. A barium swallow, computed tomography scan, or magnetic resonance imaging are usually sufficient to diagnose the presence of a vascular ring or sling, although angiography or magnetic resonance angiography may be necessary for exact anatomic definition.

APPROACH

The evaluation of a wheezing child begins with an immediate assessment of the degree of respiratory distress and consideration of the need for general supportive measures. Patients with suspected respiratory failure should be managed aggressively, as outlined in Chapters 1, 5, and 68. Clinical features suggestive of impending respiratory failure include severe respiratory distress, agitation or lethargy, dusky mucous membranes, signs of autonomic excess (tachycardia, diaphoresis, peripheral vasoconstriction), poor air movement on lung auscultation, pulse oximetry reading of less than 90%, and elevated noninvasive end-tidal carbon dioxide measurements. Blood gas analysis will also aid in the determination of respiratory failure, although this may not be necessary.

Supplemental oxygen should be offered promptly to any patient with respiratory distress and adjusted to maintain a pulse oximeter reading of 93% or greater. Higher altitude medical centers may accept lower pulse oximetry readings. In otherwise healthy children with no feeding difficulty or respiratory distress, recent American Academy of Pediatrics recommendations suggest that a pulse oximeter reading of 90% or greater is acceptable for patients with bronchiolitis. Patients suspected of having reversible bronchospasm should be given a bronchodilator such as albuterol by inhalation, while further evaluation and management are proceeding according to the priorities established earlier in this chapter.

Expeditious management is essential in patients with poor baseline pulmonary function because they can develop respiratory failure quickly. Such patients include children with significant BPD/CLD and advanced cases of progressive chronic lung disorders such as cystic fibrosis. Moreover, careful titration of inspired oxygen concentration is important in patients with chronic respiratory insufficiency to avoid respiratory drive suppression.

CHILDREN YOUNGER THAN 1 YEAR OLD

An algorithm for elucidating the cause of wheezing in the child younger than 1 year old is presented in Fig. 80.1. It is important to note that some diagnoses more commonly presenting after age 1 year may present before 1 year as well. The abrupt onset of wheezing, often immediately preceded by an episode of choking, gagging, or vomiting, is highly suggestive of pulmonary aspiration of a foreign body. If subacute in presentation, accompanying fever or upper respiratory symptoms may point to bronchiolitis or asthma, which may be preceded by these symptoms. Most young infants who present with a first episode of wheezing have bronchiolitis. A similar complex of physical findings in an older infant with a history of bronchiolitis or wheezing and clear improvement after bronchodilator administration is characteristic of asthma.

The remaining disorders are often found in infants who have overt evidence of chronic or severe underlying illness and who typically present with recurrent or persistent episodes of wheezing and respiratory distress. Pulmonary aspiration of gastric contents may occur in young infants and in children with neurologic disability, as well as the occasional otherwise healthy child or adolescent. A report of mechanical ventilation at birth and/or a prolonged neonatal intensive care unit admission may be a clue to BPD or CLD. Recurrent pneumonia, failure to thrive, and steatorrhea are characteristic of infants with cystic fibrosis, whereas pneumonia in association with repeated extrapulmonary infection is suggestive of an immune deficiency. A heart murmur and other clinical findings consistent with congestive heart failure are indicative of congenital heart disease and pulmonary edema. Wheezing accompanied by stridor commonly indicates the coexistence of viral croup but may reflect intrinsic congenital airway narrowing, such as tracheobronchomalacia or extrinsic compression by a mediastinal structure. In the absence of any of the clinical clues listed, the first episode of wheezing in an otherwise healthy child, especially when it occurs during the winter months, is most likely to represent bronchiolitis.

CHILD 1 YEAR OR OLDER

After 1 year of age, congenital diagnoses in children become less prominent, and the evaluation may be thought of similarly with some differences, as noted in Table 80.3. As with the first

age group, it is important to note that overlap occurs with each of these age groups. After age 3, symptoms are most likely attributable to asthma, but rare conditions occur in all age groups. Figure 80.2 outlines an algorithmic approach to the more common causes of wheezing in the child who is older than 1 year. The sudden onset of respiratory distress and wheezing associated with an episode of choking and coughing is likely to indicate foreign-body aspiration, particularly in a toddler who has been eating or playing with a small object. An abrupt onset of wheezing may also accompany stridor, urticaria, and hypotension in the older child with an allergic or anaphylactic reaction. When symptoms present subacutely, associated cough and rhinorrhea suggest the diagnosis of bronchiolitis in the toddler 1 to 3 years of age, but most recurrent episodes of wheezing represent asthma. Typically, asthma exacerbations are precipitated by a concurrent upper respiratory infection, weather change, or allergic trigger, and the patient may show responsiveness to bronchodilator administration. Less commonly, recurrent episodes may represent an exacerbation of CLD, whereas nonrecurrent episodes may be caused by pneumonia or bronchitis.

Wheezing and recurrent pneumonia in multiple pulmonary segments are characteristic of patients with defects in host defense mechanisms, such as cystic fibrosis, an immune deficiency syndrome, or the immotile cilia syndrome. Children in this age group who present with these disorders usually have a history of lower respiratory illness that began in infancy, as well as other signs and symptoms suggestive of chronic disease. Repeated pneumonia in the same pulmonary segment in an otherwise healthy child that begins in late infancy or in early childhood is likely to represent a previously unrecognized bronchial foreign body. In the absence of any of the clinical clues previously listed, the first episode of wheezing in an otherwise healthy child is likely to represent asthma.

It is imperative that *all* patients with wheezing receive outpatient follow-up with their primary care provider or, in some instances, with a specialist. With few exceptions, follow-up evaluation should take place within a day to a week of the ED visit.

CHAPTER 81 ■ WEIGHT LOSS

CYNTHIA R. JACOBSTEIN, MD, MSE

Weight loss occasionally prompts a visit to the emergency department (ED). More commonly, it is an important physical examination finding in a patient presenting with another complaint. Acute weight loss is most commonly caused by a negative fluid balance occurring in the face of illness and can be life threatening. These problems have special importance to the emergency physician. Chronic weight loss may result from a number of medical and nonmedical causes leading to inadequate nutrition. Any complaint of weight loss, or documented weight loss, is a significant finding that demands careful evaluation and follow-up.

PATHOPHYSIOLOGY

The health of infants and children depends on a balanced intake of fluid and nutrients that serve as building blocks for new tissue. The major determinants of body weight are water and the organic fuels, carbohydrates, protein, and fat. Weight loss occurs when the daily energy balance becomes negative for one of these determinants (Fig. 81.1). Overall, during childhood, the major cause of weight loss is protein-energy intake inadequate to meet the energy demands of cell metabolism and tissue synthesis. Causes include decreased energy intake, normal energy intake with increased metabolic requirement, and normal energy intake in the face of malabsorption or impaired use. During acute illness, fluid loss in excess of intake, in the presence of protein-energy malnutrition, is the most common cause. Water losses occur primarily not only through the gastrointestinal (GI) tract but also through the urine and skin. Fever, infection, trauma, and thermal injury all cause a dramatic increase in metabolism that is rarely balanced with intake. During chronic illness, a cyclic pattern of adequate intake alternating with starvation results in gradual weight loss over time.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of weight loss is extensive and can be thought of as broad mechanistic categories including inadequate fluid and/or energy intake, decreased absorption, excessive wastage, and increased catabolism or abnormal energy use (Table 81.1). Multiple mechanisms may come into play for a given case of weight loss. The single most common cause of acute weight loss in all age groups is dehydration that occurs in conjunction with an acute infectious illness. In infants and toddlers with chronic weight loss or lack of appropriate weight gain, failure to thrive (FTT), or undernutrition, is usually identified in the first 3 years of life. This is a complex disorder resulting from physical and/or psychosocial problems. In older patients with chronic weight loss, an underlying medical or psychiatric illness is more likely than in infants (Table 81.2). In some instances, the exact diagnosis is not made at the time of the ED visit, but a workup may be initiated and an appropriate referral should be made.

A few life-threatening diseases associated with weight loss must be separated out from conditions that carry no immediate risk (Table 81.3). Severe dehydration in the presence of gastroenteritis or other acute illness may be catastrophic in any age group (see Chapter 17). In young infants, several disease states need to be considered. The salt-losing form of congenital adrenal hyperplasia (CAH) presents with anorexia, vomiting, dehydration, and progressive weight loss. In female infants, virilization of the external genitalia provides a clue to the diagnosis; however, this is lacking in male infants. The characteristic electrolyte abnormality of hyponatremia and hyperkalemia, and the rapidity of onset of the patient's illness, supports the diagnosis of CAH (see Chapter 86). Inborn errors of metabolism cause a wide variety of symptoms, but poor feeding, anorexia, vomiting, weight loss, and lethargy are typically present (see Chapter 94). Those presenting in the first weeks of life are severe and fatal if the correct diagnosis is not made. These disorders may masquerade as (or be complicated by) sepsis, hypoglycemia, hypocalcemia, or GI obstruction, but an inborn error must always be considered in neonates presenting with weight loss. Clinical deterioration in a previously normal baby, history of fetal death, or consanguinity increases suspicion. Infants and young children with congenital immune deficiency syndromes have a significant component of weight loss and wasting, in addition to repeated infections, seborrheic dermatitis, alopecia, chronic diarrhea, and hyperplastic joints. Infants with acquired immunodeficiency syndrome often lose weight before diagnosis. Both groups of children with immunodeficiency are at risk for life-threatening infections. Congenital heart diseases and pulmonary diseases are also associated with poor growth and may require short-term intervention.

In older children, a few diseases associated with weight loss are acutely life threatening and include adrenal crisis, diabetes mellitus with ketoacidosis, severe dehydration, and eating disorders. Older children and adolescents with Addison's disease have gradual onset of fatigue and weakness, anorexia, weight loss, and low blood pressure. If the diagnosis is not made, adrenal crisis may supervene, leading to circulatory failure, which may be rapidly fatal. Evidence of hyperpigmentation (particularly around the genitalia, nipples, axilla, and umbilicus) provides a clue to the diagnosis. Ketoacidosis is the initial manifestation in many children with diabetes; these children often give a history of weight loss in the presence of polyphagia, polydipsia, and polyuria. Eating disorders may lead to electrolyte abnormalities and concomitant dysrhythmias.

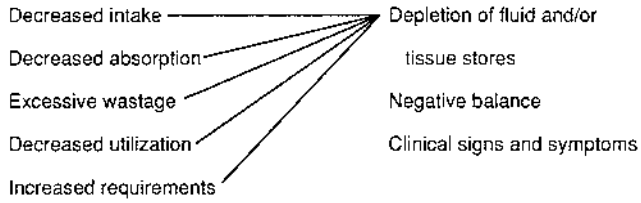

FIGURE 81.1 Pathophysiology.

EVALUATION AND DECISION

General Approach

A thorough history and physical examination are key components in the evaluation of the patient with weight loss. Consideration of the child's age and the severity and duration of the weight loss, along with the presence of other systemic symptoms and specific physical examination findings, help narrow the extensive differential diagnosis. Many diagnoses are exclusive to specific age groups. For the emergency physician, severity is an important consideration because sudden losses are more suggestive of life-threatening disorders that require prompt recognition and treatment.

Acute weight loss (occurring in less than 2 weeks) is most often caused by anorexia, poor fluid and energy intake, increased losses, and increased metabolic need in association with an intercurrent illness. Weight loss is a sensitive indicator for dehydration and commonly occurs in the presence of any significant febrile illness. In this setting, the history includes an estimation of intake, losses, and increased need for fluid and energy intake. The types of losses pinpoint the location of GI pathology. The presence of other symptoms consistent with an acute infectious process substantiates the cause. Circulatory compromise suggests severe depletion (see Chapters 3 and 17) or adrenal crisis (see Chapter 86).

Chronic weight loss (occurring over more than 2 weeks) results from a combination of factors including anorexia, poor utilization or malabsorption, and increased requirements, as well as health consequences imposed by the underlying disease state. When considering the cause of chronic weight loss, broad categories exist, including loss (i) secondary to a medical cause (underlying infection, absorptive defect, inflammatory, or neoplastic disease); (ii) related to a psychosocial or psychiatric cause; or (iii) resulting as a consequence of both

TABLE 81.1

DIFFERENTIAL DIAGNOSIS OF WEIGHT LOSS

Decreased intake	
Anorexia of acute or chronic disease	Major affective disorders
Diencephalic tumor	Anorexia nervosa
Neuromuscular disease	Mental retardation
Congenital syndromes	Failure to thrive
Hypopituitarism	Superior mesenteric artery syndrome
Dieting	Diabetes insipidus
Drug use	Iron deficiency
Gastroesophageal reflux	Plumbism
Constipation	
Decreased absorption	
Pancreatic insufficiency	Enterokinase deficiency
Cystic fibrosis	Amino acid transport defect
Shwachman syndrome	Abetalipoproteinemia
Bile salt deficiency	Hypobetalipoproteinemia
Mucosal abnormalities	Lymphangiectasia
Lactose intolerance	Acute infectious gastroenteritis
Celiac disease	Parasite gastroenteritis
Liver disease	Familial chloride diarrhea
Postinfectious malabsorption	Milk allergy
Inflammatory bowel disease	
Excessive wastage	
Gastroenteritis	Pyloric stenosis
Gastroesophageal reflux/ vomiting/rumination	Secretory diarrhea
Short bowel syndrome	
Hernia/vomiting	
Bulimia	
Increased requirements/Abnormal use	
Chronic infection (e.g., tuberculosis, urinary tract infection)	Inborn errors of metabolism
HIV infection	Addison's disease
Congenital immune deficiencies	Congenital adrenal hyperplasia
Collagen-vascular disease	Hyperthyroidism
Congenital/acquired heart disease	Diabetes mellitus
Chronic pulmonary disease	Hyperthermia
Neoplasm	
Renal insufficiency	
Renal alkalosis/acidosis	
Bartter's syndrome

Pyloric stenosis	

problems. Once again, the importance of a thorough history and physical examination cannot be overemphasized. A complete review of systems, in search of fever, night sweats, arthritis, abdominal pain, and/or diarrhea, dermatitis, and other constitutional symptoms, helps the physician reach the diagnosis. A detailed dietary and feeding history (including frequency, types, and amounts of foods ingested) is invaluable. The attitude of the child and family toward food and eating habits should be explored. An estimation of energy intake is attempted from a record of intake the day preceding the interview. Formula preparation and juice consumption are important historical pieces for babies. Gross overestimation of intake often indicates a psychosocial cause for the poor growth because of an inexperienced parent, poor parent-child interaction, and/or multiple caregivers. A search for a cause of family stress or dysfunction, economic problems, and available resources is essential. The presence or absence of symptoms of depression (poor school performance, disturbed sleep, loss of appetite, and apathy) is also important.

A complete and careful physical examination with attention to vital signs, state of hydration, and findings suggestive of specific disease states (e.g., pallor, jaundice, murmur, and/or cyanosis, clubbing, lymphadenopathy, dermatitis, hyperpigmentation, abdominal mass and/or tenderness, oral ulcers, anal skin tags, arthritis, neurologic abnormalities) provides useful clues. Nutritional inspection includes an evaluation of body fat, muscle mass, hair, skin, and nails. Physical signs associated with specific vitamin deficiencies are nonspecific and occur late in the course of malnutrition. Dysmorphic features should be noted and a thorough neurologic examination should be performed. Infants should be observed nursing or being bottle-fed, with attention to any gagging, choking, reflux, or respiratory distress.

Measurements of weight, recumbent length in babies younger than 2 years, standing height in children older than 2 years, and head circumferences in those younger than 3 years are necessary components of the physical examination. Normal growth is present when sequential measurements consistently lie within the 5th to 95th percentiles on standard growth charts from the National Center for Health Statistics (NCHS). Revisions of the 1977 NCHS growth charts were published in 2000 by the Centers for Disease Control and Prevention (CDC) and are available at the CDC Web site. Values on standard growth curves for children 0 to 36 months old are obtained from recumbent length measurement, as standing height measurements may be as much as 2 cm shorter. Use of growth charts to evaluate the child's weight and height relative to each other and previous values is important. In infants and toddlers with proportionately low measurements of all parameters, head circumference, weight, and height, congenital defects ranging from metabolic/genetic disorders to prenatal or perinatal asphyxia represent the differential diagnosis. This group of children may never achieve normal growth, even in the face of nutritional interventions. Infants/toddlers with normal head circumference and mild or proportionate weight reduction to height include those with constitutional growth delay, genetic dwarfism, or endocrine disorders. The final category represents the majority of infants and toddlers. Children in this group have normal head circumference and low weight out of proportion to height. Inadequate nutrition is the cause. Anthropometric measurements may be helpful in sorting out adequacy of growth of children consistently less than 5% after the ED evaluation. Looking at growth parameters over time is extremely helpful, although usually unavailable in the ED; a consistent fall in a downward direction requires a diligent search for an underlying chronic illness.

The severity of malnutrition can be defined further by using the actual weight expressed as a percentage of the ideal weight for the patient's actual height. Mild protein-energy malnutrition exists when the actual weight is 80% to 90% of the ideal body weight for actual height, moderate when this is 70% to 80%, and categorized as severe when this is 60% to 70%. The degree of malnutrition is important when considering the refeeding regimen and decision making regarding the patient's disposition.

Growth curves have been created for special groups of children who exhibit different growth patterns than does the general population. The growth of premature infants can be evaluated on the basis of their corrected age or on special growth curves. The premature infant normally attains "catch-up" growth during the first 2 years of life (after which normal growth curves can be used). Another standard growth curve has been created for the evaluation of growth during the adolescent age that includes the patient's sexual maturity rating. These graphs account for the variability in the timing of the adolescent growth spurt, and deviation from the standard growth curves should be interpreted with caution.

No routine screening panel of laboratory tests is indicated in patients with undernutrition. Rather, they should be performed as indicated by the history and physical examination. Considerations include complete blood cell count, sedimentation rate, C-reactive protein, iron profile, blood lead, electrolytes, blood glucose, blood urea nitrogen, and creatinine, liver function tests, serum protein profile, urinalysis with urine culture, stool examination, and toxicology screen (Table 81.4).

Infants

Infants should regain their birth weight by 10 to 14 days of age. Average daily weight gain in the first 3 months of life is 25 to 30 g. This decreases to 20 g in the third to sixth months and to 12 g in the second half of the first year. When evaluating the

TABLE 81.4

POSSIBLE LABORATORY TESTS

Primary	Secondary
Complete blood cell count	Bone age
Iron profile	Thyroid function tests
Serum glucose, electrolytes	Immunologic studies
Blood urea nitrogen, creatinine	Chromosomes
Serum proteins	Urine for ketones/reducing substances
Urinalysis, urine culture	Plasma ammonia
Stool hemoccult, clinitest	Plasma lactate
Calcium, phosphate	Serum/urine amino acids
Liver function tests	Urine organic acids
Sedimentation rate, C-reactive protein	Electroencephalogram/head imaging
Chest radiograph	Sweat test
Electrocardiogram	Lactose breath test
Purified protein derivative	Stool for trypsin
Toxicology screen	Stool for fat
	Vitamin B_{12}
	Upper gastrointestinal radiographic study/colonoscopy
	Blood lead level
	Cortisol

infant with weight loss or inadequate weight gain, the physician should include in the history perinatal events and the onset and character of the symptoms. The presence of vomiting and acute weight loss in an otherwise well baby with a good appetite suggests gastroesophageal reflux or pyloric stenosis (Fig. 81.2). Poor sucking or swallowing and delayed development indicate neurologic or neuromuscular disease. Vomiting and anorexia, altered mental status, seizures, and characteristic body fluid odors (see Chapters 46 and 94) point to metabolic disease. Renal insufficiency or tubular disease or liver disease also may cause anorexia and vomiting and, thus, poor growth. Frequent infections, dermatitis, and diarrhea

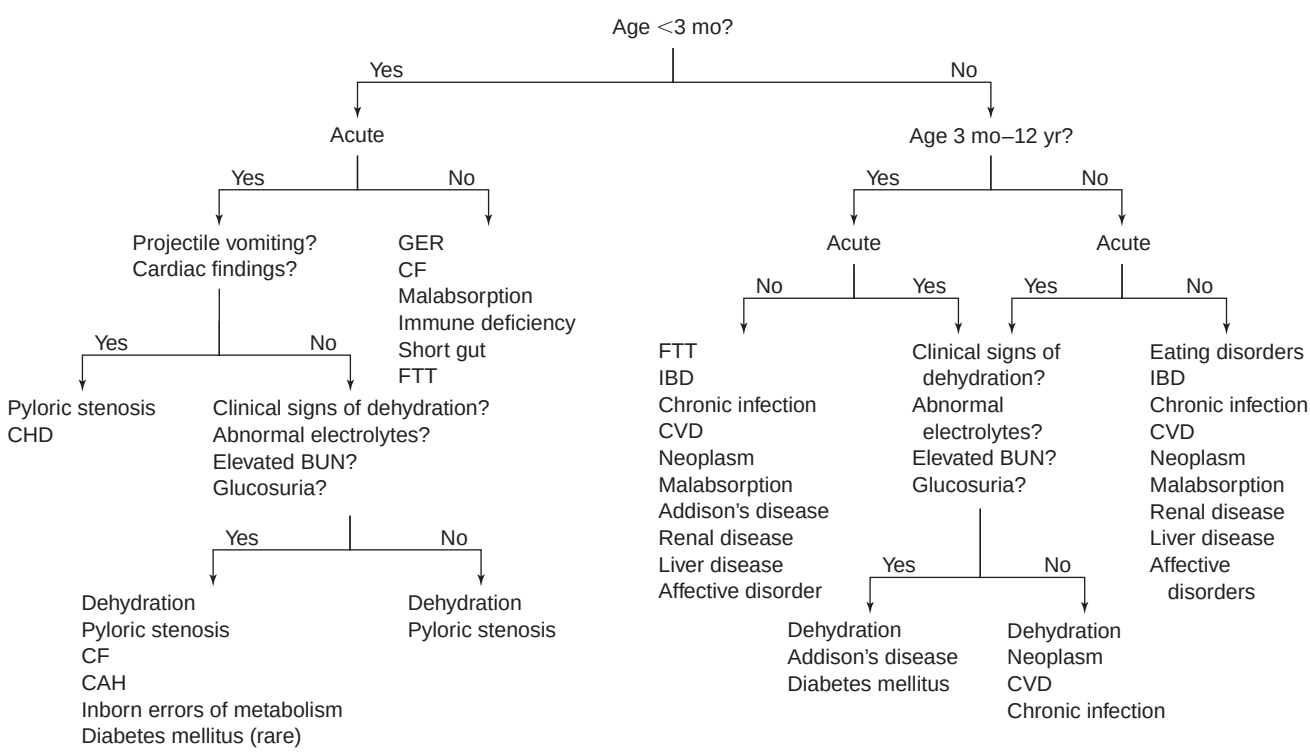

FIGURE 81.2 An approach to the evaluation of weight loss. GER, gastroesophageal reflux; CF, cystic fibrosis; FTT, failure to thrive; IBD, inflammatory bowel disease; CHD, congenital heart disease; CVD, collagen vascular disease; BUN, blood urea nitrogen; CAH, congenital adrenal hyperplasia.

are associated with immune deficiency syndromes. The infant who tires or becomes diaphoretic with feedings may have congenital heart or pulmonary disease. The presence of malodorous, loose stools suggests primary malabsorption or cystic fibrosis. Blood-streaked, water-loss stools may be related to milk protein allergy or infectious (especially bacterial) enteritis.

The physical examination includes measurement of length, weight, and head circumference as described previously. When all three parameters give abnormal measurements, a neurologic, genetic, or metabolic cause is suspect. When length and weight are subnormal but proportional, skeletal dysplasias, endocrinopathies, or constitutional short stature is likely. When only weight is below normal value, an acute illness, dehydration, or deprivation is probably the culprit; the infant should be evaluated for signs of dehydration, cardiac or pulmonary disease, and neurologic abnormalities. As noted previously, observation of a feeding infant may offer some relevant clues. The evaluation of an infant with suspected FTT as a result of child abuse is discussed in Chapter 132.

Older Children

A similar approach to weight loss is used for children beyond infancy (Fig. 81.2). Average weight gain from the age of 2 years until puberty is 2 to 3 kg per year and average growth is 5 to 8 cm per year. A careful history, physical examination, and growth assessment identify the child with growth failure that requires further investigation. Two of the more common causes of chronic weight loss in this age group are diabetes mellitus and inflammatory bowel disease (IBD). For diabetes mellitus, important points include a history of increased appetite, polyuria, and polydipsia. With regard to IBD, colicky abdominal pain, diarrhea, and other symptoms such as arthritis or rash are pertinent. However, weight loss may be the sole manifestation. In this age group, mental health disorders are also an important consideration. The incidence of diagnosed depression in children continues to increase because of both improved recognition and a rising incidence in our society.

Adolescents

Growth failure in adolescents may be the harbinger of chronic illness. The history and physical examination again help uncover the pathology. Consideration of underlying inflammatory, chronic infections, or neoplastic disease is important (Fig. 81.2).

Eating disorders often emerge during adolescence. As in FTT, the diagnosis is made with a careful dietary history and physical examination. These patients exhibit an intense fear of fatness, a relentless pursuit for thinness, a preoccupation with food, and a distorted body image. In cases complicated by severe malnutrition, metabolic derangements, dehydration, or acute psychosis, patients with eating disorders are cared for initially in the hospital. Additional considerations for weight loss in the adolescent include the occurrence of fad dieting and drug use (e.g., stimulants).

Laboratory Tests

The potential list of tests to aid in the evaluation of weight loss is extensive (Table 81.4). Specific diagnostic testing should be performed on a case-by-case basis using a thorough history and physical examination to guide the evaluation. A complete blood cell count serves many purposes and may uncover macrocytosis caused by hypothyroidism or malabsorption of folate or vitamin B_{12}; microcytosis caused by iron deficiency, chronic blood loss, or chronic infection; polycythemia related to chronic heart or lung disease; neutropenia indicative of Shwachman syndrome; elevated neutrophil count secondary to infection; abnormal cell counts or morphologies caused by underlying neoplasm; or thrombocytosis caused by chronic infection or underlying malignancy. Electrolytes may confirm the presence of significant dehydration, and hyponatremia in the presence of hyperkalemia suggests the diagnosis of adrenal insufficiency. Alterations in serum proteins may reflect aberrant absorption, decreased synthesis, or chronic infection. The urinalysis evaluates tubular function and may reveal glucosuria or disaccharide intolerance or galactosemia, as well as infection and renal tubular acidosis. The stool should be checked for the presence of blood, infectious agents, and reducing substances. With the results from this battery of tests, in conjunction with the physical examination and history, a diagnosis or appropriate referral can be made.

SUMMARY

Weight loss is a complaint that requires careful evaluation. With an acute episode of weight loss, many patients seen in the ED will have fluid loss and mild protein-energy malnutrition related to an intercurrent illness with anorexia, increased metabolic need, or increased losses. Most of these children will return to baseline spontaneously when their illness resolves. Chronic weight loss or growth failure is indicative of less common diseases and those for which the differential diagnosis is extensive. In small children, the most common cause is psychosocial growth failure. In older children and adolescents, an organic cause becomes more likely.

Disposition

As always, the general appearance of the infant or child determines the timing and the scope of the evaluation. Hospitalization is indicated in any child who is suspected to have sustained trauma or been abused and may be indicated in those with physical findings consistent with severe malnutrition, hypothermia, bradycardia, or hypotension. Children with mild to moderate protein-energy malnutrition can be referred back to their pediatrician for outpatient management. Nutrition is a central component of well-being in the growing child, and malnutrition carries significant morbidity and mortality. Thus, persons who care for children need to have a sense of normal growth and must develop an approach for the evaluation and treatment of growth failure.

CHAPTER 82 ■ ASTHMA AND ALLERGIC EMERGENCIES

MICHELLE D. STEVENSON, MD, MSE, AND RICHARD M. RUDDY, MD

ASTHMA

Background

Asthma is the most common chronic disease of childhood, affecting approximately 9% of children in the United States. Male, African American, and Puerto Rican children are more likely to experience asthma. Many children, particularly those who are economically disadvantaged, are treated in the emergency department (ED) only during acute exacerbations and receive little or no other ongoing, consistent care. This places the additional burden on the emergency physician both for facilitating appropriate follow-up care and for managing acute exacerbations.

National data demonstrate a significant increase in the annual rate of outpatient visits for asthma since the year 2000, whereas ED visits made by children have appeared to plateau around 750,000 annual visits. In the United States alone, asthma results in an estimated 12 to 14 million school absences per year and was responsible for 186 deaths in children in the year 2004. The reason for sustained high levels of morbidity due to childhood asthma is a subject of active investigation and has not been fully elucidated. However, socioeconomic factors appear to play a major role. Risk factors for life-threatening asthma have been identified and are listed in Table 82.1. Unfortunately, despite these alarming statistics, patients, parents, and physicians often grossly underestimate the life-threatening potential of asthma.

The approach to the assessment and management of acute asthma presented in this chapter is in general agreement with the *Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma* developed by the National Asthma Education and Prevention Program (NAEPP), which became available in prepublication form in 2007. This chapter presents an approach based on current knowledge and provides a set of guidelines that can be adapted to meet the needs of the individual patient or ED setting. Areas of controversy and new therapies are also reviewed.

Pathophysiology

Asthma has been increasingly recognized as a multifactorial inflammatory disorder with several phenotypes. Genetic predisposition, environmental exposure, and allergic sensitization play a strong role in the predisposition to wheeze, particularly in children. Therapy must ideally reverse the airway narrowing and block or modify the impact of the cellular role of mast cells, eosinophils, macrophages, neutrophils, T lymphocytes, and epithelial cells.

The two most important components that impact bronchospasm in asthma occur through immunoglobulin E (IgE)-mediated mast cell degranulation and the recruitment of other cellular components that contribute to chronic inflammation and subsequent airway remodeling. Clinically, this separates the immediate reduction in pulmonary function due to antigen stimulation in the first hours from a later reduction beginning at 4 to 12 hours associated with cellular recruitment. Key to this late-phase response is the attraction and impact of inflammatory cells, with TH_2 lymphocytes contributing greatly. The release of leukotrienes, cytokines [particularly interleukin (IL)-4, IL-5, and IL-13], and other mediators drives this process. Neutrophils play a key role in the pathogenesis of severe asthma exacerbations for reasons that are not understood.

In patients with hyperreactive airways, it is clear that viral infection, including respiratory syncytial virus (RSV) and rhinovirus, increase the responsiveness of the airways and bronchial inflammation, probably by cytokine-triggered upregulation. Further defining the contribution of allergic sensitization, the importance of TH_2 cytokine imbalance, and the role of eosinophilic infiltration is an area of ongoing research. Numerous inflammatory mediators are important in the pathogenesis of asthma and may vary across individual patients.

Regardless, the physiologic consequences of asthma are progressive air trapping with dead space ventilation, increased airway resistance, and mismatching of alveolar ventilation and perfusion. As the acute episode progresses, there is further decrease in forced vital capacity, forced expiratory volume at 1 second (FEV_1), and peak expiratory flow rate (PEFR). Each breath is initiated at higher lung volumes that lie on the steep, stiff portion of the compliance curve. At this point, high-pressure changes are required to achieve acceptable tidal volumes. Arterial oxygen saturation decreases with ventilation-perfusion abnormalities. Hypoxemia may cause pulmonary artery hypertension and hyperventilation. Hyperventilation occurs early in the course of acute asthma, out of proportion to any respiratory or metabolic demands. If the acute asthmatic process continues unchecked, minute ventilation cannot be maintained and $PaCO_2$ ultimately rises as the child becomes fatigued.

Metabolic changes also occur with acute asthma. The increased work of breathing increases oxygen and energy consumption, leading to a metabolic acidosis. Compensation for

TABLE 82.1

RISK FACTORS FOR LIFE-THREATENING ASTHMA

Asthma history
Previous severe exacerbation (e.g., intubation or ICU admission for asthma)
Two or more hospital admissions for asthma in the past year
Three or more ED visits in the past year
Hospitalization or ED visit for asthma within the past month
Using >2 cannisters of short-acting β_2-agonist per month
Difficulty perceiving asthma symptoms or severity of exacerbations
Other risk factors: lack of a written asthma action plan, sensitivity to *Alternaria*
Social history
Low socioeconomic status/inner-city residence
Illicit drug abuse
Major psychological and/or psychosocial problems
Comorbidities
Cardiovascular disease
Other chronic lung disease
Chronic psychiatric disease

ED, emergency department.

this acidosis may not be possible because of already maximal respiratory effort. As respiratory muscles fatigue, respiratory acidosis develops. Combined respiratory and metabolic acidosis set the stage for respiratory failure.

Although the pathophysiology of acute asthma in children and adults is similar, young children are particularly susceptible to status asthmaticus. In children younger than 5 years, peripheral airway resistance is substantially higher than in adults. A small degree of narrowing of peripheral airways results in disproportionate increases in resistance to airflow. Respiratory reserve in children is limited and increases with age as the size of the conducting airways grow larger. Part of this is related to the respiratory surface area being much smaller in children younger than 5 years than in adults. Another age-related mechanical factor, decreased elastic recoil, contributes to earlier small airway closure during normal tidal breathing in young children. This leads to airway collapse and atelectasis during asthma exacerbations or respiratory infection. The horizontal insertion of the diaphragm in infancy makes diaphragmatic recruitment during airway obstruction less efficient. In infants and young children, the contribution of bronchial smooth-muscle constriction to airway obstruction may be less important than that by edema, mucous plugging, and atelectasis.

Triggers

Triggers for acute asthma attacks may be nonspecific and include acute viral infection, allergy, weather change, cigarette smoke or other inhaled irritants, exercise, and cold air. Low-level infections in the upper airways such as sinusitis and otitis media (OM) have been implicated in exacerbations of previously stable asthma in children. Rhinovirus infections play a significant role in acute exacerbations in children. Allergic reactions not only trigger acute episodes of asthma but can also induce a state of bronchial lability. Allergy may promote acute attacks through immediate mediator release and by chronic airway obstruction through the late-phase inflammatory response. Drug sensitivity, particularly to aspirin products, may induce hyperreactive airways. However, exposure to ibuprofen in patients who are not allergic to aspirin or nonsteroidal antiinflammatory drugs (NSAIDs) does not appear to worsen asthma morbidity and may actually reduce outpatient visits.

Clinical Manifestations

In children with known asthma and an obvious exacerbation, clinical evaluation and initial treatment should begin almost simultaneously. However, for the purposes of clarity, these phases of management are considered in sequence.

The evaluation of the child with wheezing begins with a rapid cardiopulmonary assessment to determine the severity of the episode. This includes the child's general appearance, paying particular attention to the degree of respiratory distress, color, and mental status. Simultaneously, oxygen is administered if there is respiratory distress or oxygen saturation is less than 90% to 92%. If indicated, immediate resuscitative and therapeutic efforts are initiated, as described in the next section. After a baseline evaluation, the child should be reassessed frequently or, when severe, continuously.

In addition to the history and physical examination, other selected studies may be useful in the assessment of acute asthma. Pulse oximetry is valuable in all children with respiratory distress and PEFR can be useful in those older than 6 years, particularly if they have previously performed it. Arterial blood gases (ABGs), chest radiographs, and laboratory blood tests should be used only selectively. Each aspect of the assessment is discussed in more detail later in this chapter. A general guide to several parameters useful for estimating the severity of the episode can be found in Table 82.2.

History

The history should include the duration of the current episode and rapidity of onset, the parent's and/or patient's subjective assessment of severity, other associated symptoms, and the suspected trigger. The child's current medications should be determined, including details of when the medications were started, the dosage, the route, the timing of the last dose, and a history of missed doses from nonadherence or emesis. A history of medications, particularly oral or inhaled steroids in the past 6 months, should be elicited. A recent significant escalation in symptoms and rescue medication use is also worrisome and is a risk factor for near-fatal asthma. In accordance with new guidelines, an estimate of the underlying chronic severity of asthma, level of asthma control, impact of symptoms on quality of life, and risk for a life-threatening episode should be made after the initiation of appropriate therapy. Details about past episodes, such as frequency of ED visits, hospital admissions, intensive care unit (ICU) admissions, and episodes of respiratory failure that required

TABLE 82.2

ESTIMATION OF SEVERITY OF ACUTE ASTHMA EXACERBATION[a]

Sign/symptom	Mild	Moderate	Severe[b]
Respiratory rate[c]	Normal to 30% increase	30%–50% increase	>50% increase
Alertness	Normal or agitated	Normal or agitated	Agitated
Dyspnea	Absent or with exertion/ activity; speech normal	Moderate; speaks in phrases; difficulty feeding	Severe; single words or short phrases; refuses feeding
Accessory muscle use	None to mild intercostal retractions	Moderate intercostal with suprasternal retractions; use of sternocleidomastoid muscles; chest hyperinflation	Severe intercostal and tracheosternal retractions; nasal flaring; chest hyperinflation
Color	Normal	Pale	Possibly cyanotic
Wheeze	Often end expiratory only	Throughout expiration	Throughout inhalation and exhalation, or decreased breath sounds
Oxygen saturation (in room air)	>95%	90%–95%	<90%
Peak expiratory flow rate[c] (% predicted or personal best)	≥70%	40%–69%	<40%
$PaCO_2$	<42 mm Hg	<42 mm Hg	≥42 mm Hg

[a]Within each category, the presence of several parameters, but not necessarily all, indicates general classification of exacerbation. Many of these parameters have not been systematically studied, so they serve only as general guides.
[b]Signs of impending respiratory arrest include the following: drowsy/depressed level of consciousness, paradoxical thoracoabdominal movements, bradycardia, quite chest, or less than 25% PEFR (if obtained).

[c]**Normal rates of breathing in awake children**

Age	Normal rate (per min)
<2 mo	<60
2–12 mo	<50
1–5 yr	<40
6–8 yr	<30

Normal pulse rates in children

Age	Normal rate (per min)
2–12 mo	<160
1–2 yr	<120
2–8 yr	<110

[c]For children 5 years or older who are not experiencing a life-threatening condition.
Adapted from Expert Panel Report of the National Heart, Lung, and Blood Institute, National Institute of Heath, U.S. Department of Health and Human Services 2007.

mechanical ventilation, should be addressed. It must be recognized that even children with intermittent or previously mild asthma may experience a severe exacerbation. Current hydration status should be evaluated with questions regarding recent fluid intake, emesis, and urine output. For children with their first episodes of wheezing, for those with mild histories and usually serious flares, or for those in an episode with focal findings without a trigger, the possibility of a foreign-body aspiration or another cause of wheezing should be explored (Table 82.3). Anaphylaxis due to a food allergy must also be considered early in the differential diagnosis of a child with acute, sudden-onset wheezing.

A personal or family history of atopic disease, including eczema and allergic rhinitis, is suggestive of asthma. The NAEPP Expert Panel Report 3 (EPR3) and others have emphasized the importance of recognition of asthma in early life, particularly in young infants with other atopic conditions, recurrent wheezing, affected sleep, or wheezing without upper respiratory symptoms. Appropriate recognition of the inflammatory process in these infants in partnership with their primary care physician is an essential component of quality asthma care. Finally, the family's ability to cope with the child's disease at home should be assessed in preparation for making a disposition decision.

Physical Examination

As noted previously, the physical examination begins immediately, with an overall assessment of the child's degree of respiratory distress. Severe retractions, accessory muscle use, nasal flaring, cyanosis, decreased muscle tone, and altered mental status are indicative of impending or existing respiratory failure and require immediate intervention. The respiratory rate and heart rate should be noted and compared to age-appropriate standards (Table 82.2).

The remainder of the respiratory examination includes auscultation for decreased breath sounds, wheezing, rhonchi, and crackles. Crackles can occur and are most often caused by focal areas of atelectasis. Any asymmetry in the pulmonary findings should be noted. Children with a severe exacerbation or marked chest pain should undergo palpation of their chest wall, neck, and axillae to examine for the presence of subcutaneous air suggesting pneumomediastinum.

There are several clinical asthma assessment scores in the literature. One such score, the Pediatric Asthma Severity

TABLE 82.3

DIFFERENTIAL DIAGNOSIS FOR WHEEZING

Congenital	Cystic fibrosis Lobar emphysema Tracheobronchomalacia/laryngomalacia Tracheal stenosis Bronchial stenosis Diaphragmatic hernia Tracheoesophageal fistula Alpha-1 antitrypsin deficiency Vascular ring
Infections	Bronchiolitis Pneumonia (viral and bacterial) Pertussis
Allergic	Asthma Anaphylaxis Allergic pulmonary aspergillosis
Acquired/Other	Foreign-body aspiration Bronchopulmonary dysplasia Bronchiectasis Mediastinal bronchial compression Recurrent aspiration Vocal cord dysfunction
Cardiac	Congestive heart failure Pulmonary edema Cor triatriatum

Score, has recently been validated in the pediatric, acute care clinical setting and is responsive to changes in patient status during treatment.

Peak Expiratory Flow Rate

PEFR can serve as a simple, quantitative, reproducible, and inexpensive measure of airway obstruction in children with mild to moderate distress. It is recommended by the NAEPP to monitor PEFR in children during an acute asthma flare that is not life threatening. Its utility is limited, however, by the inability of children younger than 5 to 7 years to perform the maneuver reliably. In addition, PEFR is effort dependent and measures predominantly large airway disease.

More recent data from a pediatric ED setting indicate that many children are cooperative to testing with peak flow meters, despite marked underutilization at home. Key components to proper peak flow meter use include use while standing, zeroing the meter, the presence of a good seal from the mouth on the device, and both a good effort and inspiration.

Normal PEFR varies on the basis of the child's sex and height and on some characteristics unique to each peak flow meter model. Knowledge of the child's personal best PEFR can be helpful in the ED. Repeating PEFR 30 to 60 minutes after treatment can assist in determination of the effectiveness of therapy. A flow rate of more than 70% is considered mild, 40 to 69% moderate, and less than 40% severe. The degree of improvement after bronchodilator therapy is more useful than the initial value before therapy. Patients with PEFRs less than 60% of predicted after ED therapy are more likely to relapse after outpatient therapy.

Oxygen Saturation and Arterial Blood Gases

Although ABGs have a role in the evaluation of a severe exacerbation, they have several disadvantages, particularly in children. They can be technically difficult to obtain, are painful, and provide less reliable results in the crying child. Pulse oximetry, however, offers a noninvasive, continuous, and generally valid measure of arterial hemoglobin oxygen saturation (Sa_{O_2}). In addition, pulse oximetry provides data regarding the need and adequacy of supplemental oxygen, response to therapy, and appropriate disposition. It should be measured initially in all children with acute asthma in the ED when available. It is one of the few objective measures in young children who are unable to perform PEFRs reliably. Pulse oximetry values of 97% or more on room air, in conjunction with spirometric evidence, may be helpful in identifying adolescent patients with dyspnea due to vocal cord dysfunction. Supplemental oxygen should be provided to maintain an Sa_{O_2} level of more than 90% (some experts recommend at least 93% in young infants), and if hypoxia persists after ED treatment, hospital admission should be considered. For children with mild degrees of hypoxia, studies have shown that initial Sa_{O_2} alone does not predict the need for hospitalization accurately for the individual patient. As a rule, however, children with lower oxygen saturations are more likely to require frequent bronchodilator therapy and hospitalization or to experience relapse. In any case, confirmation of adequate oxygenation is reassuring and obviates the need for ABGs, except in critical cases.

ABGs provide an objective measure of ventilation and oxygenation. In the ED, it should be considered in the evaluation of any child in whom impending or existing respiratory failure is suspected clinically, although it should never delay the initiation of therapy. ABGs must be interpreted in conjunction with the clinical picture. The trend of the Pa_{O_2} and Pa_{CO_2} is more important than the initial value. Mild hypoxia and hypocapnia are expected early in the course of acute asthma. As obstruction progresses and fatigue develops in the child, hypoxia becomes more severe and the Pa_{CO_2} rises to "normal" or above "normal" range, resulting in a mixed metabolic and respiratory acidosis. It should be emphasized that a "normal" Pa_{CO_2} of 40 mm Hg in a child with tachypnea or significant respiratory distress may be a sign of impending respiratory failure and requires aggressive management and close monitoring. Despite the usefulness of the blood gas as an adjunctive measure, the decision to intubate remains clinically based.

Other Studies

The role of chest radiographs in the ED management of acute asthma is limited. Typical findings on routine films such as hyperinflation, atelectasis, and peribronchial thickening do not correlate with severity and rarely alter management. Patients for whom a chest radiograph may alter clinical management include those with persistence of focal findings after bronchodilator therapy, markedly reduced oxygen saturation after therapy, or clinical suspicion of a complication or cause for wheezing other than asthma. These factors also apply to the decision to obtain a chest radiograph in children who present with wheezing for the first time.

Serum potassium measurement should be considered in children at risk for hypokalemia secondary to receiving frequent or prolonged continuous β_2-agonist therapy. A complete blood cell (CBC) count is generally not useful and, if drawn after adrenergic therapy, often reveals a leukocytosis with neutrophil predominance that should not be misinterpreted as secondary to bacterial infection.

Differential Diagnosis

Wheezing (see Chapter 80) is a continuous, high-pitched, musical, auscultatory finding generally most prominent on expiration; it is caused by the obstruction of intrathoracic airways. It must be distinguished from stridor, a harsh, high-pitched, audible sound most prominent on inspiration. Stridor (see Chapter 72) is associated with diseases that cause upper airway obstruction, such as croup and epiglottitis, as discussed in Chapter 92. Croup typically involves the upper airway but not infrequently may present with evidence of both upper and lower airway obstruction.

Some children present with chronic cough (see Chapter 14) as the only symptom of hyperreactive airways or "cough variant asthma." Typically, the cough is worse at night and the child is asymptomatic during the day. Many of these children have a family history of atopic disease or will have reduced peak flows. There are also children whose acute exacerbations are characterized by severe coughing without obvious wheezing. In the ED, the most practical approach may be a trial of bronchodilators that can be therapeutic and diagnostic. It is important to understand that most patients with persistent cough after an upper respiratory tract infection do not respond to inhaled β-agonist therapy. Pertussis should be considered in the differential diagnosis of children with paroxysms of cough.

Although wheezing is most commonly associated with asthma, other explanations should be considered (Table 82.3). Several entities that may cause wheezing can be differentiated from asthma through a careful history, physical examination, and attention to the patient's response to therapy. The two most common problems other than asthma that bring children to the ED with wheezing are bronchiolitis and viral pneumonia. Much less frequent is a foreign-body aspiration.

Bronchiolitis (see Chapter 92) is an acute infection of the small airways most commonly caused not only by the RSV but also by parainfluenza, adenovirus, metapneumovirus, and influenza. Outbreaks usually occur during the winter and peak from January through March. Bronchiolitis generally affects children younger than 1 year most severely and manifests with a history of an upper airway infection, followed by fever, feeding difficulty, progressive wheezing, respiratory distress, and, occasionally, apnea. Some infants, particularly those with chronic lung disease, respond to bronchodilators.

Foreign-body aspiration is seen most commonly in children 6 months to 5 years of age (see Chapter 28). Although the presentation is usually subtler, classically, patients have a history of sudden onset of choking, coughing, or wheezing when eating or playing with a small object. The examination may reveal asymmetric breath sounds or wheezing associated with varying levels of respiratory distress. These children may have some, although generally incomplete, response to bronchodilators. The chest radiograph is often normal, but in some cases, it may demonstrate differential hyperinflation on inspiratory/expiratory or bilateral decubitus views, focal atelectasis, or, occasionally, a radiopaque foreign body.

Complications

Throughout the ED stay, the potential for complications of acute asthma should be kept in mind. These may be a consequence of the disease itself, the therapy, or both. It is also important to recognize that depression and anxiety are significantly associated with asthma in adolescents, which can lead to impairment in quality of life. Furthermore, epidemiologic studies have shown that asthma, as a chronic condition, is a risk factor for invasive pneumococcal disease.

The most common acute pulmonary complication is atelectasis secondary to mucous plugging. Air leaks that lead to a pneumomediastinum and/or a pneumothorax are potentially life threatening. Children who require positive pressure ventilation of any kind are at particular risk for air leak complications. A pneumothorax should be suspected in any child with a sudden deterioration associated with chest pain, asymmetry of breath sounds, or a shift of the trachea.

Cardiac arrhythmias are associated with adrenergic agents and theophylline. Although theophylline is not recommended for acute asthma, it is still used in chronic asthma control. This drug combination, particularly in association with hypoxemia and acidosis, increases the risk of arrhythmias.

Frequent β_2-agonist therapy can cause hypokalemia and lactic acidosis, although these are rarely clinically significant. The syndrome of inappropriate antidiuretic hormone secretion (SIADH), which may result in symptomatic hyponatremia, is also a potential, although rare, complication of acute asthma.

Management

Initial Approach

The primary goals in the acute management phase of an asthma exacerbation are to correct hypoxemia and to rapidly reverse airflow obstruction. Supplemental oxygen, repetitive β_2-agonists, and the early addition of systemic corticosteroids achieve these goals. Patients should be monitored closely and evaluated serially to determine their response to therapy, to identify those who require more aggressive therapy, and to make a final disposition. For children who are discharged, the emergency physician should prescribe an intensified regimen for a minimum of 3 to 5 days and should recommend that follow-up be kept within a month to monitor outcome and for long term management issues to be addressed.

This section of the chapter presents a stepwise approach to the ED management of acute asthma in children. This approach is generally consistent with the NAEPP EPR3 recommendations and is summarized in algorithm form in Fig. 82.1. Specific dosage recommendations are shown in Table 82.4.

Clinical practice guidelines are increasingly used for commonly encountered ED diagnoses such as asthma. Investigators

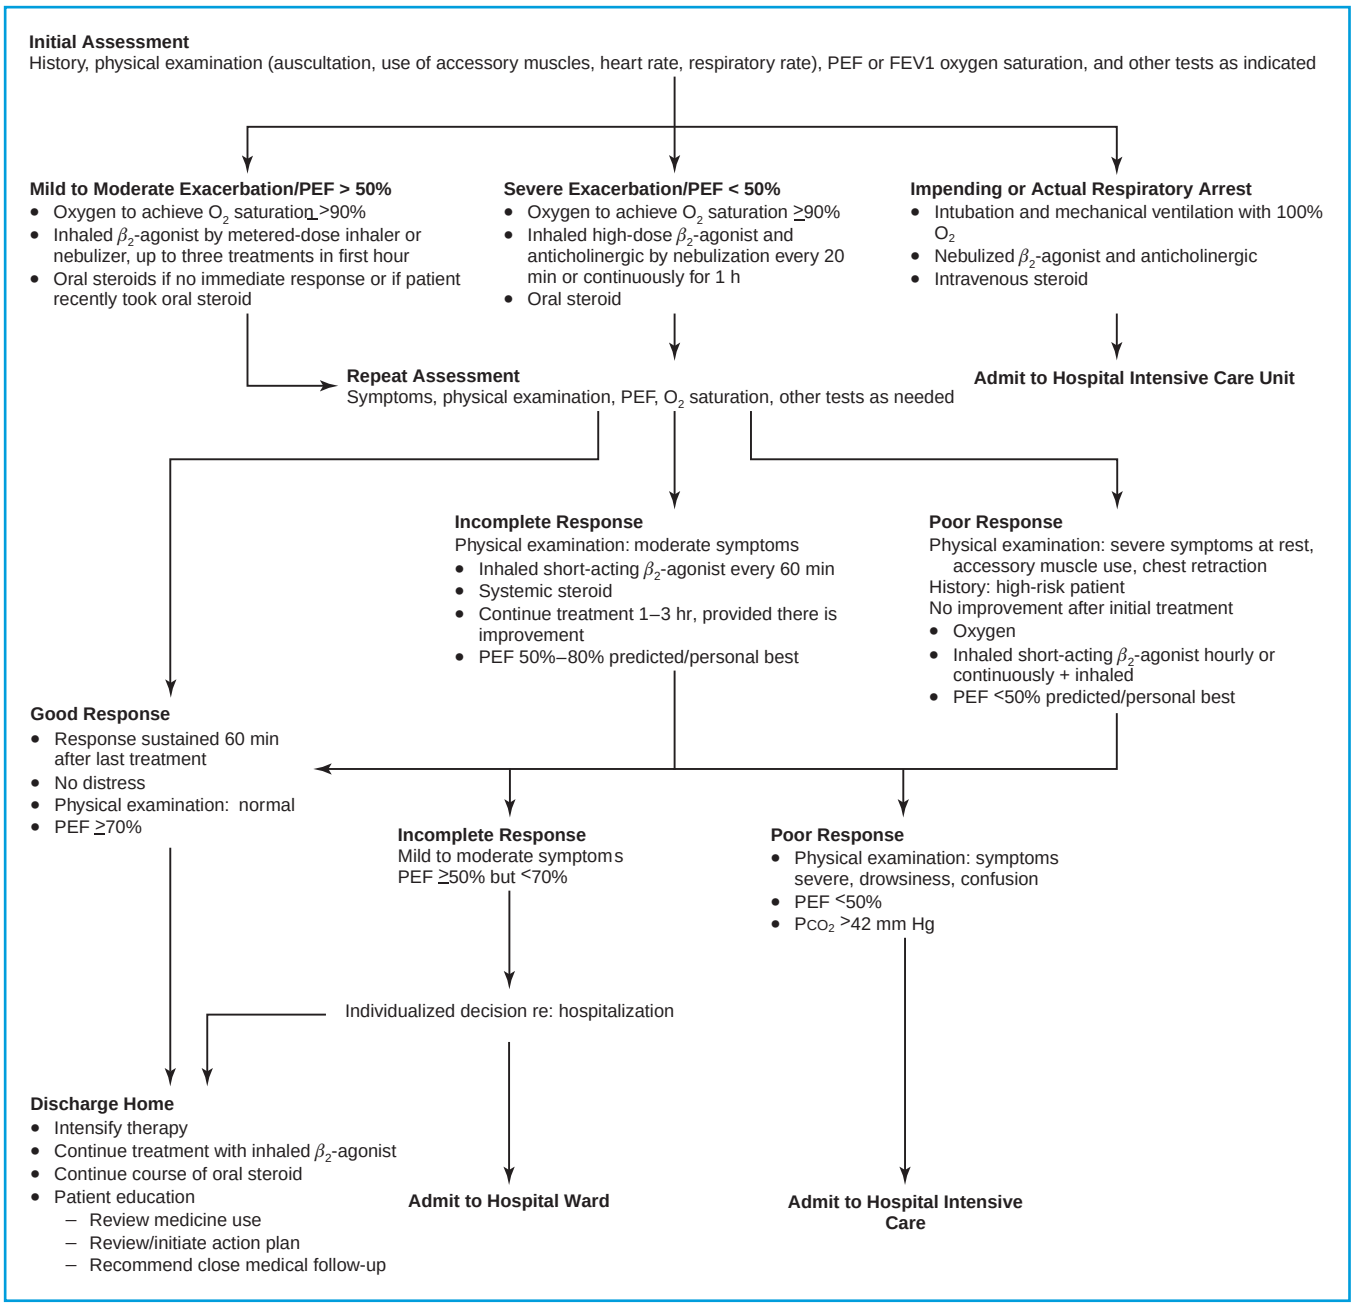

FIGURE 82.1 Approach to acute asthma in children. PEF, peak expiratory flow; FEV1, forced expiratory volume in 1 second. Adapted from National Asthma Education and Prevention Program. *Expert Panel Report 3: Guidelines for the Diagnosis and Management of asthma*. U.S. Department of Health and Human Services Publication, Bethesda, MD: National Institutes of Health, National Heart, Lung, and Blood Institute, August 2007.

have shown that these guidelines, when implemented in a pediatric emergency medicine setting, can be useful in implementing and monitoring adherence to important published recommendations. A sample initial order set that may be used for a majority of children with non–life-threatening asthma is given in Fig. 82.2.

Oxygen

All children with acute asthma can be assumed to be hypoxemic unless oxygen saturation is measured immediately and indicates otherwise. In addition, β_2-adrenergic therapy may exacerbate hypoxemia transiently by increasing blood flow to poorly ventilated areas of the lung, thereby increasing ventilation-perfusion mismatch. Hence, unless SaO_2 is more than 90%, humidified oxygen should be administered immediately. Oxygen is most effectively delivered by mask or nasal cannula. It should be delivered at a flow rate sufficient to maintain SaO_2 levels of more than 90% (93% in infants). In contrast to adults, oxygen-induced suppression of respiratory drive is rare in asthmatic children. It is always recommended to administer

TABLE 82.4

EMERGENCY DEPARTMENT ACUTE ASTHMA THERAPY

Therapy	Dose	Maximum	Comments
Oxygen	Maintain SaO_2 > 90% (>93% in infants)		
Adrenergic agents			
Albuterol (0.5%) nebulizer solution	Intermittent: 0.15 mg/kg q15–20 min in 2 mL NS × 3 and then 0.15–0.3 mg/kg q1–4 h	5 mg/dose	
	Continuous: 0.5 mg/kg/h 2.5 mg minimum	15 mg/h	
Albuterol MDI	4–8 puffs every 20 min × 3 and then every 1–4 h as needed		Use valved holding chamber for all ages Face mask in children <4 yr
Levalbuterol nebulizer solution (0.63 mg/3 mL, 1.25 mg/3 mL)	Intermittent: 0.075 mg/kg (minimum 1.25 mg) q20 min × 3 and then 0.075–0.15 mg/kg q1–4 h	2.5–5 mg	Use one-half the dose of racemic albuterol
	Continuous: 0.25 mg/kg/h	5–7.5 mg/h	
Subcutaneous			
Epinephrine 1:1,000	0.01 mg/kg sq q15–20 min	0.3–0.5 mg	See the text for indications
Terbutaline (0.1%)	0.01 mg/kg sq q15–20 min	0.25 mg	See the text for indications
Intravenous			
Terbutaline (0.1%)	Loading dose: 10 μg/kg over 10 min; initial maintenance: 0.4 μg/kg/min		Titrate up by 0.2 μg/kg/min Usual effective range: 3–6 μg/kg/min
Anticholinergics			
Ipratropium bromide			
Nebulizer solution (0.25 mg/mL)	0.25 mg every 20 min × 3[a] (child) 0.5 mg every 20 min × 3[a] (adult)	0.5 mg	May mix with same nebulizer as albuterol in moderate to severe exacerbations; should be added to β_2-agonist
Metered-dose inhaler (18 μg/puff)	4–8 puffs every 20 min × 3 doses	8 puffs	
Corticosteroids			
Methylprednisolone	1 mg/kg IV bolus	60 mg	
Prednisone	1 mg/kg po	60 mg	
Dexamethasone	0.6 mg/kg po or IM	16 mg	

NS, normal saline; sq, subcutaneous; IV, intravenous; po, orally; IM, intramuscular.
[a]May give with second and third albuterol.

nebulized β_2-adrenergic therapy in children in the ED, with pressurized oxygen.

β_2-Agonists

Repetitive, inhaled β_2-agonists are the mainstay of initial bronchodilator therapy in children. They work by relaxing bronchial smooth muscle directly and may also modulate mediator release from mast cells and basophils. Inhalation therapy has been shown to be as effective as a subcutaneous injection for mild to moderate obstruction and is associated with fewer systemic adverse effects. The highly β_2-selective agent albuterol demonstrates strong potency, good duration of action, and little cardiotoxicity. Frequent (every 15 to 30 minutes) doses of nebulized albuterol appear to be effective in reversing airway obstruction. Although the ideal dose of albuterol (0.5%) has not been determined, the NAEPP EPR3 guidelines recommend 0.15 mg per kg (0.03 mL per kg) per dose, with a minimum dose of 2.5 mg. From a practical standpoint, patients older than 1 year who weigh less than 30 kg should be given 2.5 mg (0.5 mL) and those who weigh more than 30 kg should be given 5 mg (1 mL), or 0.5 mg per kg per hour via continuous nebulization.

Systematic review has concluded that an albuterol metered-dose inhaler (MDI) and chamber are at least as effective as nebulized treatments of children of all ages and more effective in certain subgroups (younger than 5 years with a moderate to severe exacerbation). It is important to administer four to eight puffs with a valved holding chamber during each treatment

Eligibity Criteria:	Exclusion Criteria (do not use this order set):
Age ≥1 yr Previous diagnosis of asthma OR > 2 episodes physician diagnosed wheezing	Underlying cardiopulmonary disease (i.e., congenital heart disease, cystic fibrosis) No wheezing or respiratory distress on initial examination Impending respiratory failure (notify MD)

Initial Assessment

- ☐ Record baseline vital signs (heart rate, respiratory rate, blood pressure, temperature)
- ☐ Measure Sao_2 via pulse oximetry on room air
- ☐ Begin O_2 if Sao_2 consistently ≤90% (≤93% if <1 yr) at any point in therapy
- ☐ Categorize severity of acute asthma exacerbation by attached method (see Table 92.9)
- ☐ Document current asthma medications and treatment in the previous 24 h
- ☐ Measure baseline peak flow (standing position) in children ≥ 6 yr of age and document effort

Treatment

Mild exacerbation

- ☐ 1. Administer six puffs albuterol via MDI and spacer
  Use facemask in children <5 yr of age
- ☐ 2. Reassess vital signs, peak flow, and pulse oximetry after 20 min
- ☐ 3. If wheezing or elevated respiratory rate persist,[a] administer:
  Six puffs albuterol with MDI and spacer
  Oral steroids (prednisone or prednisolone) 1 mg/kg (max 60 mg)
- ☐ 4. Repeat vital signs, peak flow, and pulse oximetry after 20 min
- ☐ 5. If wheezing or elevated respiratory rate persist,[a] administer:
  Six puffs albuterol with MDI and spacer
- ☐ 6. Repeat vital signs, peak flow, and pulse oximetry after 20 min

Treatment

Moderate to severe[b] exacerbation

- ☐ 1. Initiate continuous cardiorespiratory monitoring and pulse oximetry
- ☐ 2. Administer eight puffs albuterol via MDI and spacer (moderate exacerbation only) OR nebulized albuterol (<30-kg dose = 2.5 mg; ≥30-kg dose = 5 mg)
- ☐ 3. Reassess vital signs, peak flow, and pulse oximetry after 20 min
- ☐ 4. If wheezing or elevated respiratory rate persist,[a] administer:
  Nebulized albuterol (<30-kg dose = 2.5 mg, ≥30-kg dose = 5 mg)
  Ipratropium (<30-kg dose = 0.25 mg, ≥30-kg dose = 0.5 mg)
  Oral steroids (prednisone or prednisolone) 1 mg/kg (max 60 mg)
- ☐ 5. Repeat vital signs, peak flow, and pulse oximetry after 20 min
- ☐ 6. Repeat steps 4 and 5

Education and Discharge Planning

- ☐ 1. Teach correct peak flow technique age ≥6 yr
- ☐ 2. Verify proper MDI technique and confirm spacer availability, and use at home
- ☐ 3. Review signs of respiratory distress (nasal flaring, retractions, rapid breathing)
- ☐ 4. Give the family written asthma education information and answer specific questions
- ☐ 5. Ensure adequate follow-up and emphasize chronic nature of asthma

FIGURE 82.2 Pediatric acute asthma exacerbation initial order set. MDI, metered-dose inhaler. [a]A respiratory score system may be used for decision making. [b]For severe exacerbations, physicians should strongly consider magnesium sulfate (50 mg per kg over 20 minutes IV) and may consider alternative therapies such as continuous albuterol.

and use the appropriate size face mask in younger children (younger than 4 years).

Levalbuterol is available as a nebulized preparation consisting of only the active *R*-isomer instead of the 1:1 ratio of *R*- and *S*-stereoisomers found in racemic β_2-agonists, at significant increased expense. It has been shown to be safe and well tolerated, with minimally fewer side effects, in asthmatic children older than 2 years with stable chronic disease. Data from pediatric ED settings fail to show consistent benefits with levalbuterol when compared with racemic albuterol. Routine preferential use cannot be made without further evidence, including cost analyses. In the meantime, levalbuterol remains an option for children with underlying medical problems, such as congenital heart disease, who may benefit from fewer β_2-agonist effects.

Subcutaneous injection of epinephrine or terbutaline remains an acceptable alternative in settings in which nebulized therapy is unavailable. It may also be indicated as initial therapy for children with severe obstruction, hypoventilation, or apnea in whom the delivery of nebulized medication to the airways is believed to be inadequate. Under these circumstances, the injection can be given simultaneously with the initial aerosol and is recommended to be given intramuscularly.

Corticosteroids

The recognition that inflammation is central to the pathogenesis of acute asthma means that corticosteroids have assumed an increasingly important role in the acute and chronic management of asthma. Early treatment of asthma exacerbations with steroids has been shown to prevent progression of airway obstruction, to decrease the need for emergency treatment and hospitalization, and to reduce morbidity. Steroids are believed to potentiate the effect of β_2-adrenergic agents within hours, in part, through alteration of cell membrane receptors and down-regulation of inflammatory mediator generation. They also appear to decrease small airway inflammation and edema within 24 hours. Steroid therapy may be particularly beneficial for

infants in whom the primary pathophysiology is small airway edema and whose response to bronchodilators may be limited.

Because there is a time lag between the administration of steroids and the onset of clinical effect, the first dose is administered as soon as possible. As a rule, almost all children who have had a significant exacerbation ultimately receive steroids. An exception is made for children with mild symptoms who require either no inhaled treatments or, at worst, one treatment that immediately produces adequate resolution in the setting of minimal therapy prior to the arrival in the ED. Exposure to chickenpox in the unvaccinated, susceptible host represents one of the rare instances in which steroids may need to be avoided acutely.

Depending on the level of distress and the child's ability to tolerate oral medications, the dose of corticosteroid is given either intravenously (methylprednisolone 1 mg per kg or equivalent; maximum 60 to 80 mg) or by mouth (prednisone or prednisolone 1 mg per kg; maximum 60 to 80 mg). Guideline 3 reduced the dosage recommended to 1 mg per kg per day in one to two divided doses. Efficacy appears similar in either form.

Dexamethasone has been studied fairly extensively in the treatment of acute asthma in children. A dose of 0.6 mg per kg (maximum 16 mg) of oral dexamethasone for 2 days, started in the ED, is at least as efficacious as a traditional 5-day course of oral steroids. This option is particularly useful in settings of nonadherence or for children prone to emesis.

The data surrounding the use of inhaled corticosteroids in addition to, or in place of, the short course of systemic steroids for the management of acute asthma exacerbations in children are inconsistent. Meta-analyses examining these issues in adults and older children show conflicting results, in part, due to variations across studies in the types of steroids and outcome measures used. Despite the need for further analysis in the acute setting, inhaled steroids are now clearly recognized by the NAEPP as the first-line drug in the chronic management of all classes of persistent asthma in adults and children. Doubling the dose of the patient's usual inhaled corticosteroid is no longer recommended by the NAEPP as a method of treating even minor acute asthma exacerbations, unless there is significant intolerance to oral steroids and the exacerbation is mild. In that case, careful titration of a higher dose of inhaled corticosteroid may be considered.

Anticholinergics

Ipratropium bromide (Atrovent®) is a quaternary ammonium derivative of atropine that limits systemic absorption and decreases its side effects. Ipratropium appears to act synergistically with albuterol, adding additional bronchodilation for patients with moderate to severe airflow obstruction, and may be mixed with albuterol for delivery. Recommendations vary, but the NAEPP EPR3 guidelines suggest 0.25 mg for children (0.5 mg in adolescents and adults) every 20 to 30 minutes, combined with the first three albuterol treatment protocols.

An acceptable alternative is to administer two doses of ipratropium with the second and third albuterol treatment protocols after the assessment of response to the initial albuterol treatment protocol has demonstrated that the exacerbation is moderate to severe. Systematic review has confirmed the utility of multiple doses of ipratropium in severe acute exacerbations in children, with one admission prevented for every 12 children treated with ipratropium [number needed to treat (NNT = 12)].

Intravenous Magnesium Sulfate

Magnesium sulfate acts as a smooth-muscle relaxant to improve bronchodilation. In children with severe acute asthma, it may reduce hospitalizations and improve peak expiratory flow. Its use should be considered especially in children with a severe exacerbation with a poor response to other therapies. Both individual studies in children and a meta-analysis in adults have shown that magnesium sulfate, when given at a dosage of 25 to 75 mg per kg (maximum 2 g), improves outcome in the more severe subgroup. A significant emphasis should be placed on infusion time of 20 minutes, which is shorter than when used for other conditions. Vital signs including blood pressure should be monitored, although most studies report few systemic side effects.

Other Asthma Drugs

Heliox. Heliox is a mixture of helium and oxygen. The gas mixture has a lower density than oxygen and therefore theoretically reduces turbulent flow and airway resistance. This effect reduces work of breathing, which may, in turn, limit or delay respiratory muscle fatigue and allow more time for standard therapeutic agents to take effect. The lower gas density may also improve ventilation to alveoli, with longer time constants resulting in better matching of ventilation and perfusion and more effective delivery of aerosolized medications. Heliox must contain a high concentration of helium (60% to 80%) and it requires a tight-fitting mask, which may limit its acceptance in young children. No adverse effects of heliox have been reported.

Hypoxia can require titration of the heliox-oxygen mixture in the severely hypoxic patient. A systematic review on this agent in adults and children with moderate to severe exacerbations of asthma did not show significant benefits for many outcomes. Improvement in pulmonary function was demonstrated in the most severe subgroups. Consequently, current guidelines recommend considering a trial of heliox-driven albuterol nebulization for severe exacerbations that are unresponsive to therapy or for life-threatening episodes.

Leukotriene Modifiers. Two drugs in this category, zafirlukast and montelukast, have been approved for preventive therapy in chronic asthma in children. Both inhibit bronchoconstriction through antagonism to leukotriene receptors. Zafirlukast (for children 7 years or older) and montelukast (for children 2 years or older) are listed by the NAEPP as an alternative, but not preferred, treatment to inhaled corticosteroids for long-term control of mild persistent asthma or in combination therapy in moderate persistent asthma. There is insufficient evidence to support leukotriene modifiers in the acute management of asthma in children. Recent data suggest that montelukast reduces the risk of worsening asthma symptoms and unscheduled physician visits when added to usual therapy during the dreaded annual September spike in asthma exacerbations.

Omalizumab. Omalizumab is a monoclonal antibody with affinity for IgE at the binding site of the IgE receptor. It can therefore competitively bind free IgE and reduce inflammatory stimulation through IgE receptors. Omalizumab has been studied as a controller medication for moderate to severe persistent

asthma in adults and children. Its role in an acute asthma exacerbation has not yet been examined.

Therapies to Avoid in Acute Asthma. Although theophylline has been added as an option in combination therapy for chronic asthma in some children, it currently has no role in the management of acute asthma and NAEPP EPR3 guidelines no longer recommend theophylline for hospitalized patients. Some children with acute asthma will be dehydrated and should receive fluid therapy to return them to a normovolemic state, but aggressive hydration offers no particular advantage. In addition, SIADH is a potential complication. Antibiotics are indicated only for specific bacterial infections such as sinusitis or OM and should be withheld for routine exacerbations of asthma.

Approach to the Child with Respiratory Failure. There is no universally accepted approach to the child with severe asthma who presents with respiratory failure or deteriorates in the ED despite the therapy already outlined. The options include continuous nebulized albuterol, intravenous (IV) β_2-agonist therapy, IV steroids and magnesium sulfate, heliox, and noninvasive and/or mechanical ventilation. The choice of therapy should be guided by the child's mental status, response to therapy, ability to sustain the increased work of breathing, degree of hypoxia, and trend in $PaCO_2$, as well as the physician's familiarity and comfort with the various treatment options. In all cases, these patients require continuous monitoring and constant involvement of clinical personnel. Arrangements should be made for admission to an ICU setting.

The use of continuous nebulized therapy is well established and is equally efficacious to intermittent albuterol in the adult ED setting. Continuous terbutaline and albuterol have been demonstrated to reverse respiratory failure and to eliminate the need for mechanical ventilation. Albuterol is administered as a 0.5 mg per kg per hour (maximum 15 mg per hour) dose.

IV β_2-agonist therapy is an option for children who fail continuous nebulized therapy. In the United States, terbutaline is administered as a 10 μg per kg loading dose over 10 minutes, followed by an initial infusion of 0.4 μg per kg per minute. The infusion is titrated up to effect in increments of 0.2 μg per kg per minute while the child is monitored for unacceptable tachycardia. The usual effective range is 3 to 6 μg per kg per minute. Although not available in the United States, albuterol is the favored IV agent in Canada and Europe.

If the child continues to deteriorate, intubation and mechanical ventilation should be considered. Noninvasive positive pressure ventilation in acute asthma has been studied in adults and children, but its use is controversial and also associated with barotrauma. Because of the difficulty of mechanical ventilation by endotracheal (ET) tube, centers may try it for short, well-monitored intervals while acute therapy is efficiently administered. There is no single ideal approach to the intubation of children with acute asthma, although some general recommendations can be made. The airway should be managed assuming a full stomach, as discussed in Chapter 5. Many authorities consider ketamine (1 to 2 mg per kg IV) to be the induction agent of choice because of its bronchodilating effects. Agents that may increase bronchospasm through histamine release, such as meperidine, morphine, D-tubocurare, and atracurium, are best avoided. After intubation, all β_2-agonist, anticholinergic, and antiinflammatory drug therapies should continue.

Volume-controlled ventilation is preferred using larger than average tidal volumes (10 to 20 mL per kg), normal respiratory rates for age, and high flow rates to ensure long expiratory times. To achieve these goals, inspiratory pressures must often exceed 50 to 60 cm H_2O. In an effort to minimize barotrauma, incomplete correction of the respiratory acidosis or "controlled hypoventilation" ($PaCO_2$ more than 50 mm Hg) should be the target with a much higher $PaCO_2$ necessary in selected cases. In addition, sedatives and neuromuscular relaxants are generally necessary. Surveillance for barotrauma is critical.

Disposition

After 2 to 4 hours of frequent bronchodilator treatments and the initiation of corticosteroid therapy, as well as potentially IV magnesium sulfate, the limit of routine ED management has been reached and a disposition decision should be made based in part on reliable home resources and follow-up. Continued management of the patient in an "observation unit" or "clinical decision unit" for up to 24 hours may avoid the need for hospital admission.

Criteria for the disposition of acutely ill asthmatic children after ED management are difficult to specifically define. Scoring systems that use various assessment tools are still being developed. As a guideline, however, admission should be considered for children who meet any of the following criteria:

1. Persistent respiratory distress
2. SaO_2 of 91% or less in room air
3. PEFR less than 50% of predicted levels after therapy (or less than 70% with other factors)
4. Inability to tolerate oral medications or fluids (i.e., vomiting)
5. Previous emergency treatment in last 24 hours
6. Underlying high-risk factors: congenital heart disease, bronchopulmonary dysplasia, cystic fibrosis, and neuromuscular disease
7. Evidence of air leak

Other factors that should be considered in conjunction with these criteria include access to emergency care and medical advice, family reliability, sophistication of available home therapy, and severity of past exacerbations.

Children who also meet the criteria listed in Table 82.5 should be admitted to an ICU setting.

TABLE 82.5

CRITERIA FOR INTENSIVE CARE UNIT ADMISSION

Severe respiratory distress
Severity in severe range[a]
$PaO_2 < 60$ mm Hg or $SaO_2 < 90\%$ in 40% O_2
$PaCO_2 > 42$ mm Hg
Significant complications
Pneumothorax
Arrhythmia
Theophylline toxicity

[a]See Table 82.2.

Discharge Management

Children who have an adequate clinical response to ED therapy may be discharged to home. Ideally, they should be observed for 30 to 60 minutes after their last treatment to ensure they do not relapse immediately, except in those who had complete resolution with one treatment. Many discharged children will experience persistent mild to moderate symptoms and considerable acute disability. It is important to understand that the basic pathophysiology, which consists of small airway obstruction, inflammation, and altered lung mechanics, is not immediately reversed in the ED and additional therapy will be required.

Education should be patient and family focused, with emphasis on inhaler technique, the discharge plan and asthma action plan, telephone access to their primary care physician for asthma problems the next 3 to 5 days, and the importance of an asthma-related follow-up appointment in 1 to 4 weeks. An effort should also be made to remove triggers, if possible. Short-course, high-dose oral steroids (i.e., prednisone, 1 mg per kg per day in single or divided dosing up to 60 to 80 mg per day for 3 to 7 days) should be prescribed and administered for essentially all children who present to the ED with a significant exacerbation. The first dose should be given in the ED as previously outlined. Children who experience frequent acute exacerbations, persistent nocturnal symptoms, or multiple absences from school also clearly benefit from the addition of an inhaled corticosteroid to their regular regimen. Inhaled corticosteroid initiation should be strongly considered upon discharge from the ED for these children. Those currently taking an inhaled corticosteroid should be instructed to continue it during the acute exacerbation.

For children who experience their first episode of wheezing or who are not receiving long-term therapy, an albuterol MDI with age-appropriate spacer is generally well tolerated in the subacute phase following the acute episodes. Children younger than 4 years should use either an MDI with a valved holding chamber and face mask or albuterol with a nebulizer. The use of a valved holding chamber device in all ages improves the delivery of medications in MDIs. Partnership with the patient's primary care physician or asthma specialist in this management is recommended. Table 82.6 lists outpatient treatment options.

ANAPHYLAXIS

Background

Anaphylaxis is a potentially life-threatening manifestation of immediate hypersensitivity. The severity of these reactions varies from mild urticaria to shock and death. Anaphylaxis most commonly involves the pulmonary, circulatory, cutaneous, gastrointestinal (GI), and central neurologic systems.

The classic anaphylactic response is an IgE-mediated reaction that occurs after reexposure to an antigen to which the patient has previously been sensitized. The term *anaphylactoid reaction* is sometimes used to refer to a clinically similar syndrome that is not IgE mediated and does not necessarily require previous exposure to the inciting agent. It has become a common practice to use *anaphylaxis* to describe the clinical syndrome, regardless of the responsible mechanism. The annual incidence rate for anaphylaxis in adults and children is estimated to be 49.8 per 100,000 person-years and appears to be on the rise.

Any route of exposure, including parenteral, oral, or inhalation, has been associated with anaphylaxis. Food allergens represent the most common inciting agents in the United States in many studies of adults and children and most often occur outside medical facilities. Other common triggers include hymenoptera stings, drugs, immunotherapy, radiocontrast media, and blood products (Table 82.7). Interestingly, anaphylaxis to immunizations is a relatively rare event, more recently estimated to be 1.5 events per 1 million administrations. The causative agent for anaphylaxis goes undetected in a significant proportion of cases. IgE-mediated anaphylaxis to the latex present in gloves, Foley catheters, and ET tubes was first recognized in the late 1970s. Patients who undergo multiple procedures such as those with myelomeningocele and genitourinary dysplasias, as well as health care workers, appear to be at greatest risk of anaphylaxis to latex-containing products.

Certain conditions are known to increase the risk of fatal anaphylaxis. Peanut, cashew, and other tree nut triggers, especially when consumed outside the home environment, represent an important risk factor. Adolescents appear to be at the greatest risk for death, possibly due to risk-taking behavior. Asthma is also a worrisome historical feature in patients presenting with anaphylaxis, as is a delay in epinephrine administration. Most patients with a fatal reaction to a food have a history of an allergy to the specific food allergen trigger, but the severity of the prior reactions was quite different.

Pathophysiology

Currently, there are three well-established mechanisms that lead to anaphylaxis after exposure to a foreign substance. The first is the classic IgE-mediated reaction. The IgE antibodies form when a person is exposed to the foreign antigen (either in its native state or as a hapten attached to a carrier protein) for the first time. IgE binds to high-affinity receptors on mast cells and basophils. On reexposure, the antigen induces bridging of IgE molecules, leading to degranulation of these cells and to the release of various preformed and rapidly generated mediators. Immune complexes or other agents capable of activating the complement cascade induce the second mechanism. This results in the formation of anaphylatoxins such as C3a and C5a, which directly trigger the release of mediators from mast cells and basophils. The third mechanism involves the ability of certain agents to stimulate the release of mediators directly by an unknown mechanism that does not involve IgE or complement. Agents capable of direct stimulation include hyperosmolar solutions such as mannitol and radiocontrast media.

The sudden release of numerous mediators from mast cells and, perhaps, from basophils is presumed to be responsible for the pathophysiologic features of anaphylaxis (bronchospasm, increased vascular permeability, and altered systemic and pulmonary vascular smooth-muscle tone). The most notable of these mediators is histamine, but others that have been implicated include prostaglandin D2, leukotrienes, platelet-activating factor (PAF), tryptase, chymase, heparin, and chondroitin

TABLE 82.6

OUTPATIENT ASTHMA THERAPY

Medication	Dose	Maximum	Comments
Quick-relief β_2-agonists			
Metered-dose inhaler albuterol	2 puffs q4–6h (routine)	q4h	Use valved holding chamber for all patients, face mask <4 yr
	4–8 puffs q4–6h (exacerbation)		May double dose during exacerbations Encourage to consult physician if more frequent use required
Nebulized albuterol	0.05–0.1 mg/kg q4–6h in 2-mL NS	5.0 mg	1.25 mg minimum May mix with cromolyn solutions May double dose for exacerbations
Long-acting β_2-agonists			Should not be used for symptom relief or for exacerbations
Salmeterol DPI	1 blister q12h (age ≥4 yr)		
Formoterol DPI	1 capsule aerosolized q12h (age ≥5 yr)		
Corticosteroids			
Oral			
Prednisone Prednisolone	1 mg/kg/day × 3–10 day	60 mg/day	May require taper if >7–10 day
Inhaled			
Beclomethasone Budesonide Flunisolide Fluticasone Triamcinolone	First-line therapy for persistent asthma Doses vary greatly, depending on severity of chronic asthma Consult with primary care physician or asthma specialist		Monitor growth in children Use valved holding chamber to limit local adverse effects
Cromolyn sodium			
Metered-dose inhaler	2 puffs q6h		
nebulized	20 mg q6h		Age ≥2 yr
Leukotriene modifiers			
Zafirlukast	10 mg bid		Age 5–11 yr
10- or 20-mg tab	20 mg bid		Age ≥12 yr
Zileuton	600 mg 4 times a day		Age ≥12 yr
300- or 600-mg tab			Monitor LFTs
Montelukast	4 mg QHS		Age 12–23 mo (granules) Age 2–5 yr (chewable)
4-mg granules; 4- and 5-mg chewable	5 mg QHS		Age 6–14 yr
10-mg tab	10 mg QHS		Age ≥15 yr
Other controller medications			
Theophylline—variety of preparations	Beginning dose 10 mg/kg/day	16 mg/kg/day	Titrate to serum concentration of 5–15 μg/mL with monitoring; many possible drug interactions
Omalizumab (Xolair)	150 mg q2–4 wk	375 mg	Age ≥12 yr
Anti-IgE	Dose dependent on serum IgE		Moderate to severe allergic asthma

NS, normal saline; bid, twice a day; QHS, at bedtime; LFT, liver function tests.

sulfate. Recently, serum PAF, a proinflammatory phospholipid, has been shown to be elevated in patients with anaphylaxis. The activity of PAF acetylhydrolase, which degrades PAF, is inversely correlated with anaphylaxis severity.

Other causes of apparent anaphylaxis for which no clear mechanism has been identified exist. These include reactions after the ingestion of aspirin and other NSAIDs and exercise-induced anaphylaxis in which vigorous exercise, often preceded by a meal or an allergenic food, is the trigger.

Clinical Manifestations

The time between exposure to the inciting agent and onset of symptoms can vary from minutes to hours, although epidemiologic data suggest that the mean latency period in children is 15 to 30 minutes. This interval depends on the sensitivity of the patient and the route, quantity, and rate of administration of the antigen. In approximately 6% of hospitalized children with anaphylaxis in one series, a biphasic reaction occurs in

Idiopathic

which symptoms may recur up to 30 hours after the initial reaction. In this series, delayed initial administration of epinephrine was associated with a biphasic reaction.

The signs and symptoms of anaphylaxis vary in both the spectrum and severity of involvement. Reactions may be limited to the skin, as in a mild urticarial reaction, or catastrophically involve multiple systems, leading to shock and death.

Skin manifestations usually emerge first but may be absent. Findings include pruritus, flushing, erythema, urticaria, and, in more severe cases, angioedema. A more detailed discussion of urticaria is found at the end of this section (see also Chapter 66). Mucous membrane involvement may appear as pruritus and congestion of the eyes, nose, and mouth. Swelling of the lips or tongue can potentially impair swallowing and ventilation.

An immediate life-threatening feature of anaphylaxis is upper airway obstruction that results from edema of the larynx, epiglottis, and other surrounding structures. Airway involvement may manifest either as subtle discomfort of the throat or as obvious stridor and respiratory distress. Anaphylaxis can also cause lower airway disease secondary to bronchospasm. This leads to findings similar to acute asthma, such as a sense of chest tightness, cough, dyspnea, wheezing, and retractions.

Another potential life-threatening feature of anaphylaxis is cardiovascular collapse and hypotensive shock. Although the mechanisms are not fully understood, these cardiopulmonary manifestations are believed to result from profound vasodilation, increased vascular permeability, capillary leak, and intravascular volume depletion, as well as a possible direct toxic effect of circulating mediators. Arrhythmias and electrocardiographic evidence of myocardial ischemia may also be seen.

Central nervous system (CNS) involvement can include dizziness, syncope, seizures, and an altered level of consciousness. These may occur either as a result of hypoperfusion or, possibly, as a direct toxic effect of mediator release.

TABLE 82.8

URTICARIA: CLASSIFICATION

Dermatographism
Physical urticaria
  Cold
  Cholinergic
  Pressure
  Solar
Familial urticaria
  Hereditary angioedema
  Familial cold urticaria
Urticaria secondary to common agents
Urticaria secondary to serum sickness

GI symptoms are relatively common and include nausea, vomiting, diarrhea, and crampy abdominal pain.

Urticaria is a common manifestation of immediate hypersensitivity reactions and a number of other disease processes (Table 82.8). In the patient with acute urticaria from an IgE-mediated process, the urticaria may be localized to the area of exposure, such as the site of a sting. In addition to the localized urticaria, there may be a systemic reaction. Urticaria may be associated with angioedema—swelling of the lower dermis and subcutaneous tissues. The angioedema associated with urticaria is pruritic. Angioedema without pruritus is usually secondary to processes other than immediate hypersensitivity.

Urticaria can be separated into acute and chronic varieties. Most immediate hypersensitivity reactions are associated with an acute reaction, but chronic, recurrent urticaria can be mediated by recurrent exposure to an unknown antigen. In determining the cause of an urticarial reaction, the classification shown in Table 82.8 is important because management may vary.

The physical urticarial reactions may be life threatening, and they should be included in the differential diagnosis of anaphylaxis. Cold urticaria is an acute reaction to cold temperatures, with hives at the site of exposure. Generalized cold exposure, such as immersion in a cold pool, can precipitate an anaphylactic reaction (30%) with hypotension and shock. Therefore, an epinephrine autoinjector should be provided to these patients. The cold urticarias are often acquired and may follow viral infections. There is a familial form of cold urticaria that is rare and associated with a delayed onset, leukocytosis, and pain that distinguishes it from acquired cold urticaria. Cholinergic urticaria is characterized by punctate hives surrounded by an erythematous flare. Exercise, anxiety, shivers, and environmental temperature change can precipitate the reaction. It has been associated with exercise-induced anaphylaxis and often causes systemic manifestations (e.g., abdominal pain, headaches). Solar urticaria is a reaction to light, often sunlight, with the development of pruritus, erythema, and edema. Solar urticaria can be a manifestation of porphyria. Pressure urticaria is associated with hives that develop at the site of significant prolonged pressure in areas of the body. It is often associated with tight clothing.

Management

Initial Assessment

Immediate resuscitative efforts must be initiated for the child who manifests the full-blown anaphylaxis syndrome or any of the independent life-threatening manifestations such as upper airway obstruction or shock. All patients who complain of an "allergic reaction" should be evaluated promptly to determine the extent of involvement, signs of progression, and the need for intervention.

History

The history should be directed toward determining the nature and severity of the reaction, the rapidity with which symptoms evolved, and the evidence of ongoing progression. Change in voice, difficulty in swallowing, dyspnea, and a sense of impending doom are characteristic of potentially serious anaphylaxis.

Attempts should also be made to determine the offending agent. This may be obvious as in a reaction to a bee sting. The history should focus on the 1- to 2-hour period before the onset of symptoms. The association of anaphylactic reactions to food is often confusing. Although patients often identify a particular food as the cause, a more detailed history may implicate something else in the meal. For example, it is common to associate reactions with chocolate whereas the nuts in many chocolate preparations generally are the offending agents.

Factors that may place the child at increased risk for a severe reaction should also be ascertained. These include a personal history of asthma or atopic disease or a previous allergic reaction.

A rapid cardiopulmonary assessment should precede any detailed physical examination to quickly determine whether any evidence of upper airway obstruction, bronchospasm, or shock exists. Once these issues have been identified and treatment has been initiated, a more detailed assessment should be performed to evaluate the patient for less serious cutaneous and GI manifestations.

Management of a life-threatening anaphylactic reaction requires simultaneous evaluation and management of the airway, breathing, and circulation, as well as the immediate administration of epinephrine as illustrated in Fig. 82.3 and discussed in a sequence in the following section. Delay in the administration of epinephrine increases the risk of adverse outcomes.

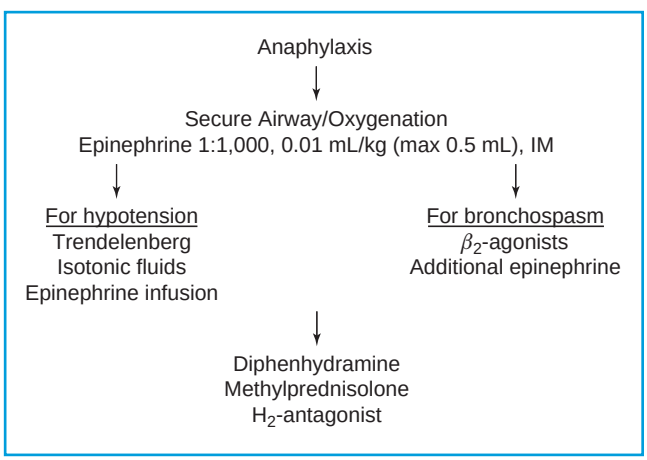

FIGURE 82.3 Management of anaphylaxis. IM, intramuscular.

Maintenance of the Airway and Oxygenation

The physician should administer 100% oxygen, with bag-valve-mask ventilation, when indicated, to assist ventilation. If there is complete airway obstruction, preparation for immediate ET intubation should parallel the rapid intramuscular administration of epinephrine, which can mitigate or ease the airway management. If intubation is unsuccessful, cricothyrotomy offers a lifesaving alternative.

Epinephrine, the first-line drug for anaphylaxis, should be administered as soon as possible. The threshold for the administration of epinephrine varies somewhat across the literature, but there is no absolute contraindication for its use in anaphylaxis. Epinephrine is clearly indicated when symptoms from more than one organ system are present. It is also recommended promptly for any patient who experiences an isolated cutaneous reaction (urticaria, flushing), who has risk factors for fatal anaphylaxis, or who has a history of a near-fatal episode. The recommendation to administer it sooner, rather than later, in the course of anaphylaxis, comes from the increased likelihood of a fatal reaction among patients who receive delayed administration of epinephrine.

As an α-adrenergic agonist, epinephrine promotes vasoconstriction, which increases blood pressure and decreases capillary leakage. As a β-adrenergic agonist, it relaxes bronchial smooth muscle, increases cardiac rate and contractility, and inhibits further mediator release. Epinephrine should be administered via intramuscular injection to the thigh as a 1:1,000 solution, at a dose of 0.01 mg per kg (maximum 0.5 mL). This dose may be repeated every 5 to 15 minutes for persistent or recurrent symptoms. It has been shown in children that absorption is more rapid and peak plasma levels are higher when intramuscular epinephrine is used than that absorbed via the subcutaneous route.

If the patient is hypotensive or hypoperfused, or if the initial intramuscular dose is ineffective, the epinephrine should be administered intravenously or through an intraosseous needle as a 1:10,000 solution, at a dose of 0.01 mg per kg (maximum 0.1 mL per kg) *over 1 to 2 minutes*. In severe cases, this may need to be followed by a continuous epinephrine infusion of 0.1 μg per kg per minute, which can be titrated to effect up to a maximum dose of 1 μg per kg per minute. Inhaled epinephrine does not achieve adequate plasma levels and should not be substituted for the intramuscular dose during initial therapy for anaphylaxis.

Bronchospasm should be treated aggressively with supplemental oxygen, inhaled β_2-agonists such as albuterol or epinephrine, and corticosteroids, as outlined in the previous section on asthma.

Maintenance of the Circulation

Hypotensive patients should be placed in the Trendelenburg position, and a rapid bolus of 20 mL per kg of a crystalloid solution of normal saline or lactated Ringer's solution should be administered and repeated as necessary. Because plasma volume may fall precipitously by 20% to 40%, large amounts of fluid may be necessary. If hypotension persists after epinephrine administration, normal saline bolus, and positioning,

a continuous infusion of epinephrine should be started as previously described.

Other Therapy

The H_1-receptor antihistamines such as diphenhydramine (1 to 1.25 mg per kg intramuscularly or intravenously; maximum 50 mg) are indicated in histamine-mediated allergic reactions. In more stable patients, some authors prefer the oral route of administration. The H_1-receptor antihistamines work synergistically with the epinephrine therapy.

Corticosteroids do not take effect during the initial resuscitative phase of anaphylaxis. Their role in preventing biphasic reactions is unclear, but corticosteroids are frequently recommended because of known efficacy for other allergic diseases. They can be administered as methylprednisolone 1 to 2 mg per kg IV (maximum 125 mg) or, for mild symptoms, prednisone 0.5 to 1 mg per kg by mouth (maximum 60 to 80 mg). Children who have received steroids within the last several months or those experiencing severe reactions should receive IV corticosteroids. Stress-dose hydrocortisone should be considered for those with life-threatening anaphylaxis.

Data in adults confirm the additional therapeutic effect of H_2-blocking antihistamines such as cimetidine (5 mg per kg; maximum 300 mg) or ranitidine (1 to 2 mg per kg; maximum 50 mg) in addition to H_1-blocking antihistamines in acute allergic syndromes. These agents may work synergistically with the H_1-blocking antihistamines and are recommended in severe or refractory anaphylaxis.

On occasion, in severe reactions from injection, a venous tourniquet above the injection site of the offending agent and local infiltration of epinephrine 1:1,000 (0.005 mL per kg) and/or the application of ice may decrease further absorption.

Management of Limited Reactions

Most children with allergic reactions present with involvement limited to a diffuse, pruritic rash; localized swelling; or benign involvement of the mucous membranes. Appropriate management of these children varies according to the specific presentation. Options include subcutaneous epinephrine (e.g., for evolving urticaria), oral antihistamines, and corticosteroids.

Diphenhydramine (5 mg per kg per day divided every 4 to 6 hours, with a maximum of 300 mg per 24 hours) and hydroxyzine (2 mg per kg per day divided every 4 to 6 hours, with a maximum of 200 mg per day) are the antihistamines most commonly prescribed for urticaria. In the case of cold urticaria, cyproheptadine (0.25 to 0.5 mg per kg per day divided every 12 hours, with a maximum of 32 mg per day) is the drug of choice whereas hydroxyzine is preferred for cholinergic urticaria or most other chronic urticaria.

Disposition

The recommended period of observation after anaphylaxis should be individualized and based upon severity, risk factors, and access to care. An observation period of 4 to 6 hours may be appropriate for patients with mild to moderate episodes that resolve promptly with therapy. Patients with severe reactions that involve upper airway obstruction or shock generally should be monitored for a minimum of 8 to 24 hours. The incidence of biphasic reactions varies across the literature but approaches 20% in some studies. Children with a history of asthma appear to be at increased risk for delayed, biphasic, and severe reactions and may also require prolonged monitoring. In addition, a longer period of observation may be indicated for patients in whom the allergen could continue to be absorbed, those with a slower onset of symptoms, or those with a history of biphasic reactions.

Patients with less severe manifestations can be discharged home on a course of antihistamines and, in selected cases, corticosteroids. As a rule, therapy initiated in the ED should be continued for a minimum of 48 hours. Follow-up with the child's primary care physician is also advised and referral to an allergist will be indicated in cases of severe disease.

Strategies to avoid exposure to the offending agent should be discussed. All children with a history of significant anaphylaxis, especially those with asthma or a reaction to peanuts or tree nuts, should be instructed to carry a preloaded syringe of epinephrine to be used in emergencies. The chosen dose should be nearest to 0.01 mg per kg per dose [EpiPen (0.3 mg) or EpiPen Jr. (0.15 mg)] and may be rounded up for patients at higher risk of a severe reaction, as outlined previously. In children weighing less than 10 kg, dosing may be more appropriately achieved via syringe administration of a predetermined dose of 1:1,000 epinephrine at 0.01 mg per kg per dose. It has been shown that practical demonstrations at the time of prescription of an epinephrine autoinjector dramatically increase the likelihood of effective administration.

Following an episode of anaphylaxis, approximately 30% of children have a second episode within 7 years. Children with atopic dermatitis, a documented sensitivity to food allergens, or a history of urticaria/angioedema appear to be at increased risk for recurrence.

ANGIOEDEMA WITHOUT URTICARIA

Background

Angioedema without urticaria or other signs of anaphylaxis can be classified as hereditary, acquired, idiopathic, or exposure related (drug, food, bite, or environmental allergen). It results in nonpitting edema of the subcutaneous tissues and is usually bradykinin and complement mediated. Acquired angioedema due to malignancy or autoimmune disease is rare in childhood. Idiopathic angioedema that is chronic is also uncommon in children, but thyroid dysfunction must be considered. A significant percentage of cases with an identifiable causative factor (such as a nonsteroidal antiinflammatory agent or food) will respond to the removal of the offending agent. Many exposure-related and idiopathic cases are presumably histamine mediated (despite lack of urticaria) and will respond to corticosteroids and antihistamines. A detailed review of potential exposures and comprehensive family history are important to guide therapy. Because of the high morbidity and mortality associated with hereditary angioedema, the rest of this section is devoted to its recognition and management.

Hereditary Angioedema

Pathophysiology. Hereditary angioedema is caused by a deficiency of C_1-inhibitor function. It is a rare episodic disorder and can be the result of either low levels of the protein (type I) or poor functionality (type II), causing recurrent episodes of vascular permeability. Because of the autosomal-dominant inheritance pattern, many children with the disorder have a positive family history. However, 20% to 25% of cases are due to spontaneous mutations. School age (8 to 12 years) is the mean age of onset. Patients may present with subcutaneous angioedema (involving circumscribed areas of edema of the skin, most commonly the extremities, without erythema or pruritis), abdominal attacks (severe pain, distention, and vomiting), or laryngeal edema (life-threatening hoarseness, stridor, and voice changes).

Triggers. Episodes of angioedema may be triggered by direct mechanical friction or trauma. Affected children should therefore avoid contact sports. Exposures that result from viral infections should be limited as much as possible (such as early daycare). Puberty often worsens acute episode frequency and duration. Stress, dental manipulation, estrogens, and angiotensin-converting enzyme inhibitors can also serve as the inciting agents of edema.

Clinical Course. Diagnosis of hereditary angioedema early in life is critical but often delayed. A complete history and physical, with special attention to the airway, posterior pharynx, and abdomen, should be performed. Occasionally, abdominal ultrasonography is useful in discriminating angioedema from a surgical process, shows hyperemia of the bowel wall, and often reveals ascites. Patients may report a prodrome of paresthesias at the location where edema will arise, with the self-limited episodes lasting from 2 to 4 days.

The diagnosis is suspected from C4 levels that are usually low because of increased conversion of C4 to C1, while C3 is normal. Functional and antigenic C_1-inhibitor levels should be determined but may be falsely low in infants younger than 2 years.

Management. Supportive care with airway management and monitoring, fluid resuscitation, and pain control represents the mainstay of management. Intubation should be strongly considered in the presence of an inability to swallow, voice changes, or dyspnea. Because of the potential for landmark distortion and an acute increase in edema, direct laryngoscopy is best performed in a controlled setting where a definitive surgical airway can be achieved when required. Unfortunately, corticosteroids and antihistamines are usually ineffective in the management of hereditary angioedema. Epinephrine (nebulized or intramuscular) is also likely to be ineffective but may transiently improve symptoms.

Human C_1-inhibitor concentrate was recently licensed in the United States for routine prophylaxis in adolescents and adults and is widely used in other countries for acute attacks. Efficacy studies of C_1 inhibitor for acute episodes and recombinant product development are underway in the United States. Otherwise, treatment options are limited in children. Currently available in Europe and Canada, C_1-inhibitor concentrate can be administered immediately (10 to 20 units per kg up to 1,000 units) parenterally to children presenting with laryngeal edema or symptoms of an acute abdominal process. This treatment generally begins to alleviate symptoms within 30 to 60 minutes. Repetitive doses are sometimes required. Hospitalization is often necessary in the course of severe laryngeal or abdominal attacks. Currently, in the United States where C_1 inhibitor is not available, fresh frozen plasma (10 mL per kg) may be considered for acute management with consultation with an allergist because its use in hereditary angioedema is controversial. Drugs for long-term prophylaxis (attenuated androgens) are available but not generally used in children. Antifibrinolytics (such as ϵ-aminocaproic acid) are sometimes used for prophylaxis in children, but reports of efficacy in acute therapy remain anecdotal.

SERUM SICKNESS

Background

Serum sickness is an immune complex–mediated disease. It was first described in 1905 in patients who had received heterologous antisera, which, at that time, was used routinely to treat various infectious diseases. Today, the most common cause of serum sickness is exposure to medication, usually described as a serum sickness–like reaction.

The clinical syndromes secondary to an immediate hypersensitivity reaction may appear similar to serum sickness. In the former, IgE is primarily responsible, whereas IgG or IgM immune complexes classically mediate the latter. In many cases, however, elements of both processes are involved. The clinical syndrome of a serum sickness–like reaction that is not mediated by immune complexes has been reported. These reactions are referred to as serum sickness–like reactions. Serum sickness–like reactions appear to be responsible for the relatively common reactions seen in association with cefaclor and many other drugs.

Currently, the medications implicated most frequently in serum sickness or serum sickness–like reactions include the penicillins, sulfonamides, cephalosporins, streptomycin, hydantoins, griseofulvin, bupropion, fluoxetine, and thiouracil. Because these drugs are all low-molecular-weight substances, they cannot act as antigens directly but must bind to proteins, usually through their metabolites. This makes it difficult to substantiate sensitization.

The use of therapeutic agents obtained from heterologous serum has decreased dramatically. These preparations are currently found in antithymocyte globulins used to prevent organ transplant rejection and in antitoxins for the management of clostridial infections, diphtheria, tetanus, and specific arachnid, snake, and scorpion envenomations. Chimeric human-murine monoclonal antibodies such as infliximab (used to treat psoriasis and inflammatory bowel disease) can also induce serum sickness.

Less commonly, exposures to various chemical, infectious agents, or autologous antigens result in a serum sickness–like illness.

Pathophysiology

In the classical serum sickness model, an animal is injected with foreign serum protein. The animal develops the symptoms

characteristic of serum sickness 7 to 10 days later. During the initial period after the injection of the foreign protein, there is a period of antigen excess. Antibodies develop approximately 6 to 10 days after the initial antigen injection and then antibody-antigen complexes are formed.

These immune complexes deposit in the tissues and may also activate complement. After this period of immune complex formation, there is a period of antibody excess during which antigen disappears from the system. Symptoms develop when soluble immune complexes are being cleared by the body. These immune complexes can activate the classical complement pathway. The classical pathway of activation begins with the formation of the C1q antibody complex, which activates a C_1 esterase that cleaves the fourth and second complement components (C4 and C2). The C4 and C2 that have been activated can then cleave C3. It is the cleavage of C3 and generation of its active components that allow for the activation of the late-acting complement components (C5 to C9). Because the immune complex activation involves the classical components, C4, C2, and C3, their serum concentration decreases. The complement activation generates the anaphylatoxins C3a and C5a, which then increase vascular permeability, release histamine, and produce bronchospasm. They activate many other cells in the inflammatory process and lead to inflammation around deposits of complexes in various tissues.

Clearance of immune complexes depends on their size and the effectiveness of the reticuloendothelial system. The most vulnerable organs to injury include kidneys and the vascular system.

It has also been shown in experimental animals that immune complex deposition can be enhanced by concomitant activation of an immediate hypersensitivity reaction. The IgE-mediated mast cell degranulation increases vascular permeability, which, in turn, enhances immune complex deposition.

Clinical Manifestations

The severity of serum sickness and the specific clinical manifestations vary widely. The reaction is characterized by fever, malaise, and a rash that is most commonly urticarial but may also appear as maculopapular or vasculitic eruption. Other manifestations include arthralgias or arthritis, lymphadenopathy, angioedema, and nephritis. Other less common problems include abdominal pain, carditis, anemia, and neuritis. Serum sickness is usually self-limited and typically resolves within 1 to 2 weeks with or without therapy.

Characteristically, the onset of symptoms occurs 7 to 14 days after the primary exposure. If there has been prior sensitization, however, reexposure can result in onset of a few days.

History

The history should be directed toward identifying the offending agent and determining the extent and severity of the symptoms. The physician should review possible exposures up to 14 days before symptoms to ascertain a possible cause for the process. Because a secondary exposure can produce a more rapid onset of symptoms (1 to 4 days), inquiries about this interval and about previous exposures may also be revealing.

In addition, the history should elicit information about the extent of systemic illness and the involvement of specific organ systems. It is important to determine the time course and nature of the rash; the degree of joint pain, swelling, or warmth; and evidence of renal involvement such as hematuria, edema, and reduced urine output. In light of the potential for involvement of other organ systems, a complete review of systems is indicated.

Physical Examination

The physical examination serves to determine the severity and extent of involvement of the reaction. A general inspection will help ascertain how ill and uncomfortable the child is. Examination of the skin may reveal a maculopapular eruption, urticaria, or palpable purpura of a cutaneous vasculitis. Painful angioedema is commonly present. Generalized lymphadenopathy often occurs. In more severe reactions, the joints show erythema, warmth, and effusion. Wheezes may be appreciated on auscultation of the lungs, and a pericardial friction rub may be audible if pericarditis is present. The liver and the spleen often enlarge. Rarely, neurologic deficits occur secondary to a vasculitis of the CNS. In serum sickness–like reactions, symptoms are generally limited to fever, pruritis, urticaria/rash, and arthralgias.

Laboratory Findings

The selection of laboratory studies should be determined by the severity of the reaction, the evidence of specific organ system involvement, and the degree of diagnostic uncertainty. For most patients, a urinalysis to look for the evidence of renal involvement is all that is required. A list of other studies that may be indicated for individual patients with immune complex–mediated disease is outlined in Table 82.9.

TABLE 82.9

POSSIBLE LABORATORY EVALUATION OF SERUM SICKNESS[a]

Blood tests
Erythrocyte sedimentation rate
Complete blood cell count with differential
CH5O, C3, C4
Blood urea nitrogen, creatinine
Antinuclear antibody
Rheumatoid factor
Hepatic enzymes
Hepatitis B screen
Heterophile antibody
Immune complex assay
Other laboratory tests
Urinalysis
Electrocardiogram
Stool hematest
Computed tomography scan

[a]Laboratory evaluation should be tailored for each individual patient as noted in the text.

The erythrocyte sedimentation rate may be elevated. Both CBC and differential counts may reveal leukopenia or leukocytosis. The C3, C4, and CH5O may decrease because of complement activation. Any of the tests for circulating immune complexes (e.g., cryoglobulins) may be elevated. Stool testing for blood should be considered for patients with abdominal pain or other symptoms involving the GI tract. If carditis is suspected, a screening electrocardiogram and chest radiographs should be obtained; an echocardiogram may also be considered. Severe headache or focal neurologic deficits are indications for neuroimaging, usually a computed tomography scan. Serum sickness–like reactions will not be accompanied by hypocomplementemia or renal dysfunction.

Management

The treatment of serum sickness is based on the extent and severity of the disease. Keeping in mind that the reaction is usually self-limited, the goal is to provide symptomatic relief and to monitor for complications. If possible, the offending antigen should be eliminated.

Pharmacologic management usually involves one or more of the following: antihistamines, NSAIDs, and corticosteroids. Pruritus, rash, and angioedema can be managed with an antihistamine such as hydroxyzine (2 mg per kg per 24 hours divided every 6 to 8 hours, with a maximum of 200 mg per 24 hours). Although experience in the treatment of serum sickness is limited, the use of second-generation, nonsedating antihistamines may also be considered (Table 82.10). Urticarial lesions and angioedema that evolves rapidly may respond acutely to subcutaneous epinephrine (1:1,000, 0.01 mL per kg subcutaneously, with a maximum 0.30 mL). Mild joint involvement and/or fever often improve with the use of an NSAID such as ibuprofen (30 to 50 mg per kg per 24 hours divided every 6 to 8 hours up to a maximum 2.4 g per 24 hours). In more severe disease or after failure to respond to these measures, a burst of corti-

TABLE 82.10

EMERGENCY DEPARTMENT MANAGEMENT OF ALLERGIC RHINITIS

Medication	Dose	Comments
Antihistamines		
Loratadine		Available over the counter
10-mg tab or 10-mg/10-mL syrup	5 mg daily	Age 2–5 yr
	10 mg daily	Age ≥6 yr
Loratadine D		Available over the counter
12 h (loratadine 5 mg/pseudoephedrine 120 mg)	1 tab bid	Age ≥12 yr
24 h (loratadine 10 mg/pseudoephedrine 240 mg)	1 tab daily	Age ≥12 yr
Clarinex® (desloratadine)		
5-mg tab or 0.5-mg/mL syrup	1 mg daily	Age 6–11 mo
	1.25 mg daily	Age 12 mo–5 yr
	2.5 mg daily	Age 6–11 yr
	5 mg daily	Age ≥12 yr
Clarinex® D (desloratadine)		
12 h (desloratadine 2.5 mg/pseudoephedrine 120 mg)	1 tab bid	Age ≥12 yr
24 h (desloratadine 5 mg/pseudoephedrine 240 mg)	1 tab daily	Age ≥12 yr
Allegra® (fexofenadine)	30 mg bid	Age 6–11 yr
30-mg tabs, 60-mg tabs/caps, 180-mg tabs	60 mg bid	Age ≥12 yr
	180 mg	Age ≥12 yr
Allegra D® (fexofenadine 60 mg/pseudoephedrine 120 mg)	1 tab po bid	Age ≥12 yr
Zyrtec® (cetirizine)		Available over the counter
5-mg tabs, 10-mg tabs	2.5 mg daily	Age 6–11 mo
5 mg/5-mL syrup	2.5 mg daily or 2.5 mg bid	Age 1–5 yr
	5–10 mg daily	Age 6–11 and ≥12 yr
Zyrtec D® (cetirizine 5 mg/pseudoephedrine 120 mg)	1 tab bid	Age ≥12 yr
Xyzal® (levocetirizine)		
5-mg tabs, 5 mg/5 mL	2.5 mg daily	Age 6–11 yr
	5 mg daily	Age ≥12 yr
Decongestants		
Oral		
Pseudoephedrine	4 mg/kg/day q6–8 h	Maximum: 180 mg/day
Topical		
Oxymetazoline	Age >6: 0.05%	Limit use to <5 days to avoid rebound congestion
	2–3 drops each nostril bid	

bid, twice a day; po, orally.

costeroids may be prescribed at a dose of 1 to 2 mg per kg per day of prednisone for 7 to 10 days, followed by a taper for 2 weeks (maximum 60 to 80 mg per day). In life-threatening serum sickness with significant circulating immune complexes, plasmapheresis may play a role, but this procedure has not been used extensively for the treatment of this disease. Most children with serum sickness can be managed as outpatients, with close follow-up by their primary care physicians. Children with more severe involvement may benefit from hospitalization.

ALLERGIC RHINITIS

Background

Allergic rhinitis is the most common manifestation of atopic disease. Peak incidence occurs in the pediatric age group, affecting up to 30% of children and adolescents. Although not a life-threatening problem, allergic rhinitis can have a significant, often underestimated, negative impact on the quality of life of affected children. Severe nasal symptoms have been directly linked to poor school performance. Annual direct and indirect costs are estimated to be $2 billion to $5 billion in the United States alone. The morbidity of allergic rhinitis results from the direct manifestations of the disease and from associated complications such as sinusitis, acute asthma, sleep disturbances, dysosmia, and the consequences of chronic mouth breathing.

Pathophysiology

Allergic rhinitis is caused by an IgE-mediated hypersensitivity response of the nasal mucosa to foreign allergens. Following sensitization to a foreign antigen, reexposure triggers an immediate hypersensitivity reaction. This early response is characterized by the activation of mast cells and the release of preformed mediators of inflammation such as histamine and chemotactic factors and newly formed mediators such as prostaglandins and leukotrienes. These mediators cause vasodilation, mucosal edema, mucus secretion, stimulation of itch receptors, and reduction in the threshold for sneezing.

Many children experience a late-phase allergic response that consists of spontaneous release of inflammatory mediators 3 to 12 hours after exposure. There also is a "priming effect" that leads to increased responsiveness to small antigen loads and hyperresponsiveness to environmental irritants.

Historically, allergic rhinitis has been categorized as seasonal or perennial. *Seasonal* allergic rhinitis is most commonly caused by exposure to tree pollens (early spring), grass pollens (late spring and early summer), and ragweed or other weed pollens (late summer and fall). Allergens responsible for *perennial* allergic rhinitis include animal dander, house dust mites, and mold spores. Updated duration-based terminology established by the World Health Organization includes *intermittent* and *persistent* allergic rhinitis. These terms were chosen because not all patient with sensitivity to typical perennial allergens exhibit constant symptoms and because year-round pollens may be found in many parts of the world. It is important to recognize that food allergens to do not typically cause isolated allergic rhinitis.

Clinical Manifestations

The classic symptoms of allergic rhinitis include nasal congestion, paroxysmal sneezing, pruritus of the nose and eyes, and watery, profuse rhinorrhea. Other complaints may include noisy breathing, snoring, repeated throat clearing or cough, itching of the palate and throat, "popping" of the ears, and ocular complaints such as redness, itching, and tearing.

The physical examination is variable but may reveal the "gaping" look of a mouth breather, dark discoloration of skin on the infraorbital ridge caused by venous congestion (allergic shiners), and a transverse external nasal wrinkle secondary to chronic rubbing of the nose (allergic salute). Intranasal findings are variable. The mucosa is often edematous and may appear pale or violaceous. The nasal secretions may be clear, mucoid, or opaque.

Management

There are several approaches to the management of allergic rhinitis. These include the identification and avoidance of environmental allergens and irritants, oral antihistamine drugs, topical decongestants, topical antiinflammatory agents (cromolyn and/or corticosteroids), and immunotherapy.

Recognizing that long-term therapy must be highly individualized, the emergency physician will generally limit interventions to those that safely provide rapid, symptomatic relief and then refer the child to the primary care physician for long-term therapy. Data in adults suggest that adequate treatment of allergic rhinitis in asthmatic patients can significantly reduce health care utilization due to bronchospasm. In this important subgroup, parents should be reminded during the ED visit to seek appropriate chronic management of allergic rhinitis.

Topical corticosteroids have been considered as first-line therapy for chronic allergic rhinitis and may require as long as 2 weeks to achieve maximal relief. Rapid relief can generally be achieved by prescribing an antihistamine in combination with a decongestant (Table 82.10). First-generation antihistamines (such as chlorpheniramine, brompheniramine) are no longer recommended as first-line therapy because of the availability of many inexpensive second-generation antihistamines with a better side effect profile. Antihistamines acutely reduce the rhinorrhea, pruritus, and sneezing associated with allergic rhinitis. A trial of loratadine or cetirizine, now both available without a prescription, is an attractive option for many patients. Recent evidence also indicates that topical therapy with nasal corticosteroids has greater efficacy with an NNT of 4.4 than with an NNT of 15.4 for nonsedating histamines. Topical decongestants such as oxymetazoline hydrochloride present another alternative but should be prescribed for only brief periods (less than 5 days) to avoid tachyphylaxis. Other nonpharmacologic measures such as saline nasal rinses may provide some symptomatic relief.

TABLE 82.11

TOPICAL TREATMENT FOR ALLERGIC RHINITIS

Trade name	Generic name	Dosage	Age
Corticosteroids			
Beconase AQ®	Beclomethasone (aqueous: 42 μg/spray)	1–2 sprays each nostril bid	≥6 yr
Rhinocort AQ®	Budesonide (32 μg/actuation)	1–2 sprays each nostril daily	6–11 yr
		2–4 sprays each nostril daily	≥12 yr
Flonase®	Fluticasone (50 μg/spray)	1–2 sprays each nostril daily	≥4 yr
Nasacort AQ®	Triamcinolone (55 μg/spray)	1 spray each nostril daily	2–5 yr
		1–2 spray each nostril daily	6–11 yr
		2 sprays each nostril daily	≥12 yr
Nasarel®	Flunisolide (29 μg/spray)	2 sprays each nostril bid	6–14 yr
		2 sprays each nostril bid-tid	≥15 yr
Nasonex®	Mometasone furoate (50 μg/spray)	1 spray each nostril daily	2–11 yr
		2 sprays each nostril daily	≥12 yr
Others			
Cromolyn Sodium (available over the counter)	5.2 mg/spray (mast-cell stabilizer)	1 spray each nostril q4–8 h	≥2 yr
Astelin®	Azelastine (137 μg/spray) (antihistamine)	1 spray each nostril bid	5–11 yr
		1–2 sprays each nostril bid	≥12 yr
Ipratropium bromide	0.03%, 21 μg/spray	2 sprays bid-tid	≥6 yr
Singulair®	Montelukast (leukotriene antagonist)	4-mg granules	6–23 mo
4 mg granules		4-mg (chewable) po QHS	2–5 yr
4- and 5-mg chewable		5-mg po QHS	6–14 yr
10-mg tab		10-mg po QHS	≥15 yr

bid, twice a day; tid, twice a day; po, orally; QHS, at bedtime.

Although there is little evidence to support allergen avoidance for indoor allergens, it is logical to limit exposures when possible in patients with significant allergic rhinoconjunctivitis, especially during pollen seasons.

The first-line approach for patients who require long-term therapy is topical cromolyn and/or corticosteroids (Table 82.11) with or without a second-generation oral antihistamine. For completeness, other categories of treatment are also listed in Table 82.11. Children with significant ocular symptoms may also benefit from local ophthalmic treatment (Table 82.12). Immunotherapy and omalizumab are important chronic therapies in development.

TABLE 82.12

OPHTHALMIC DROPS

Trade name	Generic name	Category	Dosage	Age (yr)
Naphcon-A®	Naphazoline and pheniramine	Antihistamine—decongestant	1–2 gtt 4 times/day	≥6
Optivar®	Azelastine hydrochloride	Antihistamine	1 gtt bid	≥3
Alomide®	Lodoxamide tromethamine	Mast-cell stabilizer	1–2 gtt 4 times/day	≥2
Patanol®	Olopatadine	Mast-cell stabilizer and antihistamine	1–2 gtt bid	≥3
Acular®	Ketotifen	Nonsteroidal antiinflammatory drug	1 gtt 4 times/day	≥3
Alamast®	Pemirolast	Mast-cell stabilizer	1–2 gtt 4 times/day	≥3

bid, twice a day; gtt, drops.

ACKNOWLEDGMENT

The discharge instructions for asthma found in Fig. 82.2 were kindly provided by Dr. Stephanie Kennebeck.

CHAPTER 83 ■ BITES AND STINGS

DEE HODGE III, MD

This chapter is oriented to the clinical diagnosis and management of injuries that result from bites and stings, especially as they relate to children. Although the largest proportion of the morbidity and mortality from these injuries occurs in the pediatric age group, little attention has been focused in the pediatric literature on the specifics of treatment.

An overall assessment should include vital signs, location and size of fang or sting marks, pain, swelling, color of surrounding skin, and any systemic symptoms. General care should include relief of pain and itching, tetanus prophylaxis, antibiotics if needed, and emotional support. Animals must be identified as venomous or not. Venomous animals are those that inject their toxin into other animals to produce a harmful effect. Poisonous creatures are those whose tissues are toxic, either in whole or in part. This chapter deals with venomous bites and stings and with wounds inflicted by nonvenomous animals. In evaluating any potential venomous bite or sting, the physician must distinguish between the asymptomatic and the symptomatic bite or sting. Clinical observation may be the only means of distinguishing between the two.

Only those venomous animals found within the continental United States and Canada are discussed here. Only marine life that exists within the tidal zone or is commonly washed ashore is considered. This chapter covers marine invertebrates and vertebrates, terrestrial invertebrates, venomous reptiles, and common mammalian bites.

MARINE INVERTEBRATES

Phylum Coelenterata (Cnidaria)

The phylum is divided into three large classes: the Hydrozoa (hydras, Portuguese man-of-war), Scyphozoa (true jellyfish), and Anthozoa (soft corals, stone corals, anemones).

The phylum includes some of the most beautiful and deadly marine creatures. All members of the phylum have specialized organelles called nematocysts, which are used for entangling, penetrating, anchoring, and poisoning prey (Fig. 83.1). When the tentacles touch an object, the nematocysts fire, releasing toxin-coated, barbed threads. Firing of the nematocysts is not fully understood; the process may be protein- or cation-mediated. The nematocysts of most species cannot penetrate human skin. However, those that do may cause severe pain, serious illness, or even death. The severity of envenomation is related to the degree of toxicity of the venom, number of nematocysts discharged, and general condition of the victim. Stings from sessile forms are generally not as severe as stings from free-floating forms. The various toxins have been named and described but have not been completely biochemically characterized at the biochemical level. Venom varies from species to species. Jellyfish venoms affect autonomic nervous systems via several mechanisms. Paralysis and central nervous system effects appear to be related primarily to toxic proteins and peptides. Burning pain and urticaria are secondary to the release of various mediators of inflammation, including serotonin, histamine, or histamine-releasing agents in the venom.

Class Hydrozoa

Feathered hydroid (*Pennaria tiarelia*) is found from Maine to Florida and along the Texas coast just below the low-tide line. It is attached to solid objects, including pilings and floats. The mild sting that occurs with handling may be treated with local care.

Portuguese man-of-war (*Physalia physalis*)—commonly considered a jellyfish—is in reality a hydrozoan colony. The float can be up to 30 cm in length. The tentacles hang from the float, may reach a length of more than 75 feet, and contain about 750,000 nematocysts each. This pelagic animal is often driven ashore by storms along the Atlantic coast. Releasing one of the most powerful marine toxins, the nematocysts of the Portuguese man-of-war may discharge even when it is dead and washed up on the beach. Because of the length and transparency of the tentacles in the water, swimmers are often stung without seeing the animal. The toxin contains polypeptides and degradative enzymes. Local effects include pain and irritation. Systemic reactions include headache, myalgias, fever, abdominal rigidity, arthralgias, nausea and vomiting, pallor, respiratory distress, hemolysis, renal failure, and coma. Death may occur if the area stung is extensive in relation to the size of the victim. Treatment is discussed in the next section.

Class Scyphozoa

The common purple jellyfish (*Pelagia noctiluca*) is only mildly toxic. Local skin irritation is the major clinical manifestation.

Sea nettle (*Chrysaora guinguecinda*) is a common jellyfish found along the Atlantic coast. Clinical manifestations are the same as those for purple jellyfish.

Lion's mane (*Cyanea capillata*) is a highly toxic creature that received considerable publicity as the instrument of death in the Sherlock Holmes classic Adventure of the Lion's Mane. The animal reaches a width of 244 cm, with tentacles as long as 61 cm. The shaggy clusters of the golden yellow tentacles that hang from the medusa resemble the mane of a lion. The animal is found along both coasts. Contact with the tentacles produces severe burning. Prolonged exposure causes muscle cramps and respiratory failure.

Treatment of hydrozoan and scyphozoan stings is based on the same general principles. It is directed at three objectives: relieving pain, alleviating effects of venom, and controlling shock. The most important step is to remove the tentacles; as

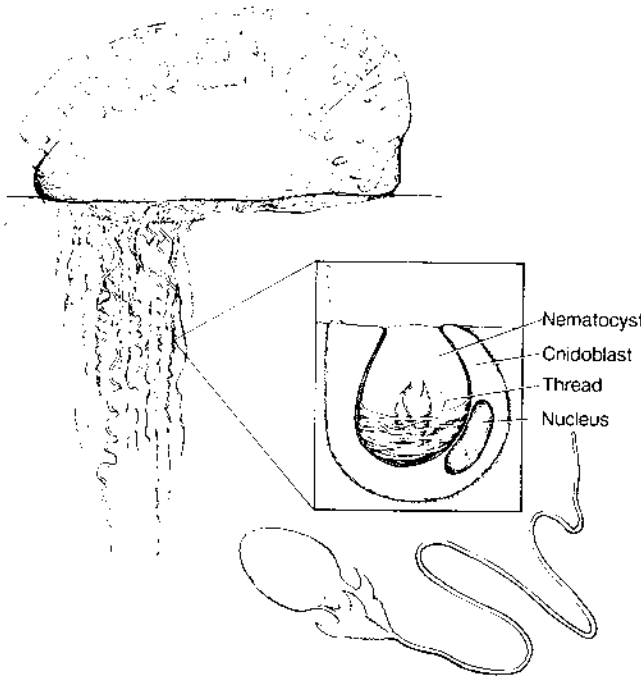

FIGURE 83.1 Marine invertebrate causing human sting.

long as the tentacle adheres to the skin, the nematocysts continue to discharge. The unexploded nematocysts are inactivated with topical application for 30 minutes with vinegar (3% acetic acid), a slurry of baking soda, or meat tenderizer (papain). Papain should not be left on for more than 15 minutes. Vinegar is generally the best disarming agent; however, for Portuguese man-of-war, vinegar has been shown to be ineffective and may activate the nematocysts. The area should be washed with seawater or normal saline. Any adherent tentacles should be carefully removed with instruments or a gloved hand, and the wound area should be immobilized. There is no antivenin available for *Physalia* or the scyphozoans, with the exception of the sea wasp, *Chironex fleckeri*, of Australia. General supportive measures for systemic reactions include oral antihistamines, oral corticosteroids, and codeine or meperidine for pain. Cardiac and respiratory support may be required. Muscle spasms have been treated with 10% solution of calcium gluconate 0.1 mL per kg (10 mg per kg) given intravenously, although the efficacy is controversial. Local dermatitis should be treated with a topical corticosteroid cream.

Class Anthozoa

The anemones found within U.S. tidal zones are only mildly toxic at worst. Coral cuts and stings can be a problem for swimmers off the Florida coast. The stinging ability of stony corals is not well defined but is considered to be of minor significance. Coral cuts, however, are important. The severity of coral cuts stems from a combination of factors, including laceration of tissue, nematocyst venom, foreign debris in the wound, and secondary bacterial infection. The clinical picture is one of stinging sensation followed by wheal formation and itching. If the wound is untreated, an ulcer with an erythematous base may form within a few days. Cellulitis, lymphangitis, fever, and malaise commonly occur.

Treatment consists of cleaning the wound and irrigation with copious amounts of saline. Removal of foreign particles must be accomplished, and debridement may be necessary. The sea provides an excellent inoculum for wound infections. Marine bacteria are generally heterotrophic, motile, and facultatively anaerobic, gram-negative rods. Organisms include *Vibrio* species, *Erysipelothrix rhusiopathiae*, and *Mycobacterium marinum*. Wounds should be left open. Broad-spectrum antibiotic therapy, particularly tetracycline, at a dosage of 40 mg per kg per day in four divided doses, has been advocated but should not be used routinely in children younger than 8 years. For children younger than 8 years, cephalexin (50 mg per kg per day in four divided doses) or trimethoprim-sulfamethoxazole (10 mg TMP per kg per day divided in two doses) should be used.

Phylum Echinodermata

Phylum Echinodermata includes starfish, sea urchins, and sea cucumbers. Of the three classes, only the Echinoedae—sea urchins—have clinical relevance for American children. The long-spined urchins (e.g., Diadema) are dangerous to handle. They do not appear to possess venom as do some of the tropical urchins, but the spines, composed of calcium carbonate, easily pierce the skin and lodge deep in the flesh. The spines may break off readily into the wound and can penetrate wet suits and sneakers. Most injuries occur during wading in shallow water. Clinically, penetration is accompanied by intense pain followed by redness, swelling, and aching. Complications include tattooing of the skin, joint arthritis, secondary infection, and granuloma formation.

In treatment, all spines should be removed as completely as possible. If spines break off in the wound, debridement should be performed with local anesthetic under aseptic conditions, but any spines not reachable will be absorbed in time. Soaking the wound in warm water may be helpful for pain. Systemic antistaphylococcal antibiotics should be used if infection develops.

MARINE VERTEBRATES

Stingrays

Background

Stingrays are the single most important group of venomous fishes, accounting for an estimated 1,000 attacks per year in North America. Stingrays are bottom feeders that have a habit of burying themselves in sand or mud of bays, shoal lagoons, and river mouths. The animals are found along the Atlantic, Pacific, and Gulf coasts and range from several inches in diameter to more than 14 feet in length. Six different species are represented in North American waters. Envenomations usually occur when an unsuspecting swimmer steps on the back of the animal and causes it to hurl its barbed tail upward into the victim as a reflex defense response. Most injuries are confined to the lower extremities, although wounds to the chest and abdomen have been reported.

The venom apparatus consists of a serrated, retropointed, dentinal caudal spine located on the dorsum of the tail. Spines

vary in length, depending on the size of the ray, but may reach a length of 122 cm in some species. The spine is encased in an integumentary sheath that contains specialized secretory cells that hold the venom. When the stingray's barb strikes the victim, it easily penetrates the skin, rupturing the integumentary sheath over the spine and causing the venom to pass along the ventrolateral grooves of the barb, into the wound. Laceration of the victim's tissues when the spine is withdrawn facilitates the absorption and distribution of the toxin. The venom is a heat-labile toxin that has been shown to contain at least 15 fractions, including serotonin, 5-nucleotidase, and phosphodiesterase. The toxin depresses medullary respiratory centers, interferes with the cardiac conduction system, and produces severe local pain.

Clinical Manifestations

Because the barb is retropointed, the wound it produces is a combination of puncture and laceration. Wounds may vary in length from 3.5 to 15 cm. The sting is followed immediately by pain, which spreads from the site of injury during the next 30 minutes and usually reaches its greatest intensity within 90 minutes. Pain and edema are most often localized to the area of injury; however, syncope, weakness, nausea, and anxiety are common complaints attributed to both the effects of the venom and the vagal response to the pain. Among other generalized symptoms are vomiting, diarrhea, sweating, and muscle fasciculations of the affected extremity. Generalized cramps, paresthesias, hypotension, arrhythmias, and death may occur. The wound often has a jagged edge that bleeds profusely, and the wound edges may be discolored. Discoloration may extend several centimeters from the wound within hours after injury and may subsequently necrose if untreated. Often, parts of the stingray's integumentary sheath contaminate the wound.

Management

Treatment is aimed at (i) preventing complications evoked by the venom, (ii) alleviating the pain, and (iii) preventing secondary infection. At the scene, the wound should be irrigated with cold saltwater. Flushing can help remove much of the venom. Bleeding should be controlled with direct pressure. On the patient's arrival in the emergency department (ED), shock, if present, should be treated with intravenous (IV) fluids. An attempt should be made to remove any remnants of the integumentary sheath if it can be seen in the wound. The extremity should be placed in hot water [40°C to 45°C (104°F to 113°F)] for 30 to 90 minutes. After soaking, the wound should be reexplored. Further debridement can then be accomplished, and the wound can be closed. Pain relief is best achieved with morphine 0.1 mg per kg IV, intramuscular (IM), or subcutaneous (SC). Tetanus prophylaxis should always be considered, but antibiotics are reserved for wounds that become secondarily infected.

Sharks

Background

Fear of sharks is as old as human history. Sensational media reports of shark attacks—and several popular movies—have asked whether it is safe to go into the water. The answer may be no but not because of sharks. The chance of being assaulted by a shark along the North American coast is roughly 1 in 5 million. Because of the large number of sporting activities that take place in the ocean environment, however, clinicians who practice in coastal areas may be called on to manage a victim of these primitive creatures.

In U.S. waters, most attacks are by the gray reef, great white, blue, and mako sharks. Factors that increase a risk of attack include swimming near sewer outlets, time of the day (late afternoon and early evening), murky warm water, increased commotion, deep channels, and bright objects. Attacks of surfers along the northern California coast were believed to be caused by sharks mistaking surfboard shapes in the water for elephant seals, part of the shark's usual diet.

Clinical Manifestations

Attack victims usually do not see the shark before it strikes. Occasionally, the attack is preceded by one or more "bumps," during which the victim may sustain extensive abrasions from the rough denticles of the shark's skin. Two types of bite wounds are described: tangential injury and a definitive bite. Tangential injury is caused by the slashing movement of the open mouth as the shark makes a close pass. Severe lacerations, incised wounds, and loss of tissue are seen. Definitive bite wounds vary according to the part of the body seized by the shark. Lacerations, loss of soft tissue, amputations, and comminuted fractures are recorded. Most injuries involve only one or two bites and are confined to the extremities.

Management

Hypovolemic shock is the immediate threat to life in shark attacks. Bleeding should be controlled at the scene with direct compression, and intravascular volume should be replaced with crystalloid until blood products are available. The victim should be kept warm and given oxygen when being transported to an ED. Wounds should not be explored in the field.

Tetanus toxoid and tetanus immune globulin therapies should be considered, and prophylactic antibiotics with a third-generation cephalosporin or trimethoprim-sulfamethoxazole are suggested.

Scorpaenidae

Background

The 80 species found in the Scorpaenidae family include the zebra fish, scorpion fish proper, and stonefish. In California, the sculpin is commonly involved. Scorpaenidae are generally found in shallow water, around reefs, kelp beds, or coral. All members of the family are nonmigratory, slow swimming, and often buried in sand. The venom apparatus consists of a number of dorsal, anal, and pelvic spines covered by integumentary sheaths containing venom glands that lie within anterolateral grooves. The venoms are unstable, heat-labile compounds. Most often envenomation occurs when the fish are handled during fishing excursions.

Clinical Manifestations

The clinical signs and symptoms are essentially the same, varying among the species only in degree. Severe pain at the site of the wound is the first and primary clinical sign for all species. The wound and surrounding area becomes ischemic and then cyanotic. Paresthesia and paralysis of the extremity may occur.

Other clinical signs include nausea, vomiting, hypotension, tachypnea proceeding to apnea, and myocardial ischemia with electrocardiographic changes.

Management

Treatment involves irrigating the wound with sterile saline. The injured extremity is then immersed in very hot water [40°C to 45°C (104°F to 113°F)] for 30 to 60 minutes or until the agonizing pain is completely relieved. Pain relief is best achieved with morphine 0.1 mg per kg IV, IM, or SC. The patient should be monitored carefully for cardiotoxic effects and respiratory depression. Antivenin is available only for the stings of the stonefish of Australia.

Catfish

Background

The catfish is a popular food and sport fish found in many lakes and rivers throughout the United States. The venom apparatus consists of a number of spines located in the dorsal and pectoral fins. The integumentary sheaths covering the spines contain venom glands. The venoms are unstable, heat-labile compounds. Most often, envenomation occurs when the fish are handled during fishing excursions. A combination of injuries is seen: wounds secondary to puncture and laceration, foreign-body reaction, and the effects of venom.

Clinical Manifestations

The spines inflict a puncture wound or laceration. The spines may become imbedded in the flesh of the victim, causing soft-tissue swelling, which may become infected or lead to a foreign-body reaction. The venom produces a local inflammatory response—local intense pain, edema, hemorrhage, and tissue necrosis.

Management

Treatment involves irrigating the wound with sterile saline. The injured extremity is then immersed in hot water [40°C to 45°C (104°F to 113°F)] for 30 to 60 minutes or until pain is relieved. Pain relief is best achieved with morphine 0.1 mg per kg IV, IM, or SC. The wound should be explored to locate any retained spines. Adequate debridement is essential. Systemic antibiotics to cover gram-negative organisms are recommended. Wounds may be closed by using a delayed primary closure.

TERRESTRIAL INVERTEBRATES

Phylum Arthropoda

The arthropods make up the largest phylum in the animal kingdom. All arthropods have an exoskeleton with jointed appendages. The phylum is divided into two subphyla: the Chelicerata, which includes scorpions, spiders, ticks, and mites, and the Mandibulata, which includes insects.

Scorpions

Background. Of 650 known scorpion species (class Arachnida), only a limited number are dangerous to humans. In the southwest United States, *Centruroides sculpturatus* is the potentially lethal inhabitant. Although *C. sculpturatus* and *Centruroides exilicauda* (Fig. 83.2) have been considered separate species in the past, more recent taxonomic classification treats the two as one species. The animal has two pinching claws anteriorly and a tail or pseudoabdomen that ends in a telson (Fig. 83.2). The telson houses a pair of poison glands and a stinger. Normally, scorpions grasp their prey with pincers and then sting the victims by arching their tails over their heads. The animals are nocturnal; during the day, they seek shelter under stones and debris. They often crawl into sleeping bags and unoccupied clothing. In one report, 80% of stings occurred in children younger than 10 years.

Clinical Manifestations. The scorpion's poison gland produces a neurotoxin and a local cytotoxin. The general neurotoxicity is excitatory, affecting the autonomic and skeletal neuromuscular system. Common symptoms include local pain, restlessness, hyperactivity, roving eye movements, and respiratory distress. Other associated signs may include convulsions, drooling,

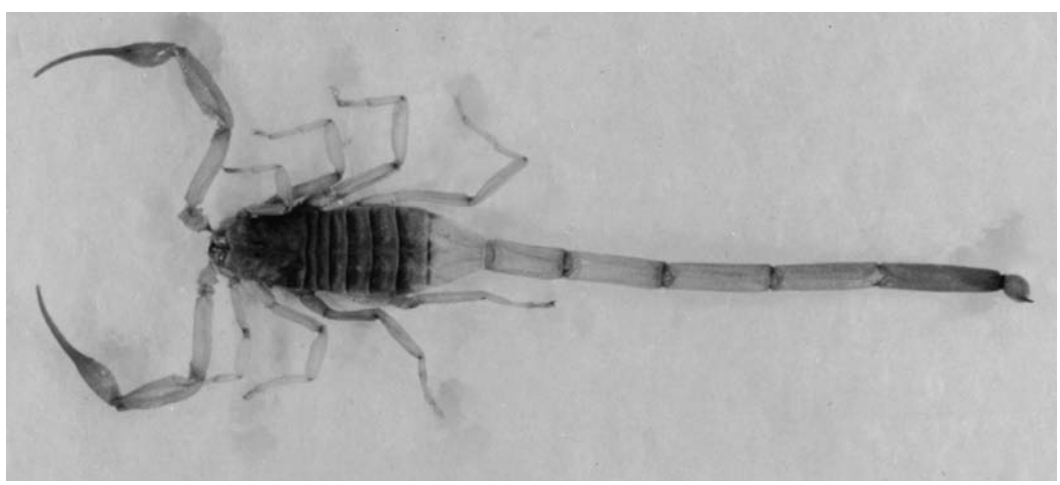

FIGURE 83.2 *Centruroides exilcauda* (sculpturatus). (Courtesy of F. E. Russell.)

wheezing, hyperthermia, cyanosis, gastrointestinal hemorrhage, and respiratory failure. Death may result from respiratory paralysis, pulmonary edema, or shock. The diagnosis may be difficult because history of a sting may not be forthcoming. There is no laboratory test for confirmation of envenomation.

Management. Numerous treatment modalities have been used in addition to general supportive care. Cryotherapy of the site of sting has been advocated to reduce swelling and local induration. An antivenin had been developed and used in Arizona; however, the production ended in 2001. Since the last vials expired, an increase in intensive care unit (ICU) admissions has been reported. Calcium gluconate [0.1 mL per kg (10 mg per kg) of the 10% solution] has been given intravenously to reduce muscular contractions and associated pain, but benefit has not been proved. Sedative-anticonvulsants, in particular, phenobarbital (5 to 10 mg per kg) or benzodiazepines (midazolam 0.05 to 0.1 mg per kg) intravenously are used to treat persistent hyperactivity, convulsions, and/or agitation. A continuous infusion of midazolam may optimize treatment in extreme cases (start at 0.1 mg per kg per hour and titrate to relief of symptoms). Corticosteroids and antihistamines have little, if any, proven benefit.

Spiders

More than 100,000 species of spiders (class Arachnida) are known to exist. All are carnivorous and have fangs and venom by which they immobilize and kill their prey. The risk of serious bites is small, except in a few species. Most spiders are shy and retiring creatures that will not bite people unless provoked. In most species, the fangs are too short and fragile to penetrate human skin, and the venom is mild, however, two species in the United States are capable of producing more severe reactions.

Loxoscelism (Bite of the Brown Recluse Spider). Three species of Loxosceles have caused envenomation, primarily in the southern and midwestern states, but can be found throughout the continental United States. These small spiders (1 to 1.5 cm in length) are characterized by a brown violin-shaped mark on the dorsum of the cephalothorax. They are found outdoors but will establish nests indoors, especially in closets. As its name implies, the most common species, *Loxosceles reclusa*, is shy and will only attack when provoked. The venom is cytotoxic and also contains a factor similar to hyaluronidase.

Clinical manifestations. Clinically, the bite is usually innocuous. Because the bite is initially unnoticed, there is sometimes a delay in seeking medical attention. The spectrum of reaction ranges from minor local reaction to severe necrotic arachnidism (Fig. 83.3). The local reaction is characterized by mild to moderate pain 2 to 8 hours after the bite. At the site of the bite, erythema develops with a central blister or pustule. Within 24 hours, subcutaneous discoloration appears and spreads over the next 3 to 4 days, reaching a size of 10 to 15 cm. At this time, the pustule drains, producing an ulcerated "crater." The local reaction varies with the amount of venom injected. Scar formation is rare if there is no evidence clinically of necrosis within 72 hours of the bite. Systemic reaction is most commonly noted in small children. Symptoms are noted 24 to 48 hours after the bite and include fever, chills, malaise, weakness, nausea, vomiting, joint pain, morbilliform eruption with petechiae, intravascular hemolysis, hematuria, and renal failure.

FIGURE 83.3 Spider bite necrotizing.

Management. Because of the delay in initial diagnosis, treatment varies with the clinical stage of the bite. There is no specific serologic, biochemical, or histologic test to diagnose envenomation accurately. The range of the brown recluse spider is limited. Many of the presumed bites outside the endemic range are caused by other spiders (Table 83.1) and by other conditions. Pediatric conditions that have been misdiagnosed as brown recluse bites include infections with staphylococci or streptococci, herpes simplex, herpes zoster, erythema multiforme, Lyme disease, fungal infection, pyoderma gangrenosum, chemical burn, poison ivy/oak, and localized vasculitis. Unless all or part of the spider is brought for identification, definitive diagnosis cannot be made. Table 83.1 lists the

TABLE 83.1

SPIDERS KNOWN TO CAUSE NECROTIC LESIONS

Genus name	Common name	Geographic distribution
Argiope	Golden orb weaver	Throughout North America (individual species more restrictive)
Chiracanthium	Running spider	Throughout United States
Loxosceles	Brown recluse	Kansas and Missouri to Texas West to California
Lycosa	Wolf spider	Throughout United States
Phidippus	Black jumping spider	Atlantic Coast to Rocky Mountains

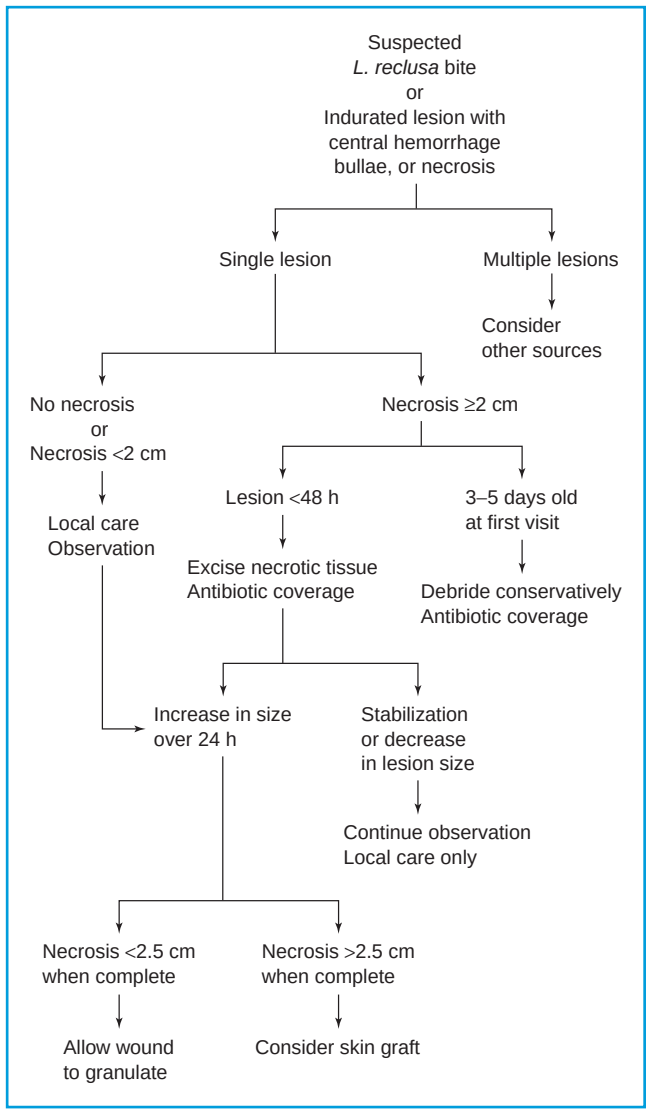

FIGURE 83.4 Management of suspected brown recluse spider bite.

spiders found in the United States, known to cause necrotic lesions. An algorithm for management of suspected bites is shown in Fig. 83.4. One recent series of adult patients suggests that serious complications are rare. Most victims will heal with supportive care. Large-dose steroids have been advocated in the past; however, studies have found no significant alteration of necrosis from the venom by steroids or heparin. Once large areas of necrosis have become demarcated, surgical excision and skin grafting are required, although the need for grafting is rare. Animal studies do not support the use of dapsone, hyperbaric oxygen, or the two in combination in the treatment of these envenomations. However, current recommendations are to limit the use of dapsone to adults with proven brown recluse bites. Dapsone should not be used in children due to the risk of methemoglobinemia. Antivenom is not yet commercially available. For systemic manifestations, vigorous supportive care is needed. Most deaths occur secondary to hemolysis and respiratory failure. A complete blood cell count (CBC) and platelet count for evidence of hemolysis is needed, as well as monitoring of hemoglobin, urine sediment, blood urea nitrogen (BUN), and creatinine levels for evidence of hemolysis and renal failure.

Latrodectism (Bite of the Black Widow Spider). The bite of *Latrodectus mactans* is the leading cause of death from spider bites in the United States. The animal is shiny black, with a brilliant red hourglass marking on the abdomen. The marking is found on the mature female and may be present on the male. The male is not a threat because it is only one-fourth the size of the female, meaning its fangs are unable to penetrate human skin. The webs are usually found in corners or out-of-the-way places. The female is not aggressive unless guarding her egg sac or provoked. The venom, a complex protein that includes a neurotoxin, stimulates myoneural junctions, nerves, and nerve endings.

Clinical manifestations. Reaction is generalized pain and rigidity of muscles 1 to 8 hours after the bite. No local symptoms are associated with the bite itself. The pain is felt in the abdomen, flanks, thighs, and chest and is described as cramping. Nausea and vomiting are often reported in children. Respiratory distress can occur. Chills, urinary retention, and priapism have been reported. There is a 4% to 5% mortality rate, with death resulting from cardiovascular collapse. The mortality rate in young children may be as high as 50%.

Management. Because of the size, color, and distinctive markings of this spider, bites are seldom mistaken if the child is old enough to describe the spider. A child who has severe pain and muscle rigidity after a spider bite should be considered a Latrodectus bite victim. A clinical grading scale has been developed by Clark (Table 83.2). Treatment with Latrodectus antivenin (Lyovac, Merck, Sharp & Dohme) should be instituted as soon as a bite is confirmed in children who weigh less than 40 kg; the usual dose is 2.5 mL (one vial). Antivenin should be administered by following the package insert and after skin testing to determine the risk of hypersensitivity to horse serum. For children who weigh more than 40 kg, it is not as urgent to institute antivenin treatment, but indications for its use include patients who are younger than 16 years, who have respiratory difficulty, or who have significant hypertension

TABLE 83.2

GRADING SCALE FOR *LATRODECTUS* ENVENOMATION

Grade	Symptoms
1	Asymptomatic Local pain at bite site Normal vital signs
2	Muscular pain—localized Diaphoresis—localized Normal vital signs
3	Muscular pain—generalized Abnormal vital signs Nausea, vomiting Headaches Diaphoresis

(grades II and III). Antivenin is usually effective within 30 minutes and may be repeated once within 2 hours if symptoms return. Serum sickness is a possible side effect. Because the dosage is low, however, serum sickness is uncommon, with a rate lower than those reported for other types of antivenom. Calcium gluconate 10% solution was given in the past to control leg and abdominal cramps. Recent series found calcium gluconate effective in only 4% of cases. Methocarbamol (Robaxin) appears to be even less efficacious than calcium gluconate. Muscle relaxants such as diazepam have also been advocated, but they are variably effective and the effects are short lived. Analgesia may be achieved with morphine or meperidine.

Tarantulas and Others

Tarantulas, although fearsome in size and appearance, do not bite unless provoked. The venom is mild, and envenomation is not a problem. The wolf spider (*Lycosa* species) and the jumping spider (*Phidippus* species) have also been implicated in bites. Like the tarantula, they have mild venom that causes only local reactions. Bites from all three of these spiders should be treated with local wound care.

Tick Paralysis

Ticks are responsible for transmitting a variety of infectious agents, including spirochetes, viruses, rickettsiae, bacteria, and protozoa. Examples of tick-borne illness, which are discussed in Chapter 92, include Rocky Mountain spotted fever, Lyme disease, tularemia, ehrlichiosis, babesiosis, relapsing fever, and Colorado tick fever. Tick paralysis is associated with the bite of the wood tick, *Dermacentor andersonii*; the dog tick, *D. variabilii*; and the deer tick, *Ixodes scapularii*. The gravid engorged tick releases a neurotoxin that can produce cerebellar dysfunction or an ascending weakness. The mechanism of action of the toxin is not well understood.

Clinical Manifestations. Following tick attachment, there is a latent period of 4 to 7 days, followed by symptoms of restlessness, irritability, and ascending flaccid paralysis. Respiratory paralysis and death may follow if the tick is not detected. Laboratory data, including cerebrospinal fluid, are usually normal, but lymphocytic pleocytosis has been reported.

Management. Management is based on general supportive care and a diligent search for the tick. Ticks should be removed using blunt forceps or tweezers. The tick should be grasped as close to the skin surface as possible and pulled upward with a steady even pressure. A twisting or jerking motion may cause the mouthparts to break off. Do not squeeze or crush the body of the tick because this may introduce infective agents. After the tick is removed, the bite site should be cleaned. Once the tick is removed, the paralysis is reversible without apparent sequelae.

Centipedes and Millipedes

Centipedes (class Myriapode order Chilopoda) are venomous, biting with jaws that act like stinging pincers. Bites can be extremely painful; however, the toxin is relatively innocuous, causing only local reaction. Treatment consists of injection of local anesthetic at the wound site and local wound care.

American millipedes (order Diplopoda) are generally harmless.

Insects

The insects (class Insecta) constitute the largest number of animal species. Hymenoptera is the most important order of the class and includes bees, wasps, hornets, yellow jackets, and ants (Fig. 83.5). Because of differences in venom composition and rate of systemic reactions, ants are covered separately in this chapter. Hymenoptera are responsible for 50% of human deaths from venomous bites and stings. A variety of toxic reactions are seen but the most common is allergic.

Bee, Hornet, Yellow Jacket, Wasp

Clinical manifestations. Clinically, the stings of bees and wasps differ because the barbed stinger of the bee remains in the victim's skin, whereas the wasp may sting multiple times. Reactions may vary. The venoms of the bee, hornet, yellow jacket, and wasp contain protein antigens that can elicit an immunoglobulin E antibody response in those who are stung. In addition, venoms contain various biogenic amines, phospholipase, phosphatase, and hyaluronidase. Because of the similarity of the venoms, cross-reactivity can occur. Local reaction to a sting results in pain, erythema, and swelling. Systemic allergic reactions may be grouped by severity. Group I consist of urticaria, generalized erythema, malaise. Group II includes angioedema or two or more of the following: chest or throat tightness, nausea, vomiting, and dizziness. Group III consists dyspnea, wheezing or stridor and two or more of the following: dysphagia, dysarthria, hoarseness, weakness, confusion, feeling of impending disaster. Group IV consists of life-threatening systemic reactions, including hypotension, and shock. Anaphylactic reactions secondary to insect stings occur in 0.5% to 5% of the population.

Management. Because the barbed honeybee stinger with venom sac is avulsed and often remains in the victim's skin, it must be removed if seen. In the past, texts suggested that removal was best accomplished by scraping the stinger and that squeezing or pulling should be avoided. A more recent study compared the effects of delays in removing stings with the effects of different methods of removal. The findings showed that the method of removal is irrelevant (scraping vs. pulling) but that delays in removal are likely to increase the dose of venom received. Stings do not need to be dried with baking soda.

Treatment of stings is based on the severity of the allergic reaction. Local reactions can be treated with cold compresses at the site of sting. Group I reactions are treated with diphenhydramine hydrochloride 4 to 5 mg per kg per day (maximum 200 mg) orally in four divided doses for several days. Group II and Group III reactions are treated with epinephrine 1:1,000 solution 0.01 mL per kg (maximum 0.3 mL) injected intramuscularly followed by diphenhydramine orally. In addition, H_2-blockers may provide additional benefit. Ranitidine (4 to 5 mg per kg per day PO divided q12h) or (2 to 4 mg per kg per day IV divided q6–8h) or famotidine (1 to 2 mg per kg per day PO divided q12h) can be used. Oral steroids (prednisone/prednisolone 2 mg per kg per day) are recommended. These children should be observed in the hospital for 24 hours. Group IV reactions may require intubation if upper airway obstruction is present. Wheezing refractory to epinephrine may be treated with an aminophylline bolus of 6 mg per kg over 20 minutes, followed by a 1.1 mg per kg per hour infusion if needed. Hypotension should be treated with a fluid bolus of saline or

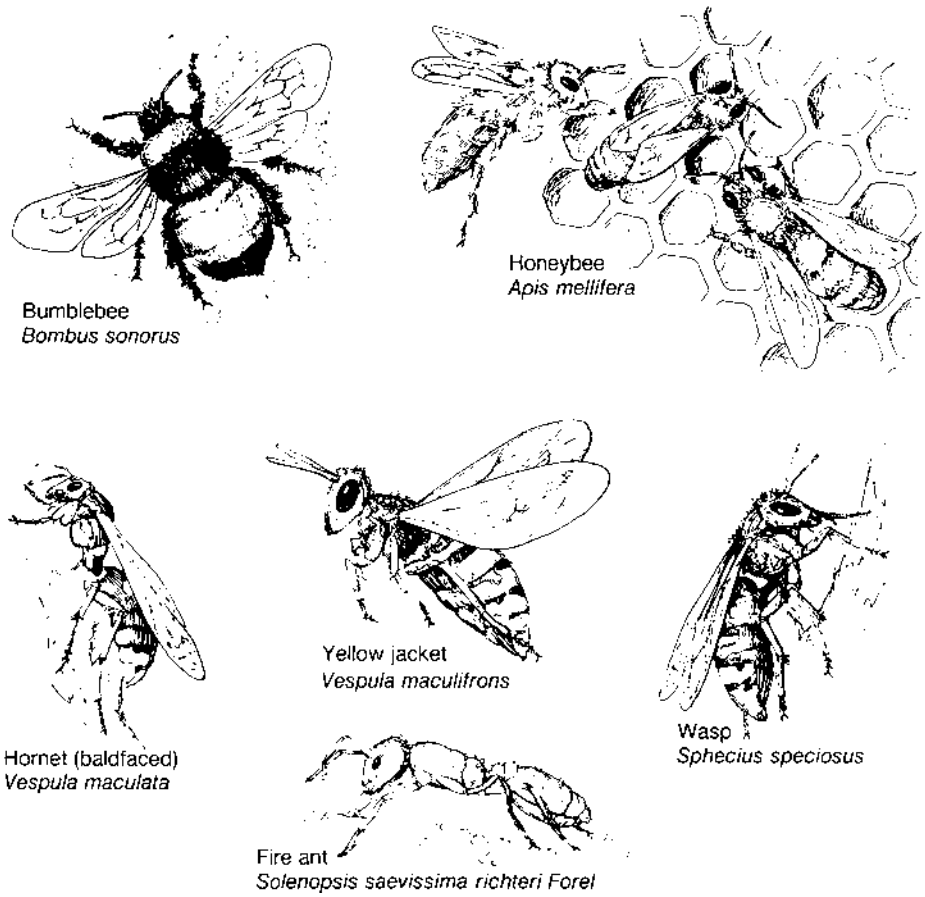

FIGURE 83.5 Hymenoptera capable of causing allergic reactions.

lactated Ringer's solution 10 to 20 mL per kg given over 20 to 30 minutes. IV epinephrine (1:10,000) should be considered if hypotension fails to respond to IM epinephrine and fluid bolus. Hydrocortisone (2 mg per kg) may be given intravenously for 4 days. All children in this group should be admitted to an ICU. Children who have had a group II, III, or IV reaction should be followed by an allergist for hyposensitization. Parents of these children should keep an insect sting emergency kit. The EpiPen and EpiPen Jr are spring-loaded autoinjectors triggered by placing pressure on the thigh with the instrument. The pens inject 0.3 or 0.15 mg (EpiPen and EpiPen Jr, respectively) of epinephrine. The pens are used as first aid in the field by the parent or guardian and are not meant to substitute for prompt definitive treatment at a medical facility. Parents should receive information regarding the use of epinephrine autoinjectors and avoidance of situations and behaviors that would attract stinging insects.

Fire Ants

Clinical manifestations. An increasing number of bites and envenomations in the South and increasingly northward has been accounted for by fire ants (*Solenopsis richteri* and *Solenopsis invicta*). The venom differs from the other Hymenoptera in that it is an alkaloid with a direct toxic effect on mast cell membranes. There is no cross-reactivity with other members of the order.

The fire ant bites with well-developed jaws and then uses its head as a pivot to inflict multiple stings. The clinical picture of the fire ant sting is one of immediate wheal and flare at the site. The local reaction varies from 1 to 2 mm, up to 10 cm, depending on the amount of venom injected. Within 4 hours, a superficial vesicle appears. After 8 to 10 hours, the fluid in the vesicle changes from clear to cloudy (pustule), and the vesicle becomes umbilicated. After 24 hours, the lesion is surrounded by a painful erythematous area that persists for 3 to 10 days. Edema, induration, and pruritus at the site occur in up to 50% of patients. Occasionally, systemic reactions occur as with other Hymenoptera.

Management. Treatment of fire ant stings is symptomatic. Local care, such as ice applied to the reactive area, and frequent cleansing of the lesions to prevent secondary infection are all that is usually required. Topical steroids, antibacterial medications, and antihistamines do not appear to be efficacious in prevention of pustule formation. Antihistamines are useful for pruritus. Systemic reactions are rare and should be treated similarly to other Hymenoptera reactions.

TERRESTRIAL VERTEBRATES

Venomous Reptiles

Background

> God said to the serpent, "Be accursed beyond all cattle, all wild beasts. You shall crawl on your belly and eat dust every day of your life. I will make you enemies of each other: you and the woman, your offspring and her offspring."
>
> —Genesis 3:14

Throughout recorded history, serpents and their encounters with humans have evoked strong emotions, folklore, and medicinal practices. Research during the past several decades has lessened the mystique surrounding the venomous substances secreted by 15% of the U.S.'s 120 snake species. The more recent emphasis on antivenin therapy and expedient supportive medical care has dramatically reduced mortality and morbidity from poisonous snakebites.

In the United States, an estimated 8,000 people are bitten annually by poisonous snakes. Predictably, the pediatric population, especially males, ages 5 to 19 years, accounts for a disproportionately large number of these victims. The highest incidence occurs in the Southeast and Southwest, between April and October, although venomous snakebites occur at least sporadically in most states. More recent data show 25% of bites are in patients younger than 17 years. Only 10 to 15 deaths are reported per year, but the morbidity in limb dysfunction and other complications, although unknown, is undoubtedly much higher. With appropriate therapy, most long-term morbidity can be prevented.

The poisonous snakes indigenous to the United States are members of the Crotalidae (pit viper) or Elapidae families (Table 83.3). The rattlesnake, water moccasin, and copperhead are pit vipers and are responsible for 99% of venomous snakebites. The coral snake is the only member of the Elapidae family in this country and, along with imported exotic snakes, accounts for the remaining 1% of serious snakebites.

The pit vipers have several characteristic features that distinguish them from nonvenomous snakes (Fig. 83.6): (i) two pits containing heat-sensitive organs that assist these poor-visioned reptiles to localize their prey are located, one on each side of the head, between the eye and nostril; (ii) the pupils are elliptical and vertically oriented in contrast to the usually round pupil of a harmless snake; (iii) two curved fangs or hollow maxillary teeth that are 5 to 20 mm long and, in larger snakes, may be spaced as wide as 3 cm, are folded posteriorly against the palate and advance forward when the pit viper strikes; (iv) the head is relatively more triangular than that of most nonvenomous snakes; and (v) the scutes, or scales, on the ventral portion caudad to the anal plate continue in a single row, whereas nonpoisonous snakes have a cleft, or double row.

The rattlesnake (*Crotalus*) is distributed widely throughout most of the United States and is the culprit in approximately 60% of all pit viper attacks. Several species are notably more menacing and toxic to humans. The large and gold diamondbacks (*Crotalus adamanteus* and *Crotalua atrox*) often stand their ground when approached by humans and inflict most lethal snakebites in North America. Other rattlesnakes that commonly cause the more severe bites include the timber (*Crotalus horridus*), prairie, and pacific (*Crotalus viridus*) rattlesnakes. Several other *Crotalus* species are implicated in less severe human envenomation.

Rattlesnakes vary considerably in size and color, even among species. The eastern diamondback, which inhabits the

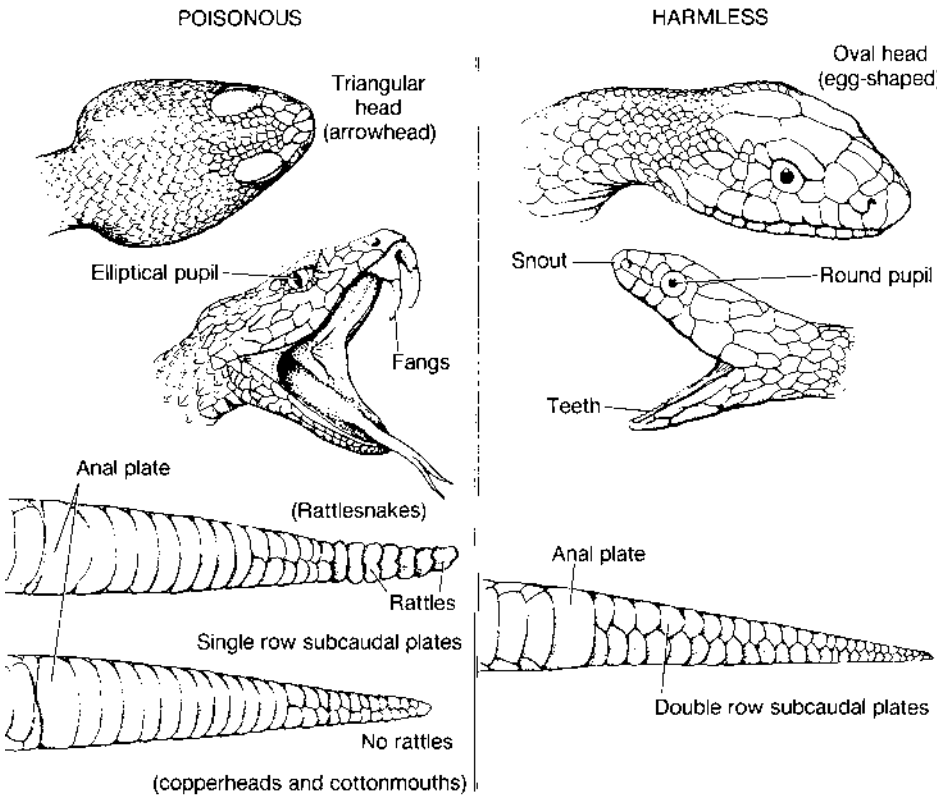

FIGURE 83.6 Comparison of poisonous and nonpoisonous snakes.

coastal Southeast, may be as large as 2 m long and 7 kg in weight; it usually has a brightly outlined symmetric diamond pattern. The timber rattler found in the Northeast and Southeast westward to Texas may be only 1 m long and have nearly black scales (especially in colder climates). Emergency physicians must become familiar with the particular species in their areas.

The pygmy rattler and massasauga are considered rattlesnakes because, in common with *Crotalus* species, they possess a "rattler" on their tail. However, these two relatively small snakes are members of the genus *Sistrorus*, and their bites are not as toxic as those of true rattlesnakes.

The copperhead (*Agkistrodon contortrix*) is a common poisonous snake that lives in the Southeast and much of the Northeast, extending westward as far as Texas and Nebraska. This snake accounts for approximately 30% of venomous snakebites but, luckily, is seldom a serious threat to life or limb. *A. contortrix* is usually 0.6 to 1 m in length and has a light pink to red-brown body, with darker brown crossbands shaped like hourglasses. The head has a coppery tinge.

The water moccasin, also known as the cottonmouth (*A. piscivorus*), is a semiaquatic pit viper indigenous to the Southeast, including the Gulf States and the Mississippi Valley as far north as southern Illinois. These are larger and more belligerent snakes, often traveling with their heads in an aggressive 45-degree angle from the horizontal plane. Their body is olive brown to black, with darker markings on the sides that often fade over the dorsum. The ventral surface is lighter in color. The oral mucosa is distinctively white, hence the name cottonmouth. Like the copperhead, bites from this species are, in general, less serious than those of the *Crotalus* species.

The relatively passive coral snake is responsible for only 10 to 15 snakebite cases per year in this country. As a member of the Elapidae family, it does not share the pit viper's distinctive physical characteristics (i.e., it has round pupils, a blunt head, and ventral caudal scutes, and lacks pits). Unlike the nonpoisonous snakes, the coral snake has two small maxillary fangs.

The snout of the coral snake is always black and is followed by a yellow ring and subsequent black band. Red and black bands then alternate down the approximately 2-feet length of the coral snake, with narrow yellow rings bordering the red band (Fig. 83.7). The nonvenomous king snake is often confused with the coral; it has red bands directly bordered by black bands. The yellow rings in this snake are within the black bands. The adage about coral snakes holds true:

> Red on yellow, kill a fellow.
> Red on black, venom lack.

There are two species of coral snakes: the eastern (*Micrurus fulvius*) and the Arizonan (*Micruroides euryxanthus*). *M. fulvius* is responsible for most human envenomations and is found in most states east of the Mississippi, with the exception of the Northeast. *M. euryxanthus* is indigenous only to Arizona and New Mexico.

Pathophysiology

Snakebite envenomation is a complex poisoning because of the assorted deleterious effects of venoms, as well as the multiple human and snake variables that influence venom toxicity. Venoms are mixtures of potent enzymes, primarily proteinases, and low-molecular-weight peptides that possess extensive pathophysiologic properties. A crotalid venom often has a

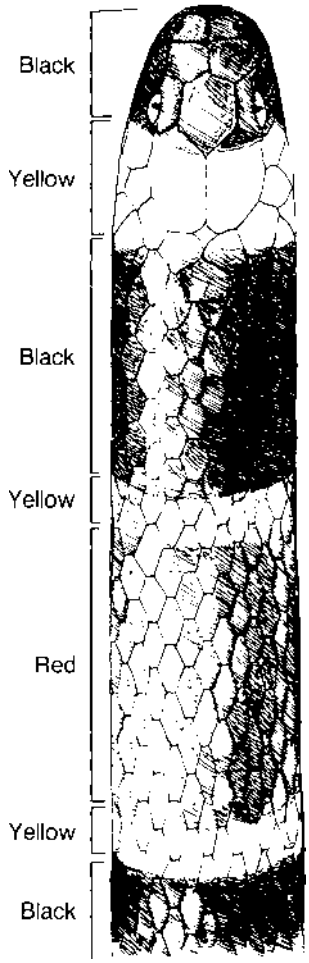

FIGURE 83.7 Coral snake.

combination of necrotizing, hemotoxic, neurotoxic, nephrotoxic, and/or cardiotoxic substances. The neurotoxins comprise a large fraction of the venom of the Mojave rattlesnake. These toxins are related to phospholipase A and bind the nicotinic acetylcholine receptors and thus prevent the depolarizing action of acetylcholine. Proteolytic enzymes aided by hyaluronidase cause much of the local tissue destruction. Many venoms induce increased endothelial permeability and venous pooling, creating intravascular depletion. A transient hemoconcentration may be present during this plasma "leak." Hemotoxic effects induce hemolysis, fibrinogen proteolysis, and thrombocytopenia, which, along with activation of plasminogen, can lead to a bleeding diathesis in severe envenomation. Respiratory failure may occur secondary to pulmonary edema or a shock state.

The ultimate toxicity of the snakebite also depends on human and snake variables. Human factors include the victim's size and general health and wound characteristics that affect venom absorption. A small child is more susceptible to a given volume of venom than a larger person. (Unfortunately, young children are commonly bitten more than once.) Fang penetration of a vessel or subfascial compartment ensures a more rapid absorption and serious systemic effects. Likewise, a bite on the head, neck, or trunk (3% of snakebites) hastens systemic absorption. Approximately one-third of snakebites involve the upper extremity and cause a higher long-term functional morbidity than do lower-extremity wounds.

Snake variables include the snake's size, the amount of venom injected, and the potency of the particular species' venom. Venom secretion is under voluntary muscular control; any condition that facilitates it (e.g., long, healthy fangs or full stores of venom) adds to the toxicity of the bite. An angered and hungry rattlesnake unloads more venom than a recently satiated and surprised rattlesnake.

Clinical Manifestations

Pit Viper. Local pain after a *Crotalus* envenomation is typically intense, and a sensation of burning occurs within a couple of minutes. The pain is greater with ensuing edema and presumably increases with larger inocula of venom. Victims of a significant rattlesnake bite often complain within minutes of a perioral numbness, extending to the scalp and periphery. This paresthesia may be accompanied by a metallic taste in the mouth.

These patients also may have nausea, vomiting, weakness, chills, sweating, syncope, and other more ominous symptoms of systemic venom absorption. A copperhead or pygmy rattlesnake envenomation produces less local symptoms, and systemic consequences are often minimal or nonexistent unless a small child, multiple bites, or larger than average snake is involved. The water moccasin's effects are more variable.

There is a relative lack of serious pain or swelling with the Mojave rattler bite, although, as in other *Crotalus* bites, the patient may complain of paresthesia in the affected extremity. Within several hours, these patients may develop neuromuscular symptoms such as diplopia, difficulty in swallowing, lethargy, nausea, and progressive weakness from the large portion of neurotoxin in this species.

The wound should be inspected for fang punctures, and if two are present, the distance between them should be noted. An interfang distance of less than 8 mm suggests a small snake; 8 to 12 mm, a medium snake; and more than 12 mm, a larger snake. Fang wounds by small snakes such as the pygmy rattler may be extremely subtle; in larger crotalid snakebites, the fang marks may be hidden within hemorrhagic blebs and edema. Occasionally, only one puncture or two scratches will be present, but both wounds may be potentially venomous. However, not all crotalid bites are envenomated; 10% to 20% of known rattlesnake strikes do not inject venom. Other causes of puncture wounds must also be kept in mind—notably rodent bites and thorn wounds. Nonpoisonous snakes sometimes leave an imprint of their two rows of teeth, but the wounds should lack fang puncture marks.

Pit viper envenomations are characterized by intense pain, erythema, and edema at the wound site within 5 to 10 minutes. There may be bloody serosanguinous fluid dripping from the fang punctures. Progressive swelling proportional to the inoculum of venom develops over the next 8 hours and may continue to some degree for an additional 24 hours. Rarely, the venom is deposited predominantly in a muscle compartment, resulting in a deceptively minimal amount of edema. The Mojave rattlesnake bite provides another example of a seemingly innocuous local wound in the setting of a potentially serious envenomation. In a severe diamondback rattlesnake bite, an entire extremity may be swollen within 1 hour.

TABLE 83.4

LOCAL SIGNS OF PIT VIPER ENVENOMATION

Pain	Ecchymosis
Edema	Vesicles
Erythema	Hemorrhagic blebs

Local ecchymoses and vesicles usually appear within the first few hours, and hemorrhagic blebs are often present by 24 hours. Lymphadenitis and lymph node enlargement may also become apparent.

Without appropriate therapy, these local manifestations progress to necrosis and may extend throughout the bitten extremity, effectively maiming the victim. Also, as in any animal wound, secondary infection is a risk; the snake's oral flora includes gram-negative bacteria. Table 83.4 summarizes local characteristics of pit viper bites.

The dramatic signs of crotalid envenomation are derived primarily from the victim's hypovolemic state, hemorrhagic tendencies, and neuromuscular dysfunction. Table 83.5 outlines the more notable physical signs.

Coral Snake. Coral snakes leave unimpressive local signs but can neurologically cripple their prey. The bite may have one or two punctures, at most 7 to 8 mm apart, as well as other small teeth marks. There is usually only mild pain and little, if any, swelling. Local wound and, eventually, extremity paresthesia and weakness may be reported. Over several hours, generalized malaise and nausea, fasciculations, and weakness develop insidiously. The patient may complain of diplopia and have difficulty talking or swallowing. Physical examination reveals bulbar dysfunction and generalized weakness. Respiratory failure may ensue.

Management

Pit Viper. As in all medical emergencies, the airway, breathing, and circulation of the patient must be addressed before attending to the snakebite (Fig. 83.8). The first priority of prehospital care of the snakebite victim is rapid transport to a medical facility. Time is of the essence, and all activities in the field must be tempered by this fact.

TABLE 83.5

SYSTEMIC SIGNS OF CROTALID (PIT VIPER) ENVENOMATION

General
  Anxiety, diaphoresis, pallor, unresponsiveness
Cardiovascular
  Tachycardia, decreased capillary perfusion, hypotension, shock
Pulmonary
  Pulmonary edema, respiratory failure
Renal
  Oliguria, hemoglobinuria, hematuria
Neuromuscular
  Fasciculations, weakness, paralysis, convulsions
Hematologic
  Bleeding diathesis

It is important to approach the patient with reassurance and to place him or her at rest. The affected extremity should be stripped of any jewelry or clothing and immobilized in a position of function below the level of the heart. The patient should be kept warm and not allowed anything by mouth.

Tourniquets, inadvertently tightened for prolonged full vascular occlusion, have created more problems than they have solved and therefore cannot be recommended for prehospital care. In experienced hands, however, a constriction band that obstructs lymph and venous flow can be valuable when a long transport is anticipated (longer than 30 to 60 minutes). The band should be at least 2 cm wide and placed 5 to 10 cm proximal to the wound (proximal to the nearest joint if the wound is nearby). The constriction should be loose enough to admit a finger and preserve good distal arterial pulses. Vigilant observation for adequate perfusion is necessary because of progressive edema; the constriction band should be shifted to remain proximal to the swelling. To be effective, the band must be applied initially within 1 hour of the pit viper bite. It may be removed when antivenin therapy is started.

Incision and suction (extractors) of the pit viper wound while advocated in the past can no longer be advised. The usefulness of extractors can be supported only if applied within minutes of the bite and even then recovery of venom is variable in a laboratory setting. No animal studies have shown an increase in survival.

In the rare situation in which skilled personnel and supplies are at the scene and a long transport is expected, it would be reasonable to allow one or two attempts at IV access. Many authorities also suggest capturing or killing the snake for later verification, but again, prudence dictates that time not be wasted in this adventure and that an inexperienced person not risk the bite of an agitated snake. If the snake arrives in the ED, treat it with respect—more than one person has been bitten by a "dead" snake, and decapitated snakes can bite reflexively for up to 1 hour.

A CBC, coagulation studies, platelet count, urinalysis, and blood crossmatching should be obtained on all patients with suspected venomous snakebite, as blood may be difficult to crossmatch after massive hemolysis. In moderate or severe poisoning, analyses of serum electrolytes, BUN, creatinine, fibrinogen, and arterial blood gas levels are also indicated. Hemolysis, anemia, thrombocytopenia, hypofibrinogenemia, prolonged bleeding times, and metabolic acidosis all may be seen in severe poisoning. Repeat the laboratory studies every 6 hours to ensure no significant changes occur.

Therapy will be based on the clinician's overall grading of venom toxicity. Local and systemic manifestations, as well as laboratory findings, weigh heavily in this judgment. The clinical pattern may change dramatically as the venom's effects unfold; thus, frequent reassessment is crucial. The physician should measure and record the circumference of the injured extremity at the leading point of edema and 10 cm proximal to this level every 30 minutes for 6 hours, then at least every 4 hours for a total of 24 hours. Table 83.6 is derived from a grading system suggested by the Scientific Review Subcommittee of the American Association of Poison Control Centers.

If the history and physical examination on arrival in the ED are consistent with a venomous snakebite, immediate laboratory

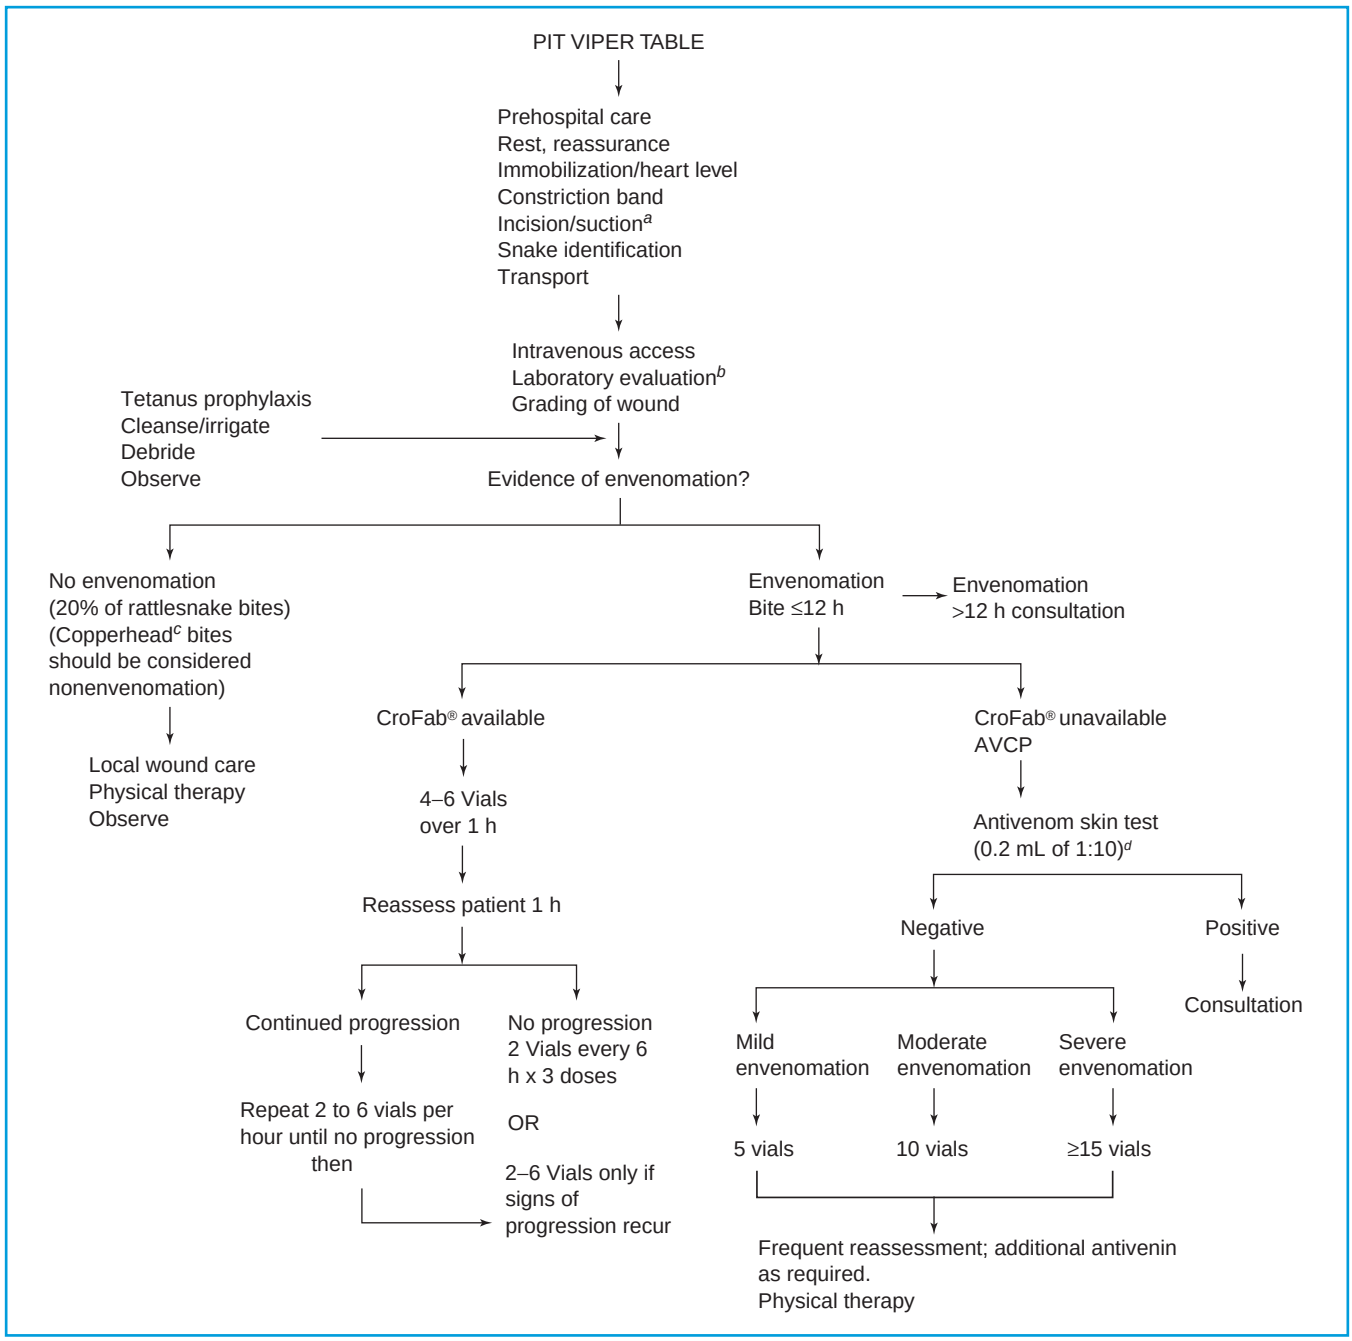

FIGURE 83.8 Management of pit viper bite. [a]Perform within 5 to 10 minutes of bite; continue suction for 30 to 60 minutes. [b]Complete blood cell count, platelet count, prothrombin time, partial thromboplastin time, urinalysis, type and hold; in moderate or severe cases, add fibrinogen, arterial blood gases, electrolytes, blood urea nitrogen, and creatinine. [c]Seldom need antivenin; exceptions with large snakes and small children. d1:100 dilution if allergy history; saline control; resuscitation medications at hand; antivenin seldom indicated if greater than 12 to 24 hours since bite.

evaluation and IV access are indicated. Aggressive supportive medical care must be available if signs of major system dysfunction are present. Any prehospital care (e.g., extremity immobilization) should be rechecked. If an occluding tourniquet is inappropriately present, the physician should place a more proximal constriction band and then cautiously remove the tourniquet, being prepared to respond therapeutically to a systemic release of venom.

The older antivenom (Crotalidae) polyvalent (AVCP; Wyeth-Ayerst Pharmaceuticals) is no longer available and was derived from horse serum and was highly antigenic. The newer antivenom was licensed in 2000 and is a polyclonal, polyvalent Fab affinity purified (FabAV; CroFab® Prothenics, Inc.) product derived from sheep. It has less adverse reactions than seen with AVCP. The antivenom is effective for rattlesnake and water moccasin envenomations. Mojave rattlesnake venom

TABLE 83.6

GRADING OF CROTALID (PIT VIPER) SNAKEBITES

	Mild	Moderate	Severe
Local	Fang mark Intense pain Edema Erythema Ecchymosis ± Vesicles Within 10–15 cm of bite	All local signs extend beyond wound site	Entire extremity involvement
Systemic	None Anxiety related	Nausea/vomiting Weakness/fainting Perioral, scalp paresthesias Metallic taste Pallor Tachycardia Mild hypotension Fasciculations	As in moderate Hypotension Shock Bleeding diathesis Respiratory distress
Laboratory	No abnormalities	Hemoconcentration Thrombocytopenia Hypofibrinogenemia	Significant anemia Prolonged clotting time Metabolic acidosis

was used in the development of FabAV; therefore, its efficacy may be better in bites from this species. Copperhead venom was not used in either AVCP or FabAV. The need for antivenin in cases of copperhead envenomation has been questioned in patients without significant systemic effects or severe swelling and pain. For maximal venom binding, the antivenin should be given within 4 hours of the snake strike. The benefits of antivenin administration after 12 hours are questionable for either antivenin. Their use is generally not indicated after 24 hours (an exception may be continued coagulopathy). The dosage regimen for FabAV is different than AVCP. Unbound Fab may be cleared before venom emerges from tissue deposits. For this reason, FabAV is given either on a fixed schedule or on a sliding scale. Relative contraindications for use include known hypersensitivity to papain, papaya, latex, or FabAV.

For patients receiving FabAV, an initial dose of four to six vials is given over 1 hour. Skin testing is not needed for FabAV. Each vial is reconstituted with 10 mL of sterile water and then the total dose is mixed in 250 mL of normal saline. The infusion should be started slowly, at a rate of 25 to 50 mL per hour for 10 minutes, while observing for allergic reaction. The rate should be increased so the 250 mL is given over 1 hour. If mild allergic manifestations develop, the infusion should be stopped and diphenhydramine (1 to 2 mg per kg IV) given. Once the allergic symptoms have resolved, a minimum of 5 minutes should pass, then the infusion should be restarted at a slower rate. Reactions have been associated with faster infusion rates. Initial dosage from FabAV (CroFab) is given irrespective of degree of envenomation. Subsequent doses are based on signs of progression. The patient should be reassessed after the initial dose. If there is progression of envenomation, then the initial dose should be repeated. If there is no progression, two different schedules are suggested. One choice is to give two vials every 6 hours for three doses. The other regimen is to give two to six vials only if signs of envenomation progression recur. All patients should be reassessed every 2 to 5 days after discharge.

Wound care includes irrigation, cleansing, a loose dressing, and consideration of tetanus prophylaxis. The affected extremity should be maintained just below the level of the heart and in a position of function. Cotton padding between swollen digits is useful. In the past, broad-spectrum prophylactic antibiotics were recommended by most authorities. Current studies question the need for these practices. Analgesics for pain may be offered if the cardiorespiratory status is not in question. Surgical excision of the wound, routine fasciotomy, and application of ice are contraindicated. Excision of the wound does not remove significant venom after 30 minutes, and cryotherapy has been associated with increased extremity necrosis and amputations. Fasciotomy should be reserved for the rare case of a true compartmental syndrome. Necrosis is usually the result of the proteolytic enzymes or inappropriate therapy and is not caused by compartmental pressure. Superficial debridement will be required at 3 to 6 days; one possible wound care regimen suggested at this stage includes local oxygen, aluminum acetate (1:20 solution) soaks, and triple dye. Physical therapy is beneficial during the healing phase.

The major thrust of supportive care is correction of the intravascular depletion that results from increased venous capacitance, interstitial third spacing, and hemorrhagic losses. Moderate or severe envenomation mandates two IV lines for separate but simultaneous antivenin therapy and volume replacement. Shock usually develops between 6 and 24 hours after the snakebite but may present within the first hour in severe envenomation. Signs of hypovolemia (e.g., decreased capillary perfusion, oliguria, tachycardia, anemia, hypotension) deserve aggressive therapy. Central vascular monitoring and accurate urine output measurements are desirable for optimal therapy. Normal saline or lactated Ringer's solution (20 mL per kg over 1 hour), followed by fresh whole blood or

other blood components, often corrects the hypovolemia (see Chapter 3). Vasopressors are usually needed only transiently in the more severe cases. A bleeding diathesis is best managed with fresh whole blood, or blood component therapy, primarily packed cells (10 mL per kg), and fresh-frozen plasma (10 mL per kg). With life-threatening bleeding, platelets (0.2 units per kg) and a more concentrated fibrinogen source (cryoprecipitate—dose one bag per 5 kg body weight) should also be considered. Abnormal clotting parameters, including fibrinogen and platelet and blood counts, should be reevaluated every 4 to 6 hours. Respiratory support is also commonly required when shock has developed. Renal failure is another potential problem in this setting.

The rate of serum sickness with FabAV (CroFab) is much lower than that seen with AVPC. Signs of serum sickness include rashes, arthralgias, edema, malaise, lymphadenopathy, fever, and/or gastrointestinal symptoms that evolve over several days. Prednisone (2 mg per kg per day, maximum 80 mg) until symptoms abate (and then a tapering schedule) has been used with success in most cases. Diphenhydramine (5 mg per kg per day in four divided doses, max 50 mg per dose) is often given as an adjunct.

Coral Snake. When coral snake wounds are present or the history or specimen is consistent with an Eastern coral snakebite, antivenin for *Micrurus fulvius* (Wyeth) is administered before development of further symptoms. The antivenin's access is restricted in the United States (contact http://www.Wyeth.com for information). This is also an equine serum and requires preliminary skin testing (see package insert). The initial recommended dosage is three to five vials by IV; an additional three to five vials may be given as needed for signs of venom toxicity. There is no antivenin available for the Arizona coral snake (*Micruroides euryxanthus*). Supportive care should provide a satisfactory outcome in these cases. Constriction bands, suction and drainage, and other local measures do not retard coral snake venom absorption, and hence, are not indicated.

Exotic Snakes. The clinician confronted with an exotic snakebite or a clinician inexperienced in snakebites should consult a local medical herpetologist, poison control center, or the American Association of Zoologic Parks and Aquariums and the American Association of Poison Control Centers. These centers keep an up-to-date database of exotic antivenoms. Access to this information is available at 800-222-1222. Report all illegally possessed reptiles to the police or to the appropriate fish and game agency.

Mammalian Bites

Background

Children suffer the majority of casualties in this country's growing epidemic of mammalian bites. The overall morbidity of mammalian bites is staggering in terms of infectious complications, cosmesis, disability, psychological trauma, and medical expenses. At least 1 to 2 million people are bitten each year, and about 1% of ED visits are prompted by bite wounds.

Dog bites account for the overwhelming majority (80% to 90%) of these injuries and thus have been the subject of numerous investigations. An estimated 4.5 million dog bites occur in the United States annually, with approximately 885,000 people seeking medical care. The most common dog attack involves a 5- to 14-year-old boy close to home and a large-breed or mixed-breed canine. The dog's owner can be identified 85% to 90% of the time; in fact, in 15% to 30% of cases, the dog belongs to the victim's family. Usually, the dog has never previously bitten anyone and often has been provoked, although most often unintentionally. However, animal jealousy has been implicated in unprovoked biting of infants. A seldom realized mortality of approximately 10 fatal cases occur each year in the United States, primarily in young children and infants.

The remainder of the mammalian bites is perpetrated by cats (5% to 10%), rodents (2% to 3%), and other wild or domesticated animals. Another mammalian species, *Homo sapiens*, inflicts approximately 2% to 3% of the bite wounds that present to medical attention. Human bites share with cat wounds a notoriously high infectious complication rate.

Pathophysiology

Anatomic wound characteristics and the microbiologic inoculum of the offending species determines the pathologic consequences of the bite. For example, many dog bites are localized crush injuries with a substantial amount of infection-prone devitalized tissue—a result of the enormous pressures dogs generate in their bites. Forces of 200 to 400 pounds per square inch, sufficient to perforate sheet metal, have been documented in dogs. Overall, however, only 5% to 10% of dog bites become infected, probably because the resulting lacerations and abrasions are so accessible to good wound hygiene. The typical feline bite, however, is a deep puncture wound and is difficult to irrigate or cleanse, thus subjecting it to a high infection rate (up to 50% in some series). The penetration of tendons, vessels, facial compartments, and bones also has a high infectious risk with increased morbidity. The hand offers all these anatomic components in a relatively small cross-sectional area; therefore, it is potentially prone to serious infections regardless of the biting species. Injuries to deeper structures, including major vasculature, the brain, peritoneum, abdominal organs, and airways, have also been sporadically reported.

Scores of aerobic and anaerobic bacteria indigenous to mammalian oral flora are inoculated into the wound during biting. Cultures of fresh wounds before clinical infection reflect the variety of these contaminants but are not predictive of the causative organism in later infections. The most commonly isolated bacteria in infected cat and dog bite wounds are *Staphylococcus aureus* and *Pasteurella* species, a gram-negative rod. In one series, *P. multocida* and *P. canis* were found in 50% and 80% of infected dog and cat wounds, respectively. Other series have isolated *P. multocida* in only 10% to 20% of infected dog wounds and incriminated other more common bacteria: streptococci, coagulase-negative staphylococci, *S. aureus*, and enteric bacteria. Some unusual isolates in clinical infection have included *Capnocytophaga canimorsus* (DF-2) and *Weeksella zoohelcum* (IIj). Two hundred cases of sepsis following dog bites have been associated with *C. canimorsus*. At least 25% of all infected mammalian bites yield mixed cultures of aerobes and often anaerobes, if carefully sought. Anaerobic bacteria are usually recovered (not alone but only in mixed cultures with aerobes).

Human bite infections are mixed bacterial infections, with *Streptococcus viridans* or *S. aureus* being the predominant organism. Anaerobic bacteria, especially *Bacteroides* and *Peptostreptococcus* species, are commonly cultured. The more serious morbidity in infected human bites of the hand has been correlated with *S. aureus* isolation and, more recently, with *Eikenella corrodens*, a facultative anaerobe.

Finally, the multiple systemic diseases that may be transmitted by mammalian bites need to be considered.

Clinical Manifestations

Mammalian bite wounds cause a spectrum of tissue injuries from trivial to life-threatening. Scratches, abrasions, contusions, punctures, lacerations, and their complications are commonly seen in the ED. The complications usually involve secondary infections or damage to structures that underlie the bite.

Although dog bites are insignificant lesions in at least half of the cases that come to medical attention, 5% to 10% warrant suturing and 2% require hospital admission. Approximately 33% of dog bites involve the upper extremity, presumably while the victim is fending off the attack. Another 33% of wounds are located on the lower extremities and 20% on the head and neck area. The remainder of bites involves multiple areas. Other than bites on the hand, the rate of secondary infection in dog bites given good local care approximates that of nonbite wounds.

Predictably, young children suffer more serious canine injuries. The dog strikes the head and neck in 60% to 70% of victims younger than 5 years and in 50% of those younger than 10 years. These wounds most often involve the lips, nose, and cheek areas, and on rare occasions, they penetrate the skull, with resulting depressed skull fractures and intracranial lesions. It has been estimated that each year 44,000 children suffer facial dog bite wounds, one-third of them requiring complex repair. The uncommon life-threatening injuries occur almost exclusively in young children and include major vascular injury, visceral penetration, and chest trauma. The deaths are usually secondary to acute hemorrhagic shock.

Cat bites are located in the infection-prone upper extremities in two-thirds of cases and are usually puncture wounds rather than lacerations or contusions. Infections that complicate these wounds result from the same organisms isolated in dog bites, but a higher incidence of *P. multocida* is found. *P. multocida* infections characteristically present within 12 to 24 hours of the injury and rapidly display erythema, significant swelling, and intense pain. These infections often respond slowly to adequate drainage and antibiotic therapy. Local infections from other organisms usually present 24 to 72 hours after the bite in a less fulminant manner. Viridans streptococcal infections are occasional exceptions to this generalization and may resemble a *P. multocida* clinical course.

Cat scratches are most commonly located on the victim's upper extremities or periorbital region and are more likely to develop secondary bacterial infection than scratches from the other common domesticated species. Corneal abrasions are also occasionally associated with the periorbital wounds. Cat-scratch disease, an uncommon complication of these injuries, is characterized by a papule at the scratch site and a subsequent regional lymphadenitis. The primary lesion is typically a crusted, erythematous papule, 2 to 6 mm in diameter that develops 3 to 10 days after the scratch. A tender regional lymphadenopathy occurs 2 weeks after the primary lesion. Malaise and fever are associated symptoms in approximately 25% of patients. Unusual manifestations of this disease include encephalopathy, exanthem, atypical pneumonia, and parotid swelling. The disease is self-limiting, with resolution of the symptoms within 2 to 3 months. *Bartonella henselae* is the causative organism. An indirect fluorescent antibody test to Bartonella is useful in the diagnosis and is available through the Centers for Disease Control and Prevention. Polymerase chain reaction assays are available in some commercial labs.

Human bites in older children and adolescents are most commonly incurred when a clenched fist strikes the teeth of an adversary. The wound typically overlies the metacarpal-phalangeal joint, and on relaxation of the fist, the bacterial inoculum penetrates more deeply into the relatively avascular fascial layers. Hand infections, regardless of infection site, usually present with mild swelling over the dorsum of the hand 1 to 2 days after injury. Infected hand bites may be superficial and localized to the wound, but if there is pain with active or passive finger motion, a more serious deep compartmental infection or tendonitis should be suspected. Osteomyelitis occasionally occurs in hand infections. In younger children, human bites are more often on the face or trunk than on the hands. Often, a playmate inflicts the wound, but child abuse must always be considered. Systemic diseases that may be spread by human bites include hepatitis B and syphilis.

Rodent bites usually occur in disadvantaged socioeconomic groups or among laboratory workers and have a relatively low incidence of secondary infection (10%). Ratbite fever is a rare disease that may present after a 1- to 3-week incubation period with chills, fever, malaise, headache, and a maculopapular or petechial rash. There are two forms: Haverhill fever (*Streptobacillus moniliformis*) and Sodoku (*Spirullum minus*), both of which are responsive to IV penicillin.

Another uncommon bacterium for which lagomorphs, particularly rabbits, are hosts is *Francisella tularensis*. Tularemia is usually spread to humans by rabbit bites, although contact with or ingestion of contaminated animals or insect vectors is sufficient for transmission. Ulceroglandular tularemia is the most common form of the disease, and gentamicin, ciprofloxacin, or doxycycline is the agent of first choice in its treatment. Streptomycin may be used but is no longer readily available in the United States.

Serious infections from multiple bacteria, including osteomyelitis, sepsis, endocarditis, and meningitis, have been reported as complications of mammalian bite wounds, as well as the more esoteric diseases already mentioned. The risk of rabies or tetanus always must be considered in animal bites.

Management

Meticulous and prompt local care of the bite wound is the most important factor in satisfactory healing and prevention of infection. In more extensive wounds, local anesthesia is achieved before wound hygiene. Then, the skin surrounding the wound should be cleaned with a soft sponge, and 1% providone iodine solution can remove obvious contaminants. The wound itself should be forcefully irrigated with a minimum of 200 mL normal saline. A 19-gauge needle or catheter attached to a 30-mL syringe will supply sufficient pressure for wound decontamination and will decrease the infection rate by 20-fold. Stronger irrigant antiseptics—povidone iodine scrub preparation, 20% hexachlorophene, alcohols, or hydrogen

peroxide—may damage wound surfaces and delay healing. Soaking in various preparations has not proved helpful in reducing infections.

Most open lacerations from mammalian bites can be sutured if local care is effected within several hours of the injury and good surgical technique is used. Facial wounds often mandate primary closure for cosmetic reasons and, overall, are low infection risks because of the good vascular supply. In fact, one study demonstrated a lower infection rate in sutured dog bite wounds than in those left open. Other more recent studies support the low infection rate in selected sutured bite wounds. The exceptions to suturing are minor hand wounds and other high-risk bites. In large hand wounds, hemorrhage should be carefully controlled. We suggest closing the subcutaneous dead space in these wounds with a minimal amount of absorbable suture material. Cutaneous sutures can be placed after 3 to 5 days if there is no evidence of infection.

Extremities with extensive wounds should be immobilized in a position of function and kept elevated as much as possible. This is especially true of hand wounds, which should have bulky mitten dressings and be supported by an arm sling. All significant wounds should be rechecked in follow-up in 24 to 48 hours.

The following wounds may be considered at high risk for infection: puncture wounds, minor hand or foot wounds, wounds given initial care after 12 hours, cat or human bites, and wounds in immunosuppressed patients. As a rule, these wounds should not be sutured. The use of prophylactic antibiotics is controversial. Suggested indications for antibiotics include the following:

- Human and cat bites through dermis
- Bites closed prematurely
- Bites more than 8 hours old with significant crush injury or edema
- Potential damage to bones, joints, or tendons
- Bites to hands and feet
- Patients with increased risk of infection
- Signs of infection within 24 hours

No single antibiotic is ideal for all the most common organisms involved in infected mammalian bite wounds. Amoxicillin-clavulanic acid (Augmentin) comes close. It is effective in *P. multocida*, Streptococcus, and anaerobe control, as well as in providing methicillin-susceptible staphylococcus aureus (MSSA) coverage. Combination therapy with phenoxymethyl penicillin (penicillin VK) and cephalexin or dicloxacillin has been suggested by some authorities. For high-risk wounds, we recommend amoxicillin-clavulanic acid (30 to 50 mg per kg per day) alone for initial therapy. An extended-spectrum cephalosporin or trimethoprim-sulfamethoxazole PLUS clindamycin is an alternative for the penicillin-allergic patient. The initial dose of antibiotic should be given in the ED and continued for the next 3 to 5 days. It must be emphasized that local care ultimately prevents infection more effectively than any prophylactic antibiotics. Studies indicate that prophylactic oral antibiotics for low-risk dog bite wounds are not indicated because the differences in the rate of infection are not significant and the cost-benefit ratio is not worth the risk of allergic reaction.

Any bite wound with signs of infection deserves aggressive drainage and debridement, as well as antibiotic therapy, after aerobic and anaerobic cultures are obtained. Moderate to severe hand infections or other wounds that involve deep structures usually require debridement and exploration under general anesthesia. Culture swabs should sample the depth of the wound; or, in cases of cellulitis, the specimen can be collected by needle aspiration of the leading edge of erythema. While awaiting cultures, a Gram stain is often helpful in differentiating the probability of staphylococci or streptococci from *P. multocida*.

Parenteral antibiotics and admission to the hospital are indicated if the child has systemic symptoms or has wounds with potential functional or cosmetic morbidity. The choice of parenteral antibiotics should be governed by the same factors considered in selection of prophylactic antibiotics and then modified by culture results.

Tetanus immunization status should be checked in every injury that violates the epidermis, regardless of the cause. Recommendations for tetanus immunoglobulin and immunization are noted elsewhere (Chapter 92).

Concern for rabies is the factor that prompts many patients to seek medical care. Although the incidence of rabies in the United States (one to five cases per year) is extremely low, the physician must always assess the possibility of rabies exposure and promptly initiate prophylaxis when indicated. Dogs and cats account for only 5% of animal rabies in the United States. The history should include the apparent health of the animal and any provocation for attack. Wild carnivores and bats should generally be regarded as rabid; rodents (rats, squirrels) and lagomorphs (rabbits) can usually be considered no risk. Exposure to bats by a sleeping or very young child even without bite or scratch should warrant serious consideration of prophylaxis. Rabies prophylaxis is not indicated in bites by a healthy dog or cat with a known owner, assuming the animal's health does not deteriorate over the following 10 to 14 days. Bites by strays and other domesticated mammals should be considered individually and with consultation of the local health department. Scratches, abrasions, and animal saliva contact with the victim's mucous membranes are capable of rabies spread.

If postexposure antirabies immunization is indicated both passive antibody (RIG, rabies immune globulin, human) and vaccine (HDCV, human diploid cell rabies vaccine) should be given. Immunization with RIG is administered only once, in a dose of 20 IU per kg. Half the dose, or as much as possible, is infiltrated locally around the wound and the remainder is given intramuscularly. The HDCV immunization should be administered intramuscularly in the opposite deltoid (vastus lateralis in infants) from RIG on days 0, 3, 7, 14, and 28 for a total of five doses, each 1.0 mL.

CHAPTER 84 ■ CARDIAC EMERGENCIES

MICHAEL H. GEWITZ, MD, AND PAUL K. WOOLF, MD

Cardiac problems in infancy and childhood are not rare, are frequently complex, and always have important implications for the general health of the child. This chapter provides information regarding the evaluation and management of the more common emergencies that arise from the presence of cardiovascular disease in childhood. For the health-care professional not well-versed in childhood cardiac disease, a brief overview is provided as background for the specific problems discussed in detail.

OVERVIEW

As with other pediatric disorders, cardiac diseases in childhood can be congenital or acquired. Major and minor structural diseases of the heart for the most part result from derangements of embryologic development and thus are present in some form at birth. The clinical manifestations of such problems may be delayed, however, for days, months, or even years. In contrast, many other disorders of cardiac physiology result from problems superimposed on inherently normal cardiac structures. These problems are frequently acute in their development when a relatively sudden change from normal cardiac physiology occurs, leading quickly to the development of symptoms. It should be remembered, however, that acquired cardiac diseases can also be associated with prolonged latent periods. For example, the most prevalent form of acquired heart disease in the United States, coronary artery disease, has its beginnings in childhood in numerous instances, although its appearance as a clinical entity occurs much later. Examples of forms of congenital and acquired pediatric cardiac problems are reviewed in Table 84.1.

The incidence rate of congenital heart disease (CHD) has been fairly constant over the past few decades and is estimated to be approximately 7–8 to 10 cases per 1,000 live births (0.7% to 0.8%). This includes all forms of defects and all ranges of severity but does not include the most common isolated congenital cardiac lesion, bicuspid aortic valve, which occurs in an additional 1% or more of people. The prevalence figures for CHD are continually increasing. It has recently been estimated, in fact, that there are now more adults alive with CHD than there are infants. This "adult CHD" population will continue to increase, of course, as more and better treatment modalities become available to correct and/or palliate even the most severe forms of defects. Many of these patients are beginning to have offspring of their own. Studies have also found the incidence of congenital cardiac problems in children of parents with CHD to range from 5% to 15%. (The disorders seen as part of the spectrum of CHD are extremely variable; comprehensive texts are available for more detailed reviews.)

Age at presentation can vary significantly, depending on the type of congenital cardiac lesion and its impact on cardiac performance. Severe obstruction to pulmonary or systemic flows may be masked in the first few days of life by persistence of a patent ductus arteriosus, whereas the presence of an important ventricular septal defect (VSD) may not become clinically evident until 4 to 6 weeks of age. This wide disparity in age at presentation is related to the physiologic interactions of the systemic and pulmonary vasculature, as well as to the anatomic specifics of any particular lesion. Table 84.2 presents examples of typical presenting ages for the more common forms of CHD. Although it is not important for the emergency practitioner to be versed specifically in all possible defects, knowledge of anatomic and physiologic possibilities is important so the practitioner's awareness of potential problems can lead to appropriate triage and initiation of care. One useful approach is to categorize lesions by the presence or absence of arterial desaturation; thus, there are cyanotic and acyanotic forms of CHD. Table 84.3 reviews some of the congenital lesions that segregate into these two groups.

Even without recalling specific lesions, however, only a few key principles of cyanosis must be understood (Table 84.4) to be able to consider the possibilities when faced with a particular patient. For example, a patient with anemia may have cyanotic CHD, yet not be visibly desaturated, or a patient may have a significant level of pulmonary valve stenosis with significant obstruction to pulmonary blood flow but not appear cyanotic. Conversely, a patient may not have a loud cardiac murmur or any murmur at all and still have a serious cyanotic cardiac lesion (see Chapter 33).

In diagnosing children with possible CHD, therefore, it is not usually necessary to remember long lists of complex lesions. An appreciation of what is anatomically possible and what is physiologically rational, however, usually leads to the ability to discern what is clinically likely in any particular situation.

The next sections deal with specific examples of the melding of these anatomic and physiologic concerns in emergency situations that involve cardiovascular diseases in children.

CONGESTIVE HEART FAILURE

Background

Heart failure is frequently described as a syndrome in which the heart cannot maintain a level of tissue perfusion adequate to meet metabolic needs. During childhood, these needs also include growth and development. This section offers an outline of the primary etiologic and physiologic factors that underlie the clinical presentation of the child in congestive heart failure (CHF).

TABLE 84.1

EXAMPLES OF ACQUIRED AND CONGENITAL FORMS OF PEDIATRIC HEART DISEASE

Forms of pediatric heart disease examples	
Congenital	
Disorders of septal or valvar development	Pulmonary, aortic valve stenosis
	Mitral or tricuspid atresia
	Ventricular septal defect
	Atrial septal defect
Disorders of venous or arterial connection	Transposition of the great vessels
	Anomalies of pulmonary venous return
Disorders of conduction system development	Congenital AV block
	Persistent bypass tract syndromes (preexcitation)
Acquired	
Disorders of cardiac muscular function	Cardiomyopathy associated with cancer therapies
	Acute myocarditis
	Acute pericarditis
Disorders of valvar function	Acute rheumatic fever
	Bacterial endocarditis
Disorders of cardiac rhythm	Drug-induced arrhythmias
	Postsurgical heart block

AV, atrioventricular.

TABLE 84.2

AGE OF PRESENTATION OF CONGENITAL HEART DISEASE[a]

First 2 wk
Left ventricular outflow obstruction
- Coarctation of aorta
- Severe aortic stenosis
- Left heart hypoplasia

Cyanotic lesions
- Transposition of great vessels
- Total anomalous pulmonary venous return
- Atrioventricular (AV) canal malformations
- Truncus arteriosus

First month
Coarctation of aorta
Ventricular septal defect (VSD)
Patent ductus arteriosus (PDA)
Truncus arteriosus
Complex lesions with multiple anomalies (e.g., double-outlet right ventricle)

6 Wk to 6 mo
VSD
AV canal malformations
Coronary artery anomalies
Truncus arteriosus

Over 6 mo
VSD
Atrial septal defect
Isolated valvar lesions (e.g., pulmonic stenosis, mitral insufficiency)
Small PDA
Partial anomalous pulmonary venous return
Coarctation of aorta

[a]There is considerable overlap regarding any particular lesion and the specific clinical setting. This list is representative and illustrative, not all inclusive.

Etiologic Considerations

Although the primary cause of CHF in infants and children is CHD, a panoply of conditions can be associated with the presentation of CHF in the presence of normal underlying cardiac structure. Table 84.5 lists the more common clinical entities associated with CHF, including primary cardiac disease and conditions in which the heart is affected secondarily. In general, the principal physiologic problems that lead to impaired myocardial performance include (i) excessive pressure loads, such as left heart obstructions; (ii) excessive volume loads, such as with large left-to-right shunts, valvar regurgitation, or severe anemia; (iii) primary inotropic depression, such as with myocarditis, endocrinologic disorders, or coronary perfusion irregularities; and (iv) rhythm abnormalities, such as supraventricular tachycardia (SVT) or severe forms of heart block.

The history is critical in determining the cause of CHF and should not be glossed over in the rush to treat. Knowledge of preexisting cardiac disease is obviously important. A history of known hematologic disorders such as thalassemia or sickle cell anemia should also be sought. Because heart failure can develop as a consequence of pressure overload of the right heart secondary to pulmonary vasoconstriction and hypoxia, a history of respiratory tract difficulties or breathing pattern irregularities should also be reviewed carefully. Knowledge of other systemic conditions is likewise crucial. For example, several studies have indicated that human immunodeficiency virus (HIV) infection can seriously affect cardiac performance seriously on either an acute and chronic basis. Late stages of HIV infection are often complicated by cardiomyopathy and CHF. Careful clinical assessment for signs of cardiac involvement should be part of the evaluation of children with HIV who present with hypotension or who have respiratory problems not responsive to direct pulmonary management. As another example, a history for Kawasaki disease should be sought in patients who present with new-onset CHF that

TABLE 84.3

EXEMPLITIVE CONGENITAL HEART LESIONS

Acyanotic lesions	Cyanotic lesions
Secundum atrial septal defect	Tetralogy of Fallot
Ventricular septal defect	D-transposition of the great vessels
Patent ductus arteriosus	Tricuspid atresia variants
Aortic stenosis/regurgitation	Total anomalous pulmonary venous return
Coarctation of the aorta	Truncus arteriosus
Pulmonic stenosis—valvar	Pulmonary atrioventricular fistula
Peripheral pulmonary stenosis	Complete atrioventricular canal defect
Mitral stenosis/regurgitation	Ebstein's anomaly of the tricuspid valve
Partial anomalous pulmonary venous return	Pulmonary atresia with septal defect
Congenitally corrected transposition of the great vessels	Single ventricle states

appears to be related to inflammatory myocardial disease, even if other classic signs are not overtly present.

In the presence of appropriate physical findings and historical information, the diagnosis of CHF is usually evident in the older child. The principal problem of diagnosis centers on the infant, in whom differentiation between CHF and primary respiratory tract disease can be difficult. Auscultation of cardiac murmurs is helpful, of course, but such murmurs may not always be audible, particularly in severe failure with low output. Parenchymal lung disease may result in systemic desaturation to the same degree as CHF with associated pulmonary congestion and ventilation–perfusion imbalance. Palpation of the liver edge below the costal margin in an infant may be related to hyperexpansion of the lungs and not to systemic venous congestion. Conversely, respiratory tract signs such as wheezing and retractions may be part of the clinical picture of heart failure in the absence of primary lung disease. The chest radiograph often fails to distinguish clearly between cardiac and pulmonary disease because pulmonary markings often mimic infiltrative patterns. Evidence of cardiac enlargement on the radiograph is a useful differential point, although the enlarged thymus of the infant may make interpretation difficult. Other noninvasive methods, such as echocardiography, also can help to establish the diagnosis of cardiac disease.

TABLE 84.4

USEFUL RULES OF CYANOTIC CONGENITAL HEART DISEASE

In the presence of normal hemoglobin moieties and normal cardiac output, right-to-left shunting must be present to produce cyanosis. This can be intrapulmonary, intracardiac, or both.
Obstruction to pulmonary blood flow alone does not produce cyanosis.
A critical mass of reduced hemoglobin must be present to allow visual estimation of cyanosis.
Right-to-left shunts are not usually associated with heart murmurs.
The presence of visible cyanosis depends on the interrelationship of pulmonary and systemic blood flows and hemoglobin concentration.

Pathophysiology

There are four primary determinants of normal cardiac function, each of which may relate to the development of heart failure. The first is *preload*, the volume at end diastole that must be ejected by the left ventricle. This is a close reflection of the intravascular volume status of the child in general, which directly affects cardiac performance through the Frank–Starling relationship. The second, *afterload*, is the opposing force to ventricular ejection and relates to the tension that must be developed by the myocardium to eject a given preload. The third determinant, *contractility*, can be viewed as an intrinsic property of cardiac muscle that permits alterations in cardiac shape necessary for ejection and is determined by fundamental properties of cardiac ultrastructure. The fourth determinant, *heart rate* (HR), is related to intrinsic electrophysiologic capabilities of the specialized cardiac conduction system and to supervening neurologic input. It is directly related to cardiac output (CO) through the classic relationship:

$$CO = HR \times SV \text{ (stroke volume)}$$

Compensatory Responses

To understand the basis for the clinical findings commonly associated with CHF, the physician must consider the physiologic responses to inadequate cardiac function. These include mechanical effects, such as ventricular hypertrophy and ventricular dilatation; neurohumoral effects, principally those that involve the adrenergic nervous system; biochemical effects at the cardiac cellular level that alter myocardial energy metabolism and the excitation–contraction coupling process; and hematologic effects that involve oxygen transport. In addition, pulmonary responses, including increased respiratory frequency and altered respiratory patterns, also comprise an important part of the clinical picture of CHF.

Clinical Manifestations

The clinical manifestations of CHF are directly related to the following compensatory mechanisms:

1. Cardiac enlargement is usually the result of ventricular dilation. Although it may often be possible to detect cardiac

TABLE 84.5

ETIOLOGIC CONSIDERATIONS FOR CONGESTIVE HEART FAILURE

Congenital heart disease	Acquired heart disease	Endocrine/metabolic	Other
Pressure overload Left ventricular outflow obstruction (e.g., aortic stenosis, severe coarctation) Left ventricular inflow obstruction (e.g., cortriatriatum) *Volume overload* Left-to-right shunts (e.g., ventricular septal defect) Anomalous pulmonary venous return Valvar regurgitation (e.g., aortic insufficiency) Arteriovenous fistulae *Other structural disease* Anomalous coronary artery Traumatic injury *Rhythm disturbance* Supraventricular tachycardia Complete heart block *Postoperative heart disease* Malfunctioning prosthetic valve	*Myocarditis* Viral infections Kawasaki disease Collagen-vascular disease *Cardiomyopathy* Chronic anemia (e.g., thalassemia major) Nutritional disorders AIDS *Pericardial disease* *Rheumatic heart disease* *Cor pulmonale* Acute (e.g., upper airway obstruction) Cystic fibrosis Neuropathies *Endocarditis*	*Electrolyte disturbances* *Hypoglycemia* *Hypothyroidism* *Calcium or magnesium disorders* *Lipid disorders* Carnitine deficiency Carbolic acid disorders Fatty acid disorders *Storage Diseases* *Mitochondrial disorders* Barth syndrome	*Ingestions/toxins* Cardiac toxins (e.g., digitalis) Arrhythmogenics (e.g., tricyclic antidepressants) Chemotherapy agents (e.g., adriamycin)

enlargement by displacement of the cardiac impulse, the chest radiograph remains the most readily available method for assessing ventricular dilation (Figs. 84.1 and 84.2). Care must be taken to distinguish the normal cardiothymic silhouette from true cardiomegaly in an infant (Fig. 84.2). The other finding related to mechanical compensatory responses is ventricular hypertrophy, which is distinguishable on the electrocardiogram (EKG; Fig. 84.3). As a compensatory mechanism, hypertrophy occurs before dilatation in pressure overload situations, whereas dilatation may occur first in volume overload of the heart. In general, cardiac size can be a reliable guide to the overall fluid volume status of the infant or child.

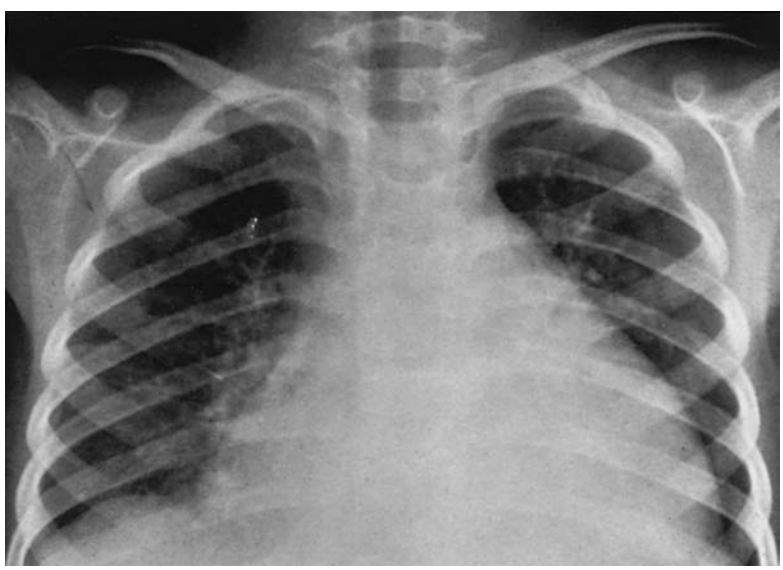

FIGURE 84.1 Chest radiograph of older child with congestive heart failure. Note cardiac enlargement and evidence of pulmonary venous congestion.

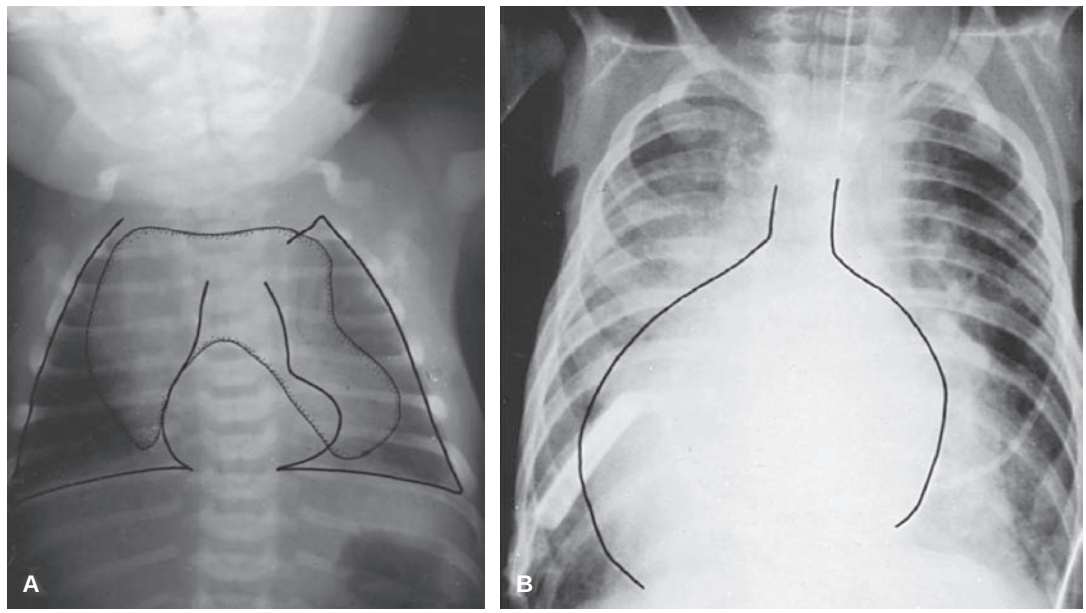

FIGURE 84.2 **A:** Normal cardiothymic shadow. Thymus is demarcated by speckled line and overlies a portion of the heart shadow. **B:** True cardiomegaly in an infant associated with pulmonary edema. Entire area enclosed in outline is cardiac shadow.

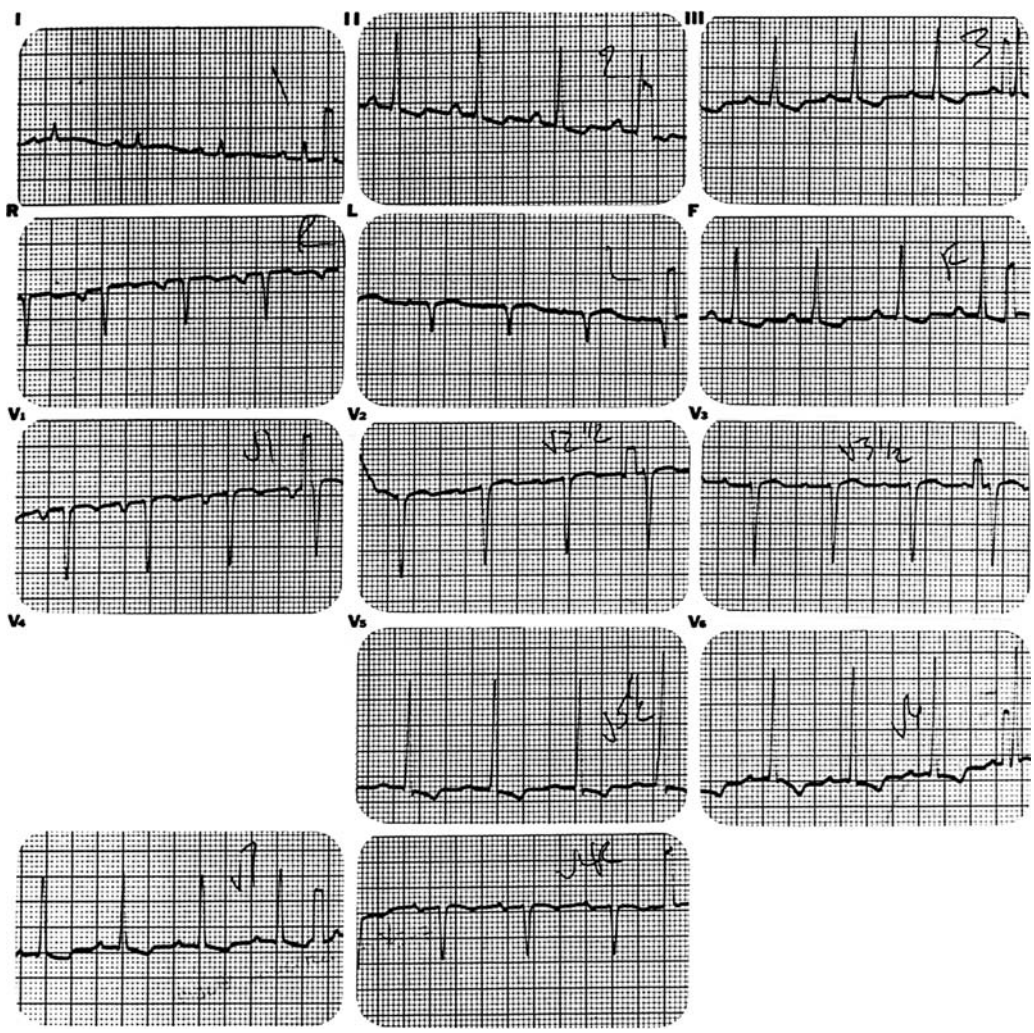

FIGURE 84.3 Electrocardiogram demonstrating left ventricular hypertrophy. Note increased R-wave voltage in left precordial leads and abnormal T-wave changes.

2. Tachycardia is easily detected clinically and, if necessary, confirmed by EKG. A rate of more than 160 beats per minute (bpm) in an infant or 100 bpm in the older child may be a signal for the increased adrenergic tone and catecholamine release associated with the neurohumoral response to diminished CO.
3. Abnormalities of cardiac auscultation are also commonly present. The protodiastolic gallop, or third heart sound (S_3), is a sign of decreased ventricular compliance and increased resistance to filling. Less often, the fourth heart sound, or atrial gallop (S_4), can be heard in children. It should be noted that these auscultatory events can sometimes be normal findings in childhood, and thus, the entire clinical picture must be evaluated before defining their significance in any particular situation.
4. Respiratory responses, notably tachypnea, are usually present as part of the total picture of CHF. Often, rales, rhonchi, and wheezing may be heard and should not be confused as signs of pulmonary parenchymal disease exclusive of heart failure. In contrast, it is not unusual, particularly in infants, for rales to be absent despite the presence of tachypnea or wheezing because considerable alveolar fluid accumulation is necessary for the development of rales. Thus, the presence of rales usually implies severe failure in an infant, whereas pulmonary interstitial fluid collection, which occurs at an earlier stage, may be represented by tachypnea and wheezing alone. In older children, dyspnea with activity and orthopnea may also be present. A chronic cough also may be a sign of pulmonary congestion developing from CHF. Associated with these findings are chest retractions that reflect the large negative intrathoracic pressures needed to ventilate stiff, fluid-filled lungs.
5. Growth failure and undernutrition may be important clinical correlates of chronic CHF. These reflect not only diminished cellular substrate availability as a result of inadequate tissue perfusion, but also increased caloric expenditure associated with heightened oxygen consumption and increased work of breathing. Feeding difficulties, which may be associated with the respiratory patterns previously noted, aggravate caloric balance even further.
6. Cool, moist extremities and a generalized pallor may also be present as a result of peripheral vasoconstriction secondary to catecholamine release and the need to maintain blood pressure (BP) in the face of reduced CO.
7. Central and peripheral fluid accumulation with elevated systemic venous pressure also accompanies CHF, reflecting impaired cardiac emptying as well as impaired sodium and protein balance. Hepatomegaly, jugular venous distention, and peripheral edema represent the clinical manifestations of this aspect of the problem. Peripheral edema, however, is an unusual finding in young infants. Pulsus alternans, a beat-to-beat variability in the strength of the pulse, is also a clinical sign of cardiac mechanical decompensation.

The child with overt CHF who is seen in the emergency department (ED) may present with nearly all the aforementioned signs and symptoms. If the child is severely ill, then pallor will be evident, tachypnea prominent, and intercostal retractions visible. The liver is enlarged and palpable well below the right costal margin; a spleen tip may also be palpable. The pulses are weak and thready, and the skin may be moist and cool to the touch. Auscultation of the chest reveals rales, rhonchi, and sometimes, wheezes. Tachycardia is present, and auscultation of the heart sounds frequently elicits a gallop rhythm. Murmurs may be strikingly absent unless preexisting heart disease is present. A child with this spectrum of findings requires urgent attention. Acute heart failure in a child usually implies an unstable situation with possible rapid deterioration.

Laboratory Findings

Usually, the clinical diagnosis of CHF can be made without extensive radiographs or laboratory tests. However, certain objective changes may corroborate the clinical findings:

1. As noted, a chest radiograph shows an increased cardiothoracic ratio and pulmonary congestion. Kerley B lines or platelike atelectasis at the lung bases, which reflect dilated pulmonary lymphatics, may be present. Pleural effusions are common.
2. The EKG is a nonspecific indicator of cardiac decompensation. The precordial voltages decrease in certain conditions associated with CHF, such as myocarditis, but may be normal or increased in other situations. The EKG can be also helpful for establishing the cause of the CHF, such as cardiac arrhythmia or myocardial ischemia.
3. Echocardiography is useful in evaluating the child with CHF. The differentiation of an enlarged cardiac silhouette secondary to impaired cardiac performance with ventricular chamber enlargement, rather than pericardial fluid accumulation, is best made by ultrasound examination. In addition, functional indices are obtained as an objective measure of cardiac performance and response to therapy. The underlying cardiac structures can also be evaluated for the presence of anatomic lesions.
4. Blood gas abnormalities may be present. Prolonged tissue hypoperfusion can result in metabolic acidosis of a significant degree, and the pulmonary abnormalities already noted may result in hypoxia.
5. Other abnormalities that may be present include electrolyte changes (hyponatremia and hypochloremia) and a reduction in hematocrit, based on dilutional factors. The erythrocyte sedimentation rate (ESR) is usually lowered in active CHF. In addition, in infants with CHF, serum glucose and calcium should be monitored because deficiencies in either may be responsible in large measure for the impaired cardiac function. In situations of suspected perfusion abnormalities or inflammatory myocardial diseases, cardiac enzymes—troponin, in particular—may be elevated.

Management

For the patient who requires emergency treatment of CHF, initial medical therapy includes several therapeutic measures as outlined in Table 84.6. First, supplemental oxygen should be given through a humidified system. In young children, a tight-fitting mask or nasal cannula may not be effective because too much energy is expended fighting such apparatuses. Second, elevation of head and shoulders is helpful in the face of pulmonary edema, with maintenance of the lower extremities in a dependent position to increase peripheral pooling, and thus, diminish pulmonary blood volume. A “cardiac chair” or appropriate modification of an infant seat establishes this posture in the small baby.

TABLE 84.6

EMERGENCY MANAGEMENT OF CONGESTIVE HEART FAILURE

History and physical examination to define etiology, if possible
Elevate head and chest
Ensure adequacy of ventilation
Administer oxygen
Initiate cardiorespiratory monitoring, including frequent blood pressure measurement
Achieve venous access and obtain laboratory studies (e.g., complete blood cell count, electrolytes)
Arterial blood gas determination
Achieve rhythm control
Treat pulmonary edema (e.g., diuretics, morphine sulfate)
Provide inotropic support (digitalis or catecholamines)
Consider afterload reduction

Third, morphine sulfate (0.05 to 0.1 mg per kg subcutaneously) can be helpful in the face of agitation and air hunger associated with pulmonary edema. Fourth, positive-pressure respiration by endotracheal intubation is sometimes indicated for severe situations, particularly if arterial blood gas analysis shows respiratory decompensation ($PaCO_2 > 50$ mm Hg). In infants, the use of controlled mechanical ventilation to improve respiratory status greatly enhances survival. Fifth, bicarbonate therapy is sometimes indicated to correct metabolic acidosis that arises from diminished tissue perfusion. Administration of sodium bicarbonate during respiratory decompensation, however, is hazardous since further $PaCO_2$ elevation can occur. In addition, bicarbonate given by rapid infusion can promote cerebral edema and rapidly affect serum osmolarity with deleterious effects. Also, an excessive sodium load can result from injudicious use of bicarbonate. Thus, only for severe acidosis (pH less than 7.2) should bicarbonate be considered, and even then, only if respiratory function is satisfactory (see Chapter 95). Sixth, an intravenous (IV) infusion should be started to aid in the administration of drugs and the strict monitoring and administration of fluids.

Blood products in the form of packed cells should be administered if the child is severely anemic. Antibiotics should be reserved for unequivocal evidence of infection or for situations in which circumstantial evidence is strongly suggestive and appropriate cultures have been drawn. The use of corticosteroids may be indicated at times, particularly for heart failure precipitated by rheumatic heart disease. However, decisions of this type should be made with cardiac consultation. Treatment of arrhythmias that result in CHF is discussed subsequently under the "Cardiac Arrhythmias" section.

Although newer pharmacologic agents regularly become available, mainstays of the medical management of acute CHF are still digitalis, or other well-tested inotropic agents, to improve contractility, and diuretics to manipulate ventricular preload and intrapulmonary fluid. Pharmacologic adjustments of afterload have also become important for both acute and chronic CHF treatment. Regardless of the specific therapy, frequent reexamination and reevaluation are mandatory.

Digitalis

The classic drugs for improving the inotropic condition of the heart, unless the CO is severely compromised and the child is acutely ill, are the digitalis glycosides. Modern molecular investigations have helped shape improve our understanding of the mechanisms of action of these agents and how to adjust their administration in specific clinical situations. Although the use of digitalis in infants was reported nearly 60 years ago, until relatively recently dosing regimens have been strictly empiric in their derivations. The use of a radioimmunoassay to determine serum digitalis levels helped define a dosing format. As noted in Table 84.7, a principal clinical value of digitalis pharmacokinetic studies has been to verify that the same unit

TABLE 84.7

DIGITALIZATION WITH DIGOXIN

I. Usual Doses (IM or oral)		
	Weight (g)	**Dose (TDD)[a]**
Premature infants	500–1,000	20 μg or 0.02 mg/kg
	1,000–1,500	20–30 μg/kg or 0.02–0.03 mg/kg
	1,500–2,000	30 μg/kg or 0.03 mg/kg
	2,000–2,500	30–40 μg/kg or 0.03–0.04 mg/kg
Term neonate		30–40 μg/kg or 0.10–0.04 mg/kg
1 mo–12 yr		40–60 μg/kg or 0.04–0.06 mg/kg (Maximum TDD: 1.5 mg)
II. Alterations in Usual Doses		
Lower if renal function is impaired Lower in presence of poor myocardial function (cardiomyopathy, myocarditis) Lower in presence of metabolic imbalance (electrolyte abnormalities, hypoxia, acidosis) Intravenous/intramuscular dose is 75% of oral dose		

[a]TDD, total digitalizing doses. Digitalizing regimen usually given as initial dose: one-half of TDD; second dose: one-fourth of TDD, at 8–12 h; third dose: final one-fourth TDD at 8–12 h after second dose. Maintenance is then started as one-eighth TDD every 12 h. (*Note:* Parenteral preparation contains 100 μg/mL and oral, 50 μg/mL.)

dose per kg of body weight is not necessarily best for children of all ages and that premature infants, in particular, require close adjustment of dose, based on body weight.

The mechanism by which digitalis improves cardiac performance centers on the regulation of the ionic movements that are part of the contractile process. In particular, inhibition of adenosine triphosphatase by digitalis interferes with the sodium and potassium channel mechanism, allowing intracellular accumulation of sodium, and consequently, increasing the level of available calcium for contraction. The associated effect of intracellular potassium depletion may be related to the development of toxicity from digitalis preparations.

The result of digitalis administration for CHF is an increase in the force of cardiac contraction, and thus, an improvement in emptying of the ventricle. Intracardiac filling pressures are reduced, CO rises, cardiac size decreases, and HR slows. Eventually, use of the compensatory mechanisms to maintain CO is mitigated.

Several important points must be remembered when prescribing digitalis glycosides, regardless of the specific one selected or the route of administration. Diligent care must be used in relaying the prescribing information to avoid errors that may have fatal consequences. Calculations of the total digitalizing dose must be double checked and clearly recorded. The microgram dosage should be unequivocally clear, and the corresponding volume to be administered should also be written down. If possible, the prescription should be checked by other medical personnel. Decimal errors are inexcusable but all too common.

The route of administration also has a significant bearing on the dosage prescribed. Parenteral digoxin preparations contain 100 μg per mL, and oral preparations contain 50 μg per mL. In the emergency setting, parenteral administration is often the preferred route. If given IV, the calculated oral dose is reduced by 25%, and the child should be monitored for sudden changes in HR or rhythm. Tissue perfusion levels should be assessed as satisfactory before intramuscular (IM) administration is contemplated because poor absorption from an IM dose (which can be painful) may undercut the therapeutic response.

Digoxin is administered at the dosages described in Table 84.7 (maximum 1.5 mg). The total digitalizing dose is given over 24 hours (one-half initially, then one-fourth in 8 to 12 hours and one-fourth in another 8 to 12 hours). The daily maintenance dosage is one-fourth of the total digitalizing dose divided into twice daily doses for younger children, once daily for older children and adults.

Poisoning from digitalis ingestion may be the precipitating cause for emergency evaluation and for the development of CHF. Various systemic manifestations may be associated with overdosage, including nausea, vomiting, weakness, and worsening of preexisting heart failure. The EKG manifestations of digitalis excess are reviewed subsequently under the "Irregular Heart Rates" section. Care should be taken to clarify the EKG distinctions between "digitalis toxicity" and the more benign "digitalis effect." In general, it is safest to assume the appearance of a new major conduction disturbance in a child who takes a digitalis preparation is related to the drug.

Treatment of digitalis toxicity involves cessation of the drug. Potassium supplementation may be helpful, specifically when potassium depletion has occurred because of dietary factors or diuretic therapy. Potassium should not be given to a patient with digitalis-related atrioventricular (AV) block (see "Cardiac Arrhythmias" section). Diphenylhydantoin (i.e., phenytoin/fosphenytoin) is particularly useful in disorders of impulse formation related to digitalis therapy [e.g., premature ventricular contractions (PVCs)]. In instances of severe heart block, pacing may be required. The presence of digitalis is not an absolute contraindication for cardioversion, and in certain instances, cardioversion may be required to convert even a digitalis-induced rhythm disturbance.

The availability of digoxin antibodies is an important adjunct in the treatment of *digoxin toxicity*.

"Digibind" and other such drugs use the Fab fragment of antibody to digoxin to lower serum concentrations rapidly. Although it is usually necessary to combine vigorous antiarrhythmic therapy (see next section) with digoxin antibody treatment, this form of therapy can provide dramatic improvement in as little as 30 minutes. It must be cautioned, however, that Fab treatment in patients receiving chronic digoxin therapy for CHF may exacerbate CO problems by essentially "withdrawing" the drug. Dosage of Fab is generally equimolar to the estimated amount of digoxin in a patient's body. The onset of action is relatively rapid, as noted and complete reversal of toxicity can occur in 3 to 4 hours. However, close supervision of the patient is needed because with the administration of digoxin antibody, rapid occurrence of hypokalemia can occur. In patients with atrial fibrillation, a rapid ventricular response may occur to exacerbate problems, and occasionally a patient may experience hypersensitivity if sheep protein allergy is present. The elimination of digoxin antibody fragments may take up to several days or longer, especially if renal insufficiency is present, and may interfere with subsequent serum digoxin levels done by radioimmunoassay. Thus, other techniques for assessment of digoxin levels may be needed to follow-up patients at risk.

To use digoxin antibodies, it is assumed that the digoxin total body load (TBL) is proportional to the nanogram per milliliter digoxin level and that each vial of digoxin-immune Fab contains 38 to 40 mg, which neutralizes 0.4 to 0.6 mg digoxin. Thus, the TBL equals serum digoxin (ng per mL) multiplied by the volume of distribution (5.6) multiplied by weight in kg divided by 1,000. The number of vials to be used equals TBL divided by 0.5. For a digoxin level of 5, therefore, in a 20-kg child, approximately 1.1 vials are needed. The TBL may also be assumed to equal 0.8 $\times$ mg of digoxin ingested, if that value is known.

Other Inotropic Agents

In situations of severely compromised CO, isoproterenol or dopamine, both β-receptor agonists, have been used successfully in infants and children. Dobutamine, an analog of dopamine, has also been found to be useful in such circumstances, particularly when impaired myocardial perfusion is part of the underlying problem.

Isoproterenol (Isuprel) has vigorous inotropic effects and marked chronotropic effects. As noted under "Cardiac Arrhythmias," for CHF with persistent bradycardia, isoproterenol is still an important choice. Cardiac rhythm effects may limit the use of isoproterenol, however, because induction of tachyarrhythmias is a consequence of its administration. In addition, hypotension may occur. The starting dose is 0.1 μg per kg per minute by continuous infusion (Table 84.12).

Dopamine has achieved a wide degree of popularity because of its ability, at low doses ("dopaminergic effects"), to augment

renal blood flow directly, in addition to improving CO. Furthermore, the chronotropic activity of the drug is somewhat lower than isoproterenol, and there is less of a tendency to produce hypotension. Several studies have established the efficacy and safety of dopamine in infants and children. The drug is available in 5-mL ampules that contain 200 mg of dopamine and is usually diluted in 100 to 250 mL of a neutral or acidic solution (usually 5% to 10% dextrose or saline). Dopamine must not be administered through the same IV solution as sodium bicarbonate because alkali will deactivate the drug. Initial doses in pediatrics range from 2 to 5 μg per kg per minute given by continuous infusion. For severe systemic hypotension, 5 to 10 μg per kg per minute may be used as the starting dose. The response should be relatively prompt, with an increase in HR and BP followed by improvement in urine output. Increasing the infusion rate may be necessary, but at higher doses (5 μg per kg per minute) the beneficial effects of dopamine on renal blood flow are mitigated, and at >20 μg per kg per minute, adrenergic effects predominate and renal blood flow may be reduced. Adverse effects from dopamine include nausea and vomiting, as well as changes in cardiac rhythm, particularly in patients with preexisting arrhythmias and especially at higher infusion ranges (greater than 10 μg per kg per minute). Dopamine may also elevate pulmonary vascular resistance and should be used with caution, if at all, in patients with pulmonary vascular obstructive disease. Monoamine oxidase inhibitors may potentiate the effect of agents such as dopamine.

Dobutamine has achieved widespread popularity for use in the cardiac population because of the relatively rapid response after initiation of infusion and because of the achievement of favorable hemodynamic effects with less myocardial oxygen debt burden than occurs with dopamine. Less chronotropic and arrhythmogenic effects appear to result from dobutamine, and it may have a more direct effect on enhancement of coronary flow. Therefore, dobutamine may have particular efficacy when impaired myocardial perfusion is suspected, as in heart failure from inflammatory myocardial disease or abnormalities that involve the coronary arteries. Dobutamine is administered in similar fashion to dopamine with initial doses that range from 2.5 to 5.0 μg per kg per minute. Higher doses may be used, but complicating adrenergic effects, in particular, potentiation of rhythm disorders, begin to predominate when high doses (15 to 20 μg per kg per minute) are used. As with dopamine, dobutamine can be used in concert with other agents, such as afterload reduction drugs (see below).

These agents should be administered under close supervision, optimally with monitoring of arterial pressure, central venous and/or pulmonary wedge pressure, HR, and urinary output.

Concern remains about the efficacy of dobutamine in the young infant (younger than 1 year of age). In such infants, dobutamine may improve CO but not result in BP elevation. Thus, in severe hypotension in the young infant associated with septic shock, for instance, dobutamine may be more appropriate as an adjunct, and not as a primary inotrope.

Diuretics

Alterations in renal perfusion and salt and water balance are well-known correlates of CHF. Reduced renal blood flow can result in increased circulation volume and increased sodium and water reabsorption (through associated secondary hyperaldosteronism). Thus, diuretics play a critical role in the management of the child with CHF.

The so-called "loop diuretics" are used most commonly for the acute treatment of CHF. Furosemide (Lasix®) is the most popular of these agents. Through effects on sodium and chloride transport in the loop of Henle, urinary concentrating capability is diminished and diuresis is achieved. An initial dose of 1 mg per kg IV (max 40 mg/dose) usually results in adequate urine flow within 1 to 2 hours of administration. If 3 to 5 mL per kg per hour urine flow is not achieved, a subsequent dose of furosemide in increments of 1 mg per kg can be given and repeated at hourly intervals to a maximum of 3 to 5 mg per kg. Of note, repeat doses of ethacrynic acid (another loop diuretic) are not advised. Close observation for changes in serum electrolytes, especially potassium, is important, particularly because IV digitalis may be given concurrently.

Thiazide diuretics are less commonly used to treat acute CHF and are now generally reserved for more chronic situations (as oral agents). Nevertheless, agents such as hydrochlorothiazide or chlorothiazide, working at the tubular level, produce good diuretic effects.

Other classes of diuretics may be particularly useful in refractory conditions or in cases in which traditional diuretics are already in use. Of these agents, metalozone (Zaroxolyn®) has been administered most often. It is for oral use; thus, onset of action is delayed. Particularly intense potassium depletion can result from metalozone, and patients who take this drug should be evaluated for potassium loss when they present in the ED.

Spironolactone is an adjunctive form of diuretic therapy. It is not a first-line drug because its diuretic effect may not occur for 2 to 3 days. Aldosterone antagonism makes it suitable for use as an additional agent when potassium loss is a problem, and it may also be useful to directly potentiate myocardial metabolic changes favoring enhanced cardiac contractility.

With the proper use of inotropes and diuretic therapy, improvement can be achieved in most children with CHF. Failure to improve an exacerbation of CHF in children already on these medications requires scrutiny for any of the following: (i) persistent arrhythmia; (ii) untreated or unrecognized infection; (iii) anemia, especially in the infant with CHF; (iv) inadequate or excessive digitalis dose, particularly in the patient with inflammatory myocardial disease; or (v) electrolyte disturbance, such as hypokalemia, which may be worsened with diuretics. If these entities can be ruled out, then more intensive treatment is indicated to improve CO in the face of declining cardiovascular status.

Other Noncatecholamine Agents

Other pharmacologic tools available to treat acute CHF are the bipyridine derivatives amrinone and milrinone. These drugs have the combined effects of inotropic support and peripheral vasodilatation. They are known to be inhibitors of myocardial cyclic adenosine monophosphate (cAMP) phosphodiesterase activity, thereby enhancing intracellular levels of myocardial cAMP. There is also a direct vascular smooth muscle relaxant action. In an ideal sense, this class of therapeutic agents represent a major therapeutic breakthrough because the inotropic effects of these drugs may be additive to other agents, especially to digitalis. Pediatric experience has documented the profound vasodilatory effects of these drugs and the need for careful invasive monitoring when they are used. Adequate filling

volumes must be maintained to ensure adequate systemic perfusion. Occasionally, hypersensitivity reactions have occurred with amrinone. Fever and thrombocytopenia are also known side effects, and potassium levels should be followed closely, especially if diuretics are also used. Milrinone may cause less platelet suppression and has become more widely used than amrinone. Chemical interaction with glucose (dextrose) solutions can occur, so these drugs should not be diluted using these fluids. In the patient with CHF in whom standard digoxin and/or catecholamine therapy does not provide improved peripheral perfusion status, use of this class of drugs is standard therapy. Infusion rates for milrinone range from 0.5 to 1.0 μg per kg per minute with a bolus dosage to start therapy of 50 μg per kg given initially over 10 minutes.

Vasodilators

The management of CHF also includes manipulation of loading conditions, following the physiologic principles defined earlier in this chapter. Both afterload and preload interventions can be useful. Agents with effects on cardiac loading have been shown to be efficacious in adults with a variety of chronic forms of cardiac dysfunction and are also appropriate for infants and children with heart failure unresponsive to more conventional treatment regimens. In heart failure, with reduced CO, systemic vascular resistance is often elevated by compensatory mechanisms used to maintain BP. Preload reserve is used through cardiac dilation to increase stroke volume, but this is accomplished at the expense of a decreased ability of the myocardium to shorten as needed to overcome the increase in afterload. Thus, there is a "mismatch" of afterload and preload reserve in heart failure. Vasodilators that work primarily on arteriolar smooth muscle cause afterload reduction, whereas drugs that affect venodilation work on preload by lowering cardiac filling volumes. Some of these agents have mixed effects (Table 84.8). In the vasodilator group, the nitrates, particularly nitroprusside, have been most actively used in the acute care setting. Sodium nitroprusside has both arteriolar and venous actions, a prompt onset of action, and usually a short duration of effect. In the patient with impaired renal function, however, caution must be exercised in its use because the by-product, thiocyanate, can accumulate with neurologic, endocrinologic, and other toxicity. Other drugs used include α-receptor blockers and angiotensin-converting enzyme inhibitors, although these are more commonly used in the long-term care setting via the oral route. Calcium channel blockers also induce vasodilation and appear to be most useful for diastolic dysfunction conditions. These situations involve heart failure developing in the face of myocardial hypertrophy and/or normal end-systolic volume, such as in hypertrophic cardiomyopathy (HCM). The negative inotropic effects of these agents require their use only with careful cardiac monitoring. A thorough history for the chronic use of these drugs is essential in patients who may present with an exacerbation of heart failure because continuation of such therapy in the acute care setting may be required. Afterload reduction therapy, when used intravenously, usually requires extensive monitoring because failure to maintain adequate cardiac filling can have serious negative results. Emergency use of afterload reduction should be limited to those well-versed in cardiopulmonary physiology, and maintenance of such treatment is best carried out in an intensive care environment.

NEWBORN WITH CHF-ASSOCIATED OBSTRUCTED SYSTEMIC OR PULMONARY BLOOD FLOW

Background

For the baby with cyanotic CHD or with obstruction to systemic blood flow, emergency intervention is crucial, indeed life sparing, and must usually be delivered before permanent long-term therapy can be undertaken. The emergency physician must be able to recognize when such a life-threatening circumstance is present and must be able to initiate therapy even before a precise diagnosis can be accomplished. Although this is most often a problem for the neonatologist or other physician caring for an infant during the first few days of life, these

TABLE 84.8

AFTERLOAD REDUCING AGENTS USED IN CONGESTIVE HEART FAILURE

Agent	Class	Action	Dosage
Nitroprusside	Nitrate	Mixed[a] dilator	1–10 μg/kg/min IV (max 12–15 μg/kg/min)
Nitroglycerin	Nitrate	Venodilator	2–10 μg/kg/min
Hydralazine[a]	Smooth muscle inhibitor	Arteriolar dilator	0.1–0.5 mg/kg/dose every 6 h or 0.2–3 mg/kg single bolus IV
Prazosin	Alpha blockade	Mixed dilator	0.01–0.05 mg/kg/dose by mouth every 8–12 h
Captopril	ACE inhibitor	Mixed	0.1–2.0 mg/kg/dose by mouth every 6 h
Enalapril	ACE inhibitor	Mixed	8 or 12 h (max 6 mg/kg/day)[b]
Diltiazem	Ca^{2+} channel blocker	Arteriolar dilator	0.2–0.5 mg/kg/dose by mouth or sublingual every 8 h
Nifedipine	Ca^{2+} channel blocker arteriolar		0.25–1 mg/kg

ACE, angiotensin-converting enzyme; Mixed, both arterial and venous vasoactivity.
[a]Precise mechanism not identified; may inhibit calcium activity.
[b]Intravenous enalapril is available for an every 8-h regimen (enalaprilat), 0.01–0.05 mg/kg/dose, max enalapril 40 mg/day.

babies are also brought to the ED after having been at home. Still others may need the help of emergency medical personnel as they are transported to cardiac centers for definitive care. Therapy in these critical infants depends on the manipulation of the ductus arteriosus.

Pathophysiology

In fetal life, the ductus arteriosus is the principal conduit allowing the preponderance of right ventricular output to bypass the nonventilating fetal lungs (Fig. 84.4). This pathway thus allows for fetal circulatory viability even in the face of extreme disorders of functional cardiac development (Figs. 84.5 and 84.6). In the case of impaired systemic blood flow, the fetus and later the neonate survives because the ductus allows right ventricular output to reach the systemic circulation. This right-to-left shunt mitigates the effects of even complete aortic and/or mitral atresia. In situations of obstructed pulmonary blood flow, the ductus serves as a conduit for systemic (left ventricular) output to reach the pulmonary circulation. This left-to-right shunt becomes crucial once the newborn becomes dependent on his or her own pulmonary

circulation for oxygenation after delivery. Typical conditions that are "ductal dependent" are listed in Table 84.9.

Clinical Manifestations

Any newborn with sudden onset of either collapsed systemic circulation or intense cyanosis should be considered at risk for the presence of a ductal-dependent state. In these babies, closure of the ductus unmasks the underlying circulatory insufficiency, resulting in the clinical picture of severe hypoxemia, shock, or both. These infants may be as old as 1 or 2 weeks, although usually this catastrophe becomes apparent within the first days of life. However, there are times when the process of ductal closure leading to the presentation can be delayed even longer than 2 weeks.

The mechanisms responsible for ductus closure have been defined. Although a prolonged discussion is not relevant in this context, it is important for the emergency physician to understand that these factors center on the balance of dilator and constrictor hormones, namely prostaglandins, and that manipulation of this hormonal system can yield prompt and substantial results. Of course, treatment of heart failure and impaired oxygenation involve more than just ductus manipulation, as outlined elsewhere in this chapter.

Management

Based on the previously described principles, prostaglandin E_1 (PGE_1, alprostadil) has become the standard medical intervention used in this urgent situation. PGE_1 provides relatively rapid stabilization until more permanent measures can be undertaken. There are few, if any, concerns that would contraindicate the use of PGE_1 when any of the conditions noted previously are suspected. Dosage is by infusion at 0.05 to 0.10 μg per kg per minute, after an initial bolus of 0.10 μg per kg. The specific site of infusion is not critical as long as patency of access can be continuously verified. Side effects can be important and, unless prepared for, these can be life-threatening. These include bradycardia, apnea, hypotension, and seizures. Rash and hyperthermia can also develop. Therefore, when PGE_1 therapy is initiated, the ability to support respiration and BP should be secured. Intubation may be required and should always be considered if a prolonged transport is planned. It has become evident over the past 25 years that manipulation of the ductus by PGE_1 administration has been one of the most important advances in the early treatment of even the most severe forms of CHD.

CARDIAC ARRHYTHMIAS

General Considerations

Background

Disturbances in cardiac rhythm are relatively common in infants, children, and adolescents. An apparent increase in the incidence of cardiac arrhythmias in children can be explained by the extensive use of EKG monitoring equipment in children's hospitals, advances in cardiac surgery that have resulted in the survival of children with complex CHD, new techniques to investigate rhythm disturbances, and an increased awareness on the part of pediatricians and pediatric cardiologists of the manifestations of abnormal cardiac rhythms in children.

Pathophysiology

The electrical impulse that initiates and coordinates the mechanical activity of the heart is propagated in an orderly manner through the normal heart. This electrical activity is initiated in the sinoatrial (sinus) node located at the junction of the superior vena cava and right atrium (Fig. 84.7). Activity then spreads through the atria to the AV node located in the lower part of the right atrium near the coronary sinus and just above the septal leaflet of the tricuspid valve. The impulse continues to the bundle of His, which then divides into the right and left bundle branches in the ventricle. The bundle branches then divide into the Purkinje fibers of the ventricular myocardium, and the entire ventricle is thus depolarized.

Arrhythmias in children are caused by disturbances in impulse formation, conduction, or both. These may occur in association with structural or functional cardiac disease, a systemic disease process that affects cardiac conduction, or because of an isolated, primary cardiac electrophysiologic abnormality. Some types of CHD have a relatively high incidence of associated cardiac arrhythmias. These include corrected transposition of the great vessels, Ebstein's anomaly of the tricuspid valve, mitral valve prolapse, congenital mitral stenosis, and the asplenia-polysplenia syndromes. Postsurgical arrhythmias are commonly seen in children after the Fontan procedure and after repair of tetralogy of Fallot, endocardial cushion defects, large atrial septal defects, or total anomalous pulmonary venous return. Acquired heart diseases that may be associated with rhythm disturbances include hypertrophic and dilated cardiomyopathies (including myocarditis), arrhythmogenic right ventricular dysplasia, bacterial endocarditis, rheumatic heart disease, Kawasaki disease, and cardiac tumors.

Other systemic diseases or abnormalities associated with cardiac arrhythmias include electrolyte disturbances, neuromuscular disorders (muscular dystrophy, Friedreich's ataxia), endocrine disorders (hyperthyroidism or hypothyroidism), inherited disorders of metabolism (glycogen storage disease, Pompe's disease), mitochondrial disorders (acyl Co-A dehydrogenase deficiency, Kearns-Sayre syndrome), collagen diseases (systemic lupus erythematosus), pulmonary diseases (bronchopulmonary dysplasia, cystic fibrosis), hematologic disorders (hemochromatosis, anemia, thalassemia major), neoplasms, renal diseases (uremia), infectious diseases, and central nervous system (CNS) diseases (increased intracranial pressure, encephalitides). Drugs and toxic substances (digitalis, general

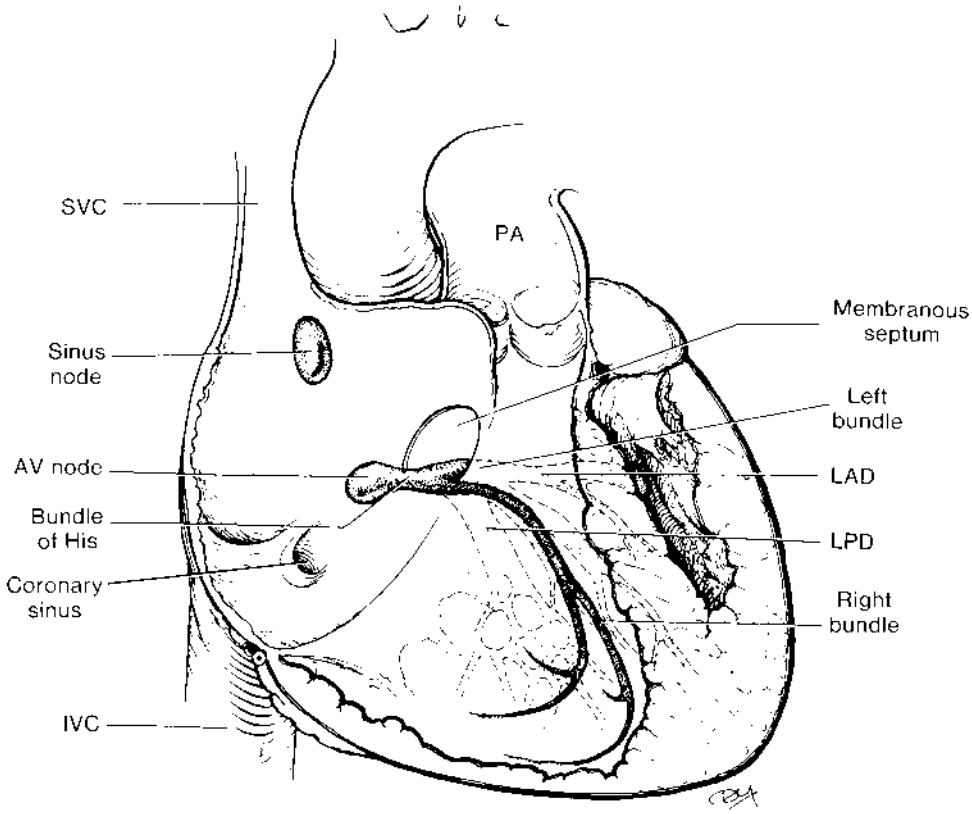

FIGURE 84.7 Schematic representation of the intracardiac conduction system. AV, atrioventricular; IVC, inferior vena cava; LAD, left anterior division; LPD, left posterior division; PA, pulmonary artery; SVC, superior vena cava.

anesthesia, theophylline, sympathomimetic drugs, epinephrine, antihistamines, tricyclic antidepressants) can also lead to abnormalities of cardiac rhythm.

Children may also have AV block, prolonged QT interval, dual AV nodal pathways, or accessory AV pathways [including Wolff-Parkinson-White (WPW) syndrome] in the absence of other systemic or cardiac disease. These represent isolated, primary congenital or acquired cardiac electrophysiologic abnormalities.

Clinical Manifestations

Many children are not aware of or are unable to express awareness of an abnormal cardiac rhythm. Thus, the physician must suspect the diagnosis from the secondary manifestations. Arrhythmias may surface in the following ways:

1. No symptoms. Physical examination reveals an abnormal or irregular HR.
2. Symptoms or signs of CHF (see previous section), shock, or sudden death
3. Symptoms related to decreased cerebral blood flow (syncope, dizziness, irritability, and inappropriate behavior)
4. Symptoms related to decreased coronary blood flow (anginal chest pain)
5. Perception of the rhythm disturbance by the child (palpitations, chest pain, skipped beats)

Management

Management of the child with a cardiac arrhythmia requires recognition of the manifestations of these disorders, diagnosis of the type of rhythm disturbance, understanding of the mechanism of the abnormality, knowledge of appropriate therapy (physiologic, pharmacologic, or electrical), judgment about the appropriate timing and urgency of therapy, and understanding of potential side effects of the therapy. Once an abnormality in cardiac rhythm is suspected or found, the precise diagnosis must be made to institute appropriate treatment. This depends on accurate interpretation of the EKG. The EKG used to evaluate cardiac arrhythmias should include a long rhythm strip in addition to a complete 12- or 15-lead EKG. Lead II is often used for the rhythm strip, but a V_1 lead or another lead in which P waves are prominent may be more helpful. The rhythm on the EKG should be evaluated for rate, regularity, origin of the impulse and mechanism, or origin of any abnormality.

Cardiac arrhythmias become emergencies when they produce or have the potential to produce hemodynamic alterations that result in a decreased CO. Most infants and children who have hemodynamically significant arrhythmias will require cardiac consultation and admission to the hospital for treatment and observation, continuous EKG monitoring (telemetry or bedside with arrhythmia analysis is preferred). Table 84.10 represents an overview of the emergent management of arrhythmias. Children with intermittent palpitations and no signs or symptoms of hemodynamic impairment may be evaluated as outpatients, using ambulatory electrocardiography, transtelephonic event monitoring, or exercise stress testing as deemed appropriate.

The cardiac arrhythmias discussed in this section are classified according to their presentation to the physician: slow HRs, rapid HRs, and irregular HRs. Slow HRs that are most commonly seen in the ED include complete (or third-degree)

TABLE 84.10

EMERGENT MANAGEMENT OF DYSRHYTHMIAS IN CHILDREN (WITH INADEQUATE PERFUSION[a])

Dysrhythmia	Pharmacologic therapies	Definitive electrophysiologic
Slow heart rate		
Complete heart block Sinus bradycardia, sick sinus syndrome	Epinephrine (E) bolus of 0.01 mg/kg IV of 1:10,000 dilution, followed by infusion of 0.1–2.0 μg/kg/min Atropine (At) 0.02–0.04 mg/kg IV (0.1 mg/ min)–(2 mg max)	Pacemaker
Rapid heart rate		
Supraventricular tachycardia	Adenosine (when perfusion deemed sufficient) Initial 0.1 mg/kg (max 6 mg/dose), subsequent 0.2–0.3 mg/kg (max 12 mg/dose) Amiodarone (Amio) 5 mg/kg IV over 20–60 min (max 300 mg/dose) Procainamide (Proc) 5 mg/kg (max 100 mg/dose over 5–10 min, can repeat q 5–10 min) max load 15 mg/kg total (500 mg), digoxin (Dig) (Table 84.7)	Cardioversion, 0.25–2 J/kg, doubling wattage until 10 or successful
Junctional tachycardia	Amiodarone 5 mg/kg IV over 20–60 min (max 300 mg/dose) (Dig) (Proc)	
Ventricular tachycardia	Amiodarone 5 mg/kg IV over 2060 min (max 300 mg/dose) Lidocaine 1 mg/kg	Cardioversion 24 J/kg
Ventricular fibrillation	Defibrillation 2 J/kg	Lidocaine 1 mg/kg and defibrillation 4–10 J/kg
Irregular heart rate		
Premature ventricular contractions Second-degree heart block	Lidocaine 1 mg/kg (I), (E), (At)	(Amio) (Proc) Pacemaker

IV, intravenous.
[a]See text for more complete discussion.

heart block and the sick sinus syndrome with resultant bradycardia of a sinus, junctional or ventricular origin. Rapid HRs include SVT, atrial flutter or fibrillation, and ventricular tachycardia (VT). Irregular rhythms are usually caused by premature ventricular or atrial contractions, sinus arrhythmia, atrial fibrillation, and second-degree heart block.

To determine whether any HR is abnormally fast or slow, one must know the normal range of rates for children of various ages. Results of 24-hour continuous EKG monitoring studies have defined the normal ranges. Table 84.11 illustrates ranges of rates accepted as normal.

TABLE 84.11

NORMAL HEART RATE RANGES

Age	Heart rate (bpm)
Newborn	80–180
1 wk–3 mo	80–180
3 mo–2 yr	80–160
2 yr–10 yr	65–130
10 yr–adult	55–90

Slow Heart Rates

Congenital Complete Heart Block

Complete (third-degree) AV heart block is the most common cause of symptomatic bradycardia in infants and children. Complete heart block, which may be congenital or acquired, results from a complete failure of conduction from atria to ventricles. The atrial rate is always faster than the ventricular rate, which is usually 40 to 80 bpm. A typical EKG is shown in Figure 84.8.

Congenital Heart Block

Congenital complete heart block (CCHB) is due to an abnormality in the region of the AV node (aplasia, hypoplasia, inflammation, or fibrosis) and may be an isolated finding or associated with either specific types of congenital heart defects [corrected or L-transposition of the great arteries, left atrial isomerism/polysplenia syndromes (heterotaxy)], or maternal collagen disease associated with the presence of anti-Ro (SS-A) and anti-La (SS-B). CCHB is being diagnosed more often in utero with the use of fetal monitoring and fetal echocardiography, but it still may not be recognized until weeks or months after birth.

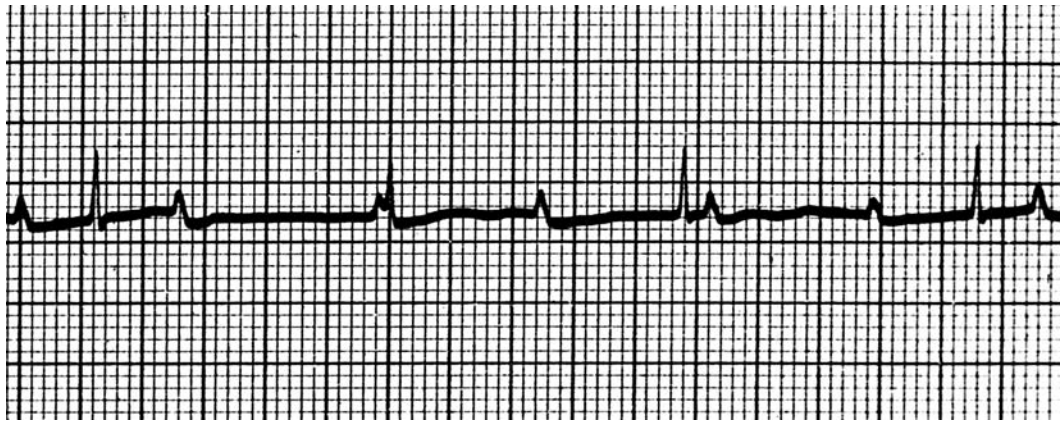

FIGURE 84.8 Example of complete heart block. Note absence of any regular PR interval. Ventricular rate 62 bpm, atrial rate approximately 95 to 115 bpm.

All infants with CCHB have bradycardia. Although some remain asymptomatic, others develop CHF and, occasionally, cardiovascular collapse and sudden death. An EKG will differentiate sinus bradycardia from complete heart block. Sinus bradycardia should respond to the usual resuscitative measures: ventilation and oxygenation, treatment of acidosis, and catecholamine support of HR and BP. The infant with CCHB who has severe CHF or who is in shock will require insertion of a pacemaker, but may also require intubation for adequate ventilation, oxygenation, and treatment of acidosis. If no improvement is obtained with these measures, then infusion of epinephrine may increase the HR slightly, allowing time for the placement of a temporary pacemaker (Table 84.12). A hydropic infant may also require a diuretic such as furosemide (1 mg per kg, IV). Distressed infants with CCHB generally have HRs less than 50 bpm. If an infant is distressed with a rate greater than 50 bpm, one should suspect significant CHD or some other associated problem such as infection or sepsis in addition to CCHB.

The infant in extremis from a slow HR may require immediate temporary pacing in the ED. This may be accomplished by the transcutaneous, transthoracic, or transvenous route.

TABLE 84.12

EVALUATION OF SICK SINUS SYNDROME

Test	Expected normal response
Atropine (0.02–0.04 mg/kg; max: 2 mg)	HR > 90 bpm >25–50% increase in HR
Isoproterenol (0.1–2 μg/min)	>25% increase in HR
Exercise	95% of expected normal rate
Electrophysiology study	Normal CSNRT (<550 ms) Normal SACT (45–105 ms)
24-Hour ambulatory monitor	Normal low rate for age Pauses <3 s

CSRNT, corrected sinus node recovery time; SACT, sinoatrial conduction time; HR, heart rate.

The transcutaneous route was first introduced by Zoll in 1952. This technique involves the use of pacing electrodes placed on the anterior and posterior chest attached to an external current source. This technique may be used successfully in critical situations to increase the HR; however, the pacing electrodes should be replaced as soon as possible with another type of pacemaker because third-degree burns have been noted under the pacing electrodes after short periods in infants. Special wires available for transthoracic pacing can be placed by the subxiphoid route in infants and children. The procedure uses techniques similar to those used for pericardiocentesis. A pacing wire is inserted through a needle that is subsequently removed once the wire is inside the heart. This type of pacing should be replaced by a transvenous pacemaker once the patient is stable. If time allows, placement of a temporary transvenous pacemaker either through the umbilical vein or femoral vein (see Procedures in Chapter 135) under direct fluoroscopic observation in a cardiac catheterization laboratory is preferred. Temporary transvenous pacing is reserved for infants with signs of CHF, most commonly seen with HRs under 50 bpm or with slightly higher rates in association with a structural CHD. However, an infant with an HR of 45 bpm should not be paced solely on the basis of HR but should be observed for signs of CHF such as tachypnea, poor feeding, or hepatomegaly. The width of the QRS on the EKG does not always correlate with the need for a pacemaker, although wider QRS rhythms frequently are associated with lower escape rates. Only a small percentage of infants with CCHB block require emergency pacing at birth. Many of these infants will not need pacemakers until they are older.

The older child with CCHB may also present with symptoms associated with CHF. More commonly, dizziness, presyncope, syncope, exercise limitation, or fatigue is the presenting complaint in the older child. At times, the appearance of a ventricular arrhythmia may be the presenting sign of difficulty in these patients. Indications for and timing of implantation of a permanent pacemaker in children with CCHB are based on the appearance of these symptoms or signs, or specific electrocardiographic findings such as an excessively slow ventricular rate, ventricular ectopy, or prolonged pauses (greater than 3 seconds).

Acquired Nonsurgical Heart Block

Acquired nonsurgical heart block may be idiopathic or associated with congenital heart defects, infectious or inflammatory processes (such as viral or Lyme myocarditis, endocarditis, or rheumatic fever), muscle diseases, cardiac tumors, or cardiac sclerosis. The emergency treatment for congenital or acquired nonsurgical heart block is similar. Pharmacologic therapy may be tried if adequate ventilation, oxygenation, and treatment of acidosis do not produce a normalization of the CO as reflected by the BP and peripheral perfusion. The initial drug to be used should be epinephrine (Table 84.12) because it is most effective in increasing the HR. Adequate intravascular volume should be maintained during epinephrine infusion because its vasodilatory effect may result in lowered BP. If CO is inadequate despite pharmacologic measures, temporary ventricular pacing is indicated.

In this setting, a single typical Stokes-Adams or syncopal attack not related to neurologic disease is considered an indication for pacemaker insertion because these attacks may be fatal. Temporary transvenous pacing may be required during the acute phase of an infectious process, but because resolution of complete heart block may occur in some inflammatory processes (e.g., myocarditis), permanent pacing may not be needed. Persistence of nonsurgical heart block (duration depending on the etiology) does warrant permanent pacemaker insertion. The temporary pacemaker should be left in place during induction of anesthesia for the permanent pacemaker implantation because serious arrhythmias have been noted to occur if adequate CO is not maintained by pacing.

Postsurgical Complete Heart Block

Postsurgical heart block is less common today than in the early days of surgery for CHDs, with a current incidence of less than 1%. Improved knowledge of the location of the conduction system, as well as the implementation of intraoperative mapping techniques, has helped to decrease this serious postsurgical complication. Postsurgical complete heart block generally presents immediately after surgery but it may occur many years after surgery. When it occurs, it may be transient or permanent. All patients with postsurgical complete heart block occurring more than 1 week after surgery should have implantation of permanent pacemakers, due to the unreliability of the escape rhythm. Emergency treatment of symptomatic, late-onset postsurgical complete heart block includes pharmacologic chronotropic agents and temporary pacing until a permanent pacemaker can be placed (as previously).

Sinus Bradycardia

Sinus bradycardia is an HR below the normal range for age (Table 84.11). An EKG is necessary to rule out second-degree or complete heart block; P waves with a normal PR interval must precede each QRS complex in sinus bradycardia. Sinus bradycardia is commonly associated with sinus arrhythmia. It often occurs in the athletic child or in the adolescent as a normal variant, especially during sleep. Other causes of sinus bradycardia include hypothermia; hypothyroidism; significant weight loss (malnutrition or anorexia nervosa); CNS disease, including increased intracranial pressure; and drugs such as morphine, propranolol, or digoxin. Therapy of the underlying disorder is indicated, but in symptomatic patients atropine may be useful as a temporizing measure (Table 84.12). Epinephrine may also be given in this emergency setting (Table 84.12).

Sick Sinus Syndrome

Sick sinus syndrome is a condition in which sinus node function is intrinsically abnormal and may present with a sinus bradycardia or a slow junctional rhythm, often in association with alternating episodes of tachycardia. Syncopal episodes may occur. This abnormal cardiac rhythm may be seen in children who have undergone atrial surgery for closure of an atrial septal defect, particularly of the sinus venosus type, the Mustard procedure for correction of D-transposition of the great arteries, Fontan repair for single ventricle complexes, or in association with a viral myocarditis or as a primary cardiac electrophysiologic abnormality. Table 84.12 outlines the evaluation of the child with a suspected sick sinus syndrome. Evaluation will generally be performed by a pediatric cardiologist.

The urgency of the clinical picture determines the treatment of the child with sick sinus syndrome. The asymptomatic patient with a slow HR can be referred for consultation with a cardiologist. The child with CHF or inadequate perfusion from bradycardia or tachycardia requires therapy directed at the specific arrhythmia and admission to the hospital. Epinephrine infusion (Table 84.12) may increase the HR temporarily in a child with bradycardia but, in this situation, may also precipitate tachyarrhythmias. Epinephrine, therefore, should be administered cautiously under continuous monitoring. Symptomatic slow rhythms may require temporary or permanent cardiac pacing.

Pacemakers

Pacemakers are used frequently in infants and children for the treatment of congenital or acquired (usually postsurgical) complete heart block or sick sinus syndrome. In addition, some patients with tachyarrhythmias or with the long QT syndrome are being treated with pacemakers. Therefore, it has become important for the emergency physician to recognize the normal and abnormal function of a pacemaker.

Pacemaker functions may be complex. They may sense or pace one, two, or three chambers. Pacemakers can be programmed to respond to external factors such as motion or minute ventilation or to synchronize with ventricular and atrial contractions. The universal "letter code" for description of a pacemaker includes three or more letters. The first letter indicates chamber paced (v, ventricle; a, atrium; d, dual; or both), the second letter indicates chamber sensed, and the third letter indicates the mode (I, inhibited; T, triggered; D, dual or both). Additional letters indicate more complex functions, such as rate responsiveness. The goal of current pacing practice is to give the patient a range of HR that can physiologically adapt to activity or other increased metabolic requirements. Rate-responsive and dual-chamber pacemakers (DDD, DDDR) that pace or sense in both the atrium and the ventricle are commonly used in children old enough to have two endocardial wires placed, although synchronized atrial sensing–ventricular pacing can also be accomplished with a single endocardial lead (VDD). Motion-sensing, rate-responsive pacers (VVIR, AAIR) are less useful in young infants than in older children. Rarely, the simple "back-up" modes of VVI or AAI may still be encountered.

Accurate evaluation of pacemaker function in the ED requires knowledge of the specific pacemaker mode. Examples of normal function, failure to capture, and failure to sense are shown in Figure 84.9. When a pacemaker malfunction is suspected, the specific problem should be identified if possible. Each pacemaker manufacturer has a computerized, telemetry-based programmer that enables the practitioner to identify and, if possible, fix the pacemaker malfunction by reprogramming. An EKG lead that shows the largest possible pacemaker stimulus artifact should be chosen with multiple leads providing more information. A pacemaker stimulus that falls outside the cardiac refractory period and fails to result in a ventricular depolarization indicates a failure of capture. In currently available pacemakers, the output of the pacemaker may be reprogrammed externally, often resulting in normal capture. As the battery generator is depleted, the rate on most pacemakers decreases to a predetermined end-of-battery life indicator, which reveals impending battery failure.

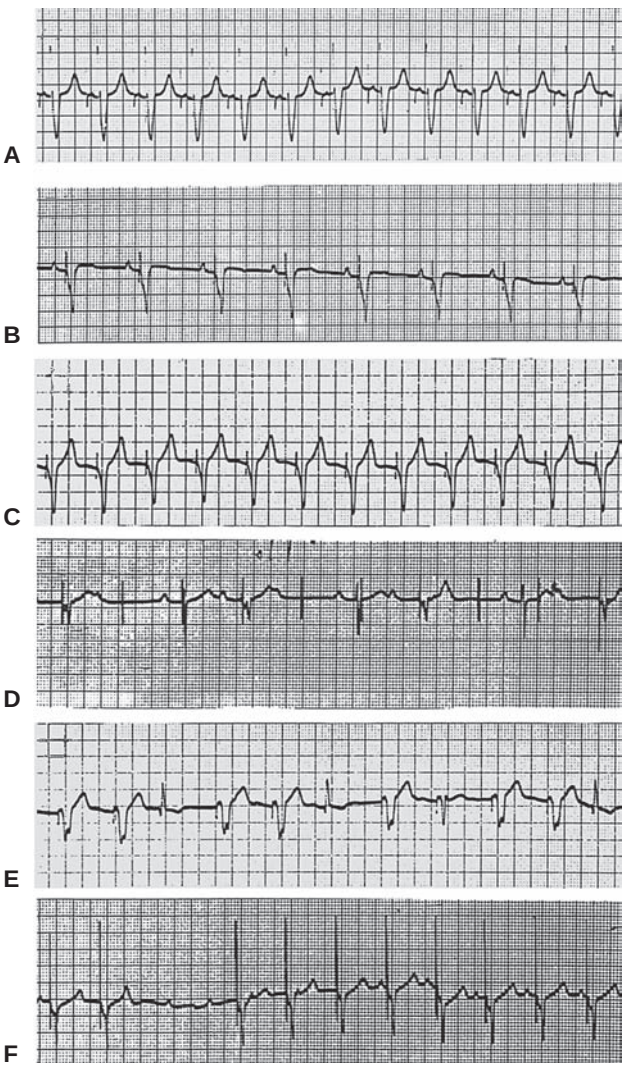

FIGURE 84.9 **A:** Electrocardiogram (EKG) showing pacemaker that paces atrium and, after 150 msec, paces ventricle. Note pacemaker stimulus artifact before the P wave and the QRS complex. **B:** EKG showing pacemaker that senses atrium and paces ventricle after a 150-msec delay. Note that pacemaker stimulus artifact only precedes the QRS complex. **C:** EKG showing ventricular pacing at 100 bpm with normal capture. Note pacemaker stimulus artifact preceding the QRS. **D:** EKG showing ventricular pacing at 85 bpm with intermittent failure of capture. Note several pacemaker stimulus artifacts are not followed by a QRS complex, indicating failure of capture. **E:** EKG showing ventricular pacing at 90 bpm and normal sensing of patient's intrinsic rhythm. **F:** EKG showing ventricular pacing at 100 bpm, as well as inappropriate sensing and failure to stimulate the heart secondary to wire fracture.

An abnormally long pause or an earlier-than-expected paced complex indicates a sensing failure, either inappropriate sensing of another electrical signal (e.g., T-wave sensing instead of QRS) or failure to sense the QRS. Sensing errors can be identified and external reprogramming accomplished.

Any patient with evidence of pacemaker malfunction should be admitted to the hospital if the problem cannot be resolved in the ED. A chest radiograph should be obtained to look for wire fractures or lead displacement. A consultation with a pediatric cardiologist and/or the pacemaker manufacturer's technical staff is generally required to troubleshoot and correct pacemaker problems. The patient with pacemaker malfunction who has symptomatic bradycardia should be managed with the regimens previously discussed (Table 84.12).

The procedure for inserting a temporary pacemaker is described in Section VII.

Fast Heart Rates

Supraventricular Tachycardia

Background. SVT, previously called paroxysmal atrial tachycardia, is the most common significant arrhythmia seen in pediatric practice. SVT describes a group of arrhythmias with similar EKG features but different mechanisms.

A typical EKG seen in a pediatric patient with SVT is shown in Figure 84.10. Note the very rapid rate and the narrow QRS complex. The P waves are different from the usual sinus P wave but may be obscured by the ST segment and not be visible at all. The rate of tachycardia in young infants ranges from 220 to 320 bpm. Older children have tachycardia rates that range from 150 to 250 bpm. SVT with "aberrant conduction" has an EKG with a wide QRS complex and may resemble VT.

Pathophysiology

These mechanisms of SVT have been clarified by the use of intracardiac electrophysiology studies. The majority of instances of SVT in children have been shown to involve reentry circuits utilizing either dual (fast and slow) AV nodal pathways or accessory AV connections (either concealed or manifest as WPW syndrome). Less commonly, enhanced automaticity of sinus nodal, atrial, or AV nodal region fibers may be responsible. More than 90% of infants with SVT have an accessory AV pathway. Older children and adolescents are more likely to have dual AV nodal pathways. Underlying electrophysiologic substrates for SVT may be isolated or seen in conjunction with CHD (approximately 23%, including Ebstein's anomaly or corrected transposition).

Reentrant SVT in the setting of AV accessory pathways is analogous to AV nodal reentrant SVT with the bypass tract functioning like a β pathway (fast conduction, long refractory period) and the AV nodal–His-Purkinje system functioning

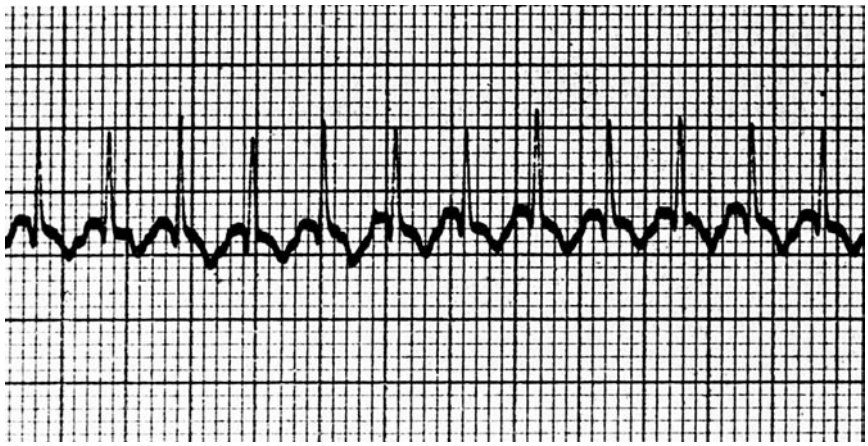

FIGURE 84.10 Supraventricular tachycardia, rate 300 bpm.

like an α pathway (slow conduction, short refractory period). Episodes of SVT are usually initiated by a premature atrial depolarization that blocks antegrade conduction in the accessory pathway and travels to the ventricles over the normal AV conducting system. The impulse, on reaching the ventricular insertion of the bypass tract, can travel retrograde up the bypass tract to the atrium reenter the AV node to start a "circus movement" or reentrant type of tachycardia.

AV accessory tracts may be either manifest on an EKG as WPW syndrome or concealed. In WPW, the pathway conducts antegrade (from atrium to ventricle) during sinus rhythm, resulting in WPW complexes, which consist of a short PR interval and a widened QRS complex with a slurred upstroke (delta wave). These complexes are generally not seen during the tachycardia, but only after conversion to normal sinus rhythm as shown in Figure 84.12. The short PR interval and delta wave characteristic of the WPW syndrome are produced by conduction over the accessory pathway, which has different electrophysiologic properties from the normal AV conduction system. The ventricular complex is a fusion beat with a variable contribution from conduction through the accessory pathway and the AV node. The greater the contribution is from the accessory pathway, the larger the delta wave and more bizarre the QRS. A concealed bypass tract indicates that the bypass tract is used only as the retrograde limb of the reentrant circuit during SVT but is not used for antegrade conduction during normal resting rhythm. Thus, the resting EKG appears normal.

Most commonly, antegrade conduction during AV reentrant SVT occurs through the AV node and the QRS complexes will be normal on the EKG. In patients with WPW, the reentrant circuit may be reversed, with the bypass tract forming the antegrade limb. In these cases, the QRS complexes will be wide and bizarre, and the arrhythmia may stimulate VT. In addition, because the ventricle must be depolarized prior to retrograde conduction up the bypass tract, atrial activation must always follow ventricular activation; therefore, the P wave follows inscription of the QRS complex. The PR interval is usually less than 50% of the R-R interval. In AV nodal reentrant SVT, the P wave may or may not be visible but, if visible, is generally closely related to the preceding QRS complex. The rate of SVT appears to reflect the conduction properties of the AV node and bypass tract when involved. Patients whose AV nodes or bypass tracts conduct slowly have slower rates during SVT. Conduction properties of the various substrates, and consequently, SVT rates can be affected by sympathetic or parasympathetic tone, as well as drugs.

The identification of the mechanism of the tachycardia in SVT is helpful from a therapeutic point of view so a medication known to act specifically on the AV node, the accessory pathway, or the atrial tissue may be chosen.

The infant with SVT is most commonly younger than 4 months of age and is more likely to be male (male:female ratio is 3:2). Episodes may appear to be precipitated by infection, fever, or drug exposure (most commonly, cold medications or bronchodilators containing sympathomimetic amines). Underlying electrophysiologic substrates for SVT may be isolated or seen in conjunction with CHD (approximately 23%, including Ebstein's anomaly or corrected transposition). Accessory AV tracts may be manifest on routine EKG (WPW syndrome: 22%) or concealed. More than 90% of infants with SVT have an accessory AV pathway. Older children and adolescents are more likely to have dual AV nodal pathways. Those previously classified as idiopathic are generally considered to have concealed accessory pathways or other reentrant circuits.

Electrophysiologic catheterization techniques have provided much information about the mechanisms of SVT. SVT in children is most commonly due to a reentrant mechanism; either within the AV node or using an AV bypass tract (either concealed or manifest as WPW). Less commonly, enhanced automaticity of sinus nodal, atrial, or AV nodal region fibers may be responsible for SVT.

An understanding of the concept of reentry is important for understanding the therapeutic approach to SVT. Figure 84.11 illustrates the application of this concept to human SVT in the case of dual AV nodal pathways. By convention, the dual pathways have been labeled alpha (α) and beta (β). The α pathway is slower conducting but has a shorter refractory period than the faster-conducting β pathway. During sinus rhythm, the atrial impulse traverses the faster-conducting β pathway to produce a single QRS complex. The impulse travels simultaneously down the α (slow) pathway, reaching the His bundle shortly after it has been depolarized and rendered refractory by the impulse that was conducted down the β pathway. In response to an atrial premature depolarization, the impulse is blocked in the β pathway as a result of its longer refractory period and proceeds slowly down the α pathway. If conduction

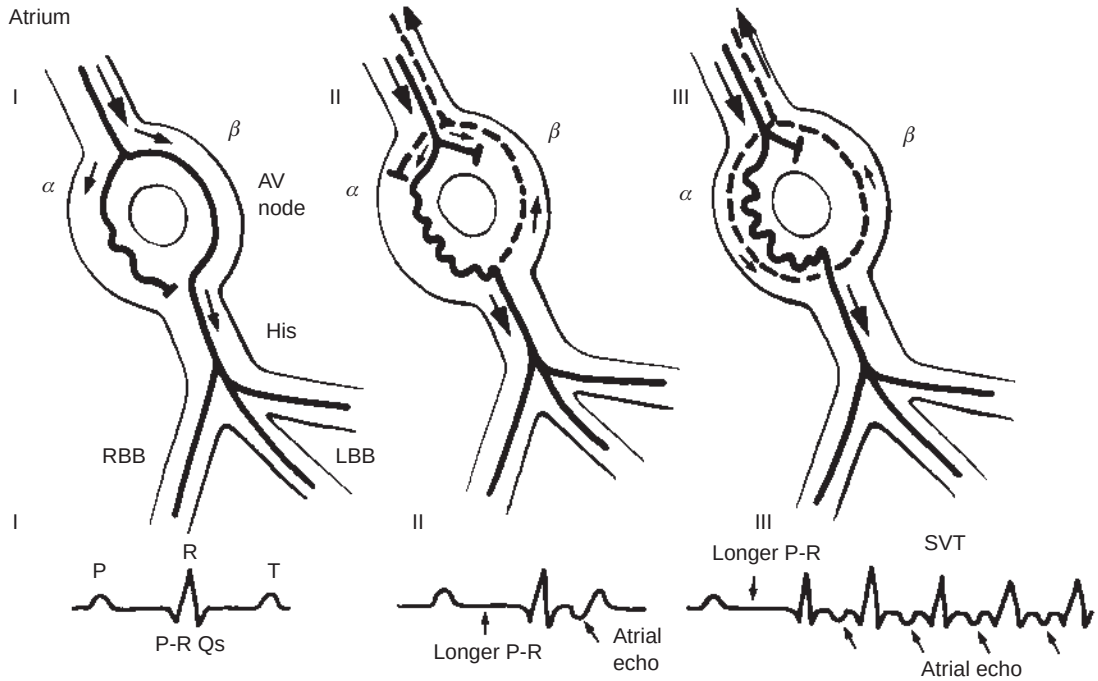

FIGURE 84.11 Schematic representation of conduction pathway and corresponding electrocardiogram in the development of atrioventricular (AV) nodal reentry. See text for full discussion. LBB, left bundle branch; RBB, right bundle branch; SVT, supraventricular tachycardia.

down the α pathway is slow enough to allow the previously refractory β pathway time to recover, a single atrial echo results. An earlier atrial premature depolarization (Fig. 84.11) also blocks in the β pathway, conducts slowly down the α pathway, and arrives later to conduct retrograde through the β pathway back to the α pathway with antegrade conduction producing a sustained AV nodal reentrant tachycardia.

If conduction delay and refractoriness in both pathways are appropriate, a continuously circulating wave front of electrical activity ensues, resulting in a reentrant tachycardia. Additional substrates for reentrant SVT can be found in the sinus node, atrium, and a variety of AV accessory pathways. Reentrant SVT in the setting of AV accessory pathways is analogous to AV nodal reentrant SVT with the bypass tract functioning like a β pathway (fast conduction, long refractory period) and the AV nodal–His-Purkinje system functioning like an α pathway (slow conduction, short refractory period). Episodes of SVT are usually initiated by a premature atrial depolarization that blocks antegrade conduction in the accessory pathway and travels to the ventricles over the normal AV conducting system. The impulse, on reaching the ventricular insertion of the bypass tract, can travel retrograde up the bypass tract to the atrium and reenter the AV node to start a "circus movement" or reentrant type of tachycardia.

AV accessory tracts may be either manifest on an EKG as WPW syndrome or concealed. In WPW, the pathway conducts antegrade (from atrium to ventricle) during sinus rhythm, resulting in WPW complexes, which consist of a short PR interval and a widened QRS complex with a slurred upstroke (delta wave). These complexes are generally not seen during the tachycardia, but only after conversion to normal sinus rhythm as shown in Figure 84.12. The WPW complex represents the presence of a bypass tract connecting atria and ventricles. The short PR interval and delta wave characteristic of the WPW syndrome are produced by conduction over the accessory pathway, which has different electrophysiologic properties from the normal AV conduction system. The ventricular complex is a fusion beat with a variable contribution from conduction through the accessory pathway and the AV node. The greater the contribution is from the accessory pathway, the larger is the delta wave and more bizarre the QRS. A concealed bypass tract indicates that the bypass tract is used only as the retrograde limb of the reentrant circuit during SVT but is not used for antegrade conduction during normal resting rhythm. Thus, the resting EKG appears normal.

Most commonly, antegrade conduction during AV reentrant SVT occurs through the AV node and the QRS complexes will be normal on the EKG. In patients with WPW, the reentrant circuit may be reversed, with the bypass tract forming the antegrade limb. In these cases, the QRS complexes will be wide and bizarre, and the arrhythmia may simulate VT. In addition, because the ventricle must be depolarized prior to retrograde conduction up the bypass tract, atrial activation must always follow ventricular activation; therefore, the P wave follows inscription of the QRS complex. The PR interval is usually less than 50% of the R-R interval. In AV nodal reentrant SVT, the P wave may or may not be visible but, if visible, is generally closely related to the preceding QRS complex. The rate of SVT appears to reflect the conduction properties of the AV node and bypass tract when involved. Patients whose AV nodes or bypass tracts conduct slowly have slower rates during SVT. Conduction properties of the various substrates, and consequently, SVT rates can be affected by sympathetic or parasympathetic tone, as well as drugs. Additional substrates

for reentrant SVT can be found in the sinus node, atrium, and a variety of accessory pathways.

The identification of the mechanism of the tachycardia in SVT is helpful from a therapeutic point of view so a medication known to act specifically on the AV node, the accessory pathway, or the atrial tissue may be chosen.

Clinical Manifestations. SVT may occur at any age. Some patients may have only asymptomatic tachycardia. The presence of symptoms or signs of hemodynamic impairment will depend on the rate of duration of the SVT, as well as the presence or absence of preexisting CHD or myocardial dysfunction. The infant with SVT may present with only a fast rate, or with signs of CHF (poor feeding, irritability, respiratory distress) or in shock. The infant may be acidotic with a clinical appearance resembling the septic infant. The older child may complain of palpitations, dizziness, chest pain, respiratory distress, or present with syncope. Because of presenting symptoms, the older child is less likely to be quite as ill when first seen as the infant or young child. The older child with a CHD or primary myocardial disease is more likely to present with signs of CHF. In a patient without CHD or preexisting myocardial dysfunction, CHF usually appears only after 24 hours of SVT.

Episodes of SVT may have no specific inciting factor or may appear to be precipitated by infection, fever, or drug exposure (most commonly, cold medications or bronchodilators containing sympathomimetic amines). However, when the patient is first seen in the ED, the precise onset of the SVT is rarely certain and the presence of associated heart defects or dysfunction is unknown. Therefore, all patients must be treated with some degree of urgency.

Management. Treatment of SVT is determined by the clinical condition of the patient and the presumed mechanism. Thus, a different mode of treatment is chosen for the patient with tachycardia in shock than for the asymptomatic patient who has only a fast HR (Table 84.13).

Any patient with SVT who presents with shock or severe hemodynamic compromise should be cardioverted. Synchronized direct current (DC) cardioversion at a dosage of 0.25 to 0.5 J per kg should be used and doubled until effective or until a dosage of 2 J per kg is reached. Underlying acidosis may need to be corrected and adequate ventilation and oxygenation provided because cardioversion may not be successful in the presence of hypoxia or acid–base imbalance. If ventricular fibrillation should occur, defibrillation will generally convert the patient to normal sinus rhythm. The patient may need a sedative or short-acting anesthetic, and preparations should be made for airway support and ventilation if needed. The presence of digoxin in a patient should not prevent the use of cardioversion when needed. A digoxin-related ventricular arrhythmia may be treated with lidocaine.

TABLE 84.13

TREATMENT OF SUPRAVENTRICULAR TACHYCARDIA

Clinical status	Treatment
Asymptomatic	Ice, vagal maneuvers IV adenosine Other pharmacologic agents 1. IV verapamil (>1 yr old) 2. IV digoxin 3. IV amiodarone
Mild congestive heart failure	Cardioversion, synchronized Ice, vagal maneuvers IV adenosine Other pharmacologic agents 1. IV digoxin 2. IV amiodarone 3. IV procainamide
Moderate congestive heart failure	Cardioversion, synchronized IV adenosine Other pharmacologic agents 1. IV digoxin 2. IV amiodarone 3. IV procainamide Pacing (esophageal or intracardiac)
Severe congestive heart failure	Cardioversion, synchronized IV adenosine (may not be effective if perfusion poor) Pacing, esophageal or intracardiac Other pharmacologic agents 1. IV digoxin 2. IV amiodarone 3. IV procainamide

IV, intravenous.

Children who have only moderate, mild, or no hemodynamic impairment can be treated successfully with vagal maneuvers or adenosine. Because the majority of SVT in children is caused by either AV nodal or AV reentry, an intervention that interrupts the reentrant circuit in the AV node will interrupt the tachycardia. There are several effective methods of interfering with AV nodal conduction. In older children and adolescent patients, carotid sinus pressure or the Valsalva maneuver can frequently terminate the tachycardia by increasing vagal tone, thus slowing conduction and prolonging refractoriness within the AV node. In infants and young children, however, these maneuvers are technically difficult and usually ineffective. In this age group, ice water or ice bags applied to the face in the perinasal area for 5 to 10 seconds can be effective in eliciting the diving reflex and stopping the SVT. This technique should be reserved for children who are monitored, with particular caution used in applying these techniques in young infants, because marked sinus slowing may occur.

The pharmacologic agent of choice for the rapid conversion of SVT is IV adenosine, an endogenous purine that breaks the reentry circuit by slowing or blocking conduction in the AV node. When pushed rapidly into as central a vein as possible, it has a rapid onset of action (usually within 10 seconds) and a short half-life with occasional side effects (wheezing, hypotension) lasting less than a minute and rarely being serious. Adenosine may be used in moderately ill patients but should not delay cardioversion in severely compromised patients. Appropriate doses are shown in Table 84.14. The majority of children with SVT will convert to sinus rhythm with adenosine.

If adenosine is not successful, or SVT continues to return after conversion to sinus rhythm, other agents that may be useful and are reviewed in Table 84.14. IV procainamide or amiodarone may be used under the guidance of a cardiologist to terminate reentrant SVT. Although effective in terminating SVT in children, digoxin is now used infrequently for acute treatment due to its slow onset of action. It works by prolonging AV nodal conduction and refractoriness in both the fast (β) and slow (α) pathways. The usual digitalizing dose appropriate for age is used (Table 84.7). As noted earlier, the IV dose should be calculated to be 75% of the oral dose. IV verapamil is rarely used in recent years. The doses are shown in Table 84.14.

Other nonpharmacologic measures can be used as well. Raising the BP with α-adrenergic agents such as phenylephrine can terminate the SVT by stimulating the vagus through the baroreceptor reflexes; SVT that is refractory to the usual pharmacologic agents can also be converted by a pediatric cardiologist by rapid atrial pacing, via either a transvenous or transesophageal electrode. Rapid atrial pacing (faster than the SVT rate) captures the atrium, interrupting the reentrant cycle, and upon cessation of pacing, normal sinus rhythm resumes. Even if normal sinus rhythm cannot be achieved, a slower ventricular rate may be obtained if 2:1 AV nodal block is produced by rapid atrial pacing.

As soon as the patient converts from SVT, an EKG in sinus rhythm should be obtained looking for the presence of WPW syndrome. There is a small but real risk of sudden death in children with WPW, and the presence of WPW on the EKG in sinus rhythm significantly affects chronic therapy. Most pediatric cardiologists will initiate chronic therapy in infants with a prolonged episode of SVT with therapy aimed at preventing recurrences during the first year of life. Chronic maintenance therapy in infants is usually instituted in the hospital on continuous EKG monitoring to observe for adverse side effects of the antiarrhythmic agent. Studies have shown that 20% to 30% of infants will have recurrences on medication. By 1 year of age, many infants will no longer have episodes, allowing for discontinuation of the medication. Persistence of either episodes of SVT or WPW on EKG after 1 year will generally warrant continued therapy. Chronic maintenance therapy in older children with PSVT may be indicated in those with frequent, symptomatic or prolonged episodes that do not convert to sinus rhythm spontaneously and those seen in the setting of WPW. Chronic maintenance therapy may be instituted in older children as outpatients, but the presence of WPW may be an indication for admission.

In the absence of WPW, digoxin is generally the treatment of choice for chronic therapy for prevention of SVT. Digoxin should not be used in the presence of WPW syndrome because of its propensity to shorten the accessory pathway refractory period and promote rapid conduction of supraventricular impulses to the ventricle in atrial fibrillation. Unless one knows from intracardiac electrophysiology study that the accessory pathway refractory period is relatively long and is unaffected by the digoxin, it should not be used primarily in patients with

TABLE 84.14

ANTIARRHYTHMIC AGENTS

Drug	Intravenous	Oral	Desired level
For Supraventricular Tachycardia			
Adenosine	100–400 μg/kg. Initial 100 μg/kg IV Increase by 100 μg/kg every 2 min to 400 μg/kg or 12 mg maximal dose		
Procainamide	5–15 mg/kg over 30–60 min load Infusion 20–80 μg/kg/min	15–50 mg/kg/day divided q3–6h	PA 4–10 μg/kg PA plus NAPA 10–30 μg/mL
Propranolol		0.5–1 mg/kg/dose q6h	50–100 ng/mL
Esmolol	500 μg/kg/dose over 1 min followed by 50 μg/kg/min over 4 min: repeat in 5 min with 500 μg/kg/min over 1 min, 100 μg/kg/min over 4 min	50–200 μg/kg/min	
Verapamil	0.1 mg/kg/dose (max 5 mg/dose)	4–8 mg/kg/day	NA
Not ≤1 yr	Repeat in 30 min if needed. Second dose 0.1–0.3 mg/kg/dose (max 10 mg/dose)		
Digoxin	See Table 84.7	See Table 84.7	0.5–2.0 ng/mL
For Ventricular Tachycardia			
Amiodarone	Amiodarone 5 mg/kg IV over 20–60 min (max 300 mg/dose)	5–10 mg/kg/day	
Procainamide	As above	As above	As above
Lidocaine	1–2 mg/kg/dose Infusion: 20–50 μg/kg/min		1–5 μg/mL
Magnesium sulfate (for torsades)	25–50 mg/kg/dose over 10–20 min (max 2 g/dose)		Mg^{++} 3–4 mg/dL

PA, procainamide; NAPA, *N*-acetylprocainamide; NA, not available for routine clinical use.

WPW. In patients with WPW, β-blockers including propranolol and atenolol can be very effective in preventing SVT by slowing AV nodal conduction and prolonging refractoriness while having no significant effects on the accessory pathway.

In the absence of WPW, β-blockers, class IA or IC agents such as procainamide or flecainide are also very effective in preventing SVT, by slowing conduction and prolonging refractoriness in the accessory pathway, interrupting the retrograde limb of the reentrant circuit. Verapamil can be effective for chronic therapy, but, like digoxin, may accelerate conduction in AV tracts. Amiodarone can be useful alone or in combination for prevention of SVT due to any mechanism. Older children or infants, who are difficult to control with multiple recurrences, must be managed individually and may require a combination of medications.

Radiofrequency ablation is highly successful in eliminating the substrates for SVT and can be performed safely after 2 years of age. The optimal timing for radiofrequency ablation is individualized on the basis of severity and frequency of episodes, response to therapy, underlying mechanism, and the preference of the patient and family.

Children with SVT should not be treated for upper respiratory tract infections with sympathomimetic amines. Instead, if needed, pure antihistamines, such as those listed in Table 84.15 should be used.

Atrial Flutter and Atrial Fibrillation

Atrial flutter and fibrillation occur uncommonly in children. Atrial flutter consists of rapid, regular atrial excitation at rates of 280 to 480 bpm (Fig. 84.13). The ventricular response depends on AV nodal conduction that may allow 1:1, 2:1, 3:1, or 4:1 conduction. The typical EKG reveals saw-toothed flutter waves best seen in leads 2 and V_1. Atrial flutter is most commonly seen in children with postoperative CHD, especially after the Fontan procedure for single ventricle complexes or the Mustard repair for D-transposition of the great arteries. It may also be encountered in children as an isolated primary electrophysiologic abnormality.

Cetirizine HCl (Zyrtec®—Pfizer)
Fexofenadine (Allegra®—Hoechst)
For coughs:
Robitussin®
Robitussin DM®
Robitussin with codeine; need a prescription
Phenergan with codeine; need a prescription
Terpin hydrate with codeine—need a prescription

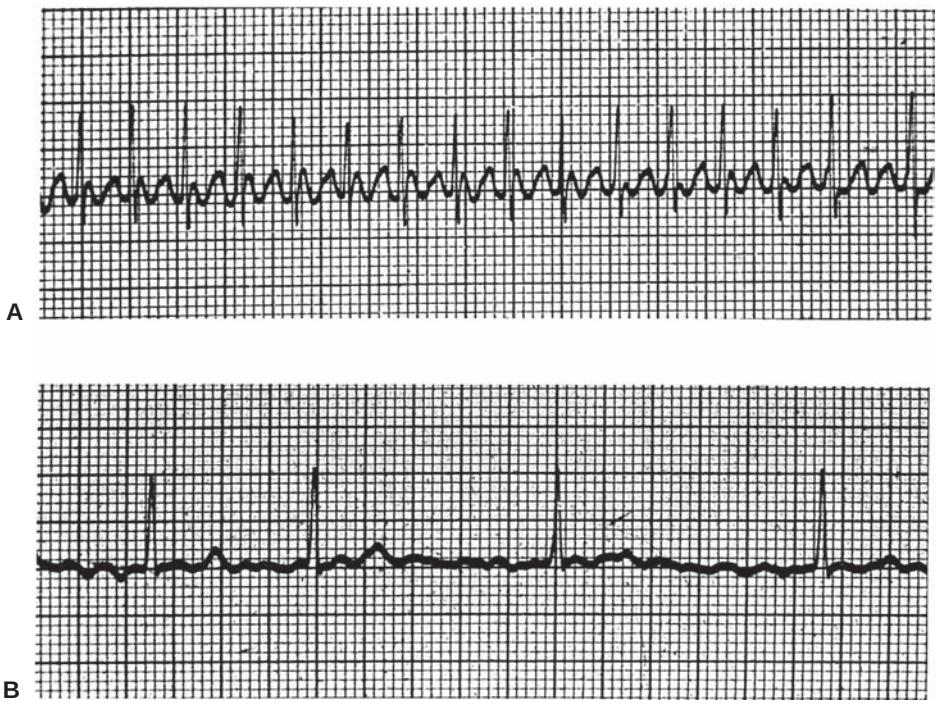

FIGURE 84.13 **A:** Atrial flutter. Sawtooth baseline is apparent. Regular QRS with ventricular rate of 250. **B:** Atrial fibrillation. Irregularly irregular QRS with course erratic baseline undulations representing fibrillatory waves.

Atrial fibrillation consists of totally disorganized rapid atrial activity (at a rate of 400 to 700 bpm) with a variable ventricular rate secondary to varying AV block. Atrial fibrillation is seen most commonly in adolescents with long-standing rheumatic or congenital mitral disease or in patients with hyperthyroidism.

Children with atrial fibrillation or flutter are treated very differently from children with reentrant SVT. Therapy is aimed at either conversion to sinus rhythm or reducing the ventricular rate by increasing AV block, as well as preventing embolization of an atrial thrombus when present. Severe cardiac compromise is an indication for immediate cardioversion. In the presence of normal LV function, a β-blocker (esmolol) or calcium channel blocker (diltiazem, verapamil) can be used to reduce the ventricular rate. In the presence of mild or moderate heart failure, IV digoxin or amiodarone should be used. As with SVT, neither digoxin nor verapamil should be used in patients with WPW. For conversion to sinus rhythm, IV ibutilide, procainamide, amiodarone, flecainide, propafenone, dofetilide, or digoxin may be effective. If atrial flutter or fibrillation has been going on for more than 48 hours, the possible presence of an atrial thrombus should be considered and evaluated by transesophageal echocardiography. In chronic atrial flutter or fibrillation with a possible atrial thrombus, anticoagulation should be instituted prior to either electrical or pharmacologic conversion to sinus rhythm. Since the AV node is not involved in a reentry circuit, adenosine will not convert to sinus rhythm, but will transiently increase AV block, helping to diagnose the exact tachyarrhythmia. In the child who is stable and who has a normal BP and adequate perfusion, the physician can wait for a response to pharmacologic conversion, but failure to achieve a normal rhythm after 24 to 48 hours may call for cardioversion. Therapeutic drug levels for these agents, which should be obtained in a steady state of drug administration, are listed in Table 84.14.

Automatic Atrial Tachycardia

Automatic atrial tachycardia secondary to enhanced automaticity of the sinus node or other atrial tissue can be an isolated electrophysiologic abnormality or seen in association with congenital or acquired heart disease (myocarditis). Adenosine is ineffective, so therapy with β-blockers, calcium channel blockers, amiodarone, procainamide, or digoxin may be used intravenously for acute control, with subsequent chronic oral therapy. Chronic drugs may also include β-blockers, flecainide, and sotalol.

Junctional Tachycardia

Junctional tachycardias most commonly occur after cardiac surgery and may be difficult to control. IV amiodarone and IV procainamide (Table 84.14) have been reported to be effective, as has hypothermia. Electrical cardioversion is ineffective.

Ventricular Tachycardia

VT is encountered much less frequently than SVT in children. VT is a tachycardia with wide QRS complexes and, when P waves are seen, the presence of AV dissociation. It has also been defined as three or more consecutive PVCs (Fig. 84.14). The HR is usually 150 to 200 bpm but may be slower or more rapid.

Clinical Manifestations. Patients may present with asymptomatic tachycardia, but there may be complaints of palpitations, and since the contractions may be hemodynamically inefficient, there may be dizziness, syncope, CHF, or cardiovascular collapse with sudden death. Causes of VT include electrolyte imbalance, metabolic disturbances, prolonged QT syndrome, Brugada syndrome, catecholaminergic polymorphic VT,

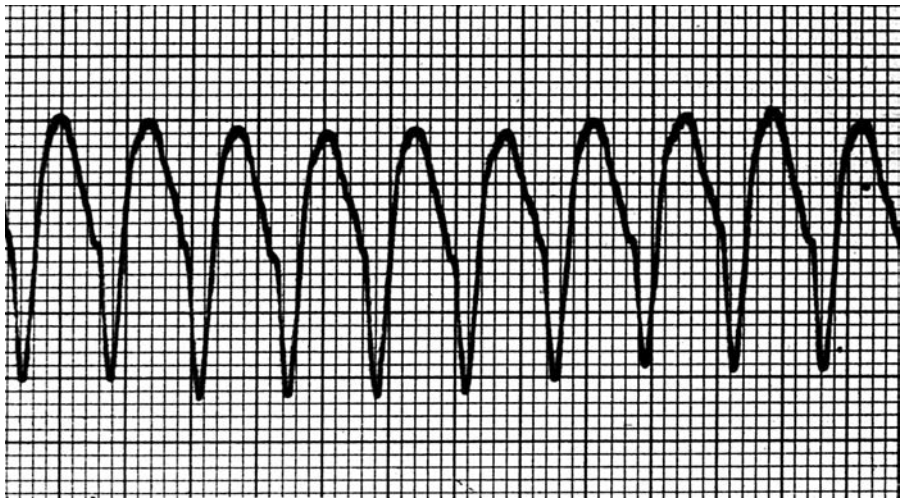

FIGURE 84.14 Ventricular tachycardia. Wide QRS with rate of approximately 250 bpm; sinusoidal pattern.

arrhythmogenic right ventricular dysplasia, drug toxins, congenital or acquired cardiac disease, cardiac tumors or other isolated primary electrophysiologic abnormalities. Specific genetic abnormalities coding for a variety of cardiac membrane channel abnormalities for ventricular arrhythmias have now been identified. Since many of the channelopathies are genetic, a family history of ventricular arrhythmia, unexpected sudden death or syncope in young relatives should be sought. Any family history of hearing deficit should also be noted.

Management. As with SVT patients, the urgency of treatment depends on the clinical status. In cases of shock, impending cardiac decompensation, or cardiac failure, synchronized DC cardioversion at 2 to 4 J per kg up to 10 J per kg should be used. In children with identifiable extra cardiac causes of VT, the underlying disturbance can be treated. Generally, sustained rapid VT requires treatment. Hospital admission and urgent pediatric cardiology consultation are indicated. Patients with CHD and VT often have some degree of hemodynamic compromise and do not tolerate the VT well, requiring urgent therapy. All patients with CHD and sustained VT over 150 bpm require therapy because sudden death occurs in up to 30% of patients with CHD who have VT. Patients with CHD and slower VT or nonsustained VT may also require treatment if hemodynamic instability exists. There is still controversy over whether asymptomatic patients with normal hearts and idiopathic slow VT should be treated with antiarrhythmic agents. The patient should not be made more toxic by the therapy than by the arrhythmia.

Effective emergency pharmacologic therapy includes IV amiodarone, lidocaine, and procainamide (Table 84.14). IV amiodarone is infused at 5 mg per kg over the first hour followed by an infusion of 5 to 10 μg per kg per min. IV lidocaine can be given as a bolus of 1 to 2 mg per kg, followed by a continuous infusion of lidocaine at 20 to 50 μg per kg per minute may be required. IV infusion of IV procainamide at 15 mg per kg given over 30 to 60 minutes, followed by a 20 to 80 μg per kg per minute IV infusion. Rapid ventricular pacing may be used for overdrive suppression for conversion to normal rhythm if pharmacologic therapy fails or is contraindicated.

After conversion to sinus rhythm, the child who has presented with VT, especially of the polymorphic or torsades de pointes type, should have a full EKG with corrected QT intervals carefully measured. There are several special treatment issues pertaining to VT in children with long QT syndrome. Sudden death occurs in 73% of patients with VT who are not treated, secondary to tachyarrhythmias (torsades de pointes) of the type that often degenerates to ventricular fibrillation. In addition, temporary atrial or ventricular pacing at a rate 10% to 20% faster than the underlying sinus rate may be needed to control the arrhythmia, especially in patients with underlying bradycardia, a common association. IV propranolol, phenytoin, and magnesium have been used successfully in these patients. Because class I agents prolong the QT interval in normal patients, they should be avoided in patients with these long QT intervals. A number of medications may prolong the QT interval and produce VT (Table 84.16). Temporary pacing and removal of the offending agent are effective therapies. For management of acquired long QT with ventricular arrhythmias, especially if bradycardia is a prominent factor, an isoproterenol infusion may be therapeutic.

Chronic treatment for VT may include propranolol, atenolol, nadolol, mexiletine, amiodarone, procainamide, sotalol, or propafenone. Those with Purkinje cell tumors, reentry circuits within the ventricle, or ectopic foci may be amenable to catheter radiofrequency ablation in selected cases. An automatic cardioverter-defibrillator may need to be implanted.

Ventricular Fibrillation

Ventricular fibrillation consists of chaotic irregular ventricular contractions with cessation of circulation. Electrical defibrillation with correction of precipitating factors (acidosis, electrolyte imbalance, hypoxia) may result in conversion to normal sinus rhythm. The treatment of cardiac arrest is discussed in Chapter 1. After epinephrine in the resuscitation protocol, the only other drug of proven benefit is IV amiodarone.

Irregular Heart Rates

Premature Ventricular Depolarizations

Background. The primary irregular rhythm that may require attention is the premature ventricular depolarization (PVD).

Potassium loss

PVDs are seen as premature, wide, bizarre-shaped QRS complexes. Generally, the T wave is opposite in direction to the main deflection of the QRS. A compensatory pause usually follows the premature beat, and P waves may reveal AV dissociation or retrograde conduction or may be absent. When a rhythmic pattern of PVDs is established, the designation of bigeminy, trigeminy, or quadrigeminy is made, depending on whether that beat followed every second, third, or fourth sinus beat. VT consists of three PVCs or more that last for 10 seconds or less.

Pathophysiology. PVCs often occur without identifiable cause in children and are often considered benign. PVCs are also seen in children with CHD (unoperated or operated) and CHF, viral myocarditis, Lyme myocarditis, cardiac membrane channelopathies resulting in long QT syndrome, cardiomyopathies, cardiac tumors, hemochromatosis, or electrolyte imbalance. They are also seen in association with various forms of drug administration, including general anesthesia, digoxin, sympathomimetic amines, and phenothiazines. PVCs may be precursors of VT or fibrillation.

Clinical Manifestations. Children who present with PVDs are frequently asymptomatic and unaware of their arrhythmia, especially if they are younger than 5 years of age. If the PVC is appreciated, the child may complain of a "skipped" or "hard" beat, a fluttering or pounding in the chest. If the PVDs are frequent and/or associated with heart disease (congenital or acquired), the child may note dizziness or other symptoms of hemodynamic compromise. Frequent PVCs in the presence of preexistent compromised cardiac function may worsen the CO and produce signs and symptoms of CHF.

Management. Isolated PVDs in an asymptomatic patient in the presence of a structurally and functionally normal heart generally do not require treatment. These benign PVDs in such patients are also generally single, uniform (the same appearance in a given lead), and decrease in frequency with exercise. However, if the PVDs are multiform; coupled; associated with an abnormal underlying EKG, abnormal cardiac structure, or abnormal cardiac function; and increase in frequency with exercise or associated with prior symptoms of dizziness, chest pain, or syncope, these should be considered to be ominous. These PVDs may require treatment because they cause (or are likely to cause) hemodynamic compromise, or lead to VT or VF. Treatment may include lidocaine, mexiletine, procainamide, propranolol, or amiodarone (Table 84.14), as outlined in the section on VT. Isolated multiform or coupled PVDs or nonsustained VT (rate 150 bpm or less) in an asymptomatic patient with a normal heart may not require treatment, but this decision must be individualized after consultation with a cardiologist. Rarely is emergency treatment of this type of patient required. Investigations that use 24-hour continuous EKG monitors, transtelephonic event monitoring exercise stress testing, echocardiography, and/or electrophysiologic catheterization studies may be used to determine the appropriate management. Restriction of caffeine and other stimulants should be recommended in all patients with ventricular arrhythmias.

Benign Atrial Arrhythmias

Premature atrial contractions (PADs) are premature P waves, usually followed by a normal-appearing QRS complex. Alternatively, depending on the electrical phase of the heart at the time of the PAD, the impulse may block in the AV node (resulting in no QRS), or be aberrantly conducted through one of the bundle branches (resulting in a wide QRS). PADs generally do not cause symptoms other than palpitations and do not require treatment. Transtelephonic event or continuous 24-hour ambulatory monitoring may be warranted if symptoms suggest the associated occurrence of SVT. Elimination of caffeine or other stimulants such as pseudoephedrine, or other sympathomimetics may decrease the frequency of PADs. Unless the PADs are demonstrated to initiate episodes of SVT, no treatment is indicated.

Variations of normal rhythms commonly seen in children and that do not require treatment include sinus arrhythmia and wandering atrial pacemaker, as long as rates remain in the normal ranges.

First- and Second-degree Heart Block

First-degree heart block reflects slowed conduction from the sinus node to the ventricle (usually in the AV node) and is manifest by a prolonged PR interval. It is seen with digoxin and other antiarrhythmic drugs; certain types of CHD (primum and secundum atrial septal defects); and inflammatory diseases such as rheumatic, viral, or Lyme myocarditis.

Second-degree heart block results in the failure of some impulses to traverse the AV node. Type 1 second-degree AV block (Wenckebach) is manifest as progressive prolongation of the PR interval, culminating in a dropped QRS. Other forms of second-degree heart block include high-grade 2:1, 3:1, and 4:1 block. Type 2 second-degree AV block is manifest as intermittent failure of a QRS to follow a P, without prior PR interval prolongation.

Management. Children with first- and second-degree heart block are generally asymptomatic and do not require cardiac therapy. Type 2 second-degree AV block may reflect an abnormality of the AV node and lead to syncope, requiring pacing. If a manifestation of digitalis toxicity, adjustment of the digitalis dose may be required. If manifestation of myocarditis or endocarditis, treatment of the primary problem is indicated.

Arrhythmias Associated with Electrolyte Abnormalities

Alterations in electrolyte concentrations may influence cardiac rate, rhythm, and automaticity, and may lead to arrhythmias. Potassium and calcium abnormalities are the most common electrolyte alterations that produce arrhythmias, but abnormalities in magnesium and acid–base balance are also important. Commonly, a combination of ionic alterations is responsible for arrhythmias. Any patient with significant arrhythmias should be evaluated for an electrolyte disturbance. The EKG changes may be characteristic and lead to suspicion of a specific electrolyte abnormality. Normal EKG intervals (PR, QRS, QTc) are listed in Table 84.17.

Hyperkalemia. Hyperkalemia is common in hospitalized children and produces recognizable EKG alterations. Peaked T waves are seen at a serum concentration of 5 to 6 mEq per L, and the QRS widens with a concentration exceeding 6 mEq per L. The QT interval increases with the increasing QRS duration. As P-wave amplitude decreases, P-wave duration increases, and the PR interval increases above 7 mEq per L. Above 8 to 9 mEq per L, P waves disappear, the ventricular rate becomes irregular, and severe bradycardia with sinus arrest, block, or idioventricular rhythms occur, often with a sinusoidal wave pattern. Ventricular fibrillation or asystole occurs at serum concentrations greater than 12 to 14 mEq per L. Low serum calcium enhances the myocardial toxicity of hyperkalemia. Likewise, acidosis potentiates hyperkalemia by producing potassium ion efflux from cells.

Hypokalemia. Serum potassium concentrations of less than 2.7 mEq per L generally produce typical EKG changes in ventricular repolarization. These changes may include U-wave amplitude greater than 1 mm, seen best in leads V_2 and V_3, and ST-segment depression greater than 0.5 mm. The QT interval lengthens and the T wave flattens with progressive hypokalemia. The PR interval may be prolonged, and intraventricular conduction may be delayed with widening of the QRS complex. With substantial hypokalemia, P-wave and QRS amplitude may increase. Other arrhythmias that have been associated with hypokalemia include ectopic atrial and ventricular complexes, ectopic atrial tachycardia with block, AV dissociation, second-degree AV block, ventricular bigeminy, VT, and ventricular fibrillation.

Patients on digoxin who become hypokalemic are especially susceptible to arrhythmias because of the synergistic effects of digoxin and hypokalemia on automaticity and conduction.

Hypocalcemia. Hypocalcemia produces characteristic EKG changes that consist of QT interval prolongation secondary to ST-segment prolongation (Fig. 84.15), and occasionally, reversal of the T wave. The EKG changes correlate with ionized calcium because the degree of QT prolongation is generally proportional to the degree of hypocalcemia. Abnormal rhythms, although uncommon, have been reported and include SVT, 2:1 AV block, complete heart block, and torsades de pointes VT. The effects of calcium and potassium on myocardial cells are antagonistic.

Hypercalcemia. Hypercalcemia, with levels above 12 mg per dL, produces a shortened QT interval (Fig. 84.13), a shortened ST segment, and normal or prominent U waves. Severe hypercalcemia causes PR interval prolongation, QRS prolongation, and occasionally, second- and third-degree heart block. Elevated serum calcium decreases the effect of hyperkalemia and potentiates digoxin toxicity. Thus, calcium should be administered cautiously to patients taking digoxin, and the HR should be monitored.

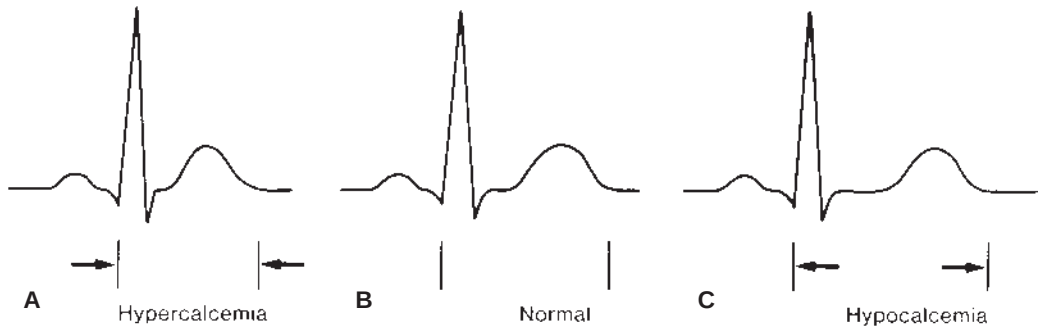

FIGURE 84.15 Electrolyte effects on EKG QT interval. Note prolongation with hypocalcemia, shortening with hypercalcemia.

Hypomagnesemia. Low magnesium levels are often associated with hypokalemia and hypocalcemia. The EKG abnormalities seen may be those associated with any or all these aberrations and include prolongation of the corrected QT interval. Ectopic beats and T-wave changes are commonly noted. Torsades de pointes VT and ventricular fibrillation have been reported.

Hypermagnesemia. Hypermagnesemia of 3 to 5 mEq per L or higher may be associated with a delay in AV and intraventricular conduction. Treatment of these electrolyte abnormalities is discussed in Chapter 100.

Sudden Cardiac Death

Sudden death is a rare occurrence in children, with an overall estimated incidence of 1 in 20,000 to 50,000 per year. In apparently normal children, however, the incidence is estimated to be 1 to 1.5 per 100,000 per year. It is felt that 5% of all deaths in children are due to sudden cardiac death (SCD). Mechanisms of SCD include arrhythmia, ischemia, heart failure, and pulmonary hypertensive crisis. SCD can occur in the setting of a variety of heart diseases (Table 84.18). Of the etiologies of SCD listed, HCM deserves special comment.

Over the 50 years since the landmark pathologic report issued in 1958, the importance of this disease entity (HCM) has become better recognized not only as a cause of sudden death but also as an important cause of ongoing morbidity and clinical concern. The problem includes the spectrum of illnesses previously classified as IHSS (idiopathic hypertrophic subaortic stenosis), HOCM (hypertrophic obstructive cardiomyopathy), and MSS (muscular subaortic stenosis). The prevalence of HCM is estimated to be 0.2% of the general population. Recently developed fetal information has indicated that asymmetric hypertrophy of the ventricular septum may actually be a component of normal cardiac development whose persistence and further exacerbation after birth underlies a distinct genetically driven pathophysiology. Most commonly, the disease becomes manifest in the adolescent and young adult, and it is known to often progress rapidly during puberty. HCM involves not only myocardial maldevelopment with asymmetric hypertrophy of segments of the heart muscle, most notably but not exclusively the septum, but also distinct mitral valve abnormalities as well. There is now well-delineated, definitively diagnostic genetic analysis possible. Reliable direct DNA sequencing is available to diagnose the typical HCM-causing mutations and to stratify risk.

The clinical findings are quite variable. If left ventricular outflow obstruction is part of the picture, a systolic murmur of varying intensity along the left sternal border is usually present. If the patient is able to change position, or is cooperative, the murmur may be accentuated when changing from supine to upright or with the Valsalva maneuver. Often an S_3 or S_4 can be heard. The arterial pulse palpation can also provide a clue to diagnosis with a "bisferiens" contour. The EKG is abnormal in nearly all patients and often appears quite bizarre. Left ventricular hypertrophy, distinct ST-T changes marked by prominent T inversion patterns, and prominent Q waves, especially in the inferior and midprecordial leads, are characteristic. The echocardiogram, of course, is readily diagnostic and should be obtained, along with cardiac consultation, in any patient with suspected HCM. This is particularly true in the ED setting since management decisions during and after resuscitation and for stabilization of the patient are impacted by the diagnosis. For example, vigorous use of diuretics should be avoided in the patient with HCM and LV outflow obstruction as high preload levels may be required to maintain systemic output. Similarly, catecholamine support for post resuscitation hypotension in HCM must be used with extreme caution, if at all.

Children presenting after resuscitation from a near sudden death episode should have a careful history, including ascertainment of the existence of previous symptoms of cardiac disease (e.g., exertional chest pain, shortness of breath, or syncope), the existence of previous cardiac disease and of a family

history of unexpected sudden death or significant arrhythmia in a young person. A detailed physical exam is also required, regardless of the specific neurologic status. An EKG should be done and assessed for long QT, WPW, or other findings of underlying rhythm or conduction tissue abnormality. The presence of ischemic ST or T-wave abnormalities or electrocardiographic evidence of myocardial infarction should suggest the presence of a rare coronary artery malformation (such as anomalous origin of the left coronary artery from the pulmonary artery or a coronary artery cursing between the aorta and pulmonary artery leading to compression with exercise). An echocardiogram should be performed in order to diagnose structural or functional abnormalities. Consideration should be given to more extensive monitoring, exercise stress testing, cardiac catheterization with coronary angiography, intracardiac electrophysiologic studies or genetic testing for channelopathies when appropriate. Insertion of an AICD for secondary prevention of SCD must be considered as part of the comprehensive cardiac assessment.

PERICARDIAL DISEASE

Background

Few medical situations exist in which a simple, quickly performed medical procedure can result in immediate, lifesaving results. Among these is pericardiocentesis for cardiac tamponade. The technical aspects of pericardiocentesis are discussed elsewhere (see Procedures in Section VII). This section addresses etiologic concerns, clinical findings, and other initial management measures that must be taken to satisfactorily evaluate and treat the child with pericardial disease.

Three forms of illness can affect the pericardium. *Pericarditis*, not always a true medical emergency, is a nonspecific term that denotes inflammatory disease. *Pericardial effusion*, a condition that requires close evaluation but does not necessarily require emergency treatment, implies fluid accumulation within the pericardial space. *Cardiac tamponade*, a true medical emergency that requires immediate attention, connotes a situation in which impairment of ventricular filling has resulted from pericardial fluid accumulation or from constriction of the heart by an abnormally thickened pericardium, resulting in impairment of CO.

Table 84.19 reviews some of the principal causes of pericarditis in childhood. When considering the cause of pericardial disease and its clinical correlates, it is important to remember that the pericardium is in continuity with the surrounding intrathoracic structures. Thus, conditions that affect the pleura, the mediastinal structures, or the diaphragm may affect the pericardium as well.

Infectious diseases remain the most likely cause of pericarditis in childhood. Although a viral etiology frequently is presumed to be causative, in only about 20% to 30% of the time is an actual viral pathogen confirmed. Coxsackie (group B) and enteric cytopathogenic human orphan (ECHO) viruses are paramount, but other agents, including rubella, Epstein-Barr virus, adenovirus, influenza virus, and mumps virus, have all been associated with pericardial inflammation and pericardial effusion. Rarely do viral diseases result in cardiac tamponade.

Purulent pericarditis is often a medical emergency, however, because of associated cardiac tamponade and because of important sequelae that may be mitigated by early effective treatment. Although it is a disease seen at all pediatric ages, approximately 30% of the cases involve children younger than the age of 6 years. *Staphylococcus aureus, Haemophilus influenzae, Neisseria meningitides, Streptococcus pneumoniae,* and other streptococci are the principal bacterial agents responsible for childhood pyogenic pericarditis, although other pathogens have been recovered occasionally. Since *H. influenzae* immunization began, this pathogen is much less frequently seen. Other organisms may also cause pericardial infection and chief among these is *Mycobacterium tuberculosis*. In patients from underdeveloped countries, in fact, *M. tuberculosis* may be equally as common as *S. aureus* as a cause of pericardial infection and must not be overlooked in that population. Associated infections, such as respiratory tract disease, osteomyelitis, or pyogenic arthritis, may be present and may be clinically helpful at indicating the specific organism involved. For example, reviews have noted that many cases of staphylococcal pericarditis were associated with infections distant to the pericardium, such as osteomyelitis, whereas most cases of *H. influenzae pericarditis* were associated with respiratory tract infection. Meningococcemia is associated with pericardial involvement in about 5% of cases.

In childhood, noninfectious pericardial disease can also be significant. The postpericardiotomy syndrome is nearly always associated with pericardial inflammation and must be thought

of in the postoperative cardiac patient who develops a pericardial effusion, fever, leukocytosis, and a high ESR after the first week and until several weeks after surgery. This syndrome may occur in as many as 10% to 15% of children who undergo open heart surgery, particularly older children and adolescents. Other important causes of pericardial inflammation include collagen vascular and rheumatic diseases and oncologic diseases, especially mediastinal lymphoma. Kawasaki disease can also be associated with pericardial effusion.

Pathophysiology

As noted earlier, pericardial inflammation is not usually life-threatening. Of concern for the physician who evaluates a child in an emergency situation are the hemodynamic sequelae of either fluid accumulation in the pericardial space or scarring and thickening of the pericardium, leading to restriction of cardiac filling. Usually, a small amount of intrapericardial fluid (less than 30 to 50 mL) exists in an equilibrium state between secretion into the pericardial space and reabsorption. With a sudden accumulation of fluid or with a more gradual increase of large amounts of fluid within the pericardial sac, interference with ventricular filling occurs, leading to decreased stroke volume and to falling BP. Cardiac filling may be compromised through several interrelated mechanisms, including an increased ventricular end-diastolic pressure, a decreased gradient for venous return, premature AV valve closure, and shortened diastolic time. The clinical manifestation of these physiologic aberrations, known as *cardiac tamponade*, is directly related to the severity of these abnormalities and to compensatory mechanisms evoked to overcome them.

Clinical Manifestations

A history of onset of respiratory difficulties after resolution of an upper respiratory illness may indicate pericardial disease in some instances. Chest pain, usually a benign symptom in childhood, is common with pericardial inflammation. This pain varies, depending on position.

Occasionally, abdominal pain may be the presenting symptom. The child with significant pericardial effusion may show clinical signs similar to several of those noted in the preceding section on CHF. Tachypnea, secondary to raised pulmonary venous pressures and decreased pulmonary compliance, is usually present. This may be associated with intercostal retractions. Reduced cardiac output may result in peripheral vasoconstriction, manifested by cool extremities, pallor, or decreased systemic BP. Elevated systemic venous pressures cause neck vein distention, hepatomegaly, and on occasion in more of a chronic picture, protein loss through either the gastrointestinal tract or the urine. Tachycardia is a universal finding and is representative of an effective compensatory mechanism, but only up to a point. This compensation is limited because diastolic filling times are further shortened by the increased HR.

The cardiac auscultatory findings directly relate to the degree of pericardial fluid accumulation. A friction rub (the scratching harsh sound that can be heard throughout the cardiac cycle) is often not audible in the presence of significant amounts of intrapericardial fluid and may become apparent only after pericardiocentesis. The heart sounds are usually distant or muffled, and the apical impulse is weak. In general, the presence of a quiet precordium in the face of the previously noted respiratory and circulatory changes should alert the examiner to the possibility of pericardial disease with effusion.

The sine qua non of cardiac tamponade is pulsus paradoxus. The finding of a paradoxical pulse greater than 20 mm Hg is unequivocal evidence of circulatory compromise. In addition, most clinicians assume as little as 10 mm Hg is suggestive of hemodynamic impairment.

The physiologic mechanisms that underlie pulsus paradoxus can be viewed as exaggerated examples of the integrated functioning of the cardiopulmonary unit. Normally, a small fall (less than 10 mm Hg) in systolic BP is noted with inspiration as a result of several factors. As negative intrathoracic pressure is generated by the inspiratory effort, the gradient for systemic venous return increases, favoring right-sided heart filling. At the same time, diaphragmatic descent exerts a traction effect on the heart, limiting filling and ejection. In addition, there may be some decrease in pulmonary venous return because the gradient from pulmonary veins to left atrium is probably reduced. Thus, left-sided heart output and systemic BP are reduced. The pericardium itself is an additional variable factor. In general, because it envelops the heart, the pericardium tends to retard expansion of ventricular volume, normally only to a limited degree. Thus, in normal respiration, the pericardium exerts an additional volume-reducing effect on the left ventricle. In pericardial disease states, as the pericardium itself becomes more rigid or as fluid in the pericardial space increases and intrapericardial pressure rises, the restriction to left ventricular output becomes greater and the consequent decline in systemic BP becomes steeper.

The best method of detecting pulsus paradoxus is to measure BP first in the usual way at expiration and then to inflate the cuff a second time to a few millimeters of mercury above the systolic BP and allow the cuff to deflate slowly. As the pressure falls, the Korotkoff sounds disappear with each inspiration. At the point at which they cease to disappear, becoming equal to that auscultated during expiration, the measured BP is recorded. The difference between the initial maximum systolic BP and the final measurement is the pulsus paradoxus.

It should be noted that pulsus paradoxus is not a finding unique to cardiac tamponade. It is a common finding in respiratory tract disease (asthma) and also may be present in CHF without pericardial effusion or in conditions with acute volume loss or circulating volume insufficiency.

Laboratory Findings

Laboratory findings vary according to the underlying causes of pericardial disease. Although cardiac tamponade is a clinical diagnosis, certain laboratory tools can be extremely helpful in clarifying the situation.

The EKG shows diminished precordial voltage in most instances of significant intrapericardial fluid accumulation (Fig. 84.16). With pericarditis, an associated current of injury pattern that reflects myocardial involvement, seen as elevations in the ST segments, may also be present. Diffuse T-wave inversions are also common. The heart size is increased on chest radiograph (Fig. 84.17) with pericardial effusion but can be entirely normal

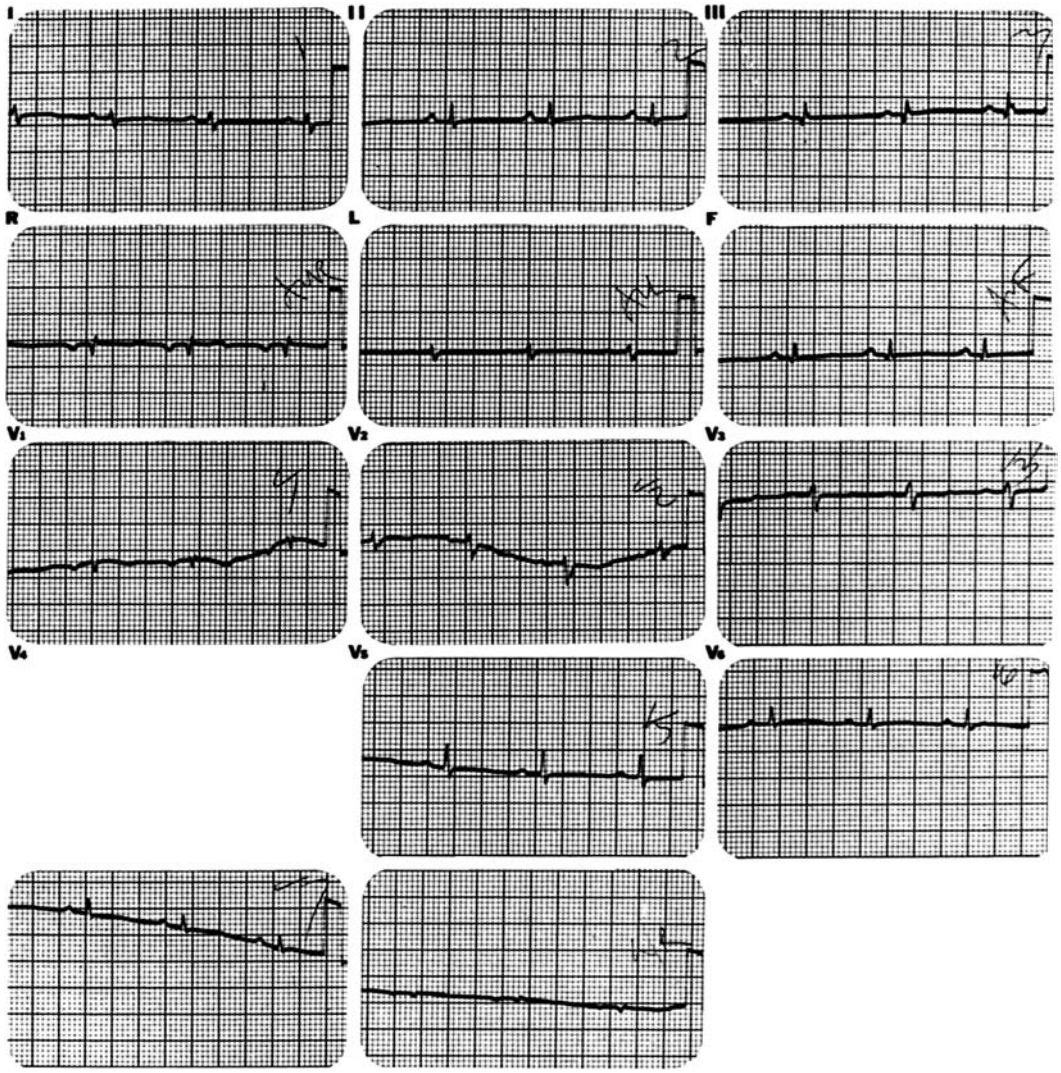

FIGURE 84.16 Electrocardiogram in pericardial effusion. Generalized low voltage present. ST-T wave flattening is present.

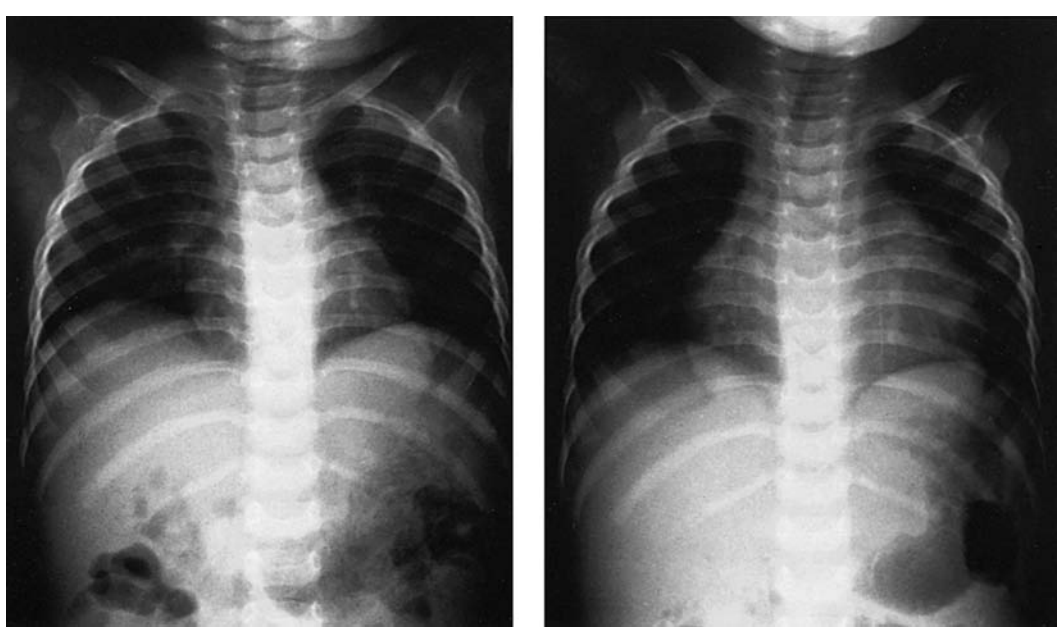

FIGURE 84.17 Radiographs from an infant 4 days before and at the time of the diagnosis of purulent pericarditis. Note the increasing heart size and the "water-bottle" silhouette.

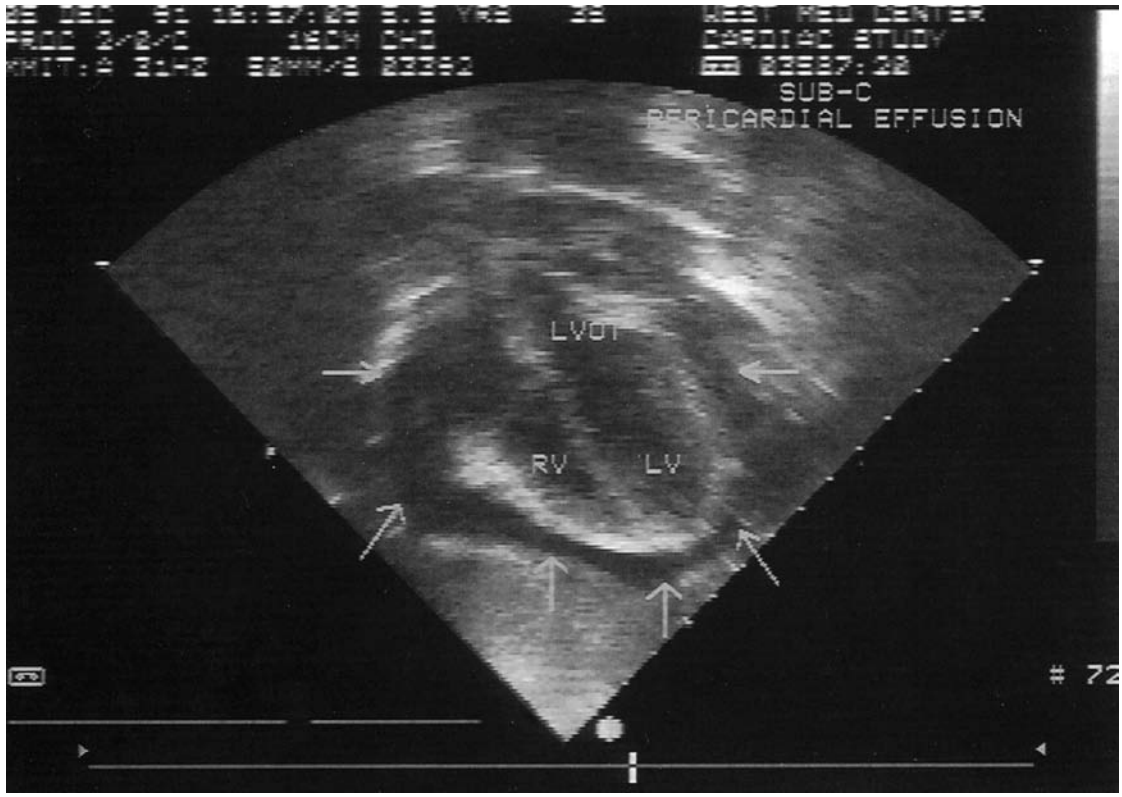

FIGURE 84.18 M-mode echocardiogram in pericardial effusion. Note absence of echoes (clear area) between epicardium and pericardium, representing intrapericardial fluid. EKG, electrocardiogram; ENDO, endocardium; EPI, epicardium; LV, left ventricle; PE, pericardial effusion; PERI, pericardium; RV, right ventricle.

if the amount of intrapericardial fluid is not excessive. The lung fields may be clear, but one should look for associated bronchopneumonia or pleural effusions that may be helpful for diagnostic considerations. In some situations, as with constrictive pericarditis, the heart size may be relatively small. If the patient has had previous chest radiographs, a sudden increase in heart size should always arouse the suspicion of pericardial effusion.

Echocardiography is the diagnostic procedure of choice for determining the presence and amount of intrapericardial fluid. An echo-free space between the epicardium and the pericardium can be readily identified (Fig. 84.18), with a negligible incidence of false-positive diagnoses in experienced hands. Quantitation is not precise, but evidence of anterior and posterior fluid accumulation suggests a large collection. Two-dimensional real-time echocardiographic studies are preferred. In addition, serial evaluation of the pericardial space is easily accomplished with echocardiography and is helpful for observing the effects of treatment and for evaluating indications for further therapeutic maneuvers after initial drainage measures.

As with the evaluation of any other potentially life-threatening infection, when infectious pericardial disease is suspected, a complete bacteriologic evaluation should be initiated before antibiotic therapy is begun.

Management

For pericarditis without evidence of pericardial effusion, emergency invasive treatment is usually not indicated. Symptomatic therapy for pain should be prescribed, and nonsteroidal anti-inflammatory drugs are useful. Bed rest is advisable. Observation in the hospital may be indicated. The patient should be followed closely for the development of complications such as myocarditis, pericardial effusion, or cardiac tamponade. Steroids usually are not indicated unless signs continue or progress despite other measures. Diagnostic evaluation to identify the cause should be initiated.

For newly diagnosed pericardial effusion, when more than mild, a definitive approach is needed. Careful evaluation of vital signs and frequent attention to development of pulsus paradoxus are mandatory. Cardiology consultation should be obtained, and the patient is usually admitted for evaluation. Diagnostic pericardiocentesis often is needed in the de novo presentation, particularly without evidence of other forms of systemic disease; it is almost always required with the suspicion of a purulent pericardial process. Antibiotic therapy alone is not adequate for treatment of purulent pericarditis. Usually, in the presence of purulent pericarditis, an open drainage procedure is indicated. It is contingent on the emergency physician to ensure cardiovascular stability in the presence of pericardial effusion because tamponade can develop rapidly once maximum pericardial distensibility has been reached (Table 84.20).

The management of cardiac tamponade requires intense medical vigilance. Although it may be possible in relatively mild or highly selected situations to manage the effusion conservatively, it is generally necessary to remove the fluid. A full discussion of the techniques used for pericardiocentesis in the emergency situation is available in Section VII of this book.

TABLE 84.20

PURULENT PERICARDITIS: IMMEDIATE MANAGEMENT

1. Ensure adequacy of ventilation and cardiac output
2. Administer oxygen
3. Initiate cardiorespiratory monitoring
4. Obtain laboratory studies (simultaneously with step 5)
   Complete blood cell count, platelet count, electrolytes, blood urea nitrogen, creatinine, glucose, arterial blood gas, blood culture, chest radiograph, electrocardiography, echocardiography
5. Achieve venous access
6. Pericardiocentesis (see Section VII)
   Send specimen for laboratory studies: cultures, CIE, viral titers, antinuclear antibody, Gram stain, cytology, cell count and differential, chemical profile
7. Administer antibiotics[a]
   Oxacillin (150–200 mg/kg/day) or nafcillin or methicillin and chloramphenicol (100 mg/kg/day) or third-generation cephalosporin
   Aminoglycoside (immunocompromised patient)
   Most centers also prefer vancomycin until cultures and sensitivities reported in view of methicillin-resistant staphylococci (MRSA)

CIE, counter immune electrophoresis.
[a]Select antimicrobials to cover *S. aureus*.

This can be a lifesaving technique and, when done successfully, shows clearly the fruitful outcome of appropriate, decisive evaluation and treatment procedures.

INFECTIVE ENDOCARDITIS

Background

One of the persistently complex problems of pediatric cardiovascular medicine has been the evaluation and management of the child with infective endocarditis. Although long-term treatment issues are generally not within the province of emergency medical care, it is critically important for the emergency physician to be aware of the clinical context in which bacterial endocarditis is a consideration. It is also incumbent on the emergency physician to initiate therapy in certain instances, and it is always crucial to avoid unnecessary clouding of the diagnosis.

Etiologic Factors and Prophylaxis Considerations

The clinical picture of infective endocarditis has been evolving steadily during the past 10 to 20 years. Although the most common pediatric setting for this problem is the child with preexisting CHD, variability exists in terms of the types of associated lesions (Fig. 84.19), and it is of concern that a substantial proportion of cases develop in children with no history of cardiac abnormality. These children may be among the most ill, presenting with their illness as part of an acute bacterial endocarditis picture.

Certain physiologic conditions appear to be consistently most important in the development of IE. Diseases characterized by a highly turbulent stream of blood and/or a high velocity of flow are most prone to this complication. Such lesions include VSD, aortic valve stenosis, and mitral valve regurgitation. Children with palliative systemic-to-pulmonary shunts are also in this category. In contrast, secundum atrial septal defect is a lesion with a negligible risk for endocarditis because the shunt flow is of low velocity. It is presumed that in "high velocity–narrow orifice" conditions, damage to cardiac surfaces occurs, resulting in a nidus for platelet deposition and vegetation formation.

While these physiologic factors appear to predispose a child to the development of endocarditis, recent reviews and published guidelines have indicated changed perspectives with regard to iatrogenic influences for IE development. Direct, unequivocal evidence has never been demonstrated to substantiate the belief that dental and medical procedures *per se* are causally related to the development of endocarditis. Dental procedures even without periodontal disease can yield bacteremia of course. Invasive diagnostic medical procedures can

TABLE 84.22

CARDIAC CONDITIONS ASSOCIATED WITH HIGH RISK OF ADVERSE OUTCOME FROM ENDOCARDITIS

- Prosthetic cardiac valve
- Previous Infective Endocarditis
- Congenital heart disease (CHD)[a]
  - Unrepaired cyanotic CHD, including palliative shunts and conduits
  - Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure[b]
  - Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic
  - Patch or prosthetic device (which inhibit endothelialization)
- Cardiac transplantation recipients who develop cardiac valvulopathy

[a]Except for the conditions listed above, antibiotic prophylaxis is no longer recommended for any other form of CHD.
[b]Prophylaxis is recommended because endothelialization of prosthetic material occurs within 6 months after the procedure.
Adapted from Wilson W, Taubert K, Gewitz M, et al. Infective endocarditis. In: Allen H, Shaddy R, Driscoll D, et al., eds. *Moss and Adams' heart disease in infants, children, and adolescents, including the fetus and young adult.* 7th ed. Lippincott, Williams & Wilkins, 2008.

as well. Unfortunately, many ordinary daily events are also associated with at least transient bacteremia (Table 84.21). It is small wonder, in fact, that more cases of endocarditis are not evident if bacteremia of oral cavity origin, for instance, were a singular factor. Conversely, invasive procedures specifically involving the heart, such as cardiac catheterization, in patients with even the highest risk, are rarely associated with endocarditis development. Therefore, current recommendations emanating from scientific bodies worldwide have questioned the long-held dictum that use of prophylactic antibiotics to prevent IE after dental or medical procedures is a useful practice in which potential harm outweighs potential risk. Given this concern, for example, a recent review by The Committee on Rheumatic Fever, Endocarditis and Kawasaki Disease of the American Heart Association suggested that prophylactic antibiotics be considered only for those conditions likely to predispose to the most serious adverse sequelae *from* endocarditis (Table 84.22). In these selected circumstances, specific antibiotic regimens have been suggested (Table 84.23).

Microbiology

Causative organisms include bacteria and fungi with streptococci species in general remain the most common causative agents, with viridans streptococci being the typical isolates. Staphylococci are also common etiologic agents, especially in children with structurally normal hearts or, ironically, in those with postoperative CHD, such as prosthetic valves. Other bacteria are much less likely to be present in childhood endocarditis. These include gram-negative organisms, present in immunocompromised children and sick neonates, *Enterococci*, *Pneumococci*, and *Hemophilus* species. These data are reviewed in Table 84.24.

Clinical Findings

Confirmation of a positive diagnosis depends on the recovery of organisms obtained by blood culture. To arrive at that point, however, a high degree of suspicion must be maintained. Often, early signs and symptoms can be subtle and persist for considerable time before the diagnosis is made. With viridans streptococcal endocarditis, this is a common situation. As a rule, lengthy persistence of fever in any child with CHD should alert the clinician to consider the possibility of endocarditis.

In the clinical context of CHD, certain conditions should prompt a careful evaluation for the presence of endocarditis. These include (i) unexplained fever or a protracted febrile course in a presumed "viral" syndrome, (ii) pneumonia, (iii) the development of a new neurologic deficit, (iv) the onset of hematuria, and (v) signs of systemic or cutaneous embolization.

The classic findings of fever, a change in the cardiac examination, splenomegaly, and evidence of emboli are usually present in severe cases but may require serial examinations. Emboli may be discovered by careful funduscopic examination, by observing for conjunctival lesions, or by meticulous scrutiny of the nail beds, palms of the hands, soles of the feet, and other skin surfaces. Microscopic hematuria should be recognized as an important sign of endocarditis in the appropriate clinical context. Scrapings of cutaneous emboli may be helpful for rapid identification of infecting organisms.

Complications

The mortality from infective endocarditis has decreased considerably in more recent years, but most series still cite a fatality rate of 15% to 20%. Although this is still a high percentage, especially for pediatric illness, it should be remembered that more than 50% mortality was the norm in the 1950s and that the disease was nearly always fatal in the preantibiotic era.

Complications occur in as many as 40% to 60% of cases. Systemic or pulmonary emboli, depending on the intracardiac site of the vegetation, are a major source of concern and require prompt initiation of treatment. Major neurologic sequelae can arise from focal embolization to the CNS; thus,

TABLE 84.23

ENDOCARDITIS PROPHYLAXIS REGIMENS

Situation	Agent	Regimen
For Dental, Oral, Respiratory Tract, or Esophageal Procedures		
Standard general prophylaxis	Amoxicillin	50 mg/kg po 1 h preprocedure (max 2 g)
Unable to take oral medications	Ampicillin Or Cefazolin Or Ceftriaxone	50 mg/kg IV or IM within 30 min of procedure (max 2 g) 50 mg/kg IM or IV (max 600 mg)
Allergic to penicillin	Clindamycin Or Cephalexin Or Azithromycin or clarithromycin	20 mg/kg po 1 h preprocedure (max 600 mg) 50 mg/kg po 1 h preprocedure (max 2 g) 15 mg/kg po 1 h preprocedure (max 500 mg)
Allergic to penicillin and unable to take oral medication	Clindamycin Or Cefazolin	20 mg/kg IV within 30 min of procedure (max 600 mg) 25 mg/kg IV or IM within 30 min of procedure (max 1 g)

Second dose of vancomycin or gentamicin not recommended. Cephalosporins not usable in patients with immediate-type hypertensitivity reactions to penicillins.

the presentation of a new neurologic deficit in a child with heart disease can be another clinical clue to the diagnosis of endocarditis. Myocarditis, myocardial abscesses, valvar obstructions associated with large vegetations, and ruptured sinus of Valsalva are other important complications that can be manifested by the appearance of new-onset CHF.

Acute bacterial endocarditis, or the development of an acute situation such as new aortic insufficiency, should be considered a true medical emergency. Often, early reparative surgery is required to save the child's life in this situation. These children are critically ill, and CHF is a grave sign in the context of suspected endocarditis. Characteristic heart murmurs may be absent in this setting; their absence should not be taken as a cause for optimism. Other indications for surgery include the development of a new cardiac arrhythmia (heart block), continued embolization, and continued positive blood cultures after initiation of appropriate therapy. Hemodynamic changes can transpire quickly, demanding frequent examinations even while the child awaits hospital admission or transfer from the ED.

Management

Treatment of infective endocarditis should be started as early as possible after appropriate evaluation is completed. Blood cultures must be drawn regardless of the presence or absence of classic clinical findings. To facilitate the diagnosis, the

physician, particularly one who evaluates a child with heart disease with unexplained fever, must obtain blood for appropriate cultures at an early stage. In most cases of endocarditis, the causative organism will be recovered from the initial two blood cultures. Particular emphasis should be placed on avoiding contamination of the sample site. Growth of spurious organisms can be misleading and dangerously time-consuming because bacteria on the skin can be implicated in endocarditis. It is not mandatory to obtain cultures at the time of fever spikes because bacteremia is fairly constant in the untreated patient. Early consultation should be sought from a cardiologist, since specialized procedures such as echocardiography may help pinpoint the diagnosis rapidly, even in relatively difficult situations (Fig. 84.20).

In every instance, the diagnosis of infectious endocarditis implies long-term antibiotic therapy; thus, most management issues arise after the patient has left the emergency area. In general, antibiotic therapy should be instituted as soon as the diagnosis is made. If the patient is critically ill, it may be necessary to initiate therapy even before the results have returned. Certainly, stabilization of the patient with heart failure, initiation of the diagnostic workup, and mobilization of the relevant medical personnel are the responsibilities of the emergency physician in dealing with the child with suspected endocarditis. If the situation requires the initiation of therapy without definition of the microbial agent, many experts recommend the combination of an aminoglycoside, such as gentamicin (5 to 7.5 mg per kg per day), and a penicillinase-resistant penicillin, such as oxacillin (150 mg per kg per day). Others advocate the use of ampicillin (200 mg per kg per day) and gentamicin for the initial therapy in this particular situation plus vancomycin in areas where methacillin-resistant staphylococci are of concern. Cephalosporins such as cefuroxime may also play a role in this context.

It is important to remember that the child with heart disease who presents with a routine febrile illness does not always immediately require antibiotics. Unnecessarily hasty administration of antibiotics when not clearly indicated can be harmful because obfuscation of the ultimate diagnosis may result in damaging delay in the initiation of effective therapy. If systemic antibiotics are contemplated for specific indications, in most cases a blood count and a blood culture should be drawn *before* antibiotic therapy begins. In particular, these measures should be taken for the child with heart disease and a major infection, such as pneumonia or cellulitis, even if no clinical evidence of endocarditis is immediately apparent. It is not mandatory to admit the child with heart disease and an intercurrent febrile illness to the hospital on every occasion, and the previously noted laboratory studies may be helpful in making such a decision. Clinical judgment remains the best immediate guide for hospitalization. Although a high degree of suspicion for the possibility of endocarditis is mandatory, the emergency physician should resist the temptation to administer antibiotics indiscriminately to the child with heart disease.

HYPOXEMIC ATTACKS

Background

Children with CHD in which pulmonary blood flow is reduced, such as tetralogy of Fallot, may experience periodic episodes of intense hypoxemia. Emergency attention is usually sought for these episodes at the nearest medical location. Therefore, the emergency physician who cares for children should have a good understanding of the associated physiologic and management principles.

Pathophysiology

The reasons for the acute nature of these episodes have never been precisely defined. Initial thoughts that "cyanotic spells" were caused by spasmodic contraction of the portion of right ventricular outflow tract known as the "infundibulum" cannot provide the entire explanation because children with pulmonary atresia in whom no subpulmonic infundibulum has developed can also experience hypercyanotic attacks. Additional theoretical concerns have focused on (i) sudden changes in systemic vascular resistance and in venous return to the heart, which consequently affect the intracardiac right-to-left shunt; (ii) alterations in sensitivity of the respiratory center; (iii) significant changes in HR; or (iv) some combination of these factors. A classic schematic cycle of postulated mechanisms is noted in Fig. 84.21.

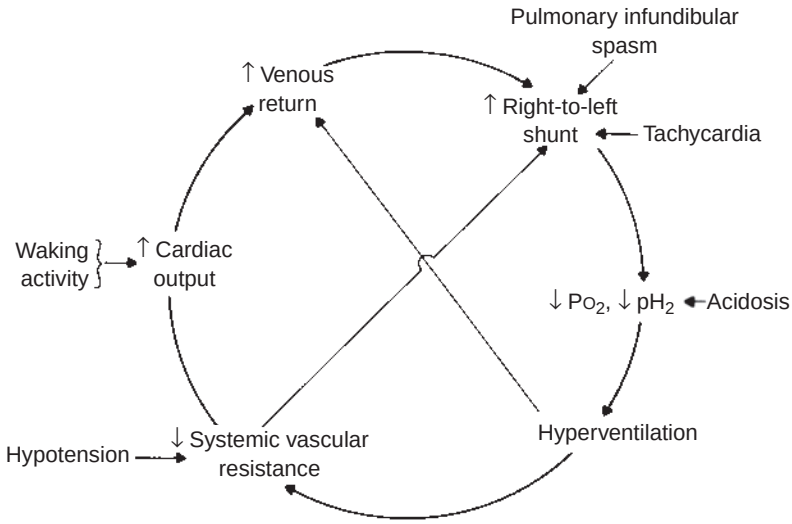

FIGURE 84.21 Schema of interrelated events in the genesis of hypoxemic spells. See text for discussion. (Reprinted from Anthony CL, Arnon RG, Fitch CW, eds. *Pediatric cardiology.* Medical Outline Series. Garden City, NY: Medical Examination Publishing, 1979:193, with permission.)

Any number of precipitant events related to these physiologic factors can be associated with the development of cyanotic spells. Often, they are morning events, noted shortly after awakening. This may be related to the sudden changes in CO that occur after arousal from a long sleep. Other likely times for the appearance of hypercyanosis include periods of dehydration, during invasive medical procedures, or in the face of other significant stresses. The incidence of cyanotic spells is much lower now than in the past because many patients with cyanotic lesions undergo early palliative surgical correction.

Clinical Findings

The diagnosis of a hypoxemic spell usually is self-evident. Aside from the obvious cyanosis and the history of heart disease, there also may be a preceding history of squatting with exertion or of other positional vagaries that parents may recall. It is not necessary for the child to have been overtly cyanotic before the onset of a spell because such episodes can occur in children with little or no preexisting visible cyanosis. During a spell, the child may be irritable and crying or may conversely may be lethargic or even unconscious. Hyperpnea is a feature of the syndrome and should be distinguished from tachypnea or other abnormal respiratory patterns that may signal other medical problems associated with heart disease. During a spell, there may be a notable absence or lessening of a previously heard heart murmur because pulmonary blood flow through the stenotic right ventricular outflow tract is reduced considerably. Laboratory investigations, such as arterial blood gas analysis, ordinarily should be avoided in the initial evaluation. If the attack is prolonged and associated with deepening sensorium changes, assessment of acid–base balance and ventilatory status may then be indicated. Monitoring with peripheral oxygen saturation meters may be helpful to chart responses to therapy.

Management

The child with hypoxemic spells requires immediate attention. Appropriate positioning, oxygen, and administration of morphine are the standard initial therapeutic measures, and these usually result in prompt abatement of the attack (Table 84.25).

Traditionally, subcutaneous morphine has been used in the treatment of cyanotic spells. Relatively large doses are given (0.1 to 0.2 mg per kg), although the precise mechanism of action is not known. Morphine probably does not act to inhibit catecholamine action at the cardiac level but may abort the cycle of hyperpnea and vasomotor changes by depressing the respiratory center. A theoretical negative effect of morphine is its tendency to lower systemic vascular resistance.

Oxygen should be administered because Pa_{O_2} levels may be low and some benefit in terms of oxygen saturation may be obtained from even relatively small increments in dissolved oxygen. In the face of significant reduction of pulmonary blood flow, however, as occurs with a "spell," oxygen may not have a dramatic effect.

The child should be placed in a knee–chest position and calmed, if possible. If the attack persists, additional therapeutic steps are needed. Sodium bicarbonate may be indicated; the dosage depends on arterial pH. High dose IV propranolol has also been recognized as efficacious in this situation, and a dose

TABLE 84.25

ACUTE MANAGEMENT OF HYPOXEMIC SPELLS

Knee–chest position
Oxygen administration
Evaluate and treat cardiac arrhythmia
Morphine sulfate (subcutaneous; 0.1–0.2 mg/kg)
Propranolol IV (0.2 mg/kg over 5 min)
IV fluids
Vasoconstrictors
Phenylephrine 10–20 μg/kg bolus, IM *or* subcutaneous; 0.1–0.5 μg/kg/min infusion IV titrated to HR or BP limits. Higher doses may occasionally be needed.
Methoxamine 0.10 mg/kg IV
Bicarbonate (2–3 mEq/kg IV; ensure adequate ventilation)

IV, intravenous; IM, intramuscular.

of 0.2 mg per kg IV over 4 to 5 minutes may yield relatively prompt improvement. Whether propranolol primarily affects the infundibular contraction, the hyperpneic ventilatory response, systemic vasomotor tone, or all these is unclear. It should be remembered that propranolol may exacerbate bronchospasm if the patient has a coincident history of asthma.

IV fluids should be administered during the severe spell, at least in maintenance doses, because pulmonary blood flow and right ventricular output depend on volume. Functionally, right ventricular outflow obstruction may be heightened in the face of depleted intravascular volume.

Vasopressors are used as alternates or adjuncts in treating hypoxemic spells. Phenylephrine can be given as a dilute IV solution of 10 mg per 100 mL and infused at 2 to 10 μg per kg per minute. HR should be monitored and frequent BP assessment carried out if this type of agent is used. Methoxamine (10 mg per 100 mL) or metaraminol (50 mg per 100 mL) may also be used. By increasing systemic vascular resistance, these drugs reduce intracardiac right-to-left shunting favorably and thus improve systemic oxygenation. Digitalis, epinephrine, or norepinephrine, however, should not be used in this setting.

If any underlying condition exists, such as a cardiac rhythm disturbance, prompt correction according to the principles noted under the "Cardiac Arrhythmias" section may alleviate hypoxemic attacks quickly. Cardiac consultation is advisable as soon as feasible to make extended management decisions, even if the spell has abated with the measures already mentioned. In most situations, if the spell has required more than oxygen and positional adjustment to relieve, hospitalization is indicated. Usually, even though relieved with therapy, spells indicate that appropriate surgery for the cardiac defect is required in the near term.

ACUTE RHEUMATIC FEVER

Background

Although the large numbers of patients with rheumatic fever seen in the past in the United States have dissipated because of improved diagnosis and treatment of streptococcal infections, the disease still occurs and has had occasional resurgence in some areas of the United States. Also, rheumatic fever remains one of the most frequent causes of cardiovascular morbidity in children from other countries. The most common age of attack is 5 to 15 years, and winter and spring seasonal peaks are still typical.

Pathophysiology

It has been established clearly that group A beta-hemolytic streptococcal infection is a necessary precedent for the development of rheumatic fever. In particular, a history of infection by this organism of the upper respiratory tract should be sought in any suspected case. The precise mechanistic relationship between antecedent streptococcal infection and rheumatic fever remains ill-defined. Several serologic types of group A streptococci can be associated with acute rheumatic fever so the antigenic factors involved are common to various strains of the organism. The particular host factors that determine who succumbs to acute rheumatic fever and who does not, despite identical infections, are also poorly defined. A clear-cut genetic pattern has never been identified, although familial susceptibility has been identified for over a century. The more common theoretic considerations that relate streptococcal infection and acute rheumatic fever are (i) an immunologic (autoimmune) response that involves host reaction to infection with a rheumatogenic streptococcus being the heart, specifically, endocardial tissue; (ii) a persistence of organism, despite therapy, with localization to cardiac tissue; and (iii) a direct reaction to the organism, such as cardiotoxicity from streptolysin O produced by the organism. Thus far, no evidence of direct cardiac infection has developed, making experimental evaluation difficult.

Clinical Findings

The diagnosis of rheumatic fever requires a high index of suspicion. The time-honored classic Jones criteria (Table 84.26), if unequivocally present, usually establish the diagnosis, but the situation may not be always so clear-cut.

A complete, careful physical examination is the mandatory first procedure. Special attention should be given to eliciting joint pathology and cutaneous findings, the presence of which may facilitate the diagnosis in difficult cases. The major Jones criteria are derived through clinical examination that usually needs to be repeated at frequent intervals. Of the major criteria, carditis can be over diagnosed easily. Misinterpretation of normal ("innocent") murmurs, whose auscultation is heightened in the presence of fever or other causes of increased CO, can lead to over diagnosis. The presence of an

  - Elevated or rising streptococcal antibody titer

Adapted from Jones TD. The diagnosis of rheumatic fever. *JAMA* 1944; 126:481, as modified in Dajani A, Ayoub E, Bierman FZ, et al. Guidelines for the diagnosis of rheumatic fever. *JAMA* 1992;268: 2069–2073.

apical systolic murmur (characteristic of mitral insufficiency) or a basal diastolic decrescendo murmur (typical of aortic insufficiency) can be important signs of carditis. The presence of a pericardial effusion, CHF, or pericarditis also strongly suggests the carditis, even in the absence of valvar murmurs. Care must be taken to exclude other causes for cardiac findings, such as deteriorating CHD, which may result in cardiac decompensation not related to a rheumatic process. If possible, the examining physician should attempt to document a change in previous clinical findings in children with preexisting heart disease (or previous rheumatic fever episodes). Although regurgitant lesions such as aortic or mitral insufficiency are common components of the acute manifestations of rheumatic fever, stenotic lesions such as aortic or mitral stenosis are usually not seen with a first attack of acute rheumatic fever.

Polyarthritis is the most frequently found major criterion. It should be remembered that this is true joint inflammation, not arthralgia. Tenderness, motion restriction, heat, redness, and swelling are the typical signs. In contrast to other forms of collagen disease, joint involvement in rheumatic fever is usually migratory and multiple and tends to localize to the larger joints of the extremities. It may be necessary to avoid rapid use of antiinflammatory agents in patients with suspected acute rheumatic fever to clarify the diagnosis of migratory polyarthritis.

The cutaneous criteria are erythema marginatum and subcutaneous nodules. These findings are not as frequent as arthritis and carditis and are rarely present as the only major criteria. Nodules usually occur in situations of recurrent rheumatic fever or chronicity. They are found over extensor surfaces of joints such as elbows or knees, are firm and decidedly nontender, and are movable on palpation. Erythema marginatum characteristically appears on the trunk and proximal extremities and is an extremely evanescent finding. The application of heat may accentuate its appearance. This rash is notable for its fine, lacy appearance with central blanching and a serpiginous pattern. It is not pruritic and is usually easily distinguished from drug rashes or other viral exanthems.

Chorea is the fifth of the major criteria defined by Jones. It is a relatively rare finding limited to children older than the age of 3 years and most often occurs some time after the initial streptococcal infection, making accurate diagnosis difficult. Chorea is typified by involuntary purposeless movement of the extremities and facial grimacing. Notable emotional lability is also a part of the picture. The ED diagnosis of acute rheumatic fever rarely depends on chorea as the principal manifestation. The physician should be aware, however, of the possibility of the diagnosis in a child who presents with this finding and should arrange for appropriate further evaluation of the cause of the chorea.

The "minor criteria" defined by Jones are nonspecific indices of inflammatory disease and, frequently, are sources of overdiagnosis of acute rheumatic fever. The fever associated with acute rheumatic fever is notable for its lack of associated chills or rigor. It is typically low grade, and fevers of greater than 40°C (104°F) or a history of a febrile seizure should point to other illnesses. The wildly fluctuating fever of juvenile rheumatoid arthritis ("quotidian" pattern) is usually not a part of the rheumatic fever picture. Elevation of the ESR or C-reactive protein should be present in acute rheumatic fever, but severe CHF may lower the ESR. A prolonged PR interval is not only a frequent occurrence in acute rheumatic fever, but is also an extremely nonspecific finding. It does not necessarily correlate with the presence of organic murmurs and can be found in other inflammatory cardiac diseases or as a result of certain drugs. Overemphasis of the significance of PR prolongation is a frequent cause of improper diagnosis.

The most recent modification of the Jones criteria includes evidence of recent streptococcal infection. Culture documentation, or confirmation with the rapid antigen detection test (RADT) can be diagnostic, but specificity of RADT can be low. Serologic evidence may be the most rewarding and diagnostic data. The antistreptolysin O (ASO) is still a commonly used single serologic test and is well standardized. Levels above 250 Todd units in older children and above 333 in younger children are present in active rheumatic fever. As many as 20% of otherwise normal children can have elevated ASO titers and, depending on the time course of the illness, other antibody determinations may be required.

The differential diagnosis of acute rheumatic fever includes many diseases that fall under the classification of "collagen-vascular," as well as other types of diseases. The Jones criteria themselves can include a spectrum of illnesses such as juvenile rheumatoid arthritis, serum sickness, systemic lupus, and even bacterial endocarditis or septic arthritis. Viral processes, such as myocarditis or pericarditis, must also be excluded, as well as unusual intracardiac lesions such as left atrial myxoma.

Careful application of the Jones criteria plus documentation of a streptococcal infection of recent onset should enable the physician to diagnose acute rheumatic fever most, but not all, of the time. Caution must be exercised in arriving at the diagnosis because initiation of therapy may suppress findings critical to the diagnosis. Thus, decisions to treat must be tempered with the understanding that it is vital to collect as much definition of the disease process as possible.

As noted earlier, acute phase reactants such as the ESR and C-reactive protein are elevated in acute rheumatic fever. A complete blood cell count should be drawn to screen for anemia or an elevated white blood cell count. Leukocytosis is not only a manifestation of infection, but may also be considered an "acute phase reactant." Throat cultures (at least two) should be obtained before penicillin therapy is started. In addition, the streptococcal serological screen previously described should be obtained. Blood cultures are frequently drawn, with appropriate concern, to rule out subacute bacterial endocarditis, a problem that can present in an identical fashion to acute rheumatic fever.

A chest x-ray to assess heart size can be helpful for gauging the severity of carditis, as well as for objective verification of its presence. An EKG should be taken to ensure that a rapid pulse rate is the result of sinus tachycardia and to enable measurement of PR interval. If pericardial disease or intracardiac myxoma needs to be ruled out, an echocardiogram can provide highly sensitive information. These latter procedures are usually completed, of course, after cardiac consultation has been requested. The appropriate laboratory procedures to help rule out other forms of collagen-vascular disease are described in Chapter 101.

Echocardiography has been advocated as a method in itself useful to establish the presence of carditis for some experts but such standards have not as yet been universally accepted. Readers should watch the literature for changes in this regards.

Management

Acute rheumatic fever requires admission to the hospital and chronic management. That is, a prolonged treatment course is indicated once the diagnosis is made. Most considerations in caring for a child with acute rheumatic fever are not made in the ED. It should be restated that a rush to treat with antiinflammatory drugs (aspirin or steroids) in a poorly documented case may obscure the ultimate diagnosis and may delay further therapy, thereby compromising more than helping the patient.

Principles of management include (i) treatment of the active streptococcal infection, (ii) rest, (iii) antiinflammatory agents, and (iv) treatment of chorea. All patients with acute rheumatic fever should receive a course of penicillin to eradicate any streptococci. IM benzathine penicillin in appropriate dosage for age and weight (see Chapter 81) is preferable. Reduced activity may be helpful while there is evidence of active inflammation. Antiinflammatory drugs (salicylates or steroids) may be indicated, but the tendency to begin such therapy before confirmation of the diagnosis, as outlined already, should be resisted. If arthritis without carditis is present, aspirin usually is sufficient (see Chapter 101). Treatment of carditis may include steroids, but that decision should be made only after the child is hospitalized and a cardiologist has been consulted. Treatment of chorea is also a long-term management issue, with agents such as diazepam or haloperidol favored. Recent evidence suggests a role for steroids in the treatment of chorea and for the presence of carditis.

Occasionally, the child with acute rheumatic fever may present with significant cardiac compromise that involves CHF associated with a large degree of valvar regurgitation or pericardial effusion that results in cardiac tamponade. Initially, heart failure or tamponade should be managed as outlined in the previous sections, and then consideration should be given to the rheumatic process.

A most important aspect of management of the patient with rheumatic fever is prevention of recurrent attacks. It has been documented clearly that penicillin can be effective in this setting, with minimal patient risk. The most reliable prophylaxis is the IM route, with injections of 600,000 units for children 27 kg or less and 1.2 million units for larger patients of benzathine penicillin G every 28 days being the preferred treatment. Oral penicillin (200,000 units twice daily 250 mg) is an alternative prophylactic regimen. Sulfonamides (Sulfadiazine) may be used in patients allergic to penicillin. Recommended dosages for the sulfonamides are 0.5 to 1.0 g daily, again depending on weight. Recent recommendations suggest continuing antibiotics for a minimum of 5 years or until 21 years of age (whichever is longer) after the initial diagnosis if there is no carditis. If there is persistent valvular disease, prophylaxis should continue until age 40, or in some cases be lifelong. Increasing age may lessen susceptibility to streptococcal disease, but reliable evidence is lacking to substantiate this impression conclusively. The physician who evaluates a child with known rheumatic heart disease for any reason should review the prophylaxis status of the child at every occasion.

CHAPTER 85 ■ DERMATOLOGIC URGENCIES AND EMERGENCIES

PAUL J. HONIG, MD, LESLIE CASTELO-SOCCIO, MD, PHD, AND ALBERT C. YAN, MD

ATOPIC DERMATITIS

Background

The definition of atopic dermatitis has at times been confusing. Many alternative terms are used to describe skin inflammation (dermatitis) that is chronic and relapsing.

Although the eruption may have a variable appearance (erythema, edema, papules, vesicles, serous discharge, and crusting), its constant feature is unrelenting pruritus. The eruption often has a characteristic distribution, depending on age (Fig. 85.1), and often occurs in allergic (atopic) individuals or those with a family history of allergies (e.g., hay fever, asthma, allergic rhinitis, food allergies, eosinophilic gastroenteritis). Although many theories relating to cause exist (e.g., genetic, physiologic, pharmacologic, immunologic), the data are conflicting.

More recent epidemiologic studies indicate that atopic dermatitis affects approximately 15% to 23% of children, beginning at 1 to 2 months of age. Of children who acquire atopic dermatitis, 60% will do so by the end of their first year of life, 90% by 5 years, 95% by 10 years, and 99% between 10 and 20 years of age. The course of an individual case is difficult to predict, but only 30% of those who develop the problem during the first year continue to have the disease during childhood. Of all children who have mild to moderate atopic dermatitis during childhood, 90% will be clear by the time they reach adolescence. For those children suffering from severe atopic dermatitis, only 15% will clear by adolescence.

Pathophysiology

No single theory explains the initiation and progression of atopic dermatitis. Some evidence suggests that a combination of factors, including altered physiologic, pharmacologic, and immunologic mechanisms, is involved in the exaggerated reactivity of the skin.

Various studies have found that patients with atopic dermatitis have altered epidermal barrier function. This is likely related to mutation or downregulation of genes involved in the cornified envelope. Patients with atopic dermatitis have had mutations identified in the filaggrin and collagen XXIX genes, both of which encode for proteins involved in forming the skin's outer protective layer. These changes result in increased transepidermal water loss, decreased quantities of sebaceous gland–derived lipids at the skin surface, and increased transcutaneous exposure to allergens. Patients also have an increased sweating response to Mecholyl®. If this drug is injected into the skin of an individual with atopic dermatitis, it causes blanching rather than the usual erythema. Simple scratching of the skin in an atopic will induce white dermatographism. Finally, the β-adrenergic blockade theory hypothesizes that reduced function of the β-adrenergic system leads to decreased production of cyclic adenosine monophosphate (cAMP). This reaction results in an increased release of pharmacologic mediators, such as histamines, producing pruritus and inflammation of the skin.

Atopic dermatitis patients have immune system dysregulation, which includes altered T-cell (Th1/Th2) function, increased production of immunoglobulin E (IgE) by B cells, elevated prostaglandin E_2, abnormal lymphokine secretion profiles, abnormalities of Langerhans cells, deficiencies in the production of endogenous antimicrobial peptides, and defects in response to staphylococcal superantigens. The way in which these changes interact to produce atopic eczema is still not definitive, but the picture is becoming clearer. Production of Th2-related proinflammatory cytokines, such as interleukin (IL)-4, IL-5, IL-13, IgE, and TNF-α, as well as cAMP phosphodiesterase, is abnormally increased. These responses lower cAMP, producing increased release of histamine, prostaglandin E_2, and other cytokines. This leads to decreases in cell-mediated interferon-γ responses and further increases in IL-4 and IL-5 responses. The resulting inflammatory mediators that arise from these complex interactions trigger the itch–scratch cycle.

Clinical Manifestations

The patient's age often determines the distribution and appearance of the skin lesions. During infancy, the itch–scratch cycle, which usually begins at 2 to 3 months of age, produces the erythematous, exudative lesions that appear on the cheeks and extensor surfaces. At times, the process becomes generalized. At about the age of 2 years, more characteristic flexural involvement occurs. Also indicative of atopic dermatitis are (i) varying sized patches of hypopigmentation, especially prominent on the cheeks (pityriasis alba; Fig. 85.2); (ii) patchy or diffuse, fine papules (follicular accentuation; Fig. 85.3); (iii) scaling in the scalp with or without hair loss; and (iv) hyperlinear palms and soles (Fig. 85.4), which may show desquamation. Involvement of the feet in such a manner occasionally leads to the misdiagnosis of tinea pedis, which occurs less often in the pediatric population before adolescence. During adolescence, the distribution remains the same; however, a greater incidence of involvement of the face, neck,

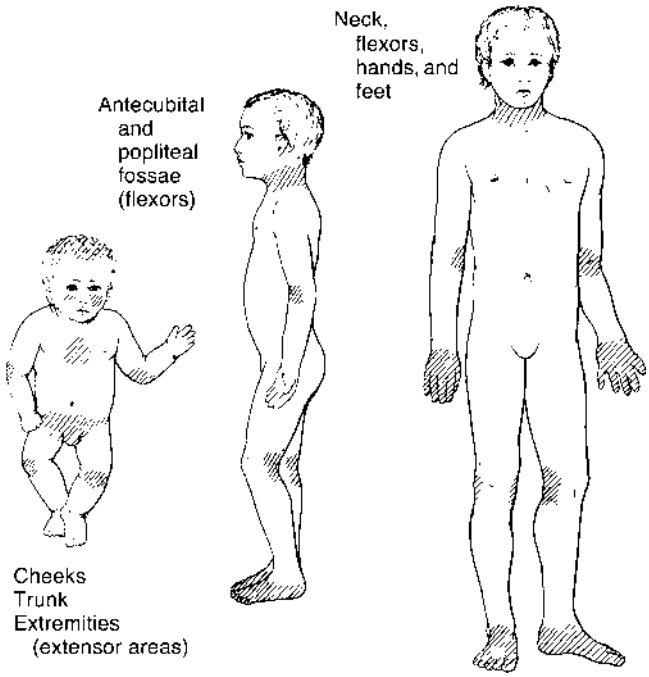

FIGURE 85.1 Distribution of atopic eczema at various ages.

posterior auricular areas, and the hands and feet occurs. The major physical findings of chronicity, hyperpigmentation, and lichenification are often present (Fig. 85.5). Characteristically, infants and children with atopic dermatitis show sparing of the nose and perinasal areas when the face is involved.

FIGURE 85.2 Postinflammatory hypopigmentation occurring in a child with atopic dermatitis (pityriasis alba).

FIGURE 85.3 Follicular accentuation in a patient with atopic eczema.

The diagnosis of atopic dermatitis is based on the presence of pruritus, typical morphology and distribution, as well as a tendency toward chronically relapsing dermatitis. Other possible features are listed in Table 85.1. Unfortunately, laboratory tests are not helpful in the diagnosis of this disorder. Although eosinophilia and elevated serum IgE levels are present, they are not specific for this condition.

Differential Diagnosis

Atopic and seborrheic dermatitis may be difficult to differentiate when first appearing in a 1- to 2-month-old infant. Both conditions may cause scaling in the scalp or diaper dermatitis. Clues pointing to seborrheic dermatitis include involvement of the flexural and intertriginous areas in the infant; a salmon-colored eruption with greasy, yellow scaling; and the lack of

FIGURE 85.4 A patient with atopic eczema who has hyperlinearity of the soles.

FIGURE 85.5 Chronic changes of hyperpigmentation and lichenification often seen in atopic eczema.

pruritus. Therapeutic clues include a rapid response to antiseborrheic shampoos (such as selenium sulfide) and steroids in seborrheic scaling of the scalp. Atopic dermatitis, in contrast, is often worsened with antiseborrheic shampoos and responds slowly to topical steroids. Infants with seborrheic dermatitis often manifest mild itching if present at all, while pruritus is universally seen in children with atopic dermatitis. Finally, infants with seborrheic dermatitis often show perinasal involvement while those with atopic dermatitis show characteristic sparing of this area.

TABLE 85.1

DIAGNOSTIC FEATURES OF ATOPIC DERMATITIS

Major
Typical morphology and distribution
Pruritus
Chronically relapsing course
Early onset of dermatitis (<2 yr of age)
Personal or family history of atopic disease

Additional Features
Xerosis
Hyperlinear palms and soles
Follicular accentuation
Pityriasis alba
Scaling of the scalp
Ichthyosis
Tendency toward nonspecific hand and foot dermatitis (pseudotinea pedis)
Tendency toward repeated cutaneous infections
White dermographism
Elevated serum immunoglobulin E

Minor
Cataracts
Keratoconus
Dennie-Morgan (infraorbital) fold

Nummular eczema is an eruption that differs from atopic eczema in that the lesions are circular, erythematous, scaling, crusted patches, or plaques. The lesions begin as papules and vesicles that spread and coalesce, forming the typical coin-shaped patches. Pruritus is variable. Affected patients do not usually have an atopic background, and IgE levels are generally not elevated. This disorder may be a manifestation of dry skin and, in fact, is aggravated by overwashing, harsh soaps, low temperatures, and low humidity. Decreased bathing, use of mild soaps, and topical steroids are generally helpful.

Xerosis, or dry skin, is a condition that is commonly seen in patients who bathe frequently and use harsh soaps. Low temperatures and humidity will exacerbate this disease. Therefore, it is more common during winter months. The rash is pruritic and appears as rough, red, dry, scaling skin. It is similar in appearance to chapped hands and cheeks seen in cold weather. Decreased bathing, use of mild soaps, and lubrication of the skin are helpful.

Many immune and metabolic disorders are also associated with a rash that is similar in appearance to atopic dermatitis. These disorders are listed in Table 85.2.

Complications

Infection of the existing dermatosis is the principal complication in atopic dermatitis and may in part be explained by a variety of factors: impaired skin integrity exposes epitopes such as fibronectin that allow pathogens an opportunity to bind the skin more effectively and the elaboration of cytokines suppresses normal production of endogenous antimicrobial peptides.

Colonization and infection with *Staphylococcus aureus* is common among atopic children and may account for flare-ups or failure to respond to therapy. There is increasing prevalence of infection with methicillin-resistant *Staphylococcus aureus* (MRSA) in patients with atopic dermatitis, particularly in those who were previously hospitalized and/or used topical calcineurin inhibitors in conjunction with topical steroids. Group A β-hemolytic streptococci are also cultured from many individuals with secondarily infected skin.

Viral skin infections also occur more often in patients with atopic dermatitis. Eczema vaccinatum, once a dreaded and often fatal complication of vaccina (smallpox) immunization, rarely occurs now that routine vaccination has been discontinued although this may change if smallpox vaccination again becomes routine. The common causes for what is termed Kaposi's varicelliform eruption are mainly herpes simplex virus (HSV; eczema herpeticum; Fig. 85.6) or, on occasion, coxsackievirus infection. Groups of umbilicated vesicles or areas of increased crusting and ulceration should be cultured for herpes simplex. A diagnostic procedure that may yield a quick answer to the presence of herpes simplex is the Tzanck test (Fig. 85.7). Material from the base of a freshly opened vesicle is scraped for a Giemsa stain. Multinucleated giant cells and balloon cells indicate the presence of herpes simplex. A much more sensitive and specific test is the rapid direct immunofluorescent test described in Chapter 67 or the polymerase chain reaction systems, which are now more readily available in hospital laboratories. This virus can also cause localized flare-ups of eczema without dissemination. Leyden

TABLE 85.2

IMMUNE AND METABOLIC DISORDERS CAUSING RASH THAT RESEMBLES ATOPIC DERMATITIS

Metabolic disorders	Immunologic disorders
Phenylketonuria	Ataxia-telangiectasia
Acrodermatitis enteropathica	Langerhans cell histiocytosis
Histidinemia	Wiskott-Aldrich syndrome
Gluten-sensitive enteropathy	X-linked agammaglobulinemia
Hartnup disease	Hyperimmunoglobulin E syndrome
Hurler's syndrome	Selective immunoglobulin A deficiency
	Severe combined immunodeficiency

described culture-proven recurrent local attacks of HSV appearing as discrete punched-out ulcerations. As a result, children with atopic dermatitis who develop eczema herpeticum have an increased risk of localized reactivation of HSV, and some of these children may require a period of supervised antiviral prophylaxis on an outpatient basis. Varicella virus lesions also tend to concentrate in areas of inflamed skin as a result of leakage of virions through dilated vessels. The viruses that cause molluscum contagiosum and warts also infect individuals with atopic dermatitis more often than the average patient (Fig. 85.8).

Management (Table 85.3)

Skin tests and hyposensitization are of little value and are rarely indicated. Dietary restrictions may be helpful in certain patients but are difficult to maintain. The four main objectives in the treatment of uncomplicated atopic dermatitis are (i) reduction of pruritus, (ii) reduction of inflammation, (iii) protection of the skin from unknown irritants, and (iv) removal of known irritants and allergens. Reduction of pruritus can be accomplished in numerous ways. The most important of these methods is limitation of bathing (at times, to only once per week) and the use of a mild soap or synthetic detergent (syndet) cleanser (e.g., Dove®, Oil of Olay®, Tone®, Caress®) Amend the position of registered trade marks. Lubrication of the skin with petrolatum, Aquaphor® ointment, Nivea® cream, Eucerin® cream, or Moisturel® (which contains no lanolin or perfumes) ameliorates dryness, which may be a factor in producing pruritus. Antihistamines can be helpful, although during infancy, the necessity for soporific doses results in their being less therapeutic and infants may experience paradoxical agitation rather than sleepiness. Old standbys include diphenhydramine hydrochloride (5 mg per kg per day in three to four divided doses) and hydroxyzine (2 mg/kg/day in three to four divided doses). Topical diphenhydramine or doxepin is not recommended due to the likelihood of systemic absorption from the skin. Oral agents such as cetirizine, levocetirizine, fexofenadine, loratadine, and desloratadine are also available but because they are less sedating, they may provide less optimal control of pruritus.

Control of inflammation is accomplished with the use of topical steroids (Table 85.4). During the acute phase, potent steroids should be used to bring the situation under control. At times, systemic steroids are used to bring an acute flare-up under

FIGURE 85.6 Eczema herpeticum.

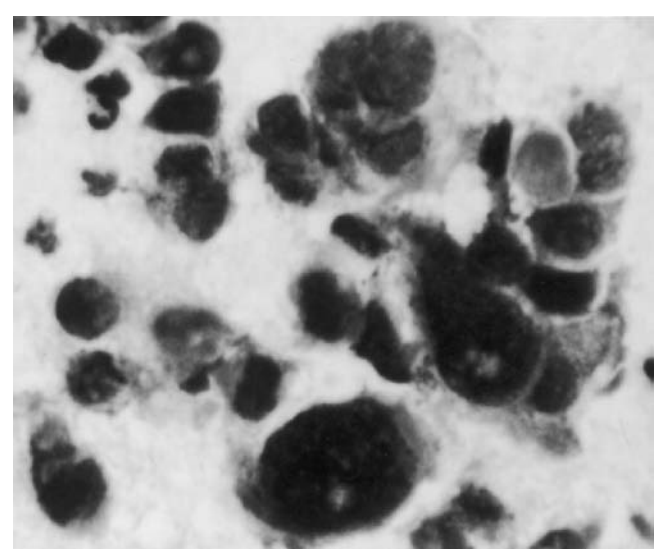

FIGURE 85.7 Positive Tzanck test demonstrating multinuclear giant cells.

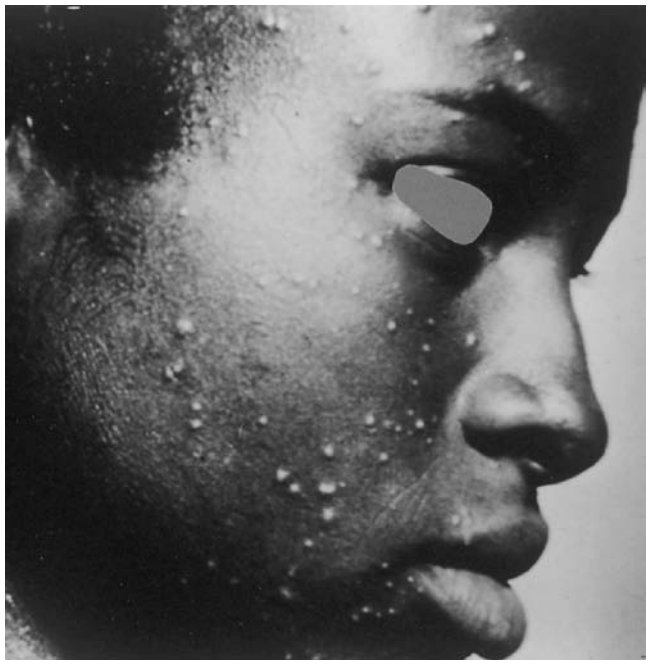

FIGURE 85.8 An atopic eczema patient whose face is covered with molluscum contagiosum.

control. Fortunately, this measure is rarely necessary. Once control is achieved, steroids of mild potency or steroid-sparing agents such as topical calcineurin inhibitors [pimecrolimus cream (Elidel®) for mild to moderate eczema or tacrolimus ointment (Protopic®) for moderate to severe eczema] or newer therapeutic emollients [MAS063DP cream (Atopiclair®), palmitoylethanolamine cream (Mimyx®), or a ceramide-based emollient (Epicream)] should be used and can often be applied less often. (Note: Steroids should not be used on the face for prolonged periods. Instead, the use of topical calcineurin inhibitors or therapeutic emollients is recommended because these appear to be safe and well tolerated on the face and periocular areas.)

Topical calcineurin inhibitors were first introduced in 2000 as a U.S. Food and Drug Administration (FDA)-approved nonsteroidal drug for the management of atopic dermatitis. Topical tacrolimus (FK506) ointment and topical pimecrolimus cream bind to cytosolic macrolide receptors and act as intracellular calcineurin phosphatase inhibitors; by blocking the dephosphorylation of calcineurin, the production of proinflammatory cytokines contributing to atopic dermatitis is likewise inhibited. Unlike topical steroids, these agents lack the steroid-associated effects of hypothalamic-pituitary-adrenal (HPA) axis suppression, ocular cataracts or glaucoma, and cutaneous atrophy. Both agents appear to be safe and effective. The U.S. FDA has placed boxed warnings on these agents because animal data indicate that high doses applied topically or taken internally have been associated with immunosuppression and immunosuppression-related complications of lymphoma and skin cancers in animal studies. Ongoing patient registries (APPLES and PEER studies) designed to monitor this risk in humans have not to date identified an increased risk for these conditions in humans.

Maintenance with the least potent steroid, calcineurin inhibitor, or therapeutic emollient applied as infrequently as possible, is advisable. However, continued therapy is usually necessary. After control has been maintained for a fairly prolonged period, an attempt to discontinue topical pharmacologic therapy can be made. Protection of the skin against unknown irritants is best done by covering it. Long-sleeve polo shirts and leotards are helpful in preventing dust and pollens from coming in contact with the skin. Removal of known irritants is achieved by (i) environmental control (i.e., no stuffed toys, wool clothing or blankets, or pets), (ii) avoidance of harsh soaps, and (iii) keeping fingernails short. At times, hospitalization for control is advisable and certainly a more desirable alternative than systemic steroids.

Appropriate antibiotics are important in the treatment of secondary bacterial infections. A child who is not showing signs of systemic infection can often be treated orally in the home setting. When methicillin-sensitive staphylococcal organisms are involved, antibiotics such as erythromycin (40 mg per kg per day), dicloxacillin (50 mg per kg per day), or cephalexin (50 to 100 mg per kg per day) provide suitable coverage. These antibiotics also treat group A β-hemolytic streptococci that may

Moderate
Aristocort® ointment 0.1% (triamcinolone acetonide)
Synalar® ointment and cream 0.025% (fluocinolone acetonide)
Dermatop® ointment and cream 0.1% (prednicarbate)
Cutivate® cream 0.05% (fluticasone)
Valisone® cream 0.1% (betamethasone valerate)
Potent
Diprosone ointment 0.05% (betamethasone dipropionate)
Lidex cream or ointment 0.05% (fluocinonide)
Topicort ointment and cream 0.25% (desoximetasone)

[a]Many of the synthetic preparations are fluorinated; hydrocortisone and prednicarbate are not.

be present. In places where MRSA is prevalent or when patients have had multiple hospitalizations for atopic dermatitis–related infection, clindamycin or trimethoprim-sulfamethoxazole may be indicated. When a child is toxic, inpatient intravenous (IV) therapy is advisable; although clindamycin, trimethoprim-sulfamethoxazole, or vancomycin is often employed as empiric therapy, antibiotic selection should be made on the basis of local antibiotic-resistance patterns.

Eczema herpeticum that is localized and has not produced toxicity in a child can be treated on an outpatient basis with oral antiviral therapy (acyclovir) and will usually clear in 2 to 3 weeks. With severe infection, especially in young infants, more aggressive therapy may be necessary. IV acyclovir dosed at 750 mg per m^2 per day divided q8h is advised for hospitalized patients. More localized primary or secondary infections can be treated orally at a dosage of 1,200 mg per m^2 per 24 hours in three divided doses for 7 to 10 days.

Patients with severe atopic dermatitis may be maintained on more intense therapies and may experience exacerbations that prompt evaluation in the emergency department. Ultraviolet light phototherapy can be extremely helpful in alleviating the pruritus and cutaneous manifestations of atopic dermatitis, but patients receiving this therapy should undergo gradual dose escalation or they may experience ultraviolet light burns. Systemic immunosuppressive and immunomodulating agents that have been used in more severe pediatric atopic dermatitis patients include cyclosporine, azathioprine, mycophenolate mofetil, and γ-interferon.

SEBORRHEIC DERMATITIS

Background

Seborrheic dermatitis is the term given to the salmon-colored patches with yellow, greasy scales occurring primarily in the so-called seborrheic areas (face, postauricular area, scalp, axilla, groin, presternal area). Seborrheic dermatitis is seen in infants or adolescents. Its onset occurs during the first 3 months of life and generally disappears shortly thereafter, only then reappearing in adolescence.

Pathophysiology

Although sebaceous gland dysfunction is often cited as a cause, the definite cause of this disorder has not been established. In fact, surface fat levels are normal in seborrheic dermatitis, but their ratio is altered. The presence of seborrheic dermatitis correlates strongly to concomitant emotional stress or neurologic disorders.

Clinical Manifestations

The two common locations of skin involvement during infancy are the scalp (cradle cap), as shown in the infant with seborrheic dermatitis in Fig. 85.9, and the diaper area. Most commonly, yellow, greasy scales are found over the anterior fontanel. Scaling is concentrated in this location because of the fear some mothers have about rubbing or scrubbing over the fontanel.

FIGURE 85.9 Seborrheic dermatitis.

Many times the scaling is limited to this area; however, occasionally, the scaling is spread to the forehead, eyebrows, nose, ears, and neck. The intertriginous and flexural areas may also become involved. This reaction is especially seen in the diaper area (Fig. 85.10). The child is not irritable, and pruritus does not seem to be present. The prognosis for clearing is excellent, and resolution usually occurs within several weeks to months.

Between the periods of infancy and adolescence, scaling of the scalp usually indicates causes other than seborrheic dermatitis (atopic dermatitis or tinea capitis). In fact, true seborrheic dandruff does not appear until puberty, when excessive production of sebum occurs. Most commonly, scalp scaling before puberty and after infancy indicates the presence of atopic dermatitis or tinea capitis (especially *Trichophyton tonsurans*). Differentiation is aided by clinical appearance, cultures, and response to therapy. Atopic dermatitis is often worsened with

FIGURE 85.10 Infant with seborrheic diaper dermatitis.

harsh shampoos and responds slowly to topical steroids. The diagnosis of tinea capitis is best made with cultures. If steroids are used in the presence of tinea capitis, scaling of the scalp often increases secondary to suppressed local immunity of the skin and increased growth of the fungus. Seborrheic dermatitis of the scalp during the adolescent period is similar in nature to the condition in adults. Scaling in the scalp appears, and the seborrheic areas are variably involved. Erythema and scaling occur between the eyebrows, on the eyelid margins, and in the nasolabial creases, sideburns, beards, mustache, posterior auricular areas, and aural canals. Rarely, the patient may develop a secondary infection with monilia or bacteria.

Management

Seborrheic dermatitis of the scalp responds readily to antiseborrheic shampoos (i.e., selenium sulfide) and topical steroids such as fluocinolone acetonide or betamethasone valerate (Table 85.4). In infants, loosening of the scales with a soft toothbrush or fine-toothed comb before shampooing often hastens clearing of the cradle cap. Topical steroids are effective in the treatment of seborrheic dermatitis. Because hairy locations are commonly involved, steroid preparations in the form of solutions, lotions, or gels are advisable. The strength of the steroid and the frequency of application are determined by the response to therapy. Steroids should not be used for prolonged periods on the face because of potential damage to the skin in that area. Secondary infection with bacteria can be treated with appropriate antibiotics. If *Candida albicans* secondarily invades the lesions, agents such as topical nystatin or econazole cream, applied twice daily, are useful.

ALLERGIC CONTACT DERMATITIS

Background

Allergic contact dermatitis is a cell-mediated reaction to antigenic material in contact with the surface of the skin. Children younger than 1 year rarely respond to contactants and, until nearly 3 years of age, have a reduced incidence of contact dermatitis. While previous estimates had suggested that the incidence in children had been about 1.5%, a considerably lower value than that given for adults, more recent data indicate that the prevalence of contact dermatitis among children ranges from 25% to 60% of those referred for patch testing.

Pathogenesis

An allergen penetrates the stratum corneum (facilitated by trauma at times) and combines with a carrier protein to form the foreign substance responsible for initiating the sensitization process. This complex is carried via lymphatics to the regional lymph nodes where processing by macrophages occurs. Recognition by T lymphocytes follows; these cells then leave the node, enter the bloodstream, and migrate into the skin. When the antigen again comes in contact with the skin, sensitized T lymphocytes combine with the specific foreign material and release inflammatory lymphokines. The characteristic dermatitis occurs 6 to 18 hours later.

TABLE 85.5

REGIONAL PREDILECTION OF VARIOUS SUBSTANCES THAT CAUSE CONTACT DERMATITIS

Head and Neck
Scalp—hair dye, hair spray, shampoo
Ear canal—neomycin
Forehead—hat band
Eyelids—nail polish, volatile gases, false eyelash cement, mascara, eye shadow/cosmetics
Perioral—dentrifices, bubble gum, chewing gum
Ears—earrings, perfume

Trunk
Axilla—deodorant, clothing dye
Breasts—metal, elastic in bra

Arms
Wrist—cosmetic jewelry (nickel), leather (*p*-phenylenediamine, chrome)

Abdomen
Waistline—rubber dermatitis from elastic in pants, jockstrap (lower)
Lower abdomen—nickel dermatitis from metal snaps

Lower Extremities
Feet—shoe dermatitis

Clinical Manifestations

The acute onset of linear or geometric areas of erythema, edema, eczematization, and papulovesiculation usually indicates the presence of "an outside job" and frequently indicates an allergic contact dermatitis. Because skin involvement is limited to areas of contact, the distribution, pattern, and shape of the dermatitis provide important clues for the clinician (Table 85.5). Therefore, a round lesion on the back of the wrist would incriminate a wristwatch; a linear pattern encircling the waist points to the rubber in the waistband of a garment; linear lesions on exposed portions of the body indicate brushing against the leaves of a poison ivy plant (Fig. 85.11); and extensive involvement of exposed areas of skin suggests an airborne allergen, as with ragweed or vaporized oil transmitted in the

FIGURE 85.11 Typical linear pattern after exposure to the poison ivy plant.

FIGURE 85.12 Facial edema and inflammation in response to exposure to airborne contact allergen (e.g., vaporized oil in smoke of burned poison ivy plants).

smoke of burning poison ivy (Fig. 85.12, see also color plate). Generally, the scalp, palms, and soles are less permeable to allergens and therefore are less often involved. Involvement of oral mucous membranes is uncommon. As previously mentioned, trauma or nonspecific factors such as pressure, heat, and perspiration may predispose the skin to allergic contact dermatitis.

The most common cause of contact dermatitis remains rhus (poison ivy, oak, sumac). However, a variety of other agents have been implicated as common causes of contact dermatitis in children: nickel, cobalt, thimerosal, fragrances, neomycin, rubber compounds, chromates, paraphenylenediamine, and colophony (rosin). Paraphenylenediamine, an agent commonly used in hair dye, has been encountered as an occasional cause of pediatric allergic contact dermatitis due to the frequent incorporation of paraphenylenediamine into commercial henna dyes used for temporary tattoos.

Rhus (Poison Ivy, Oak, Sumac)

Rhus dermatitis is the most common allergen involved in the production of contact dermatitis. The poison ivy plant (Fig. 85.13A) occurs in all parts of the United States as a shrub or vine, often on trees or fences. Poison oak (Fig. 85.13B), an upright shrub, appears only on the West Coast. Poison sumac (Fig. 85.13C) grows as a shrub or tree east of the Mississippi. Seventy percent of the population will become sensitized if exposed to the oleoresin, known as *urushiol*, contained on the leaf, stem, or root of the plant. The active ingredient in this oil is pentadecylcatechol. The oil can be carried on clothing and pets or by the wind.

Each plant produces an identical redundant eruption. From the time of exposure, the average time to appearance of the rash is 48 hours. At that time, onset of pruritus, inflammation, and grouped or linear papulovesicles or bullae occurs. With severe exposure, the face and eyelids become uniformly edematous. The eruption can last from 1 to 3 weeks. Occasionally, black, pseudonecrotic areas may be present on affected areas and indicate the presence of oxidized oleoresin shed from the poison plant, a phenomenon referred to as *black spot poison ivy*, and may clinically be mistaken for ecthyma gangrenosum. However, the intense itch of black spot poison ivy distinguishes it from ecthyma.

Avoidance of exposure is the best prophylaxis in treatment. Topical barrier agents such as the product that is used by forest rangers have been developed to prevent rhus dermatitis in high-risk individuals. However, at times, protection is impossible.

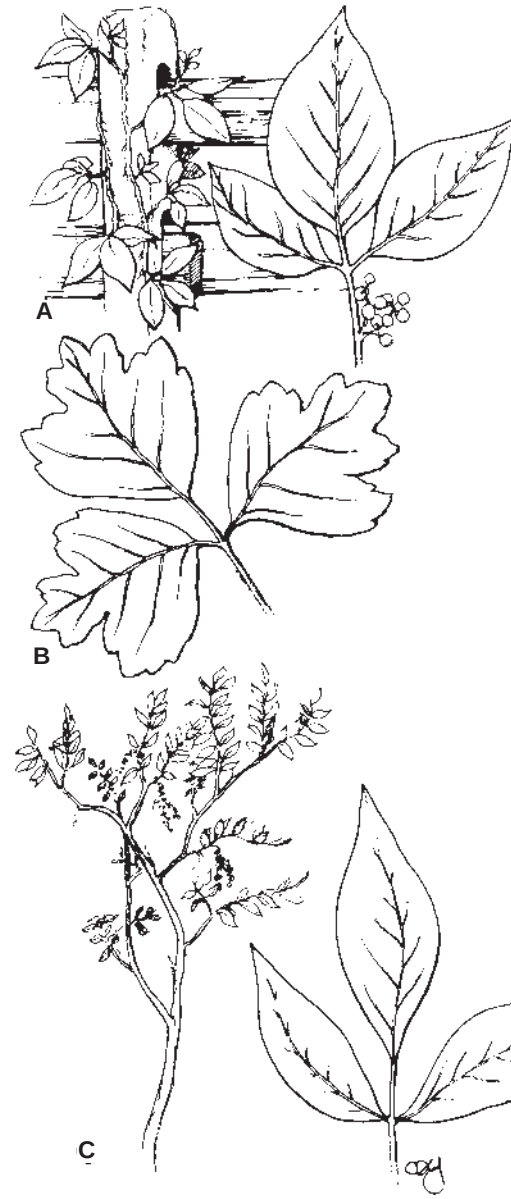

FIGURE 85.13 **A:** Poison ivy (*Rhus radicans*). **B:** Poison oak (*Rhus toxicodendron*). **C:** Poison sumac (*Rhus vernix*).

Once an individual is exposed, contaminated clothing should be removed and laundered and the body should be bathed with any soap as soon as possible, preferably within 5 to 10 minutes. Once the oil has been removed, spread does not occur, even from vesicular fluid. Although sequential outbreaks on various parts of the body suggest spread, lesions appearing later in time indicate initial exposure to a lesser dose of the offending oil.

Antipruritic lotions such as calamine are useful. Topical steroids are somewhat effective, but topical antihistamines and anesthetics should be avoided because they can themselves be sensitizers. Oral antihistamines can be helpful. With generalized reactions, oral prednisone 1 to 2 mg per kg once daily for 1 to 2 weeks, then tapered over the following week, is advisable.

Nickel Contact Dermatitis

Nickel dermatitis is seen commonly in children in response to nickel-containing jewelry or clothing. Earlobes are commonly

involved because of the popularity of pierced ears; the wrists may be involved because of watches or bracelets; the infraumbilical area frequently becomes involved because of nickel-containing metal snaps on pants. Most articles of jewelry contain nickel, including those made of gold and silver. Any person wearing these items is at risk. Perspiration begins the process by leaching the nickel from the jewelry around the neck, wrist, fingers, or infraumbilical areas. Treatment consists of removing the offending object, avoiding further contact with nickel-containing jewelry, and applying topical steroids to the affected areas of skin. For families wishing to identify nickel-containing products in their households, a nickel allergy test kit utilizes dimethylglyoxime, which when applied to a cotton swab in conjunction with ammonium hydroxide will turn pink when exposed to nickel.

Shoe Contact Dermatitis

Erythema, blistering, weeping, crusting, or lichenification of the dorsal aspects of the toes and instep of the feet, with sparing of the interdigital webs, suggest shoe contact dermatitis. The responsible antigens are usually the rubber, glues, dyes, and tanning agents used in making the shoes. Although not often recognized, the problem is common. Children who sweat freely are more likely to be affected because of the leaching of allergens from the shoes onto the skin. Secondary infection is common, and an "id" reaction, similar to that seen in tinea pedis, can cause involvement of the hands and other areas of the skin distant from the primary site.

Patch testing kits for shoe components are available to determine specific sensitizing substances. This testing should be done by a dermatologist only after the skin problem is brought under control. Control is achieved by avoiding shoes when possible, treating secondary infection with appropriate antibiotics, and using topical steroids. Oral antihistamines are helpful for reducing pruritus. An id reaction consisting of huge bullae on the hands and feet can occur. The child is often unable to walk. Hospitalization and the use of systemic steroids [see "Rhus (Poison Ivy, Oak, Sumac)" section] are necessary.

Cosmetics

Many practicing physicians do not know that nail lacquers (containing sulfonamides and formaldehyde resins) or nail hardeners (containing formaldehyde) are a common cause of allergic reactions on the skin of the eyelids. The skin in this area is thin and permeable. Simply rubbing the eyes with fingernails that have polish on them can induce the problem. Paraphenylenediamine, which is contained in hair dyes, will also cause eczematous eruptions of the scalp and face.

Management

Elimination and avoidance of the causal antigen is the most effective preventive and therapeutic measure. Topical steroids and antihistamines help with inflammation and pruritus.

With localized involvement, moderate- to high-potency topical steroids can be helpful in reducing symptoms while the dermatitis clears. With generalized skin involvement, oral steroids (prednisone or prednisolone) are effective at a dosage of 1 to 2 mg per kg per day over 7 to 10 days then tapered over the next 7 days (rebound less likely). Patch testing should not be performed during an acute episode because contact with the allergen may cause worsening of the rash.

DIAPER DERMATITIS

Background

Diaper dermatitis is a general term used to describe skin abnormalities beneath the diaper secondary to a variety of causes. The problem is common in children 2 years of age or younger who require the use of a diaper. It generally disappears after toilet training.

Pathophysiology

The pathogenesis of the problem is multifactorial (Fig. 85.14) and not clearly defined. The possibilities include the concentration of bacteria or fungi, the action of organisms on the urine, and moisture itself.

No firm proof exists that bacteria play a major role. However, bacterial overgrowth does occur on moist skin with increasing time. Bacteria have been implicated in liberating ammonia from urine and raising urine pH. The rise in pH increases the activity of fecal proteases and lipases, which can damage skin. Bile salts can potentiate this damage.

C. albicans is found on the skin in 40% of infants with active diaper dermatitis within 72 hours of the appearance of the rash. Because studies show that this organism is present in less than 10% of infants without diaper dermatitis, *C. albicans* may be playing a significant role. Sources of *C. albicans* include the gastrointestinal (GI) tract and secondary implantation from a mother with candidal vaginitis.

Chronic exposure of the skin to moisture, especially under occlusion by the diaper, leads to maceration and alteration of the epidermal barrier with overgrowth of bacteria (including group A β-hemolytic streptococci) and *C. albicans*. If one major instigating factor exists, the effect of chronic exposure to moisture is critical to the development of diaper dermatitis.

Another consideration is the predisposition of certain individuals to react more easily and negatively to varying irritants. Generally, infants with an atopic or seborrheic background are at greater risk for the development and persistence of diaper dermatitis.

Clinical Manifestations

Differentiation of the various types of diaper dermatitis is difficult. Clues from the history and physical examination are necessary when characterizing the cause of this problem. The different types of diaper rashes include occlusion dermatitis, atopic dermatitis, seborrheic dermatitis, moniliasis, and mixed or not diagnosable rash.

Occlusion Dermatitis

Occlusion dermatitis (Fig. 85.15, see also color plate) results from two components. The first, friction, occurs mainly on those portions of the diaper area where contact with the diaper is greatest (inner thighs, lower abdomen, and prominent

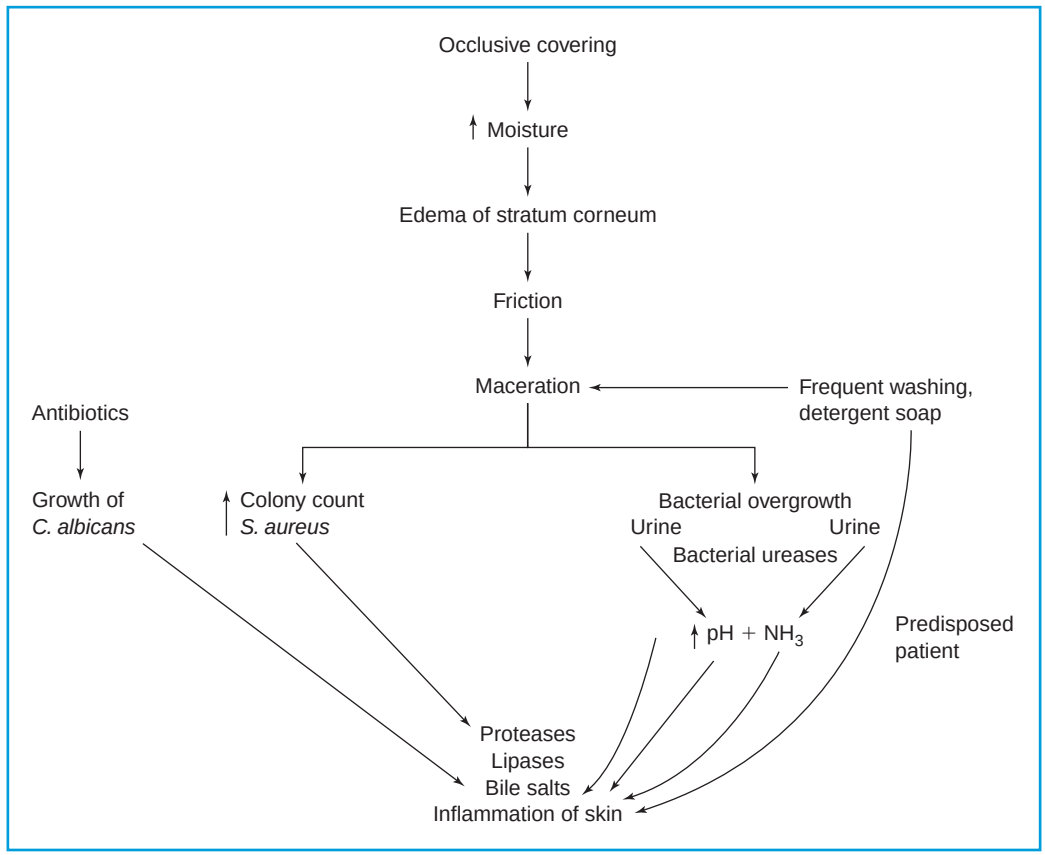

FIGURE 85.14 Proposed sequence of events producing skin inflammation in the diaper area.

surfaces of the genitalia and buttocks). The rash waxes and wanes and often has a shiny, glazed surface appearance. Occasionally, papules are associated with the rash. The second component, trapped moisture, causes the erythema and maceration that occurs in the intertriginous parts of the diaper area (inguinal, genital, intergluteal, and folds of the thighs). This problem is often associated with and precipitated by tightly applied diapers, commercial plastic diapers (especially those made with elastic edges to prevent leakage around the thighs), and rubber pants placed over cloth diapers. Such coverings increase friction and prevent the evaporation of moisture.

FIGURE 85.15 Infant with occlusion diaper dermatitis.

Atopic Dermatitis

The appearance of the rash in the diaper area is not different from occlusion dermatitis. It is, however, more chronic and difficult to treat. Examination may disclose lesions on other body surfaces (cheeks, antecubital and popliteal spaces) typical of atopic involvement, and a family history of atopy often exists.

Seborrheic Dermatitis

Generally, seborrheic dermatitis (Fig. 85.10) has an erythematous, salmon-colored base that is covered with yellow, greasy scaling. Similar involvement of other seborrheic locations such as the scalp, postauricular area, or other flexures helps establish the diagnosis. At times, a family history of seborrheic dermatitis exists.

Moniliasis

Moniliasis is the most characteristic of the diaper rashes. The skin in the diaper area has clusters of erythematous papules and pustules that coalesce into an intensely red confluent rash with sharp borders. Beyond these borders are satellite papules and pustules. At times, the infant has concomitant oral thrush. When the problem is chronic and recurrent, seeding from the GI tract or from a mother with monilial vaginitis should be considered.

On rare occasions an id reaction occurs (Fig. 85.16). Besides the primary monilial diaper rash lies an antigenic dissemination with involvement of the intertriginous areas and

FIGURE 85.16 Infant with monilial diaper dermatitis with id reaction.

scattered small patches or plaques of scaling erythema on other parts of the skin surface. Generally, *C. albicans* cannot be cultured from these plaques.

Mixed or Not Diagnosable Rash

Mixtures of the previous categories of diaper dermatitis are often found on infants. A diagnosis is often difficult to make. Secondary invasion with *C. albicans* is common as mentioned. The potential for secondary bacterial infection exists. If blistering occurs, *S. aureus* infection should be considered. Foul-smelling areas of maceration within skin folds may also indicate group A β-hemolytic streptococcal intertrigo.

Management

Treatment is determined by the cause of the dermatitis. In general, proper skin care, which includes decreased frequency of washing, use of mild soaps, and keeping the diaper off as much as possible, will help resolve diaper dermatitis resulting from any cause. With occlusive dermatitis, avoidance of tightly fitting diapers, plastic-covered paper diapers, and rubber pants is important. When atopic dermatitis is present, the use of topical steroids is necessary. It is important to avoid fluorinated or other potent steroids in the diaper area because occlusion by the diaper enhances the steroid effect and is more likely to produce skin atrophy and striae. The newer antifungal–steroid combinations should also be avoided for these same reasons. Therefore, 1% hydrocortisone cream no more than twice daily over a short period is recommended. Hydrocortisone (1%) is also effective for seborrheic diaper dermatitis and can be used intermittently.

With monilial diaper dermatitis, the use of preparations such as econazole, miconazole or nystatin twice daily is effective. If thrush is also present, oral nystatin suspension, 200,000 units (2 mL) four times a day for 7 days, is advisable. This medication will also be useful if the infant is seeding *C. albicans* from the GI tract onto the skin of the diaper area. Because another potential source of *C. albicans* is from a vaginal infection in the infant's mother, the mother should be questioned for this problem; if a vaginal discharge is present, it should be checked by a gynecologist and treated appropriately. Patients with id reactions, as described previously, require oral nystatin or econazole on the diaper and intertriginous areas and 1% hydrocortisone applied to the plaques. Resolution usually takes 7 to 10 days. Mycolog II® and Lotrisone® creams are recommended by many physicians for monilial diaper rashes; however, the clinician should be cognizant that these preparations contain a fluorinated steroid and have been associated with adrenal suppression when used in intertriginous areas. Secondarily infected dermatitis, such as bullous impetigo, should be treated with the appropriate systemic antibiotics.

Whether traditional diaper creams and ointments are effective is still unproven. Their ability to provide an effective barrier that reduces irritation remains to be established.

DRUG REACTIONS IN THE SKIN

Background

When a drug is being taken by a child, any reaction of the skin that is not expected should be considered a drug reaction until proven otherwise. Hospitalized patients are more likely (30%) to have a reaction to a drug because of multiple exposures. Approximately 2% to 3% of these inpatients have cutaneous reactions. The rate of adverse effects depends on the particular drug. Arndt et al. showed that reactions occur at the rate of 59 per 1,000 drug courses for trimethoprim-sulfamethoxazole, whereas with the use of chloral hydrate, only 0.2 skin reactions per 1,000 courses occurred. When considering all drugs, they found skin reactions at a rate of 3 per 1,000 courses of therapy. In general, antibiotics, anticonvulsants, and blood products were responsible for most reactions.

When considering penicillin and its derivatives alone, allergies to these substances affect 1% to 10% of the population. Fatal anaphylaxis occurs in approximately 2 of 100,000 patients taking penicillin. Penicillin reactions appear less often in children, as is the case with any drug reaction. An increased risk for the development of anaphylactic reactions to penicillin is present in atopic individuals.

Pathophysiology

The pathogenesis of such reactions can be on an immune or nonimmune basis. When occurring on an immune basis, any of the four types of immunologic mechanisms (IgE-mediated, immune complex, cytotoxic, cell-mediated) can be involved. However, reactions also occur on the basis of overdose, specific toxicity, common side effects of a particular drug, and unusual drug interactions. Pathogenic mechanisms in specific situations often cannot be identified.

TABLE 85.6

DRUGS COMMONLY ASSOCIATED WITH ALLERGIC SKIN REACTIONS

Trimethoprim-sulfamethoxazole
Ampicillin
Semisynthetic penicillins (carbenicillin, cloxacillin, dicloxacillin, methicillin, nafcillin, oxacillin)
Sulfisoxazole
Penicillin G
Gentamicin
Cephalosporins
Dipyrone
Nitrazepam
Anticonvulsants (phenytoin, barbiturates, carbamazepine)
Nitrofurantoin
Glutethimide
Indomethacin

Clinical Manifestations

The appearance of drug reactions is nonspecific and may mimic almost any known dermatosis. Therefore, the clinician cannot make a diagnosis of a drug reaction based on the appearance of the rash alone because the skin can react only in a limited number of ways to many different stimuli. However, certain patterns should raise suspicion of the presence of an adverse reaction.

Laboratory analysis is usually not helpful in the diagnosis of drug eruptions. Peripheral eosinophilia, believed to occur commonly with adverse drug reactions, is actually uncommon. Skin biopsy can be helpful.

Specific Reaction Patterns

Urticaria. Urticaria constitutes the most common expression of drug sensitivity. Most commonly, reactions occur within 1 week of drug exposure. When an individual is on multiple agents and has a reaction, the clinician should suspect those agents that were most recently introduced or those medications that are known to be commonly associated with drug reactions (Table 85.6). When questioning for the use of medications, it is important to ask not only about prescription items but also about over-the-counter preparations. Occasionally, patients who use aspirin, acetaminophen, laxatives, vitamins, or ear, nose, or eye drops do not consider these substances to be medications or drugs.

Maculopapular Eruptions Similar to Those of a Viral Exanthem. Maculopapular eruptions are the second most common of all drug-induced rashes and may be caused by many different agents. These eruptions are symmetric and consist of erythematous macules and papules with areas of confluence. Variable involvement of the palms, soles, and mucous membranes, as well as purpura, may occur. The presence and severity of pruritus are variable. Ampicillin is a medication often associated with this type of skin reaction, particularly in patients with infectious mononucleosis.

Erythema Multiforme. Erythema multiforme is an acute and often recurrent inflammatory syndrome often secondary to drugs, particularly antibiotics and anticonvulsants (e.g., penicillins, sulfonamides, hydantoins, barbiturates, lamotrigine), or infections. More recent observations suggest that a significant portion of idiopathic recurrent erythema multiforme cases is likely caused by HSV. The skin findings include macules, papules, vesicles, and pathognomonic target or iris lesions (Fig. 85.17) that tend to be more or less symmetrically distributed. Bullous lesions may also be present. In the more severe cases, constitutional symptoms occur; when mucous membranes are involved, the terms *erythema multiforme major* or *Stevens-Johnson syndrome* are used (Figs. 85.18 and 85.19, see also color plate). Erythema multiforme consists of two lesion types: macular–urticarial and vesicular–bullous. There is a predilection for the backs of the hands, palms, soles, and extensor surfaces of the limbs. The lesions may begin at these sites and then spread diffusely, or they may begin generalized. In 25% of the patients, the mucous membranes are involved and, in fact, can be the sole site of involvement. The usual sites of mucous membrane involvement are the lips, buccal mucosa, palate, conjunctivae, urethra, and vagina. With severe involvement, the pharyngeal, tracheobronchial, and esophageal mucous membranes are also affected. Less common sites are the anal and nasal mucosa. When the eyes are involved, there may be simple conjunctivitis, severe keratitis, or panophthalmitis. These changes may lead to blindness in 3% to 10% of these patients. Therefore, close attention to involvement of the eyes is necessary. Lesions may continue to erupt in crops for as long as 2 to 3 weeks. Again, drugs and certain infections, such as *Mycoplasma pneumoniae*, have been

FIGURE 85.17 Iris or target lesions pathognomonic of erythema multiforme.

FIGURE 85.18 Adolescent with Stevens-Johnson syndrome secondary to sulfonamides. Note the involvement of mucous membranes of the mouth.

associated with Stevens-Johnson syndrome. Death occurs in 3% to 15% of patients with erythema multiforme major. Patients with Stevens-Johnson syndrome may also progress to toxic epidermal necrolysis (TEN). Avoidance of etiologic drugs, treatment of underlying infections, and supportive care have been the mainstay of therapy. Systemic corticosteroids have a limited role if treatment can be started early in the course of the reaction but should not be prolonged beyond 1 week, particularly if no benefit is seen. However, case reports and case series have suggested that IV immune globulin may significantly decrease morbidity and shorten the course of this syndrome and may be considered if organ function (such as vision) is at risk.

Toxic Epidermal Necrolysis. Drug-induced TEN is a life-threatening eruption characterized by a rapidly progressive, tender, red skin areas and skin sloughing and must be differentiated from the illness known as *staphylococcal scalded skin syndrome* (SSSS), caused by a circulating staphylococcal exotoxin. If a child who has TEN has been taking drugs long term or shortly before onset of the rash, is older than 6 years, or has a mixed rash (i.e., areas with the appearance of erythema multiforme and TEN), a biopsy must be performed to distinguish between the two disorders. With drug-induced TEN, dermal–epidermal separation is visible on histologic examination. If epidermolytic toxin has been released by staphylococci, epidermal cleavage occurs in the granular layer (Fig. 85.20). With extensive exfoliation of skin, fluid and electrolyte disturbances may occur and the potential for bacterial sepsis is present. Again, case reports and case series have suggested that IV immune globulin may significantly decrease morbidity and shorten the course of this syndrome.

FIGURE 85.19 Same child as seen in Figure 85.18 with Stevens-Johnson syndrome secondary to sulfonamides. Note photo distribution of lesions.

Vasculitis. The classic lesions of vasculitis are palpable purpura. Although these lesions are characteristic, vasculitis may be manifest by erythematous macules, papules, urticaria, and hemorrhagic vesicles and bullae (Fig. 85.21, see also color plate). The diagnosis is made by a skin biopsy, which shows leukocytoclasis, endothelial cell necrosis, and destruction of dermal vessels.

Erythema Nodosum. The lesions of erythema nodosum appear as deep, tender, erythematous nodules or plaques of the extensor surfaces of the extremities (Fig. 85.22, see also color plate). They are believed to be hypersensitivity phenomena secondary to infections (e.g., streptococcal pharyngitis, tuberculosis, coccidioidomycosis, histoplasmosis), inflammatory bowel disease, sarcoidosis, malignancies, and occasionally, drugs. The exact immunologic mechanism has not been clarified.

Photosensitive Cutaneous Eruption. When a drug causes an exaggeration of the sunburn response, a phototoxic eruption should be considered. However, photoallergic eruptions usually do not occur on first exposure to a medication because immunologic induction must first occur. Because a hypersensitivity reaction is also involved, the eruption, although concentrated most heavily on sun-exposed areas, can also occur on non–sun-exposed areas. Tetracycline and sulfonamides can be involved in this reaction. Non-steroidal antiinflammatory agents and antifungals, such as voriconazole, may be associated with photosensitive eruptions (known as pseudoporphyria) in which blistering and skin fragility occur in photo-exposed areas.

Fixed Drug Eruption. Fixed drug eruption refers to a localized round or oval dermatitis that tends to recur at the same location each time there is exposure to the offending drug. The lesions are generally erythematous and may or may not contain vesicles. They disappear over 7 to 10 days after cessation of the drug, leaving various shades of postinflammatory hyperpigmentation in their place. The discoloration may persist for months or years. Initially, lesions are solitary but then can become multiple; they often involve the palms, soles, glans penis, and lips.

Management

Vital to the management of any suspected drug reaction is the identification and removal of the offending drug. Pruritus can be controlled with antihistamines, and open lesions are

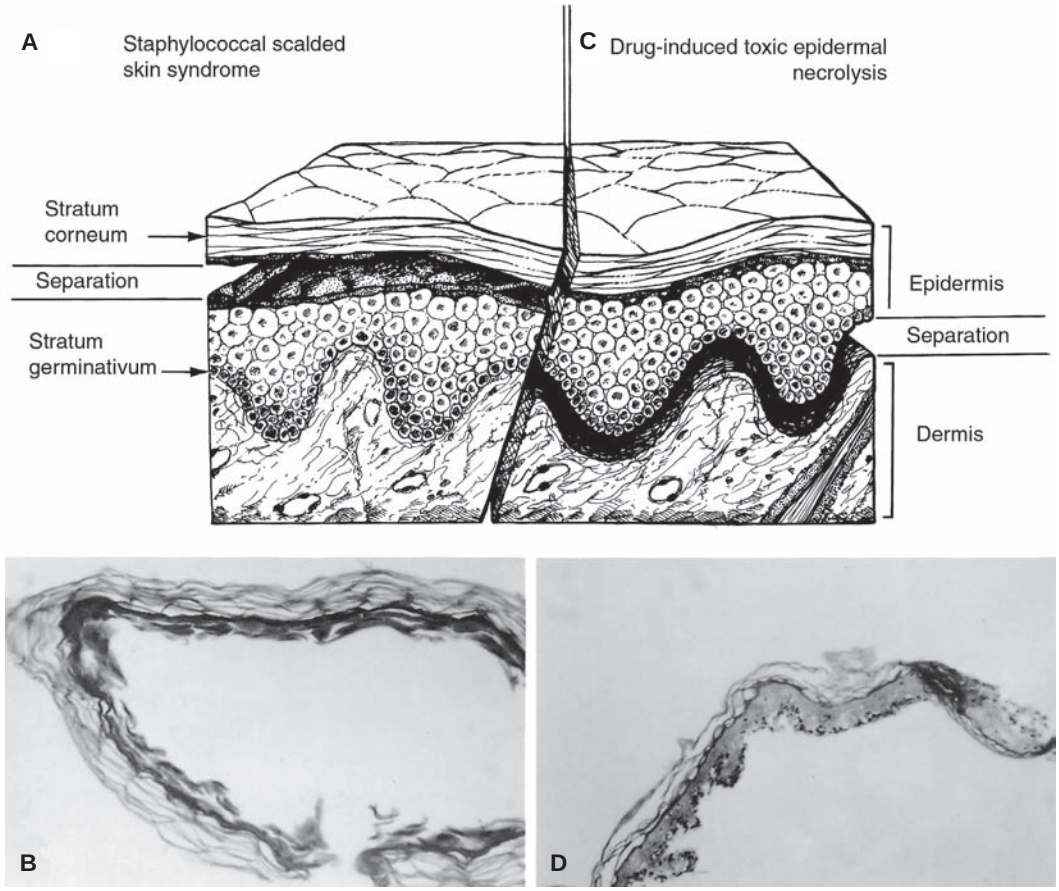

FIGURE 85.20 **A** and **B:** Pathology in staphylococcal scalded skin syndrome. **C** and **D:** Pathology in drug-induced toxic epidermal necrolysis.

responsive to compressing with Burow's solution and topical silver sulfadiazine. When extensive exfoliation occurs, attention to fluid and electrolyte balance and secondary infection is essential. Any patient with mucous membrane involvement should have an ophthalmologic examination to rule out the presence of corneal involvement. Hospitalization should be considered in any patient who has severe involvement of the skin, is toxic, or has extensive exfoliation.

The literature suggests that steroid therapy of Stevens-Johnson syndrome and drug-induced TEN is of no value, will prolong hospital stays, and may in fact be harmful. If used, steroids (i.e., an equivalent of prednisone 1 to 2 mg per kg per day) must be started within the first 2 days of the eruption to be effective. Progression of the reaction after 5 days of steroid therapy indicates that the medication is ineffective and should be discontinued. If skin denudation is greater than 20% of the child's body surface area, steroid therapy should be avoided. If denudation progresses to greater than 25% of body surface area, transfer to a burn unit should be considered. While the data are somewhat conflicting, recent investigations suggest

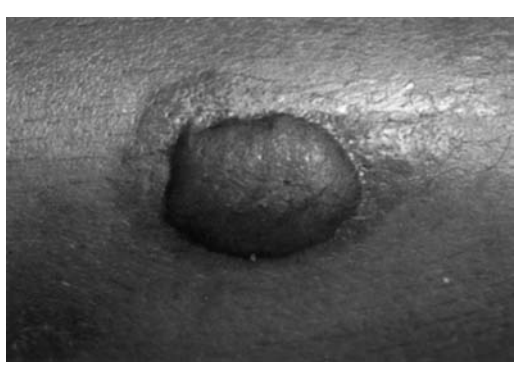

FIGURE 85.21 Hemorrhagic bulla in patient with vasculitis.

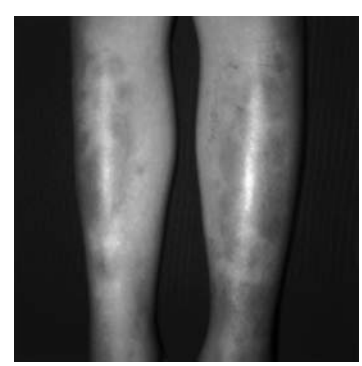

FIGURE 85.22 Extensor surface involved with lesions of erythema nodosum.

that the use of IV immunoglobulin with dose ranges from 0.25 to 0.75 gm per kg per day given over 3 to 5 days shows promise as a highly effective agent in the treatment of severe Stevens-Johnson syndrome and TEN.

STAPHYLOCOCCAL SCALDED SKIN SYNDROME

Background

The term *toxic epidermal necrolysis* has often been used indiscriminately. Because the gross dermatologic changes are the same despite different causes, this term should be used to indicate only the visible changes. In this way, the physician will approach patients with an open mind and be more likely to consider the alternative possibilities: although rare, a drug-induced TEN in children and bacteria-induced TEN in adults. Staphylococcus-induced disease, or the SSSS, is presented in this section. Included under the heading of staphylococcus-induced disease are bullous impetigo (staphylococcal pustulosis); in newborns, scarlatiniform rashes induced by *S. aureus*; and the generalized exfoliative syndrome caused by *S. aureus* seen in newborns (Ritter's disease) or in children (Lyell's syndrome).

Pathophysiology

The mechanism of these reactions was initially described by Mellish and Glasgow. They injected coagulase-positive phage group II staphylococci into newborn mice, producing erythema and a positive Nikolsky's sign (denudation of skin with gentle rubbing) in 12 to 16 hours, followed by bullae and extensive exfoliation in 16 to 20 hours. Since then, phage group I and III staphylococci have also been implicated. The cellular basis was later elucidated by Amagai et al. Staphylococcal toxins (exfoliative toxins A and B) specifically cleave the superficial epidermal cellular adhesion molecule desmoglein 1. The disease is believed to occur primarily in children because they lack antibodies against the organism and are unable to metabolize and excrete the toxin as do adults.

Clinical Manifestations

The illness begins with malaise, fever, and irritability. The irritability is often caused by significant tenderness of the skin when touched. Mothers will relate that their infant does not want to be held and cries when handled. This is followed by a "sunburn" erythema, which begins and is most intense around the neck, intertriginous areas, and periorifically (especially around the eyes and mouth). The erythema spreads to varying portions of the skin surface, and the child may be very toxic. With mild involvement of the skin, superficial desquamation (flaking) then follows similar to the reaction that occurs after ordinary sunburn (Fig. 85.23). With severe involvement, large sheets of skin shear away, leaving a denuded, oozing surface similar to the reaction that occurs after a burn (Fig. 85.24). The skin can often be rubbed off (Nikolsky's sign). Vesicles, pustules, and bullae can also occur during the exfoliative phase. Often, a purulent discharge emits from the eyes, but no

FIGURE 85.23 Desquamation of the skin of the face in the staphylococcal scalded skin syndrome.

TABLE 85.7

TOXIC SHOCK SYNDROME

Fever
Toxic epidermal necrolysis-like rash
Desquamation (after 10 days)
Hypotension
Vomiting/diarrhea
Hyperemia of the mucous membranes
Sterile pyuria
Elevated bilirubin and enzyme levels
Low platelet count
Disorientation or alteration in consciousness

conjunctival injection is present. Mucous membranes are not involved. Most children do well, and clearing of the skin occurs in 12 to 14 days, leaving no residua.

Complete blood cell count and urinalysis are not helpful in the evaluation of such children. Although blood cultures should be performed, they are usually negative, as are cultures of intact vesicles or bullae. At times, *S. aureus* can be grown from exfoliating skin, the umbilicus, circumcision wounds, throat, eyes, ears, nose, or rectum. Histologic examination of the skin distinguishes between changes caused by staphylococci or a drug. In SSSS, skin clippings or a shave or punch biopsy will show separation of the superficial layer of the epidermis subcorneally (Fig. 85.20A and 85.20B). Patients who have drug-induced TEN will have dermal–epidermal separation (Fig. 85.20C and 85.20D). Children who are taking medications long term or shortly before the eruption of the rash, children older than 6 years, or children with a mixed rash (i.e., areas of TEN and erythema multiforme) should have a skin biopsy taken for differentiation.

Toxic shock syndrome (secondary to staphylococci and streptococci) has also been characterized (Table 85.7).

Causes other than *S. aureus* or drugs may produce a similar clinical picture of toxic erythema. These conditions include certain fumigants, lymphomas, aspergillosis, irradiation, and graft-versus-host reaction.

Management

Most of the time, SSSS is a self-limited disorder. Antibiotics probably ameliorate the course of the disease, but steroids have no beneficial effects. In fact, steroids may exacerbate the dermatitis by increasing the ability of the organisms to proliferate and produce greater amounts of epidermolytic toxin.

Neonates and children younger than 1 year should be admitted to the hospital and started on IV antistaphylococcal antibiotics (cefazolin, oxacillin) after blood cultures are obtained. The addition of IV clindamycin because of its effects on bacterial ribosome metabolism should also be considered to help decrease production of bacterial toxin in ill patients. In addition, any older child who is toxic or who has severe skin involvement with significant denudation should be admitted. Close attention should be paid to the child's state of hydration and electrolyte imbalances when a significant amount of skin is lost. Secondary infection, similar to a patient with a major burn, is an important consideration.

Older children with mild involvement limited to dry desquamation, who are not toxic, can be managed on an outpatient basis. Depending on local bacterial antibiotic sensitivity profiles, these children can be started on oral dicloxacillin or erythromycin, cephalexin, clindamycin, or trimethoprim-sulfamethoxazole and followed closely. Skin care is nonspecific unless extensive denudation occurs, then the use of Silvadene® cream is warranted.

BITES AND INFESTATIONS (SEE ALSO CHAPTER 83)

Children are often bitten by insects (especially mosquitoes and fleas) and at times are infested by parasites. The papules, urticaria, blisters, and hemorrhagic lesions produced are commonly misdiagnosed. The season of the year, area of the country, grouping and appearance (central punctum) of the lesions, and distribution on exposed surfaces provide the clues necessary for diagnosis.

Mosquitoes and Fleas

Mosquitoes are probably the most common cause of insect bites in children, followed closely by fleas (Fig. 85.25). Bedbugs have also become more common in various parts of the country. Mosquito bites are generally limited to the warm months of the year. In contrast, fleabites, which predominate from spring to fall, can also occur during the winter months as a result of cats and dogs living indoors. At times, fleabites occur without an animal living in the household. Generally, the clinician should ask for a history of visits to a household that has pets or whether the patient's family has recently moved into a home in which the prior owners had pets. In the latter situation, fleas can live in carpeting for a long time.

The distribution of lesions is a valuable clue in making the diagnosis of mosquito or fleabites. Insect bites generally involve the exposed surfaces of the head, face, and extremities. The lesions are usually urticarial wheals that occur in groups or along a line on which the insect was crawling. Some lesions may manifest a central punctum. On occasion, both mosquito bites and fleabites can cause blistering lesions. These lesions are not caused by secondary infection but rather by a violent

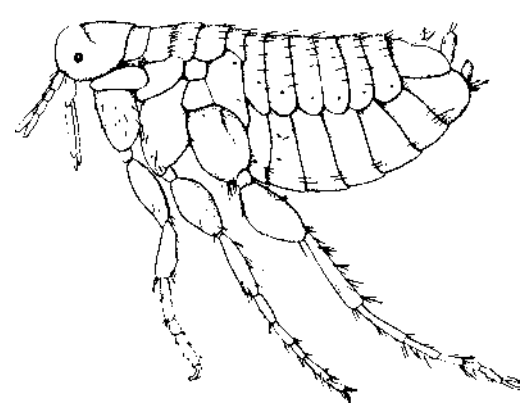

FIGURE 85.25 Flea (*Pulex irritans*).

immune response to the bite. Certainly, excoriation with resulting secondary infection with *S. aureus* or group A streptococci can complicate a simple bite.

A recurrent papular eruption called papular urticaria can occur in young children who become sensitized to insect bites. Although the lesions tend to occur on exposed parts of the body, with sensitization, they may appear at sites distant from the primary bite.

Unfortunately, no specific treatment exists for insect bites. Antihistamines, calamine lotion, or topical steroids have a limited or temporary effect. Prevention through the prophylactic use of insect repellents offers the best solution. Obviously, elimination of the biting insects by treatment of the homes with insecticides or treatment of the infested animals is important.

Tick Bites

Tick bites usually cause only local reactions. Rarely, they are associated with significant systemic illness, including Rocky Mountain spotted fever, tick paralysis, and Lyme arthritis.

When ticks are removed, it is important not to leave fragments of the mouthparts in the skin or to introduce body fluids containing infectious organisms. Various methods have been recommended for removal of ticks from the skin. The only safe method is to use a blunt curved forceps, tweezers, or fingers protected by rubber gloves. The tick is grasped close to the skin surface and pulled upward with a steady even force. The tick must not be squeezed, crushed, or punctured. If mouthparts are left in the skin, they should be removed.

Spider Bites

Loxosceles reclusus, or the brown recluse spider (Fig. 85.26), found most commonly in the south central United States (from southeastern Nebraska through Texas, east through southern Ohio and Georgia), is responsible for most skin reactions caused by the bite of a spider. This spider is small, the body being only 8 to 10 mm long, and bears a violin-shaped band over the dorsal cephalothorax. The venom contains necrotizing, hemolytic, and spreading factors.

The initial symptoms include mild stinging and/or pruritus. A hemorrhagic blister then appears, which can develop into a gangrenous eschar. Severe bites can cause a generalized erythematous macular eruption, nausea, vomiting, chills, malaise, muscle aches, and hemolysis. Treatment includes oral steroids within 6 to 12 hours after the bite, antibiotics to prevent secondary infection, the use of dapsone in selected cases, and surgical removal of the necrotic area to prevent spread of the toxin. An antivenom has been developed at the Vanderbilt School of Medicine.

Scabies Infestation

The cardinal symptom of any infestation with scabies is pruritus. Infants and children excoriate themselves to the point of bleeding. Two clues should be considered when attempting to make this diagnosis: (i) distribution (concentration on the hands, feet, and folds of the body, especially the finger webs, and genital areas) and (ii) involvement of other family members. It is important not only to ask other family members if they have pruritus but also to examine their skin. In contrast to adults, infants may develop blisters and exhibit lesions on the head and face.

The diagnosis is made by scraping involved skin and looking for mites under the 10× microscope objective (Fig. 85.27). The materials necessary to examine the skin for scabies are a glass slide, immersion or mineral oil, and no. 15 scalpel blade. A drop of mineral or immersion oil should be placed on the glass slide, and the no. 15 blade edge should be dipped into this oil. The best areas to scrape are the interdigital webs of the hands or tiny linear lesions that represent burrows caused by the mite. One procedure that may accentuate burrows involves the use of fountain pen ink applied to the suspected area of skin. After the surface ink is cleaned away, the mite burrows can be identified by means of the ink that has trickled into them. Also, local magnification with a dermatoscope or other magnifier may reveal the presence of air bubbles within burrows, which indicates the presence of live mites.

Once an infestation occurs, it usually takes 1 month for sensitization and pruritus to develop. The introduction of 5% permethrin cream (Elimite®) has obviated the need for lindane

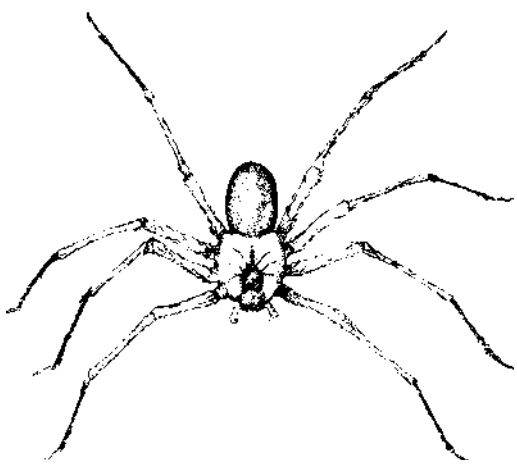

FIGURE 85.26 Brown recluse spider (*Loxosceles reclusus*).

FIGURE 85.27 Mite that causes scabies (*Sarcoptes scabiei*).

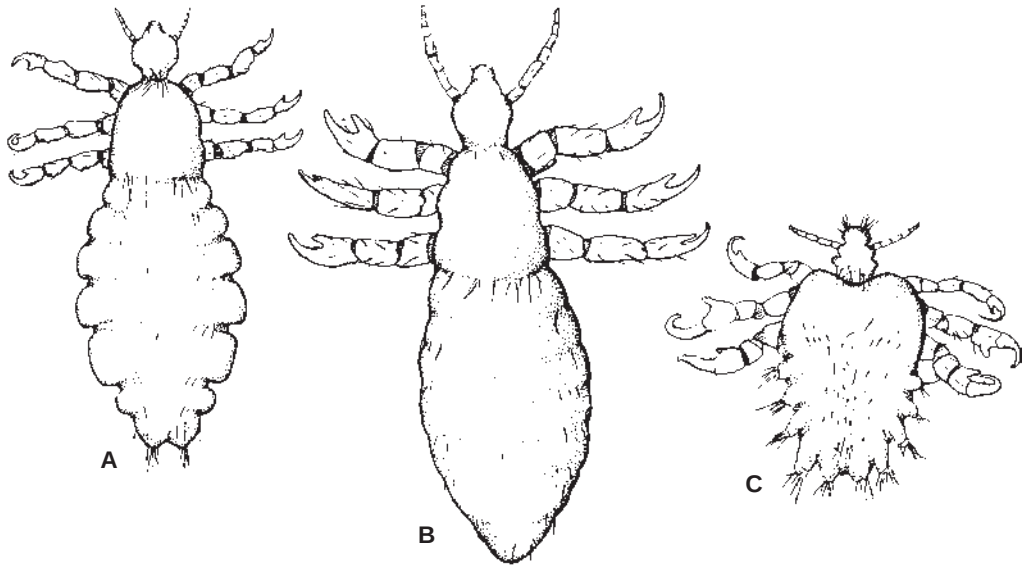

FIGURE 85.28 **A:** Head louse (*Pediculus humanus* var. *capitis*). **B:** Body louse (*Pediculus humanus* var. *corporis*). **C:** Pubic louse (*Phthirus pubis*).

and its potential toxicity. This cream should be applied from head to toe and left on for 8 to 14 hours. The preparation is then washed off with soap and water. All family members and close contacts (e.g., babysitters, grandparents) should be treated simultaneously. The safety of permethrin for use in pregnant women and very young infants has not been proven; these patients alternatively can be treated for four consecutive nights with precipitated sulfur (4%) compounded in petrolatum. The treatment should be repeated once 7 to 10 days later to eliminate any hatched eggs.

Louse Infestation

Three forms of lice infest humans: (i) the head louse, (ii) the body louse, and (iii) the pubic or crab louse (Fig. 85.28). The major louse infestation in children involves the scalp and causes pruritus. The female attaches her eggs to the hair shaft. The egg then hatches, leaving behind numerous nits (Fig. 85.29) that resemble dandruff. Secondary infection can occur from vigorous scratching. Body lice generally reside in the seams of clothing and lay their eggs there. They go to the body to feed, particularly the interscapular, shoulder, and waist areas. Red pruritic puncta that become papular and wheal-like then occur. Pubic lice occur in the genital area, lower abdomen, axillae, and eyelashes. Transmission is usually venereal. Blue macules (maculae caeruleae) that are 3 to 15 mm in diameter can be seen on the thighs, abdomen, or thorax of infested persons. These macules are secondary to bites.

Because the body louse resides in clothing, therapy consists mainly of disinfecting the clothing with steam under pressure. Pediculosis capitis is effectively treated with 1% permethrin or pyrethrin creme rinse (Nix®, Rid®, A-200®). The patient's hair should be shampooed, rinsed, and toweled dry. Enough medication to saturate the hair and scalp is applied. The medication is washed out after 10 minutes. Malathion has also been recently made available again for the treatment of head lice. This agent is quite effective but carries the risks of flammability and potential toxicity of an organophosphate compound. Patients with resistant disease may also respond to topical petrolatum applied to hair and scalp nightly for 1 week as a lice suffocant or trimethoprim-sulfamethoxazole given for 5 to 7 days, which kills the symbiotic parasite present in the GI tract of head lice. Pediculosis pubis is best treated with the same permethrin or pyrethrin preparations used for head lice. Any nits are removed with a fine-toothed comb. The safest treatment for lice in the eyelashes is the application of Vaseline® twice daily for 8 days. The lice stick to the Vaseline®, cannot feed, and die. Another treatment alternative is physostigmine ophthalmic ointment, although it may carry more significant toxicity.

FIGURE 85.29 Nits in the hair of a child with head lice.

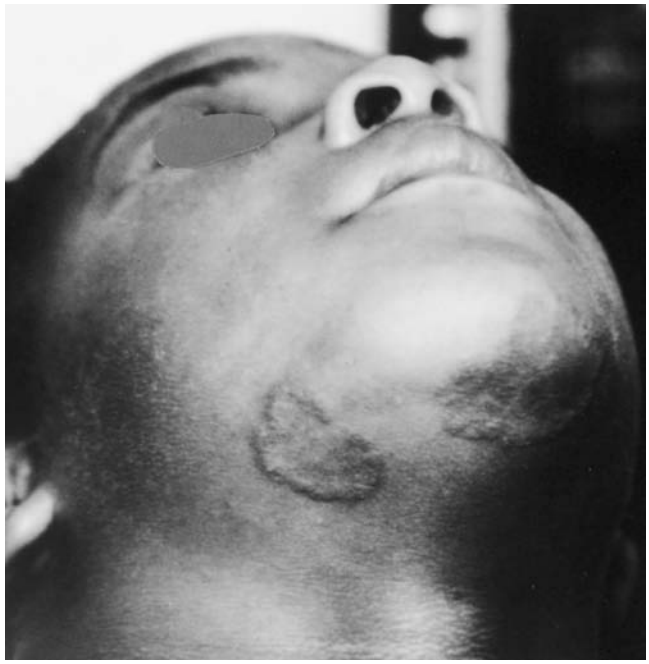

FIGURE 85.30 Child with tinea corporis.

SUPERFICIAL FUNGAL INFECTIONS OF THE SKIN

Tinea Corporis

Tinea corporis (Fig. 85.30) is characterized by one or more sharply circumscribed scaly patches. The center of the circular patch generally clears as the leading edge spreads out. The leading edge may be composed of papules, vesicles, or pustules. The lesions are most commonly confused with nummular eczema. The diagnosis can be made by scraping the active outer rim of papules and examining the scales with a potassium hydroxide (KOH) preparation under the microscope (Fig. 85.31). These lesions do not fluoresce under the Wood's light. The most common offending fungi are *Trichophyton* species (tonsurans, rubrum, mentagrophytes) and *Microsporum canis*. Treatment with topical antifungal agents such as clotrimazole, miconazole, econazole, terbinafine, and butenafine produces clearing in 7 to 10 days. Therapy should be maintained for at least 2 weeks. If improvement does not occur, treatment with griseofulvin (15 to 20 mg per kg per day in two divided doses) will usually resolve the problem.

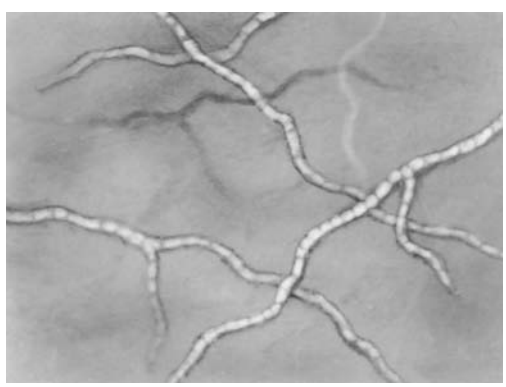

FIGURE 85.31 Characterization of a positive potassium hydroxide preparation demonstrating branching hyphae running across the microscope field.

TABLE 85.8

TINEA CAPITIS *MICROSPORUM* SPECIES

Round patches of scaling alopecia
Fluoresce blue-green
Kerion formation

Tinea Capitis

Although tinea capitis was commonly caused by the *Microsporum* species in the past, it usually results now from infection by *Trichophyton tonsurans*. The two forms have different clinical appearances. The *Microsporum* species (Table 85.8) generally causes round patches of scaling alopecia (Fig. 85.32). Illumination of a lesion with a Wood's lamp gives a blue-green fluorescence. Kerion formation can occur as a swollen, boggy abscess. The *Trichophyton* species (Table 85.9) usually causes scattered alopecia with seborrheic-like scaling, not always oval or rounded; the alopecia is irregular in outline with indistinct margins. Normal hairs grow within the patches

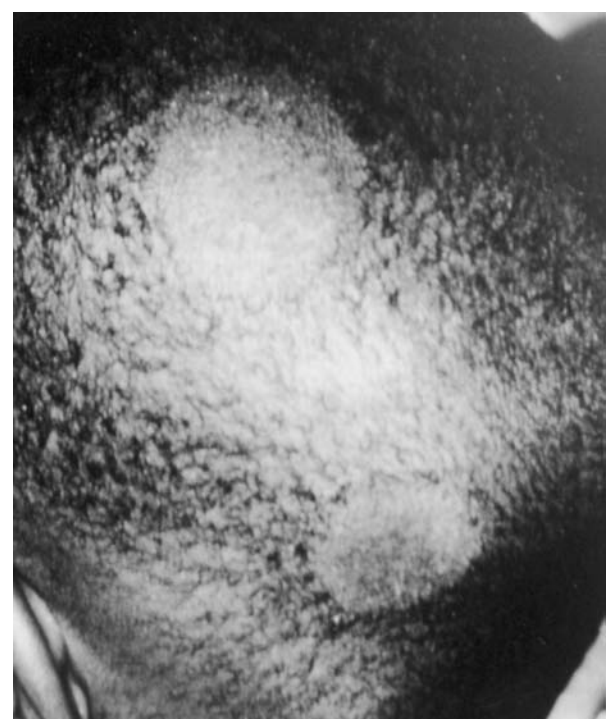

FIGURE 85.32 Tinea capitis secondary to infection with *Microsporum audouinii*.

TABLE 85.9

TINEA CAPITIS *TRICHOPHYTON* SPECIES

Black dots, diffuse scaling (dandruff)
Nonfluorescent
Folliculitis, suppuration, kerion formation

of alopecia. At times, the hairs break off at the surface of the scalp, leaving a "black dot" appearance (Fig. 85.33). Diffuse scaling may simulate dandruff, and although minimal hair loss is present, it is not perceived. Wood's light examination of lesions caused by *Trichophyton* species does not produce fluorescence. The organism can cause a folliculitis, suppuration, and kerion formation (Fig. 85.34). Diagnosis is made by culturing the affected scalp area (Fig. 85.35). The clinician should consider the presence of tinea capitis when a nonresponsive seborrheic or atopic dermatitis of the scalp is present, black dots are seen, or increased scaling follows the use of topical steroids. With the use of dermatophyte test media, a color change occurs in the media (yellow to red) in the presence of a growing dermatophyte. If a kerion is present, the swelling (allergic reaction to the fungus) can be controlled by a combination of griseofulvin and prednisone.

In the differential diagnosis of patchy hair loss, as is seen in tinea capitis, the clinician should consider alopecia areata (Fig. 85.36). However, with alopecia areata, no inflammation or scaling of the scalp occurs. *Trichotillomania* (also *trichotillosis*), the term given to the habit children develop of rubbing, twirling, or playing with their hair to the point that the hair breaks and is lost in irregular sometimes geometric patches, should also be considered. Hairs are characteristically of different length within the affected area, indicating breakage at different times. In addition, there is no scaling or inflammation typically seen. Traction alopecia occurs with certain hairstyles. Hair is lost at the margins of the hairline with the ponytail style or frequent use of hair rollers. Tight braiding or cornrowing can cause hair loss on any area of the scalp. At times, papules or pustules occur where the skin has been disrupted by the traction. Infants who

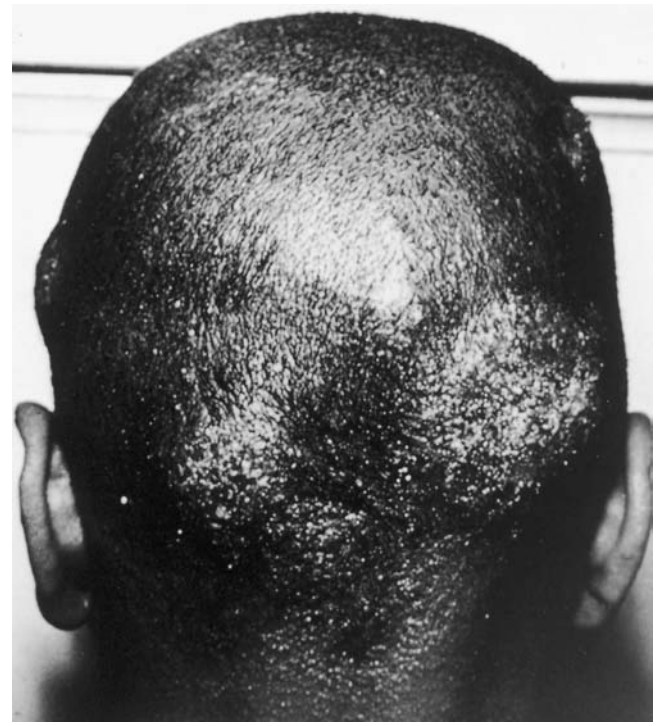

FIGURE 85.34 Patient with tinea capitis and multiple kerions.

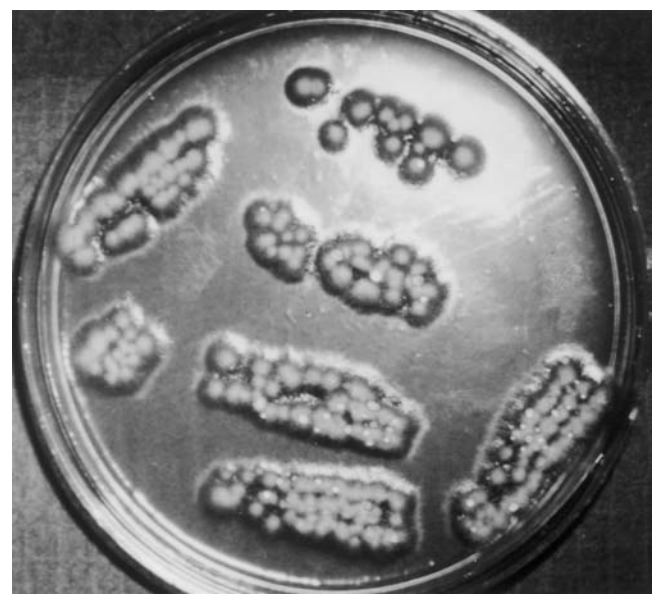

FIGURE 85.35 Toothbrush implants of scalp brushing that are growing fungus.

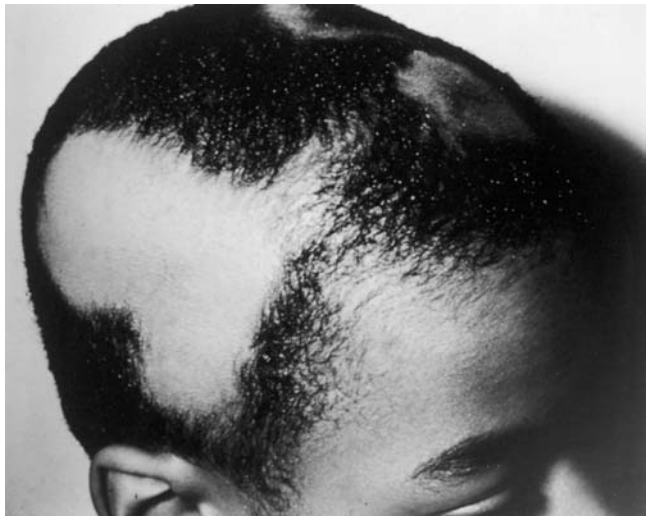

FIGURE 85.36 Child with alopecia areata.

are left on their backs for long periods may lose hair at the occiput from the constant friction in that area.

Treatment for tinea capitis consists of orally administered griseofulvin 15 to 20 mg per kg per day in two divided doses with a glass of whole milk or fatty food for 6 to 8 weeks. Adjunctive therapy includes the use of 2.5% selenium sulfide shampoo twice weekly. With the use of this shampoo, shedding of spores is decreased within 1 to 2 weeks. Terbinafine granules (5 to 8 mg per kg per day) have been approved by the U.S. FDA for use in tinea capitis, and this medication shows good efficacy, particularly for tinea capitis and can be used from 2 to 4 weeks. Fluconazole has been used for tinea capitis as well but has shown suboptimal efficacy rates.

Tinea Cruris

Tinea cruris begins as a small, red, scaling rash in the groin that spreads peripherally and clears centrally. The edges are sharply marginated and scalloped, extending down the thighs. Generally, the scrotum is not noticeably involved. This fungal infection is most common in semitropical regions where heat and high humidity are prevalent. Tight-fitting clothes also contribute to the problem by preventing evaporation. Other conditions to consider are seborrheic dermatitis (which usually can be differentiated by involvement of other areas of the body such as the ears, scalp, and eyelids), intertrigo (generally secondary to friction and maceration), contact dermatitis, candidiasis (which usually involves the inner thigh and causes the scrotum to appear bright red), and erythrasma (which will fluoresce under Woods' lamp). The clinician should always check the feet to ensure there is not fungal involvement in that area as well. In general, this condition affects only postpubertal children. Diagnosis is made by KOH preparation. Nonspecific measures for treatment include loose-fitting clothing, reducing the amount of perspiration by using dusting powders, and decreasing intake of caffeine-containing foods. Clotrimazole, miconazole, tolnaftate, and econazole are useful as topical antifungal agents. Oral griseofulvin may be needed in severe cases. Again, commercially available compounded agents such as Mycolog II® and Lotrisone®, which include potent topical steroids, should be avoided in the intertriginous areas because of the risk of atrophy and HPA axis suppression.

Tinea Pedis

Tinea pedis is generally caused by *Trichophyton rubrum* or *Trichophyton mentagrophytes*. It occurs most commonly in postpubertal children. The cracking and peeling of the skin suggestive of tinea pedis in prepubertal children more often indicates the presence of atopic eczema or hyperhidrosis. Tinea pedis is a penalty of civilization in that it occurs primarily in those individuals who wear shoes. KOH preparation will demonstrate hyphae, especially when samples are taken from between the fourth and fifth interspaces of the toes. Clinically, the skin has a dry, white, hazy appearance and is often pruritic. When secondary bacterial infection is present, an odor occurs. At times, an inflammatory lesion (caused by *T. mentagrophytes*) causes blistering. The presence of an id reaction indicates dissemination of antigen to other parts of the body, especially the hands.

The differential diagnosis of tinea pedis includes simple maceration, contact dermatitis, and atopic eczema. Treatment consists of drying the feet thoroughly after washing; wearing dry, clean socks; avoiding caffeine-containing foods to decrease sweating; keeping shoes off as much as possible; and walking barefoot or in sandals. Topical antifungal agents (see "Tinea Cruris" section) and/or oral griseofulvin are used to treat this condition. Newer medications (see "Tinea Capitis" section) are being used for this problem with increasing frequency.

Tinea Versicolor

Tinea versicolor refers to a superficial infection of the skin caused by *Malassezia furfur,* which produces color changes of the skin, hypopigmentation, hyperpigmentation, and sometimes a salmon-colored redness (Fig. 85.37). Wood's light examination usually shows yellowish brown fluorescence. Because moisture promotes growth of the organism, exacerbations occur in warm weather or in athletes who sweat excessively. The infection is difficult to eradicate and recurs frequently. A KOH preparation

FIGURE 85.37 Adolescent with tinea versicolor.

shows short, stubby hyphae and large clusters of spores, often referred to as "spaghetti and meatballs."

Treatment consists of lathering the entire body with selenium sulfide shampoo (2.5% concentration) or ketoconazole shampoo after wetting the skin surface in a shower. The lather is left on for 20 minutes and is then showered off. This procedure is carried out daily during the first week, with decreasing frequency over the ensuing weeks. Maintenance therapy once weekly throughout the summer or warmer seasons is advisable because of the high incidence of recurrence. Localized areas of involvement can be treated with topical antifungal agents (e.g., econazole, ketoconazole topically). Adolescents can be treated with 400 mg of ketoconazole given as a single oral dose and then 200 mg at monthly intervals during the warm summer months or during a sports season when the patient sweats frequently. Because tinea versicolor tends to be a recurrent problem, retreatment in subsequent years may be necessary.

VASCULAR LESIONS

Pyogenic Granulomas

Pyogenic granulomas (Fig. 85.38A) are vascular nodules that develop rapidly at the site of an injury, such as a cut, scratch, insect bite, or burn. The histologic picture is that of proliferating capillaries in a loose stroma. Although this lesion was previously believed to be caused by infection of a small wound, the definite cause has not been established. Pyogenic granulomas occur commonly in children and young adults, usually on the fingers, face, hands, and forearms.

Clinically, the lesions are bright red to reddish brown or blue-black. The vascular nodules are pedunculated, ranging from 0.5 to 2 cm in size. Their surfaces are glistening, or raspberry-like, often becoming eroded and crusted. They bleed easily. Generally, they are asymptomatic. Because spontaneous disappearance is rare, the lesions must be removed by curettage, excision, electrosurgery, cryosurgery, laser surgery, or some combination of these various modalities.

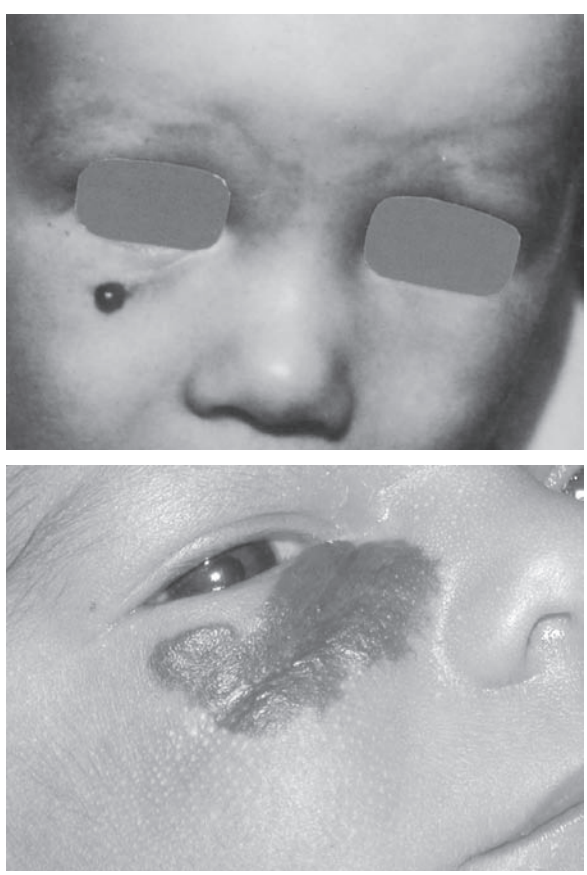

FIGURE 85.38 **A:** Pyogenic granuloma on the cheek of a child. **B:** Periocular hemangioma with risk of amblyopia.

Hemangiomas

Hemangiomas of infancy (infantile hemangiomas) represent benign vascular tumors that are present in approximately 3% of newborns and up to 10% of all infants. These are seen most frequently in premature and low-birth-weight infants and occur more commonly in girls (80%) than in boys. Superficial lesions possess a red color resembling a strawberry or raspberry. Deep lesions appear soft, compressible, and often are faintly bluish. Mixed lesions may show features of both superficial and deep hemangiomas. These lesions typically undergo a proliferative phase during the first 6 months, plateau in growth during the second 6 months, and then begin a slow process of involution. Although most lesions generally involute with little to no complications given time, certain hemangiomas pose potential risks based on their anatomic location.

Rapidly enlarging hemangiomas near the eyes (Fig. 85.38B) may result in amblyopia through obstruction of the visual axis (deprivation amblyopia) or because of the compression of the eyeball itself (strabismus or anisometropia) and require prompt intervention with systemic steroids or sometimes surgery. β-Blockers have recently been introduced in a small number of patients to treat severe hemangiomas of infancy with favorable responses. At present, limited data are available; so, caution should be taken particularly in light of potential complications such as bradycardia, hypotension, hypoglycemia, bronchospasm, and hypothermia. Hemangiomas in a "beard distribution"—around the mouth, preauricular areas, chin, or anterior neck—may indicate the presence of airway hemangiomas and warrant further evaluation by direct laryngobronchoscopy or radiologic imaging studies. Hemangiomas overlying the midline lower back may represent markers for spinal dysraphism or tethered cord syndrome and warrant imaging. Hemangiomas occurring in any area, but especially the oral or genital areas, may ulcerate and become secondarily infected, which may result in permanent scarring. Treatment with topical or oral antibiotics with nonadherent dressings can be helpful in managing these cases. Some may require treatment with a pulsed dye laser. Pain may also be an issue for these children. Finally, large, segmental facial hemangiomas have been associated with PHACE(S) syndrome, in which children suffer from posterior fossa malformations, arterial anomalies including coarctation of the aorta, structural cardiac malformations, endocrinologic and structural eye abnormalities, and midline sternal defects or supraumbilical raphe (Table 85.10). Intracranial vascular anomalies may predispose this subset of these children to an increased risk for stroke.

TABLE 85.10

COMPLICATIONS RELATED TO HEMANGIOMAS

Anatomic location	Associated complication
Periocular	Amblyopia
Beard area	Airway involvement
Midline prevertebral	Tethered cord syndrome; spinal dysraphism
Genital area	Ulceration
Large, facial lesion	PHACES (posterior fossa malformation; large facial hemangioma; arterial anomalies; coarctation of the aorta or other cardiac malformation; eye abnormalities; midline sternal defects)

Some vascular tumors, including kaposiform hemangioendotheliomas and tufted angiomas, may resemble hemangiomas. These unusual vascular tumors may undergo sudden swelling with resulting hemolytic anemia, thrombocytopenia, and congestive heart failure, resulting in a life-threatening syndrome known as *Kasabach-Merritt phenomenon*. Patients with this syndrome may require high doses of systemic corticosteroid or other chemotherapeutic interventions to control these complications.

URTICARIA

Background

Urticaria as a symptom complex is often encountered in the pediatric population, occurring in 2% to 3% of all children. In most cases, no cause is identified. A small number of cases are caused by allergic reactions from the ingestion of drugs or foods (e.g., nuts, eggs, shellfish, strawberries). Urticaria also follows viral (e.g., Epstein-Barr virus, hepatitis), bacterial (streptococcal), or parasitic infections. Physical factors, including dermographism, cholinergic stimulation (induced by heat, exercise, and emotional tension), cold (acquired and familial), and solar exposure, can induce urticaria. Finally, urticaria may be caused by factors producing a vasculitis or other autoimmune phenomena (particularly thyroid diseases) and substances causing degranulation of mast cells (radiocontrast material). Episodes of urticaria that last less than 6 weeks are termed *transient* or *acute*. The most common causes of urticaria are infection, insect bites, drugs, and foods. Chronic urticaria is defined as that which lasts for more than 6 weeks. No cause is found in 90% of children. These cases include the physical urticarias or urticarial vasculitis.

Pathophysiology

The lesion itself follows vasodilation and leakage of fluid and red blood cells from involved vessels. The vascular damage can be caused by mediators such as histamine complement and immune complexes. IgE can attach to and cause degranulation of mast cells in sensitized individuals, with resulting histamine release. Urticarias are usually acute and transient but at times become chronic and recurrent.

Clinical Manifestations

The typical urticarial lesions are familiar to all physicians. They can be localized or generalized (involving the entire body). At times, the lesions are giant with serpiginous borders. Individual wheals rarely last more than 12 to 24 hours. Most commonly, the lesions appear in one area for 20 minutes to 3 hours, disappear, and then reappear in another location. The total duration of an episode is usually 24 to 48 hours; however, the course can last 3 to 6 weeks. In young children, urticaria may have an annular or polycyclic (coalescent annular) or arcuate (partially annular) appearance and may be associated with edema of the hands or feet. Because this is frequently confused with erythema multiforme (which manifest with more fixed, targetoid lesions), this annular urticarial hypersensitivity has sometimes been referred to as *urticaria multiforme*.

Management

Acute relief can be accomplished with intramuscular epinephrine (1:1,000) 0.01 mL per kg (max 0.3 mL) in severe cases and intramuscular or IV diphenhydramine 1 mg per kg (max 50 mg). Oral antihistamines are useful for maintenance therapy for transient urticaria. Hydroxyzine hydrochloride (2 mg per kg per day in three to four divided doses) or diphenhydramine hydrochloride (5 mg per kg per day in three to four divided doses) should be prescribed for at least 10 days. Other longer-acting antihistamines include loratadine, desloratadine, cetirizine, levocetirizine, and fexofenadine, which are typically given once daily.

PITYRIASIS ROSEA

Pityriasis rosea can occur in all age groups but is seen predominantly in children older than 10 years and only rarely in those younger than 5 years. The cause is unknown; however, a viral cause is suspected. Less than 5% of cases occur in multiple family members. In 80% of children, a large, oval, solitary lesion known as the *herald patch* appears on the trunk (Fig. 85.39) before the eruption of subsequent lesions. Individual lesions are oval and slightly raised, pink to brown, with peripheral scaling. Because the lesions follow the cleavage lines (Fig. 85.40) of the skin, the backs of patients have a "Christmas or fir tree" appearance. Generally, the face, the scalp, and distal extremities are spared. On occasion, an inverse distribution occurs (lesions on the face and extremities with truncal sparing). The rash is pruritic early in the course but then becomes asymptomatic. It generally lasts 4 to 8 weeks.

The herald patch can be mistaken for tinea corporis, but a KOH preparation eliminates that possibility. When pityriasis rosea appears in adolescence, it must be differentiated from secondary syphilis. Clinical clues are helpful (Table 85.11), but serologic testing is necessary.

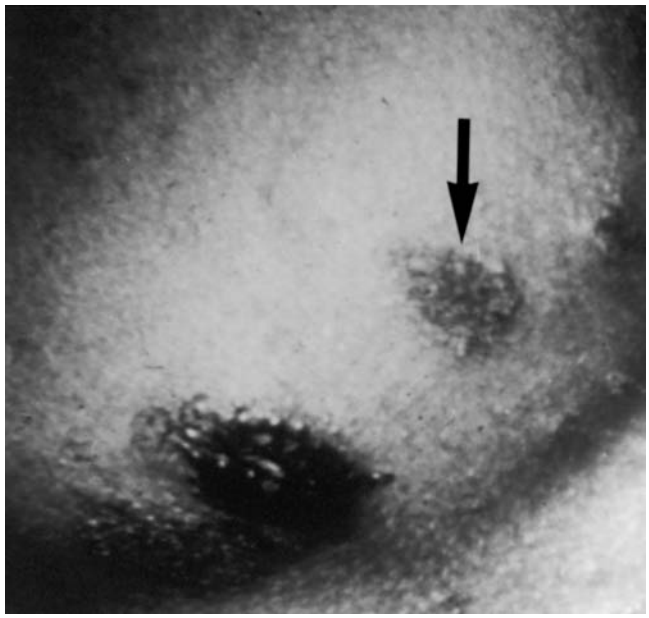

FIGURE 85.39 Herald patch (*arrow*) in adolescent with pityriasis rosea.

Treatment is symptomatic. Antihistamines and topical emollients can help alleviate the pruritus. Symptomatic patients may respond to a 14-day course of erythromycin or acyclovir to abbreviate the course of pityriasis rosea.

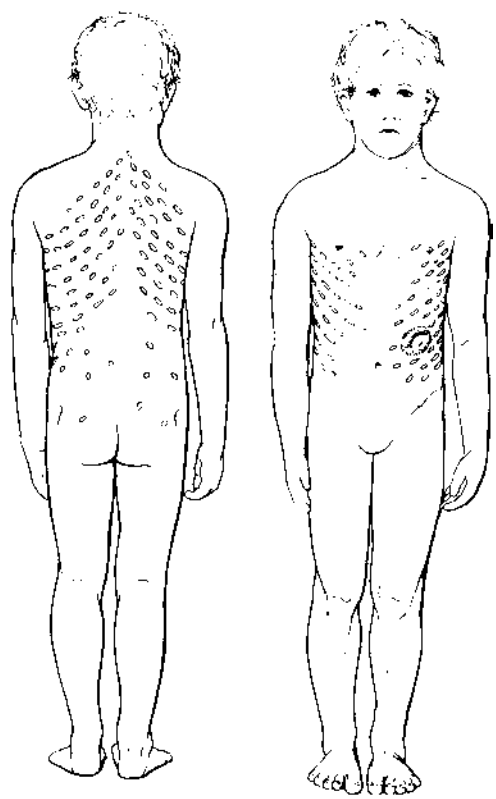

FIGURE 85.40 Typical distribution of pityriasis rosea.

TABLE 85.11

DIFFERENTIAL DIAGNOSIS

	Pityriasis rosea	Syphilis
Herald patch	+	–
Ovals follow dermatomes	+	–
Lymphadenopathy	–	+
Mucous membrane lesion	–	+

PANNICULITIS

Erythema Nodosum

Erythema nodosum seems to be a hypersensitivity reaction leading to inflammation of the subcutaneous fat and may be related to infection (streptococci, tuberculosis, coccidioidomycosis, histoplasmosis), inflammatory bowel disease, sarcoidosis, and drugs (such as oral contraceptive agents). The exact immunologic mechanism has not been clarified. The entity occurs predominantly in adolescents during the spring and fall. Women are affected more often than men.

The lesions of erythema nodosum appear as deep, tender, erythematous nodules or plaques on the extensor surfaces of the extremities (Fig. 85.22). The sedimentation rate is generally elevated and usually returns to normal with disappearance of the eruption, unless an underlying disease is present. The reaction usually lasts 3 to 6 weeks. Treatment should be directed toward the cause when and if established; otherwise, it is symptomatic (nonsteroidal antiinflammatory drugs and antihistamines). Hospitalization is unnecessary. Corticosteroids should not be used, except in severe cases after an underlying infection has been ruled out.

Cold Panniculitis

Cold panniculitis is secondary to cold injury to fat. During the cold of winter, infants and some older children develop red, indurated nodules and plaques on exposed skin, especially the face. The subcutaneous fat in infants and some children solidifies more readily at a higher temperature than that of an adult because of the relatively greater concentration of saturated fats. Infants who hold ice chips or popsicles in their mouths are also susceptible to this phenomenon (Fig. 85.41, see also color plate). The lesions gradually soften and return to normal over 1 or more weeks. Treatment is unnecessary.

WARTS AND MOLLUSCUM CONTAGIOSUM

Warts

Warts affect 7% to 10% of the population and are one of the most common dermatologic problems encountered in pediatrics. The peak incidence is during adolescence. Sixty-five percent of common warts disappear spontaneously within 2 years,

FIGURE 85.41 Infant with popsicle panniculitis of the cheek.

and 40% of plantar warts disappear within 6 months in prepubertal children. However, immunosuppressed patients may experience extensive spread of the lesions.

The common wart resembles a tiny cauliflower. Lesions disrupt the natural skin lines and may also manifest with small black dots, representing thrombosed capillaries. The shape of the wart varies with its location on the skin. They may be long and slender (filiform) on the face and neck or flat (verruca plana) on the face, arms, and knees. When located on the soles, they are called *plantar warts*, and when in the anogenital area, they are referred to as *condyloma acuminata*.

The tendency for recurrence of warts makes the treatment of this condition frustrating. Because most warts disappear spontaneously with time, procedures that are least traumatic for the child should be attempted first (Table 85.12). The simple, nontraumatic method of airtight occlusion with plain adhesive tape or duct tape for 1 month has been shown to be successful on many occasions. Topical application of 17% salicylic acid in flexible collodion (Duofilm®; Table 85.13) is good for home use, as are some of the over-the-counter preparations (e.g., Compound W®, Occlusal®). When simple methods are unsuccessful, touching the warts with liquid nitrogen or volatile cryogens such as dimethyl ether, propane, or isobutane (Verruca-Freeze®) for 10 to 30 seconds or surgical removal can be attempted on a 2- to 4-week schedule until the lesions clear completely. Both procedures are painful.

Plantar warts can be treated with 40% salicylic acid plaster. Circular pieces, slightly larger than the plantar wart, are cut from a sheet of this material. They are placed on the wart and kept in place continuously with adhesive tape for 1 to 2 weeks. At that point, the dead tissue is carefully pared away.

TABLE 85.12

MANAGEMENT OF WARTS

Decrease irritation—cover with waterproof or duct tape (1 to 2 mo)
Over-the-counter preparations, such as Compound W® (1 mo)
Salicylic in collodion (Duofilm®) (1 mo)
Refer to dermatologist

TABLE 85.13

USE OF DUOFILM®

1. Soak wart for 5 min.
2. Dry.
3. Surround with petroleum jelly.
4. Apply Duofilm® (let dry for few minutes).
5. Cover with waterproof or duct tape.
6. Repeat twice a day.
7. Pare dead skin.

Treatment is continued until normal skin is seen in place of the wart.

Anogenital warts can be treated with 20% podophyllin. This medication is carefully applied only to the wart and washed off in 4 to 6 hours (see Chapter 90). Severe burning of the skin occurs if the material is not completely removed. Retreatment every 1 to 2 weeks should be done until the warts resolve. Alternatively, topical preparations such as podophyllotoxin gel (Condylox®) or imiquimod cream (Aldara®) may be used at home. Podophyllotoxin gel is applied on the condylomata three consecutive nights each week while imiquimod is used every other night three times weekly. Both agents may be used for up to 3 months or so or until the warts clear. Child abuse should be considered in any child with genital warts.

Molluscum Contagiosum

The lesion, produced by the common poxvirus, is a papule with a white center (Fig. 85.42). It occurs at any age during childhood. It is more common in swimmers and wrestlers. Patients with atopic eczema are especially susceptible. Most lesions resolve in 6 to 9 months, but some may persist for more than 3 years. Spread is by autoinoculation.

Lesions can be single or numerous and favor intertriginous areas such as the groin. They are usually 2 to 5 mm in diameter, but several can coalesce and form a lesion 1.5 cm in diameter. They may become inflamed, which sometimes heralds

FIGURE 85.42 Molluscum contagiosum. Papules with white centers that contain the virus.

spontaneous disappearance. At times, an eczematous reaction occurs around some lesions, and they can sometimes become secondarily infected.

Since spontaneous resolution is common, treatment if elected should be gentle. Removal of the white core will cure the lesion. This treatment can be performed by applying a local anesthetic cream (e.g. EMLA® or LMX-4®) under occlusion to the lesion 1 to 2 hours before treatment. This procedure will anesthetize the area and allow the physician to prick the skin open over the core with a 26-gauge needle, and squeeze the core out with a comedone extractor. Multiple light touches with liquid nitrogen can also be effective. With widespread lesions, nonpainful procedures are preferable as multiple painful treatments will cause great fear in the patient and make future visits to a physician difficult for the family. Application of 0.1% tretinoin cream one to two times daily may induce enough inflammation to hasten the host's immune response or cause extrusion of the central core but caution should be observed since tretinoin may exacerbate secondary eczematization around molluscum lesions. A dilute formulation of cantharidin, a natural toxin derived from the blister beetle, can be used successfully to treat molluscum. Cantharidin can be applied to individual molluscum lesions for 1 to 4 hours and then washed off. The medication is generally painless when applied but may result in subsequent blistering of treated areas and should be avoided on the face or genital areas.

CONGENITAL HSV

Congenital HSV infection encompasses a broad clinical spectrum ranging from localized cutaneous and mucosal lesions to life-threatening central nervous system and internal organ involvements. Studies have shown that the prevalence of HSV-2 infection has increased by 30% from 1976 to 1994. The greatest increases occurred in white teenagers and white women in their twenties. The risk of acquiring HSV during pregnancy was 2% in susceptible women. The risk of acquiring the infection is similar in each trimester. Less than 10% of those who were seropositive gave a history indicating genital herpes infection. Other patients noted nonspecific genital urinary symptoms such as dysuria, leukorrhea, hematuria, and pelvic pain. If seroconversion occurs in the mother before delivery, the risk to the infant is small. However, if a primary infection occurs shortly before labor, neonatal HSV infection can occur in up to 50% of newborns. Whereas most infections are transmitted by direct contact with the infected birth canal during the second stage of labor, some evidence supports transplacental infection of the fetus.

The incubation period of congenital HSV infections ranges from 2 to 30 days after exposure. Lesions present at birth or shortly thereafter have been explained by transplacental passage of the virus. The clinical manifestations of congenital HSV infection are diverse, but more than 50% of infected neonates present with external involvement. In vertex deliveries, the scalp is a common site for the vesicles. Conversely, infants delivered by breech often develop lesions of the buttocks and perianal area initially. The lesions are not unlike those seen in older children or adults in that they are grouped tense vesicles arising on an erythematous base that may evolve into frank erosions. However, the infection may present on the skin as individual vesicles, pustules, bullae, or denuded skin. Unfortunately, when infants have disease limited to the integument, HSV infection is often not considered as a possibility. Instead, these children are treated for "impetigo." The correct diagnosis may not be considered until constitutional symptoms such as fever, hypothermia, poor feeding, irritability, lethargy, and vomiting have appeared. By then, dissemination of the disease has occurred.

Diagnosis of congenital HSV infection should be suspected in any infant younger than 1 month who has a vesicular eruption on an erythematous base. A Tzanck preparation of the base of an unbroken vesicle is an easy and rapid diagnostic tool to aid in the recognition of this potentially lethal disease (Fig. 85.7). Giemsa, Papanicolaou, or hematoxylin-eosin stains of the smeared preparation of vesicles infected with HSV will reveal multinucleated giant cells, intranuclear inclusions, ballooning degeneration, or margination of nuclear chromatin. Rapid slide tests, using monoclonal antibodies, are also available for rapid diagnosis. Viral culture still remains the gold standard for proving that HSV is present, although many institutions are moving toward polymerase chain reaction–based systems.

The differential diagnosis of vesiculopustular lesions in the newborn includes bullous impetigo, congenital cutaneous candidiasis, congenital syphilis, neonatal pustular melanosis, and cytomegalovirus infection. Differentiation of these entities requires the use of Gram stains, KOH scrapings, serologic studies for syphilis, and appropriate cultures. Although many serologic tests are currently available to detect the presence of HSV antibodies, none of these studies is valuable in arriving at an early diagnosis of congenital infection. Direct culture of the herpes virus from a lesional vesicle takes 24 to 48 hours for identification.

All infants with suspected congenital HSV should be preferably treated with IV acyclovir. If not available, IV ganciclovir may also be used. Acyclovir should be given at a dosage of 60 mg per kg per day, divided every 8 hours (20 mg per kg per dose), in a 1- to 2-hour IV infusion.

DISORDERS OF PIGMENTATION

Hypopigmentation

A dominant form of partial albinism occurs in which localized areas of skin and hair are devoid of pigment. Ocular albinism is also seen. Two syndromes with albinism are Waardenberg's syndrome (white forelock, heterochromia of the iris, sensorineural hearing loss) and Chediak-Higashi syndrome (immunodeficiency, leukocytes with giant granules).

Loss of pigmentation can be a result of the absence of melanocytes as in vitiligo and halo nevi. Vitiligo is a symmetric, patchy loss of pigmentation. Hair located in areas of vitiligo is often white. Vitiligo can be associated with alopecia areata, pernicious anemia, Addison's disease, hypothyroidism, diabetes mellitus, hypoparathyroidism, and other endocrine disorders. Vitiligo and some of the diseases associated with it may be autoimmune disorders. Antibodies directed against melanocytes have been detected.

Suppression of melanocytic pigment production can cause loss of pigmentation as in postinflammatory hypopigmentation.

An example of this condition is the white patch of hypopigmentation and scaling often seen on the face, trunk, or extremities of children with atopic eczema. The ash-leaf macule is a flat, hypopigmented (whitish) spot that is present in more than 90% of patients with tuberous sclerosis. In white patients, they are more easily seen by shining a Wood's lamp on the skin.

Hyperpigmentation

Diffuse hyperpigmentation is associated with Addison's disease, acromegaly, and hemochromatosis.

Pigment deep in the dermis appears gray or blue at the surface of the skin. Mongolian blue spots are an example. The nevus of Ota is dermal pigment in the distribution of the ophthalmic branch of the fifth nerve; this pigmentation can also involve the sclera and palate.

Certain syndromes, including neurofibromatosis, are associated with pigmented skin lesions. Patients with this disease have café-au-lait spots, which are flat, nonpalpable, coffee-colored lesions of varying size and shape. When six or more lesions are present, greater than 0.5 cm in size, neurofibromatosis should be considered. The Peutz-Jeghers syndrome is a dominantly inherited condition that includes freckle-like lesions of the lips, nose, buccal mucosa, fingertips, and subungual areas associated with polyps in the small intestine, stomach, or colon. Melena and intussusception are the chief complications that may develop, usually in the second decade of life. Albright's syndrome should be suspected when unilateral café-au-lait spots with irregular borders occur in the lumbosacral area. Included in this syndrome are bony abnormalities and precocious puberty. Children who have large, swirling areas of pigmentation following lines of Blaschko (lines representing planes of cutaneous embryogenesis) may have forms of cutaneous mosaicism as can be seen in linear and whorled nevoid hypermelanosis.

Single or multiple red-brown papules or nodules occurring on the extremities or face of children may have a confusing tissue structure. Although the lesions are benign, they have commonly been misdiagnosed as malignant melanoma. Therefore, the name *benign juvenile melanoma* has been assigned to this condition. Other names include *Spitz tumors* or *spindle-cell epithelioid nevi*. True malignant melanomas are rare in children. They usually arise from congenital pigmented nevi.

CHAPTER 86 ■ ENDOCRINE EMERGENCIES

MICHAEL S.D. AGUS, MD

Because the symptoms and signs of endocrinologic disease are associated with a wide range of non-endocrinologic diseases, many endocrine conditions are not recognized in the emergency department (ED). However, to achieve a favorable outcome, endocrinologic causes should be included in the differential diagnosis of ill children and appropriate testing should be performed. In many cases, the results of specific diagnostic tests will not be available on an emergency basis, and management will have to be initiated based on a probable diagnosis. In this chapter, emphasis is placed on the clinical and laboratory findings that are helpful in recognizing endocrinologic emergencies and in effectively treating those emergencies. Table 86.1 summarizes the major clinical features, recommended investigations, and treatments of pediatric endocrine emergencies.

DIABETIC KETOACIDOSIS

Background

Severe ketoacidosis is a life-threatening complication of diabetes that is present in 20% to 40% of newly diagnosed type 1 (juvenile-onset) diabetic patients; it accounts for 65% of all admissions of diabetic patients younger than 19 years of age. The mortality rate for diabetic ketoacidosis (DKA) in children is 0.15%. Clinically significant cerebral edema is the most serious immediate risk to the child, occurring in 1% of cases, and it remains so during the first 24 hours of therapy, despite the more apparent issues of hypovolemia and acidosis. Reported mortality rates from cerebral edema are approximately 25%; however, 25% of survivors have significant morbidity. Characteristic biochemical findings of DKA include hyperglycemia and metabolic acidosis. DKA may be precipitated by acute infection, inadequate quantities of endogenous or exogenous insulin, or emotional factors. Recurrent or frequent episodes should lead to careful evaluation for this latter possibility. Nonketotic hyperosmolar coma, although rare in children, can be managed adequately using the principles outlined in the following sections.

Pathophysiology

Insulin deficiency initially leads to hyperglycemia that, once above the renal threshold of 180 mg per dL, leads to polyuria due to an osmotic diuresis. Without vigorous oral repletion at home, the child quickly becomes hypovolemic, prompting a stress response and elevations of the counterregulatory hormones glucagon, catecholamines, cortisol, and growth hormone. These hormonal changes produce significant insulin resistance that worsens the hyperglycemia, hypovolemia, and stress response, ultimately leading to further functional insulin deficiency to such a severe degree that adipose tissue is broken down in large quantities into free fatty acids, subsequently converted into ketoacids in the liver. Ketoacids readily dissociate in the blood to produce free hydrogen ions, and metabolic acidosis ensues. This reaction is partially compensated for by a respiratory alkalosis (hyperventilation), with a resultant lowering of P_{CO_2} and plasma bicarbonate (HCO_3^-).

Intracellular potassium is depleted because of transcellular shifts of this ion brought about by the exchange of potassium with excess free hydrogen ions and extracellular dehydration. Protein catabolism secondary to insulin deficiency causes a negative nitrogen balance and results in additional efflux of potassium from cells. The potassium is then lost in the urine during the osmotic diuresis. Volume depletion causes secondary hyperaldosteronism, which further promotes urinary potassium excretion. Thus, total body depletion of potassium occurs, although the plasma potassium concentration may not reflect the loss at the time of presentation.

Clinical Manifestations

In cases of new-onset diabetes, the child usually has a history of polyuria and polydipsia for a few days or weeks before the acute decompensation. In fact, autoimmune destruction of the pancreatic beta cells has been underway at that point for many months. A prolonged history of polyuria, or hyperglycemia without acidosis, should raise the possibility of type 2 diabetes, particularly in obese children from ethnic and racial minorities. Significant weight loss often occurs despite a vigorous appetite. In children known to have diabetes, the prodrome may be less than 24 hours and precipitated by an intercurrent illness, inappropriate sick day management, or omission of insulin doses. Patients may complain of nausea, vomiting, and abdominal pain, and the parents may have noticed increasing listlessness. Less than 2% of children are in coma at the time of hospital admission, although a higher percentage has an altered state of consciousness. The history and physical examination usually suggest the diagnosis; however, particularly in the patient with new-onset diabetes, presenting clinical features can be misdiagnosed, especially in the infant or young child. For example, abdominal pain may be misinterpreted as appendicitis; hyperpnea may be mistaken as a sign of pneumonia or asthma; and polyuria may be incorrectly diagnosed as a urinary infection. Enuresis, polydipsia, and irritability are sometimes wrongly categorized as behavioral problems.

On physical examination, particular attention should be paid to the degree of dehydration, including skin turgor and

TABLE 86.1

SUMMARY OF CLINICAL FEATURES, INVESTIGATIONS, AND INITIAL TREATMENT OF PEDIATRIC ENDOCRINE EMERGENCIES

Condition	Major clinical features	Urgent investigations	Initial treatment
Diabetic ketoacidosis	Polyuria, polydipsia, dehydration, ketotic breath, hyperpnea, nausea, vomiting, abdominal pain, coma	Blood glucose, pH	0.9% saline 10–20 mL/kg in first 1–2 h IV; insulin infusion 0.1 Unit/kg/h; later, may need KAcetate 10–60 mEq/L and KPhos; 10–20 mEq/L
Hypoglycemia	*Older child:* hunger, sweatiness, dizziness, convulsions, coma *Neonate:* apnea, hypotonia, hypothermia, irritability, tremor, convulsions	Blood glucose Serum for growth hormone, cortisol, insulin; first voided urine for organic acids and toxin screen	25% dextrose 1–2 mL/kg IV bolus or 10% dextrose 5–10 mg/kg/min IV infusion, glucagon 0.5–1 mg IM stat (if hyperinsulinism)
Congenital adrenal hyperplasia	Ambiguous genitalia in females; poor feeding, weight loss, irritability, vomiting, dehydration	Plasma sodium, potassium, glucose, 17-hydroxyprogesterone; karyotype and pelvic ultrasound	0.9% saline 20 mL/kg in first hour IV; hydrocortisone 25 mg IV stat (neonatal dose)
Adrenal insufficiency	Nausea, vomiting, abdominal pain, weakness, malaise, hypotension, dehydration, hyperpigmentation	Plasma sodium, potassium, glucose, cortisol, and ACTH (for retrospective confirmation of diagnosis)	Hydrocortisone 100 mg IV stat; 10% dextrose in 0.9% saline 20 mL/kg in first hour
Hypercalcemia (hyperparathyroidism)	Headache, irritability, anorexia, constipation, polyuria, polydipsia, dehydration, hypertension	Plasma calcium, phosphate	0.9% saline at two to three times maintenance rate; furosemide 1 mg/kg
Hypocalcemia (hypoparathyroidism)	Cramps, carpopedal spasms, paresthesias, lethargy, apathy, convulsions, hypotension	Plasma calcium, phosphate, alkaline phosphatase	10% calcium gluconate 1 mL/kg IV over 15 min
Diabetes insipidus	Polyuria, polydipsia, dehydration, irritability, fever, drowsiness, coma	Paired plasma and urine osmolality and sodium	*Central:* IV fluids at two-thirds maintenance rate plus replete deficit over 48 h; pitressin 1–10 mUnit/kg per h IV *Nephrogenic:* IV fluids at urine output plus replete deficit over 48 h
Syndrome of inappropriate antidiuretic hormone secretion	Anorexia, headache, nausea, vomiting, irritability, seizures, coma	Paired plasma and urine osmolality and sodium	*Seizures:* 3% saline at 1–3 mL/kg IV; furosemide 1 mg/kg IV stat; benzodiazepines *Otherwise:* fluid restriction
Thyroid storm	Goiter, exophthalmos, high fever, tachycardia, congestive cardiac failure, delirium, stupor	Free T_4, TSH	Propranolol 10 μg/kg IV over 15 min; Lugol's iodine 9–15 drops/day orally; methimazole 20–30 mg q6–12 h (initially); tepid sponging
Neonatal thyrotoxicosis	Goiter, failure to gain weight, irritability, tachycardia, congestive cardiac failure	Free T_4, TSH	Propranolol 1 mg/kg TID orally; potassium iodide two drops bid orally; methimazole 0.5–0.7 mg/kg/day divided tid orally
Congenital hypothyroidism	Asymptomatic: hypothermia, hypoactivity, poor feeding, constipation, prolonged jaundice, large posterior fontanel	Free T_4, TSH	L-thyroxine 10–15 μg/kg/day orally
Hypopituitarism	See features listed for adrenal insufficiency and hypoglycemia		

IV, intravenous; IM, intramuscular; ACTH, adrenocorticotropic hormone; TSH, thyroid-stimulating hormone; tid, three times daily; bid, twice per day.

dryness of mucous membranes. In severe cases, the child may exhibit signs of compensated shock, including a thready pulse and cold extremities, and rarely, as uncompensated shock with hypotension. The smell of ketones on the breath and the presence of deep, sighing (Kussmaul) respirations reflect the ketoacidosis. The patient's consciousness level, which may range from full alertness to deep coma, should be noted. The child may have exquisite abdominal tenderness with guarding and rigidity, which can mimic an acute abdomen. The ears, throat, chest, and urine should be examined because infection is often a precipitating factor. Careful attention should be paid to the skin exam because there have been several case reports of fasciitis copresenting with DKA. The presence of hyperpigmentation (acanthosis nigricans) on the posterior neck is a sign of long-standing insulin resistance and should alert the clinician to the possibility of noninsulin-dependent diabetes.

Diagnostic laboratory findings include plasma glucose greater than 200 mg per dL (commonly 400 to 800 mg per dL), the presence of glucose and ketones in the urine, acidosis (venous pH less than 7.3 and serum bicarbonate less than 15 mmol per L), high or normal plasma potassium, and slightly elevated blood urea nitrogen. Occasionally, DKA can occur with normoglycemia when persistent vomiting and decreased intake of carbohydrates are accompanied by continued administration of insulin or when patients have kept themselves particularly well hydrated with nonglucose-containing fluids. The measured serum sodium is usually low or in the low to normal range. Leukocytosis with a left shift may be noted but does not necessarily signify an underlying infection. Hyperglycemia in the absence of acidosis should cause the clinician to consider additional possibilities (see "Hyperglycemia" section).

Management

Careful clinical assessment and judgment are required. Children who have a recognized risk factor for cerebral edema (Table 86.3) require particularly meticulous attention to the details of their care. This section primarily focuses on the child who is significantly dehydrated, acidotic, and unable to take oral fluids because of vomiting or altered level of consciousness. Many cases of mild DKA can be managed with rehydration, either orally or intravenously, and with supplemental insulin either at home or in the ED. This possibility is addressed at the end of this section. For the severely dehydrated child, initial treatment is directed toward expansion of intravascular volume and administration of insulin. Subsequent treatment is directed at the normalization of the remaining abnormal biochemical parameters. Medical intervention carries significant risks of hypokalemia and cerebral edema (Tables 86.2 and 86.3).

Fluid and Electrolyte Replacement

Fluid replacement should be instituted promptly. In the first 1 to 2 hours, if hypovolemia is apparent, 10 to 20 mL per kg isotonic (0.9%) saline should be infused intravenously to establish an adequate intravascular volume and to improve tissue perfusion. This bolus may need to be repeated if the pulse rate and capillary refill rate do not improve, but rarely is more than 20 mL per kg required. The goal of this initial rehydration therapy is not euvolemia but adequate perfusion of end

Hypokalemia
Hypophosphatemia

Areas of Management Decisions
- *Fluids*. Treat hypovolemia with crystalloid extracellular fluid expander. Use normal saline (0.9%) and infuse 10–20 mL/kg in the first 1–2 h. (Avoid hypotonic solutions initially because they are inefficient volume expanders and may contribute to cerebral edema.) Continue infusion at this rate until perfusion is improved and urine output is reestablished. After first 1–2 h, start half-normal saline—use greater tonicity, up to normal saline, if the initial serum sodium is less than 135 mmol/L or if the serum sodium falls with therapy. Total fluid administration in first 48 h should rarely exceed one and one-half to two times maintenance.
- *Alkali*. Avoid bicarbonate therapy in DKA. Only consider if arterial pH <6.9 and impaired cardiac contractility and vascular tone, or if patient has life-threatening hyperkalemia.
- *Potassium*. Start potassium therapy with administration of insulin. Starting concentration in fluid should be 40 mEq/L as a combination of potassium acetate and potassium phosphate. If the patient is hypokalemic (<4 mmol/L), a higher concentration of potassium, 60–80 mEq/L, may be necessary. Administer high concentrations of potassium only with electrocardiographic monitoring. If hyperkalemic (>6 mmol/L), decrease the concentration to 0–20 mEq/L.
- *Insulin*. Should be given as a continuous IV infusion (0.1 Unit/kg/h).
- *Glucose*. Add 5% glucose to solutions when plasma glucose is approximately 300 mg/dL. Continue adding glucose up to 12.5% in a peripheral IV in order to keep plasma glucose in target range of 200–300 mg/dL.
- *Phosphate*. Add one-half of potassium in IVF as potassium phosphate up to 20 mEq/L, unless severe hypophosphatemia (PO_4 < 2 mmol/L)

Monitoring
- *Clinical monitoring*. Blood pressure, pulse, respirations, neurologic status, and fluid intake and output. Continuous noninvasive $ETCO_2$ monitoring, if available.
- *Laboratory monitoring*. Obtain initial glucose, electrolytes, blood gases, and blood urea nitrogen. Measure blood glucose every hour initially as guide to insulin dosage. Repeat electrolytes and pH measurements two to four times hourly as necessary, every hour if severe abnormalities.
- *Use flow sheet*.

organs. This may be best judged by monitoring mentation, capillary refill, and urine output.

Once adequate intravascular volume is established, the fluid deficit should be replaced over the next 48 hours. During the first 4 to 6 hours of this period isotonic fluids should be used with appropriate additional electrolyte supplementation as detailed below. The total body water deficit may be estimated based on a clinical estimate of dehydration, or intravenous (IV) fluid may be administered at a rate between one and one-half and two times maintenance fluid requirements (see Chapters 17 and 100). Ongoing urinary losses in excess of 5 mL per kg per hour (osmotic diuresis) should also be replaced.

The Na^+ deficit typically approximates 10 mEq per kg body weight and Na^+ maintenance is 3 mEq per 100 mL of maintenance fluid. From a practical point of view, half-normal (0.45%) saline can be started after the initial 4- to 6-hour period of isotonic fluids. The measured serum sodium should rise with initiation of therapy. If the initial serum sodium is less than 136 mmol per L, or if the serum sodium falls with therapy, the IV fluid should be changed to a more concentrated sodium stock, and the patient should be watched particularly closely. Serum sodium failing to rise with therapy has been identified as a risk factor for cerebral edema. Correcting the serum sodium for the degree of hyperglycemia may be useful in following the patient's total body sodium status:

$$\text{Corrected } [Na^+] = \text{measured } [Na^+] + [1.6 \times (\text{measured plasma glucose} - 100)/100]$$

If the corrected [Na^+] is less than 136 mmol per L or drops to less than 136 mmol per L during therapy, sodium concentration of the IV fluid should be increased to three-fourths normal (0.68%) or normal saline (0.9%). In addition, the serum sodium and the neurologic status of the patient should be followed more closely because this is a reported risk factor for cerebral edema (Table 86.3).

All children with DKA have total body potassium depleted (5 mEq per kg body weight); therefore, potassium replacement is an important part of therapy. If the initial serum [K^+] is 3 to 4.5 mmol per L, 40 mEq per L of potassium is added to the infusion after vascular competency has been established and the child has urinated. If the serum [K^+] is 4.6 to 5.0, only 20 mEq per L of potassium should be added, and if the [K^+] is above 5.0, potassium should be withheld in the initial fluids. Generally, K^+ is provided as potassium acetate (or chloride) and potassium phosphate in equal amounts. If the initial serum [K^+] is less than 4 mmol per L, potassium replacement should be initiated promptly; if less than 3 mmol per L, IVF concentrations of K^+ of 60 mEq per L or greater may be necessary. With the higher concentrations of potassium, the phosphate component must be adjusted not to exceed the maximum rate. If the K^+ initial concentration is low, monitoring via an electrocardiogram (EKG) is indicated.

Phosphate depletion is almost universal in patients with DKA; however, the clinical significance of this reaction remains uncertain. As noted earlier, half of the K^+ replacement is with potassium phosphate, up to a maximum of 20 mEq potassium phosphate per liter except in the rare situation of severe hypophosphatemia (serum phosphate less than 2 mmol per L). Infusion of excess phosphate results in hypocalcemia, which may be complicated by tetanic seizures.

Alkali Therapy

In retrospective reviews of patients with DKA who developed significant cerebral edema, bicarbonate administration was identified as a significant risk factor (Table 86.3). This may be because the sickest patients are the ones most likely to have received bicarbonate therapy; however, without further clarification of the pathophysiology, bicarbonate therapy is reserved for patients with both severe acidosis (pH < 6.9) and secondary hemodynamic compromise that is unresponsive to inotropic agents.

A theoretical mechanism for the complications observed with alkali therapy is the development of a paradoxical acidosis of the central nervous system (CNS) and resultant cerebral depression. Paradoxical acidosis occurs because administered HCO_3^- combines with excess H^+ ions in the bloodstream to form H_2O and CO_2. Because the blood–brain barrier is relatively more permeable to CO_2 than to HCO_3^-, CO_2 accumulates in the CNS, resulting in further exacerbation of acidosis in this compartment, while acidosis is being corrected systemically.

Insulin and Glucose

Regular insulin is used for the treatment of ketoacidosis, but it should not be administered until the initial isotonic fluids have been administered for 1 hour. Insulin is initially necessary to stop ongoing ketone body production, the primary cause of the acidosis. Insulin should be started after 1 hour of initial fluid expansion to steadily correct the acidosis and may be either infused intravenously or, if necessary, injected intramuscularly at hourly intervals. Subcutaneous injections of insulin should be avoided because of the uncertainties of absorption in a dehydrated patient. The starting dose of insulin for continuous infusion is 0.1 Unit per kg per hour, infused by a regulated pump. Failure of the glucose to decrease in response to insulin suggests improper insulin preparation, inadequate hydration, or serious underlying disease (e.g., appendicitis or fasciitis with resultant significant increases in counterregulatory hormones). It is unnecessary and possibly detrimental to give an initial bolus of insulin. The dose for the hourly intramuscular (IM) injection, used if IV access cannot be obtained, is also 0.1 Unit per kg per hour.

Once the blood glucose approaches 300 mg per dL, glucose should be added to the IV fluids. As long as the child remains acidotic, insulin infusion should never be stopped; instead, the amount of glucose in the IV infusion should be increased in stepwise fashion up to a concentration of 12.5 g per dL to maintain the blood glucose between 150 and 250 mg per dL. If

the blood glucose continues to drop, the rate of IV fluid administration should be increased to twice maintenance. If the blood glucose still cannot be maintained, the insulin infusion should be decreased by increments of 0.025 Unit per kg per hour.

When the child is able to eat and the anion gap has closed (normal = 10 to 12), IV infusion of insulin can be discontinued. Because IV insulin is metabolized rapidly, subcutaneous insulin must be given 30 minutes prior to the discontinuation of the infusion. The initial dose of subcutaneous insulin should be calculated based on a daily dose of 0.75 Unit per kg per day in the prepubertal child up to 1.0 Unit per kg per day in the pubertal child and beyond. If hourly IM injections are used, they should be continued until the blood glucose is less than 300 mg per dL and acidosis is correcting. By this time, perfusion is reestablished and subcutaneous insulin can be administered four times a day.

Cerebral Edema

Despite several investigations of the causes and risk factors for clinically significant cerebral edema in patients with DKA, and subsequent modifications in therapy, the incidence of the complication has not changed significantly during the past 20 years and remains at approximately 1%. Table 86.3 lists the leading risk factors published in more recent years. Clinical signs and symptoms of significant cerebral edema include abnormal motor or verbal response to pain, decorticate or decerebrate posturing, new cranial nerve palsy, and abnormal respiratory pattern. Other concerning signs are decrease or fluctuation in level of consciousness (e.g., Glasgow Coma Scale), age-inappropriate incontinence, vomiting, headache, and heart rate deceleration. If these signs are noted by the physician at the bedside, a clinical diagnosis of cerebral edema must be made and treatment initiated. The patient should receive mannitol 1 g per kg IV over 10 minutes. There is some evidence that hypertonic saline (3%) may be an appropriate substitute for mannitol; however, only case series data are currently available. Endotracheal intubation should be considered, primarily if the patient's mental status does not assure a safe airway, and secondarily if the patient is not able to maintain a respiratory alkalosis to partially compensate for the metabolic acidosis. If intubated, the patient should be initially hyperventilated to the P_{CO_2} he/she was maintaining prior to the neurologic decompensation (generally 10 to 20 mm Hg in the presence of significant ketoacidosis); this can be gradually reduced over several hours as the acidosis resolves and the cerebral edema is treated. Only after the patient is fully stabilized should a confirmatory computed tomography of the head be considered.

Monitoring

Close monitoring is mandatory, and a well-organized flow sheet ensures all parameters are being observed. Admission to an intensive care unit or specialized intermediate care unit should be considered if the patient is younger than 1 year of age, has a Glasgow Coma Scale score of less than 12, has an initial measured [Na^+] of more than 145 mmol per L, or has an initial [K^+] of less than 3 mmol per L. The patient should be maintained on continuous cardiorespiratory monitoring with hourly assessments of blood pressure and level of consciousness until the patient's trajectory of illness has been clearly established. Careful neurologic examination, with particular attention to arousability and pupillary reactivity, should be performed frequently. The fluid input and output must be reviewed hourly to ensure appropriate rehydration is occurring. The IV fluids should be checked frequently so that pump failure or fluid leakage into the subcutaneous tissues can be corrected quickly. In the severely ill child, an EKG should be performed in the setting of hyperkalemia or hypokalemia.

The plasma glucose should be measured hourly until the blood glucose is stable and less than 300 mg per dL, and as long as the child is on an insulin infusion. Glucose measurement may be less frequent once the patient has been changed to subcutaneous insulin. Serum [K^+] needs to be measured every 2 to 4 hours until the acidosis and hyperglycemia are normalized, or more frequently if hypokalemia is encountered or bicarbonate therapy is used. Calcium, phosphate, magnesium should be assessed initially and followed every 2 to 4 hours, more frequently if any are being actively replaced. With the advent of point-of-care ketone measurements, it may be advisable to follow serum ketone concentration every 2 to 4 hours, although continuous noninvasive capnography with nasal cannula end-tidal CO_2 ($etCO_2$) or transcutaneous CO_2 monitoring are also useful in tracking the degree of acidosis over time. Venous pH may be obtained to follow resolution of the acidosis if the above monitoring options are not available. Arterial sampling is not necessary for metabolic monitoring.

When the child is better hydrated and the acidosis resolves, mental alertness will improve and symptoms of nausea, vomiting, and abdominal pain should remit. If they do not resolve, an abdominal disorder should be considered. Some patients complain of blurred vision, which is caused by lens distortion resulting from fluid shifts of rehydration and correction of hyperglycemia—this should resolve within 24 hours of conclusion of therapy. When the anion gap has closed, most patients are able to tolerate oral fluids, at which point rehydration can be continued orally.

Mild Ketoacidosis

Some children with new-onset diabetes may also have hyperglycemia without ketoacidosis or with only mild acidosis. Generally, these patients are hospitalized for 24 to 48 hours to allow time to educate the family and stabilize the insulin dosage. These children require rehydration (as described in the next section) similar to patients with known diabetes and mild ketoacidosis. Insulin therapy can be initiated subcutaneously, at a total daily dose of 0.25 to 0.5 Unit per kg per day for the prepubertal child and 0.5 to 0.75 Unit per kg per day for the adolescent. There are two general regimens for dividing this total daily dose. In the conventional regimen, two-thirds of the total daily dose is administered in the morning, and one-third before dinner; two-thirds of the morning dose and evening dose should be as an intermediate-duration insulin (NPH, Lente), the remainder as rapid-acting insulin (lispro, aspart). Using the basal-bolus approach, one-half of the total daily dose is administered as insulin glargine or detemir, two 24-hour–acting analogs, and rapid-acting insulin (lispro, aspart) is dosed as a combination of coverage for ingested carbohydrates and as a correction for the degree of hyperglycemia above a chosen target—these initial dosages should be calculated along with the help of a consulting diabetes specialist.

Children with known diabetes often develop hyperglycemia and ketosis without significant acidosis (venous pH greater than 7.3 or bicarbonate greater than 15 mmol per L) during the

course of intercurrent illness, especially gastroenteritis, or secondary to omission of insulin doses. Even the mildly dehydrated (5%) child with slight acidosis who presents to the ED benefits from an IV fluid bolus (10 to 20 mL per kg of normal saline); furthermore, this bolus will be given while awaiting laboratory test results. Once the laboratory results are available, the physician must decide whether to hospitalize the child, continue treatment in the ED, or send the child home. For purposes of definition, a patient does not have DKA if venous pH is greater than 7.3 and serum bicarbonate is greater than 15 mmol per L. Children who are significantly acidotic should be hospitalized and managed as outlined in the earlier section of this chapter. Several factors must be considered before sending a child home:

1. Is the child fully conscious and alert?
2. Can the child drink and retain oral fluids?
3. Can home glucose monitoring be done and are all related supplies available in the home?
4. Can ketones be measured at home, either in the urine with chemical test strips or in the serum with a point-of-care blood measurement device?
5. Will the child have competent supervision at home?
6. Does the family have access to both a telephone and transportation?
7. Is there a clinician available with whom the family can communicate by telephone?
8. Is the family comfortable with managing the mild acidosis at home?

If these questions can be answered in the affirmative, the child may be sent home.

Recommendations should be made to the family regarding fluid intake, insulin administration, and monitoring. Specific recommendations may vary with the age of the child and the experience of the family, but the following scheme may be helpful. Oral intake should be about the same as would be given intravenously to resolve the deficit and provide maintenance [e.g., the 10-year-old child (30 kg) would normally receive a 300-mL bolus followed by 100 to 140 mL per hour, for a total of up to 1 L during the first 6 hours intravenously if he/she was hospitalized; therefore, the physician should suggest that the family try to get in 150 to 180 mL of liquid every hour for the next 6 hours]. It is best if this liquid is taken in as sips.

Additional short-acting insulin will be required in addition to the patient's usual long-acting doses. In the ED, two decisions will need to be made regarding insulin: First, how much short-acting insulin (lispro or regular) should be given to the child before discharge? One way to dose additional insulin is using the 5–10% to 10–15% rule:

- If blood glucose is 250 to 400 mg per dL without urinary ketones, 5% of the child's usual total daily dose will suffice.
- If blood glucose is more than 400 mg per dL without ketones, or is 250 to 400 mg per dL with moderate or large ketones, 10% of the daily dose will be needed.
- If blood glucose is more than 400 mg per dL and ketones are moderate or large, the child will need 15% of the daily dose and admission to the hospital should be reconsidered.

Second, how much should be given at home and with what frequency? Once home, the preceding 5–10% to 10–15% rule is generally applicable and should be given every 4 hours, based on blood glucose and blood or urinary ketones. The family can begin using this algorithm once the child is able to return to a normal intake. For any child to be safely discharged home, however, he or she must be able to maintain adequate oral intake and have frequent contact with a clinician who is comfortable managing pediatric diabetes. Last, hourly monitoring of blood glucose, urine output, and ketones is recommended with the expectation that the blood glucose should decline, the urine output should fall, and the ketones should begin to clear.

HYPERGLYCEMIA

Background

According to American Diabetes Association guidelines, fasting laboratory plasma glucose of greater than 126 mg per dL or a random glucose greater than 200 mg per dL on two separate occasions is diagnostic of diabetes in an otherwise healthy person. These guidelines were developed primarily by specialists in adult diabetes and may not be completely applicable to the pediatric population.

Therefore, it is essential that any elevated glucose level be evaluated within the context of the ill child and that other factors, such as simultaneous medication administration, be considered.

Pathophysiology

As noted in the previous section on diabetes and the following section on hypoglycemia, glucose homeostasis reflects the balance between glucose input (from gut absorption, hepatic glycogen breakdown, or gluconeogenesis) and disposal (via storage or oxidation). With the exception of gut absorption, this process is largely regulated by insulin, although counterregulatory hormones also have a significant effect. Furthermore, tissue factors and medication also impact the insulin effect.

Clinical Manifestations

Plasma glucose concentrations in the 200 to 300 mg per dL range rarely result in symptoms. This level of hyperglycemia may be accompanied by intermittently increased frequency of urination; however, parents are rarely aware of their child's frequency of urination once the child is toilet-trained unless the frequency becomes disruptive (e.g., the child begins having "accidents" at school). Children and adolescents have no sense of what is the normal frequency of urination, so they rarely complain unless the frequent urination is accompanied by dysuria. Higher levels of glucose (greater than 300 mg per dL) may be associated with subtle clinical findings, such as blurring of vision or dryness of oral membranes.

Significant hyperglycemia may occur without significant symptoms and can be tolerated for a prolonged period without clinical signs. In the ED, hyperglycemia is likely to be seen in several different situations. First, the child may be known to have diabetes and present with an intercurrent illness or traumatic injury. Both illness and injury result in increased counterregulatory hormones, which may lead to relative insulin resistance and hyperglycemia. The second presentation is the child

for whom diabetes is suspected because of classical symptoms of polyuria, polydipsia, and polyphagia accompanied by weight loss. Almost half of children with new-onset diabetes mellitus present to their pediatrician or to the ED in this way. Third, some medical conditions are associated with persistent hyperglycemia, such as recurrent urinary tract infections and vaginal yeast infections. Furthermore, type 2 diabetes is increasingly being reported in minority adolescents; in many, hyperpigmentation of the posterior neck and axilla (acanthosis nigricans) may be noted. Fourth, a laboratory panel obtained for some other reason (e.g., abdominal pain) may reveal hyperglycemia.

Management

In the child with diabetes, unless the child is clinically dehydrated or is unable to take oral fluids, hyperglycemia is not a crisis. Oral fluids should be encouraged, and supplemental short-acting insulin (lispro or aspart insulin) may be required; it can be dosed according to the 5–10% to 10–15% rule:

- If blood glucose is 250 to 400 mg per dL without urinary ketones, 5% of the child's usual total daily dose will suffice.
- If blood glucose is more than 400 mg per dL without ketones, or is 250 to 400 mg per dL with moderate or large ketones, 10% of the daily dose will be needed.
- If blood glucose is more than 400 mg per dL and ketones are moderate or large, the child will need 15% of the daily dose and admission to the hospital should be reconsidered.

Failure to respond to these simple measures, whether in the ED or at home, should lead to a consultation with the child's endocrinologist. If oral fluids must be restricted and the child is hyperglycemic (e.g., a child with traumatic injury requiring surgery), IV fluids without glucose should be used and glucose should be monitored frequently. As blood glucose concentration reaches 200 mg per dL, dextrose should be added to the IV fluid to maintain target blood glucose of 150 to 250 mg per dL. Additional supplemental insulin may be required, depending on when the child last received insulin and the response to simple hydration. Supplemental short-acting insulin should be dosed subcutaneously according to the 5–10% to 10–15% rule every 4 hours, and the child's usual long-acting insulin should be continued.

The child with classic symptoms merits further evaluation to determine whether he or she is dehydrated, hyperosmolar, or acidotic. If the child is simply hyperglycemic, hospitalization is often required for initiation of treatment and diabetes-related education; however, IV fluid resuscitation and intensive care are not indicated.

In children with classic signs or symptoms of hyperglycemia (i.e., polydipsia, polyuria), a plasma glucose should be obtained. If this test reveals hyperglycemia, as defined by the American Diabetes Association, the child should be referred for further evaluation and treatment of diabetes.

Last, if hyperglycemia is a coincidental finding, the diagnosis requires thoughtful consideration. How traumatic was the blood draw? How upset was the child? What medications or IV fluids were given to the child just before the phlebotomy? What was the child drinking while waiting to see the physician? Are the symptoms in any way related to the hyperglycemia? How sick is the child? The sicker the child is, the less likely it is that hyperglycemia is reflective of diabetes. Three simple evaluations are helpful in determining whether the hyperglycemia is circumstantial or suggestive of diabetes. Brief hyperglycemia resulting from a stress response to phlebotomy or secondary to oral intake rarely results in significant glucosuria; therefore, a urine dip for glucose is often helpful. Second, in the absence of ongoing stress or input, glucose tends to fall over time. A fingerstick glucose is rarely stressful. Therefore, repeating a glucose measurement by fingerstick 1 to 2 hours after the original sample was sent is useful in separating disease from nondisease. Third, hyperglycemia secondary to these factors is usually mild (150 to 250 mg per dL). More significant hyperglycemia should raise the suspicion of diabetes, glucose intolerance, or an underlying medical illness that is producing a significant counterregulatory response.

HYPOGLYCEMIA

Background

Hypoglycemia is defined as plasma glucose of less than 50 mg per dL, regardless of whether symptoms are present. Hypoglycemia is a chemical finding that should lead to a diligent search for a cause. A differential diagnosis of hypoglycemia, as it may present in the ED, is provided in Table 86.4.

Hypoglycemia may be secondary to insulin therapy for diabetes. Excluding this category, almost all hypoglycemia in children occurs during periods of decreased or absent oral intake,

TABLE 86.4

CAUSES OF CHILDHOOD HYPOGLYCEMIA

Decreased Availability of Glucose
Decreased intake—fasting, malnutrition, illness
Decreased absorption—acute diarrhea
Inadequate glycogen reserves—defects in enzymes of glycogen synthetic pathways
Ineffective glycogenolysis—defects in enzymes of glycogenolytic pathways
Inability to mobilize glycogen—glucagon deficiency
Ineffective gluconeogenesis—defects in enzymes of gluconeogenic pathway

Increased Use of Glucose
Hyperinsulinism—islet cell adenoma or hyperplasia, ingestion of oral hypoglycemic agents, insulin therapy
Large tumors—Wilms' tumor, neuroblastoma

Diminished Availability of Alternative Fuels
Decreased or absent fat stores
Inability to oxidize fats—enzymatic defects in fatty acid oxidation

Unknown or Complex Mechanisms
Sepsis/shock

Hypopituitarism

often coupled with increased energy demand (e.g., viral gastroenteritis with fever). Postprandial hypoglycemia is unusual in children, except in those who have had prior gastrointestinal surgery.

Pathophysiology

Because glucose is necessary for cellular energy production in most human tissues, the maintenance of an adequate blood glucose concentration is important for normal function. The plasma glucose reflects a dynamic balance among glucose input from dietary sources, glycogenolysis and gluconeogenesis, and glucose use by muscle, heart, adipose tissue, brain, and blood elements.

The liver plays a unique role in glucose homeostasis because it stores glucose as glycogen. With fasting, this glycogen is degraded to glucose, which is released into the bloodstream. In addition, the liver synthesizes new glucose from glycerol, lactate, and certain amino acids. During fasting, lipolysis occurs and the resultant fatty acids are used for the production of both energy and ketones (acetoacetate and β-hydroxybutyrate) by the liver. The energy generated from the metabolism of fatty acids is essential to sustain maximal rates of gluconeogenesis and ureagenesis in the liver. The ketones are an important auxiliary fuel for most tissues, including the brain.

Muscle contains significant quantities of glycogen and protein. Under fasting conditions, the glycogen is degraded and used endogenously but is not released as free glucose into the bloodstream. Certain amino acids, particularly alanine and glycine, are released from the muscle and subsequently used by the liver for gluconeogenesis. Muscle derives an increasing proportion of its energy requirement from fatty acids as fasting proceeds.

Brain tissue is highly dependent on glucose for its energy requirements. Under certain circumstances, it can extract a limited proportion of its energy requirement from other substrates (e.g., glycerol, ketones, lactate), although this process requires a period of adaptation and does not negate the need for a constant supply of glucose.

Insulin is the primary hormone that regulates the blood glucose level. Insulin stimulates the uptake of glucose and amino acids into skeletal, cardiac, and adipose tissue and promotes glycogen and protein synthesis. It inhibits lipolysis and glycogenolysis. The net effect of insulin action is to accelerate the removal of glucose and gluconeogenic substrates from the bloodstream. Opposing or modulating the effects of insulin are cortisol, glucagon, epinephrine, and growth hormone. The effects of these hormones include inhibition of glucose uptake by muscle, mobilization of amino acids for gluconeogenesis, activation of lipolysis, inhibition of insulin secretion, and induction of gluconeogenic enzymes. The net effect is to increase the availability of gluconeogenic substrates to the liver, and to increase the accessibility and use of nonglucose fuels by other tissues.

Clinical Manifestations

Prompt recognition of hypoglycemia is important because brain damage may result if the hypoglycemia is prolonged or recurs frequently. The acutely ill child warrants a glucose determination if the level of consciousness is altered because hypoglycemia may accompany an illness that interferes with oral intake. Historical evidence may aid in establishing the cause of hypoglycemia. Because hypoglycemia in children occurs after a period of fasting, a careful chronology of dietary intake during the preceding 24 hours should be obtained. The possibility of ingestion should be considered because ethanol, β-blockers, and oral hypoglycemic agents are in common use.

The symptoms and signs of hypoglycemia are nonspecific and are often overlooked, especially in the infant and young child. The clinical findings of hypoglycemia reflect both the decreased availability of glucose to the CNS and the adrenergic stimulation caused by decreasing or low blood glucose. Adrenergic symptoms and signs include palpitations, anxiety, tremulousness, hunger, and sweating. Irritability, headache, fatigue, confusion, seizure, and unconsciousness are neuroglycopenic symptoms. Any combination of these symptoms should lead to a consideration of hypoglycemia. Any child presenting with a seizure, other than a breakthrough seizure with known epilepsy, or unconsciousness should have a plasma glucose determination.

Management

If hypoglycemia is suspected, blood should be drawn, if at all possible, before treatment. An extra tube (3 mL, red top) should be obtained and refrigerated until the laboratory glucose is known. Rapid screening should be performed using a bedside glucose meter while awaiting definitive laboratory results. Therapy should be instituted if this screen is suggestive of hypoglycemia. This method may lead to some overtreatment because of error of bedside devices; however, treatment holds minimal risk. It is preferable to overtreat than to allow a child to remain hypoglycemic until definitive laboratory results are available. If the laboratory glucose confirms that the blood glucose was less than 50 mg per dL, the reserved serum can be used for chemical (β-hydroxybutyrate, acetoacetate, amino acid profile, acylcarnitine profile), toxicologic, and hormonal (insulin, growth hormone, cortisol) studies, and may provide the correct diagnosis without extensive additional testing. If adequate blood is obtained before correction, other metabolites to be considered are glucagon, c-peptide, lactate, and pyruvate. If blood is obtained with 15 minutes of glucose administration, it may still be helpful, although possibly not diagnostic.

The first voided urine after the hypoglycemic episode should be saved for toxicologic, organic acid evaluation, and acylglycine profile. In the ED, the urine should also be tested immediately for ketones. With hypoglycemia, ketones should be large. Failure to find large ketones in the presence of hypoglycemia strongly suggests either that fats are not being mobilized from adipose tissue, as might occur in hyperinsulinism, or that fat cannot be used for ketone body formation, as might occur in enzymatic defects in fatty acid oxidation. Both the urine and the serum results will be useful in determining the underlying cause of hypoglycemia. The preferred treatment for hypoglycemia is rapid IV administration of 0.25 g of dextrose per kg body weight (2.5 mL per kg of 10% dextrose, 1.0 mL per kg of 25% dextrose). The plasma glucose should then be maintained by an infusion of dextrose at a rate of 6 to 8 mg per kg per minute. Generally, this goal can be accomplished by providing 10% dextrose at one and one-half times maintenance rates. Glucagon (0.03 mg per kg up to a maximum of 1 mg intramuscularly) may be used to treat hypoglycemia that is known to be caused by hyperinsulinism but is not indicated

as part of the routine therapy of hypoglycemia. Glucocorticoids should not be used because they have minimal acute benefit and may delay identification of the cause of hypoglycemia.

The adequacy of therapy should be evaluated both chemically and clinically. The plasma glucose should be monitored frequently and consistently until a stable level higher than 70 mg per dL is attained on more than one measurement. Adrenergic symptoms should resolve quickly. The resolution of CNS symptoms may be prolonged, particularly if the child was initially seizing or unconscious. Seizures that do not respond to correction of hypoglycemia should be managed with appropriate anticonvulsants (see Chapters 69 and 96). The mild acidosis (pH 7.25 to 7.35) usually seen in hypoglycemia will correct without specific intervention. Marked acidosis (pH less than 7.10) suggests shock or serious underlying disease and should be managed appropriately (see Chapter 3). Any child with documented hypoglycemia not secondary to insulin therapy should be hospitalized for careful monitoring and diagnostic testing.

HYPOPITUITARISM

Background

The term *hypopituitarism* generally applies to any condition in which more than a single pituitary hormone is deficient. This condition may include deficiencies resulting from a lack of hypothalamic-releasing factors, as well as deficiencies of anterior and posterior pituitary hormones. Diabetes insipidus (DI), the lack of antidiuretic hormone (ADH), may occur alone or in association with other hormonal defects and is discussed in a subsequent section.

Pathophysiology

Adrenocorticotropic hormone (ACTH) primarily affects adrenal glucocorticoid production; generally, it does not affect mineralocorticoid synthesis, which is primarily regulated by the renin–angiotensin system. A deficiency of ACTH production manifests as cortisol deficiency. Because cortisol plays a role as an insulin counterregulatory hormone, a lack of either ACTH or cortisol may result in hypoglycemia. Because the only identified role for thyroid-stimulating hormone (TSH) is the stimulation of thyroid hormone production, a deficiency of TSH is most likely to manifest as hypothyroidism. Luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are involved in gonadal maturation, as well as the regulation of gonadal functions. LH and FSH play an important role in testicular descent and penile growth in the fetus, as well as affecting the onset of puberty in the adolescent. The circulating levels of these two pituitary hormones are low in children and have no demonstrable function. Prolactin is primarily involved in the maintenance of lactation and is of minimal significance in childhood. Growth hormone is a principal regulator of linear growth and an important insulin counterregulatory hormone. The absence of growth hormone may be associated with hypoglycemia, particularly in infants and young children.

Clinical Manifestations

The symptoms and signs of hypopituitarism depend on missing hormones. Isolated growth hormone deficiency is most likely to present with poor linear growth, although occasionally an infant or young child will present with hypoglycemia. The acute presentation of hypopituitarism is most likely to occur when the child is stressed by injury, illness, or fasting. The presentation may involve either an unusually rapid decompensation, reflecting the role of cortisol in adaptation to stress, or as hypoglycemia, mirroring the role of both cortisol and growth hormone in opposing the effects of insulin. In the older child, no specific symptoms or signs indicate a lack of LH and FSH. An association between a lack of these hormones and anosmia has been noted (Kallmann's syndrome). In the adolescent, a deficiency of LH and FSH may be evidenced as pubertal delay. No specific signs or symptoms have been associated with a deficiency of prolactin in childhood.

In the neonatal male, hypopituitarism may be accompanied not only by hypoglycemia, but also by micropenis (less than 2 cm, stretched length). This condition illustrates the role of LH and FSH in stimulating testicular function in utero. Significant liver dysfunction in the neonatal period may be associated with congenital hypopituitarism. Hypopituitarism is seen with various midline structural anomalies, including optic nerve hypoplasia, cleft palate, absence of the septum pellucidum, and spina bifida.

In the older child, intracranial mass lesions, particularly with craniopharyngioma and other pituitary abnormalities, may cause hypopituitarism. The presence of visual field abnormalities may aid in localizing the site of the lesion. A history of severe head trauma, surgery for CNS tumors, or CNS irradiation should increase the suspicion of hypopituitarism.

Management

The child with hypopituitarism may require any or all the following therapies. Adequate cortisol replacement is an absolute necessity in children with known or suspected secondary adrenal insufficiency (ACTH deficiency). Cortisol replacement under stress conditions (e.g., trauma, fever) should be the equivalent of 50 mg of hydrocortisone per m^2 per day (hydrocortisone IV infusion 12.5 mg per m^2 every 6 hours; hydrocortisone continuous IV infusion at 50 mg per m^2 per day; cortisone 50 mg per m^2 intramuscularly every 24 hours). A child with hypopituitarism presenting in extremis or with severe electrolyte abnormalities should immediately receive an initial rescue dose of 50 mg per m^2. In general, all cases of adrenal insufficiency should be treated with hydrocortisone because it is the only pharmacologic glucocorticoid that stimulates both the glucocorticoid receptor and the mineralocorticoid receptor. If a patient is known to have hypopituitarism, other steroids may be used in equipotent doses and the mineralocorticoid production can be assumed to be normal because it does not involve the pituitary.

Because both cortisol and growth hormone are insulin counterregulatory hormones, children with hypopituitarism are prone to hypoglycemia. If enteral intake is interrupted for prolonged periods, glucose should be supplied intravenously. Blood glucose should be monitored to ascertain the adequacy of therapy. Both adrenal insufficiency and diabetes insipidus can lead to fluid and electrolyte abnormalities; therefore,

electrolytes should be determined at presentation and followed closely. Changes in IV therapy should be based on serum electrolytes. Judicious use of 1-desamino-8-D-arginine vasopressin (DDAVP) may be helpful in managing diabetes insipidus, as outlined subsequently; however, this treatment is usually unnecessary at the time of acute presentation.

Although both thyroid hormone and sex hormone(s) may need to be replaced, this treatment is not required in the ED. Growth hormone replacement therapy should only be initiated or continued in an inpatient if the child has a history of hypoglycemia and is not critically ill. Administration of growth hormone to critically ill adults has been shown to increase mortality, apparently as a result of hyperglycemia and increased incidence of sepsis, so it should generally be withheld in the critically ill patient.

Because hypopituitarism often results from intracranial lesions, the demonstration of a pituitary or a hypothalamic mass, or a history of a significant cranial insult, should lead to a diligent search for hormonal deficits. Similarly, documented pituitary deficits should lead to a thorough radiologic investigation of the cranial cavity.

ACUTE ADRENAL INSUFFICIENCY

Background

Acute adrenal insufficiency occurs when the adrenal cortex fails to produce enough glucocorticoid and mineralocorticoid in response to stress. Patients at risk of this life-threatening event include individuals with primary adrenal disease and those who have adrenal insufficiency secondary to hypothalamic-pituitary suppression (Table 86.5). This emergency has become more common with the widespread use of suppressive doses of corticosteroids in the treatment of chronic disease (e.g., nephrotic syndrome, acute lymphoblastic leukemia, asthma). Infection, trauma, or surgery in the susceptible patient generally precipitates the acute crisis. The diagnosis must be based primarily on clinical suspicion because prompt commencement of therapy is mandatory for survival and definitive diagnostic test results may not be available for days. Congenital adrenal hyperplasia is a unique form of adrenal insufficiency that is discussed in a subsequent section of this chapter.

TABLE 86.5

COMMON CAUSES OF ACUTE ADRENAL INSUFFICIENCY IN CHILDREN

Primary Adrenal Insufficiency
Adrenoleukodystrophy (X-linked)
Congenital adrenal hyperplasia
Autoimmunity
Tuberculosis
Meningococcal septicemia
Adrenal hemorrhage
Secondary Adrenal Insufficiency
Suppression of adrenocorticotropic hormone by pharmacologic doses of glucocorticoid administration
Pituitary or hypothalamic tumors
Central nervous system surgery or irradiation
Structural abnormalities (septooptic dysplasia)
Congenital hypopituitarism

Pathophysiology

Because the production of corticosteroids by the adrenal cortex is under pituitary and hypothalamic control, adrenal insufficiency can result from either an adrenal (primary) or hypothalamic–pituitary (secondary) disorder. Specific adrenal problems resulting in adrenal insufficiency include inborn errors of hormonal biosynthesis (discussed in the "Congenital Adrenal Hyperplasia" section), autoimmune destructive processes, X-linked adrenoleukodystrophy, and adrenal hemorrhage. Hypothalamic–pituitary causes include CNS tumors, trauma, and radiation therapy for a variety of neoplastic disorders. Exogenous administration of glucocorticoids also suppresses the adrenal–pituitary axis, an effect that often lasts well beyond the cessation of corticosteroid therapy.

Glucocorticoids are essential for withstanding stress; therefore, adrenal insufficiency is most likely to be manifested during an intercurrent infection or after trauma. Mineralocorticoids, especially aldosterone, play an important role in salt and water homeostasis by promoting salt resorption in the distal renal tubules and collecting ducts. Mineralocorticoid production is primarily regulated by the renin–angiotensin system; thus, adrenal insufficiency resulting from hypothalamic–pituitary causes is rarely associated with a lack of aldosterone. However, aldosterone deficiency is a common feature in primary adrenal insufficiency. Because of the nature of the pituitary–adrenal axis, primary adrenal insufficiency is accompanied by significantly elevated ACTH levels.

Clinical Manifestations

The historical information suggestive of adrenal insufficiency depends on the cause. Children with a primary adrenal defect are more likely to have had a gradual onset of symptoms, such as general malaise, anorexia, fatigue, and weight loss. Salt craving and postural hypotension may also have been noted. Waterhouse-Friderichsen syndrome, acute adrenal infarction, should be considered in a patient with fulminant sepsis and hypotension unresponsive to vasopressors or inotropes, especially if due to meningococcemia. A child with secondary adrenal insufficiency is more likely to have a history of neurosurgical procedures, head trauma, CNS pathology, or chronic disease necessitating the prolonged use of glucocorticoids.

Findings on physical examination are more likely to be characteristic of the precipitating illness or trauma rather than specifically suggestive of adrenal insufficiency. Although a lack of glucocorticoid and aldosterone can be associated with hypotension and dehydration, a better clue to the possibility of adrenal insufficiency is inappropriately rapid decompensation in the face of metabolic stress. Hyperpigmentation may be present in primary adrenal insufficiency, especially of long duration. Red hair and peripheral eosinophilia may be noted in Addison's disease or autoimmune destruction of the adrenals.

Biochemical evidence suggestive of adrenal insufficiency includes hyponatremia, hyperkalemia, hypoglycemia, and hemoconcentration. Mild metabolic acidosis and hypercalcemia may be present. The definitive diagnosis depends on the demonstration of an inappropriately low level of cortisol in

the serum. Blood should be obtained for the measurement of both cortisol and ACTH at baseline if the diagnosis is suspected, and then cortisol measurement is repeated 60 minutes after IV or IM administration of 0.25 mg of a synthetic ACTH preparation (i.e., cosyntropin). Results are unlikely to be available on an emergency basis.

Management

Treatment of adrenal crisis is based on rapid volume expansion and the administration of glucocorticoids. Immediate management consists of 50 to 100 mg of hydrocortisone intravenously. Subsequent management is hydrocortisone 50 mg per m^2 per 24 hours given intravenously continuously or divided every 6 hours. Volume expansion is accomplished with normal saline (20 mL per kg) in the first hour, followed by fluids appropriate for maintenance and replacement. Additional Na^+ may be needed in primary adrenal insufficiency because of ongoing urinary Na^+ losses. These fluids should contain 10% dextrose and should not contain potassium until the serum potassium is within the normal range.

Mineralocorticoid therapy is rarely important in the acute phase, provided fluid therapy is adequate; however, patients with primary adrenal insufficiency may need replacement with a mineralocorticoid for long-term management. Hydrocortisone acts at the mineralocorticoid receptor when dosed at stress levels of 50 mg per m^2 per day. Subsequent long-term therapy can be accomplished with fludrocortisone. Specific therapy directed toward correction of the hyperkalemia is rarely required unless cardiac EKG changes (peaked T wave, prolonged QRS duration) or arrhythmias are present. Hypoglycemia is remedied by the use of dextrose and by the hyperglycemic effects of glucocorticoids. The precipitating factor, such as infection, also requires appropriate therapy.

Improvement in peripheral circulation and blood pressure should occur quickly with therapy. Dramatic improvement often occurs in all parameters within hours after the first dose of glucocorticoid. Because adrenal crisis is commonly brought on by another stress such as infection, the symptoms of malaise, anorexia, and lethargy may take longer to resolve. Once instituted, high-dose glucocorticoid therapy should be continued for 48 hours, and adequate hydration should be maintained either orally or intravenously. The patient known to be at risk for adrenal insufficiency should wear an identifying bracelet to alert ED personnel to this possibility.

CONGENITAL ADRENAL HYPERPLASIA

Background

Inborn errors of adrenal steroid biosynthesis are grouped under the term *congenital adrenal hyperplasia* (CAH). Two major modes of presentation occur in early infancy and require prompt diagnosis and treatment: acute salt-losing crisis and ambiguous genitalia (Table 86.6). CAH may also present in children as precocious virilization. This form of CAH warrants investigation, but it does not require emergency management. The most common form of CAH presenting in infancy is 21-hydroxylase deficiency, which is recessively inherited and accounts for 90% of all cases. Clinically apparent salt wasting develops in approximately two-thirds of affected patients. In the United States, the incidence of 21-hydroxylase deficiency is approximately 1 in 15,000 live births.

Pathophysiology

The enzymes 21-hydroxylase, 11β-hydroxylase, 3β-hydroxysteroid dehydrogenase, and 20,22-desmolase are involved in the production of both cortisol and aldosterone (Fig. 86.1 and Table 86.6). Because the hypothalamic–pituitary axis is under feedback control by cortisol, the lack of production of this hormone caused by the enzyme deficiency results in a significant increase in ACTH. In turn, ACTH stimulates the adrenal to increase steroid hormone production. Because cortisol synthesis is impaired, the precursors of cortisol accumulate significantly. The symptoms and signs characteristic of each enzymatic deficiency reflect either the absence of cortisol or aldosterone or the accumulation of their precursors.

TABLE 86.6

CLINICAL AND LABORATORY FEATURES OF VARIOUS FORMS OF CONGENITAL ADRENAL HYPERPLASIA

	Clinical Features				
	Newborn with sexual ambiguity				
Enzyme deficiency	Female	Male	Salt wasting	Hypertension	Postnatal virilization
21-Hydroxylase					
Nonsalt wasting	Y	N	N	N	Y
Salt wasting	Y	N	Y	N	Y
11β-Hydroxylase	Y	N	N	Y	Y
3β-Hydroxysteroid dehydrogenase	Y	Y	Y	N	N
17α-Hydroxylase	N	Y	N	Y	N
Cholesterol desmolase	N	Y	Y	N	N
18-Hydroxylase	N	N	Y	N	N
17β-Hydroxysteroid dehydrogenase	N	Y	—	—	Y

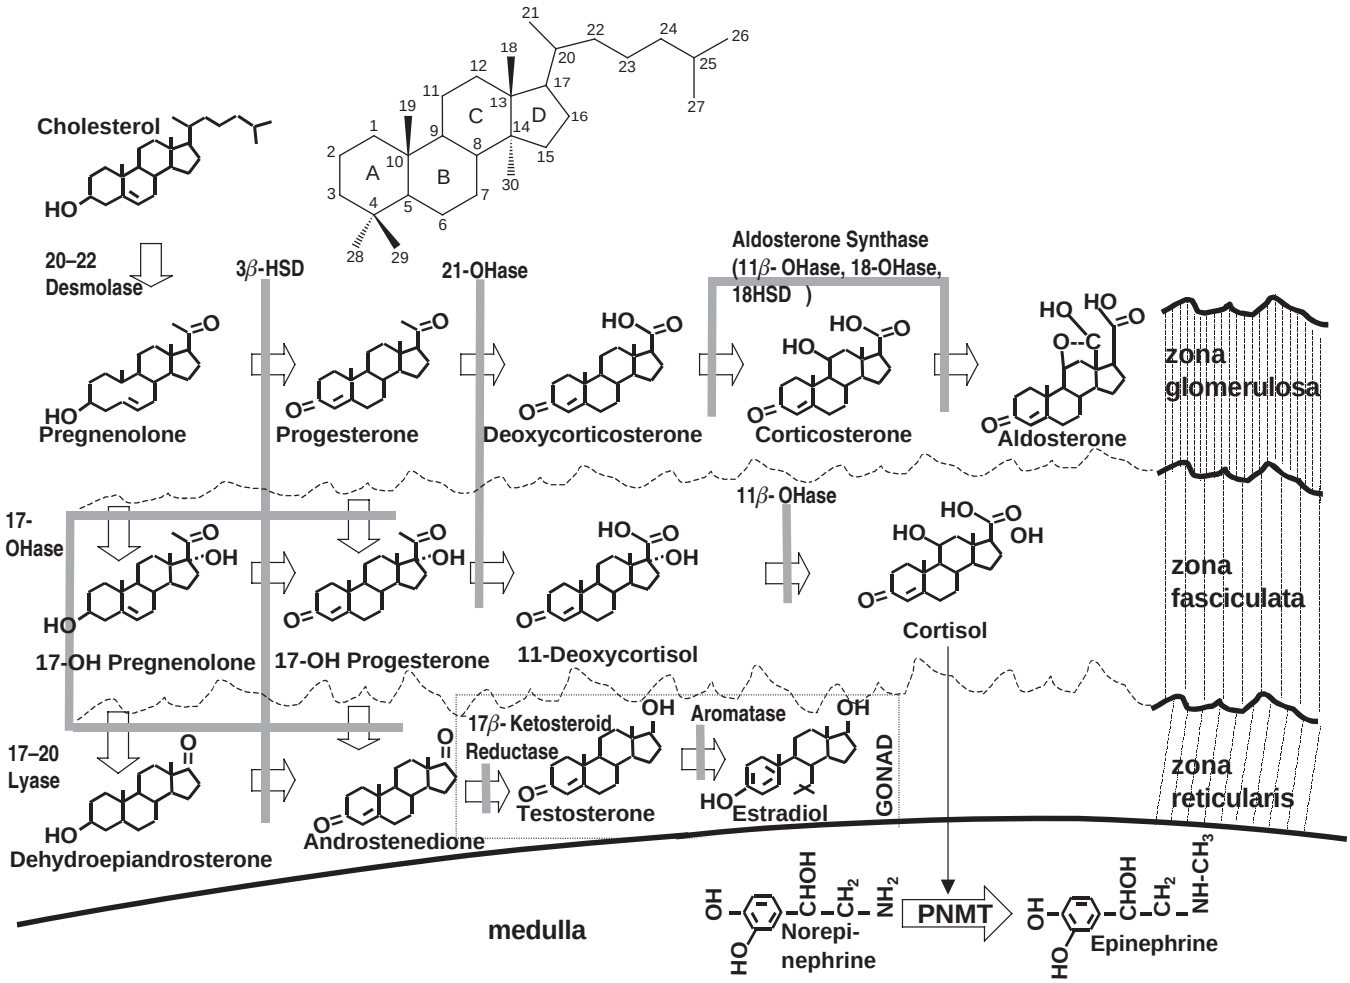

FIGURE 86.1 Adrenal steroid hormone biosynthesis. The pathways for the synthesis of adrenal steroid hormones (adrenal cortex) and catecholamines (adrenal medulla) are arranged from left to right. Synthesis of all compounds originates from cholesterol in the mitochondria of the adrenal cortex. Subsequent conversions are shown with enzyme names located next to *open arrows*, and *gray lines* indicating enzymatic blocks in the various forms of congenital adrenal hyperplasia (CAH). Mineralocorticoids (aldosterone) are produced in the zona glomerulosa, glucocorticoids (cortisol) in the zona fasciculata, and androgens (testosterone) and estrogens (estradiol) in the zona reticularis. Cortically produced cortisol is required for full induction of the medullary conversion of norepinephrine to epinephrine. (Courtesy of Joseph Majzoub, MD, Children's Hospital Boston.)

Impairment of mineralocorticoid synthesis by 21-hydroxylase, 3β-hydroxysteroid dehydrogenase, and 20,22-desmolase deficiency can result in salt wasting. Although 11β-hydroxylase deficiency also blocks aldosterone production, the immediate precursor to the block, desoxycorticosterone, has potent mineralocorticoid activity. Thus, instead of developing salt loss, patients with this enzyme defect often develop hypertension during childhood.

Androgenic compounds accumulate in 21-hydroxylase and 11β-hydroxylase deficiencies. Females with these defects are virilized in utero and are born with ambiguous genitalia; therefore, females are often identified in the newborn period. Some female infants are so virilized that they are mistaken as males with bilateral cryptorchidism. Males have normal genital development; therefore, the diagnosis is generally missed until they present with salt-wasting crisis during infancy or with evidence of precocious puberty during childhood. Deficiency of 3β-hydroxysteroid dehydrogenase leads to underproduction of testosterone. Boys with this deficiency are undervirilized because only weak androgens are produced, whereas girls are mildly virilized because of these weak androgens. Lack of cortisol renders the patient more susceptible to hypoglycemia and reduces the tolerance to severe stress, such as dehydration.

Clinical Manifestations

CAH may manifest at birth with the discovery of ambiguous genitalia, between 2 and 5 weeks of age when the baby presents with acute salt-losing crisis, or during childhood with the onset of precocious puberty. The affected child may come to the ED for any of these reasons. Caution is in order in considering newborn screening for CAH. Although many US states now screen newborns for CAH, the results may not be

available for 3 to 4 weeks and the acute salt-losing crisis may occur before this time. Furthermore, the report of an abnormal test result may precipitate a visit to the ED: Unless the child is ill, consultation with a pediatric endocrinologist is highly recommended.

The subsequent discussion deals primarily with the recognition and management of the acute salt-losing crisis, which is life-threatening. Salt wasting is present shortly after birth, but acute crisis usually does not occur until the second week of life. The appearance of symptoms can be insidious, with a history of poor feeding, lack of weight gain, lethargy, irritability, and vomiting. The nonspecificity of symptoms may lead to consideration of diagnoses far removed from CAH and delay initiation of treatment.

Examination of the child should include the vital signs and an assessment of the degree of dehydration. In severe cases, there may be shock and metabolic acidosis. The genitalia should be examined carefully because the degree of ambiguity of the genitalia varies considerably. Virilized females may have an enlarged clitoris and fusion of the labial folds. An undervirilized male may have a small phallus and/or hypospadias. The presence of gonads in the inguinal canals or labioscrotal fold is suggestive of a male karyotype. Hyperpigmentation of the labioscrotal folds and the nipples is occasionally present in the neonatal period; however, it is rarely prominent enough to alert the examiner to the possibility of CAH.

In the ED, the most urgent investigations are plasma electrolytes and blood glucose. The combination of hyperkalemia and hyponatremia is often the first clue to the diagnosis of CAH, especially in males. The plasma potassium is elevated, but in the presence of vomiting and diarrhea, the rise may be blunted.

Levels between 6 and 12 mmol per L are commonly encountered, often without any clinical cardiac dysfunction or EKG changes. The plasma bicarbonate level is usually low, reflecting the metabolic acidosis that results from the retention of hydrogen ions in exchange for sodium loss. The blood glucose is usually normal; however, hypoglycemia may occur secondary to the lack of cortisol and the reduced caloric intake during the acute illness. Serum should be drawn for determination of an adrenal steroid profile to include cortisol, 17-hydroxyprogesterone, dehydroepiandrosterone, androstenedione, and testosterone. Ideally, blood should be obtained for these tests before the administration of hydrocortisone. In the child in crisis, the diagnosis must be based on physical findings and electrolyte abnormalities, and treatment must be instituted before the definitive adrenal steroid profile is available.

Management

Fluid and Electrolyte Replacement

If the child is dehydrated, fluid replacement is urgent. Volume expansion should be affected by the rapid infusion of 20 mL per kg normal saline in the first hour or more rapidly, if needed. Because the dehydration in salt-losing CAH represents urinary losses of isosmotic fluid, replacement should consist of normal saline (0.9%). The volume to be replaced should constitute the child's daily requirements and the estimated fluid loss. Fluid input and output should be monitored carefully.

Mineralocorticoid Replacement

Principal management of the mineralocorticoid deficit is by the provision of sodium. In addition, hydrocortisone has some mineralocorticoid effect, particularly at high dosages (50 mg per m^2 per day). For long-term management, the child will require mineralocorticoid replacement (fludrocortisone 0.1 mg per day). Most infants also require oral Na^+ supplements for the first several months of life.

Glucocorticoid Replacement

Hydrocortisone (25 mg) should be given in an IV bolus, followed by hydrocortisone 50 mg per m^2 per 24 hours as a constant infusion or divided every 6 hours. Alternatively, cortisone acetate 25 mg intramuscularly immediately, followed by 25 mg every 24 hours, may be used. Glucocorticoids can suppress ACTH and the precursor steroids production within a few hours of administration, thus making the diagnosis of an enzymatic deficiency more difficult. However, it is better to avoid the possibility of mortality by giving the steroid than to delay treatment for diagnostic purposes.

Correction of Hyperkalemia, Hypoglycemia, and Acidosis

Infants with CAH tolerate hyperkalemia far better than do other children and adults, with potassium levels as high as 12 mmol per L reported without clinical signs. Volume restoration with normal saline is the major and, usually, the only measure needed to lower the potassium. In the presence of arrhythmias, IV 10% calcium gluconate 1 mL per kg can be given for its membrane-stabilizing properties. Therapy with glucose and insulin is contraindicated because of the danger of precipitating hypoglycemia. If hypoglycemia is found at the time of presentation, it should be treated acutely by the administration of dextrose (0.25 g per kg) intravenously and by the subsequent inclusion of 10% dextrose in the infusate. Acidosis generally does not require specific treatment; however, the low serum bicarbonate may take days to fully correct. Bicarbonate therapy is reserved for patients with both severe acidosis (pH < 6.9) and secondary hemodynamic compromise that is unresponsive to inotropic agents.

Presentation of Known CAH to the ED

In patients with known CAH, or other forms of adrenal insufficiency, the inability to produce an adequate cortisol response to acute illness may only manifest once the acute illness has become severe. In these cases, the contribution of the CAH to the patient's pathology may become unclear to the physician at the bedside and treatment of adrenal insufficiency may be delayed. Emergency glucocorticoid therapy, delivered at the stress dose of hydrocortisone 50 mg per m^2 per day should be administered to any patient with known CAH or other form of adrenal insufficiency in the setting of temperature above 38.5°C, emesis and/or diarrhea, bony fracture of any type, or in the setting of altered mental status or shock. If the patient appears ill, and initial dose of hydrocortisone 50 mg per m^2 may be given either intramuscularly or intravenously, followed by that dose divided in four and given every 6 hours. If the patient is not ill-appearing and is tolerating oral fluids and medications, his/her usual daily dose may be tripled and given in three equal parts daily, or hydrocortisone 50 mg per m^2 per

day may be given orally in three equal parts daily if the home dose cannot be readily established.

PHEOCHROMOCYTOMA

Background

Pheochromocytomas are functional tumors that arise in chromaffin tissues. In most children, these tumors are in the adrenal medulla, but they may be found in aberrant tissue along the sympathetic chain. Less than 5% of all pheochromocytomas occur in children. They are twice as common in males as in females, with the incidence of malignancy estimated to be 2% to 4%. Most information on pheochromocytoma is derived from adult studies, especially regarding signs and symptoms. Few detailed studies are available on children.

Pathophysiology

Catecholamines are low-molecular-weight substances produced in the CNS, the sympathetic nerves, the adrenal medulla, and the extraadrenal chromaffin cells. Catecholamines affect metabolic processes in most tissues of the body and have many effects, including accelerated heart rate, increased myocardial contraction, and changes in peripheral vascular resistance. Excessive production of catecholamines by a pheochromocytoma results in intensification of the normal physiologic effects.

Clinical Manifestations

The detection of a pheochromocytoma requires expert clinical awareness. Most patients are symptomatic, but the symptoms are nonspecific and, in the child, are likely to be attributed to other disease entities. The symptoms and signs are related to the excess production of catecholamines and can be explained on the basis of the pharmacologic effects of these substances. The most common symptoms are headache, palpitations, and excessive or inappropriate sweating. The headache, characteristically, is pounding and may be severe. The palpitations may be accompanied by tachycardia. Almost all patients will have one of the three symptoms listed, and most will have at least two. Other symptoms may include nervousness, tremor, fatigue, chest or abdominal pains, and flushing.

The most useful screening tool for pheochromocytoma is the blood pressure cuff because most pheochromocytomas are associated with hypertension.

Because this hypertension may be continuous or paroxysmal, frequent and repeated blood pressure determinations may be necessary. Hypertension is most likely to be found when the patient is symptomatic. A hypertensive patient who is asymptomatic is unlikely to have a pheochromocytoma. Paroxysmal symptoms and hypertension should lead to consideration of this diagnosis.

The diagnosis of a pheochromocytoma should also be considered in patients with malignant hypertension, in those who fail to respond or respond inappropriately to antihypertensive medications, and in those who develop hypertension during the induction of anesthesia or during surgery. Incidence of pheochromocytomas is increased among patients with neurofibromatosis and with the multiple endocrine neoplasia syndrome types II and III. Documentation of excess catecholamine in either the urine or serum confirms the diagnosis of pheochromocytoma. The most readily available and widely used test for this purpose remains the measurement of urinary catecholamines or their metabolites (3-methoxy-4-hydroxymandelic acid and total metanephrines) in a 24-hour urine collection accompanied by a patient symptom log. The finding of significant elevations of these substances is adequate confirmatory data. Some false-negative results may occur using urinary catecholamines. When the degree of suspicion is high, repeated specimens may be needed. Plasma metanephrine concentration has now been shown to be a superior screening and confirmatory test, however, and ought to be employed where available.

Once the diagnosis is confirmed, anatomic localization is necessary using either computed tomography or nuclear magnetic resonance imaging. Occasionally, arteriography with selective sampling for epinephrine production is necessary for localization.

Management

Pheochromocytoma is cured by the surgical removal of the tumor. The focus of ED management should be on controlling hypertension and hypertensive crisis that may occur before the surgical procedure. α-Adrenergic blocking agents are useful in controlling hypertension and in minimizing blood pressure fluctuations during the surgical procedure.

Preferred drugs for controlling hypertension are phenoxybenzamine (Dibenzyline®) and prazosin (Minipress®). Dosage schedules and quantity must be tailored to the individual for adequate control of hypertension. Hypertensive crisis may be appropriately managed with IV phentolamine (Regitine® 1 mg IV for children; 5 mg IV for adolescents) or sodium nitroprusside (0.5 to 8.0 μg per kg per minute). Beta blockade must be avoided because it may lead to unopposed alpha action on the part of secreted catecholamines and resultant severe hypertension.

DIABETES INSIPIDUS

Background

DI is caused by an inability of the kidneys to concentrate urine and is characterized clinically by polyuria and polydipsia. Either a deficiency of ADH secretion from the hypothalamus and posterior pituitary gland or renal unresponsiveness to ADH can cause this disease (Table 86.7). Most central causes of DI in children are acquired and can present at any age. In contrast, the most common cause of nephrogenic DI in children is X-linked recessive and manifests in males during early infancy. Renal lesions associated with nephrogenic DI can present in later childhood.

Pathophysiology

ADH is synthesized in the supraoptic and paraventricular nuclei of the hypothalamus. It is transported along nerve axons to the posterior pituitary gland, where it is stored. ADH

is released in response to increased plasma osmolality, hypernatremia, and decreased right atrial pressure secondary to hypovolemia. The distal convoluted tubules and the collecting ducts of the kidneys respond to ADH by inserting a water channel (aquaporin) into the luminal membrane of the collecting duct and allowing water reabsorption along the medullary concentration gradient. Lack of ADH (central DI) can result from a wide variety of hypothalamic and pituitary lesions (Table 86.7). Conversely, in nephrogenic DI, ADH levels are normal or elevated because the defect resides in the renal collecting tubules, which are resistant to the action of ADH. In either case, failure of water reabsorption results in polyuria. A normal thirst mechanism contributes toward fluid balance by promoting adequate fluid intake; however, if this balance is not achieved, hypertonic dehydration ensues. If a hyperosmolar state develops abruptly, it may lead to dehydration of neural tissues, which can cause serious neurologic sequelae or result in death. The pons is particularly sensitive to this effect resulting in central pontine myelinolysis.

Clinical Manifestations

Urine excretion is increased in both volume and frequency in the child with DI. This condition may manifest as enuresis in the younger child. Provided the thirst mechanism is intact and fluids are accessible, the child can compensate for the water loss by drinking more. A history may be elicited of the child's awakening in the middle of the night to drink. If fluids are not available or if fluid intake is interrupted because of an illness, dehydration rapidly ensues. In the young infant who is not provided with adequate fluids and consequently is chronically dehydrated, the child may fail to thrive or may have a history of intermittent low-grade fevers due to intermittent hypernatremia. However, if the cries of the infant are interpreted as hunger rather than thirst, the infant with DI may be obese.

Physical examination may be normal, or signs of dehydration, such as dryness of mucous membranes, decreased skin turgor, sunken eyes, and in an infant, a depressed anterior fontanel, may be present. Because of the hyperosmolarity, the degree of dehydration may be underestimated on physical examination. Hypothalamic or pituitary lesions can lead to other endocrine abnormalities such as secondary hypothyroidism and growth failure. A craniopharyngioma or optic nerve glioma may affect the visual fields or cause raised intracranial pressure, which is indicated by papilledema.

DI is diagnosed by demonstrating that the kidneys fail to concentrate urine when fluid intake is restricted. This condition can be difficult to prove in children. Criteria for the diagnosis of DI may be met by finding an elevated serum osmolality (greater than 300 mOsm per L) and an elevated serum [Na^+] (greater than 145 mmol per L) in the presence of dilute urine (osmolality less than 600 mOsm per L). Blood glucose and serum creatinine levels are normal.

In many cases, the diagnosis can be ruled out by the demonstration of appropriately concentrated urine and normal serum osmolality on specimens obtained upon awakening. The definitive diagnosis is made by a formal water deprivation test. This test is performed electively in cases in which the diagnosis is uncertain and should never be performed if the child is already dehydrated. The measurement of ADH by radioimmunoassay is available but generally is not useful in the diagnosis of DI.

Management

In most cases, a diagnosis of DI is not known at the time of presentation; therefore, the acute management is directed toward correction of the dehydration and the hyperosmolar state. The treatment of DI is similar to that described for hypernatremic dehydration (see Chapter 17), with the notable addition that the fluid required for the replacement of urinary fluid losses will be far greater. In fact, the high urinary output, despite significant dehydration, often provides the first and most convincing evidence for DI. If the child is hypotensive or if the serum [Na^+] is greater than 160 mmol per L, initial volume expansion is necessary, using 20 mL per kg normal saline during the first hour or more rapidly, if needed. Once an adequate intravascular volume has been achieved, further fluid replacement is accomplished slowly because overly rapid volume correction can cause cerebral edema, seizures, and death.

If the child is not hypotensive, or once the hypotension has been corrected, free water replacement is done over 48 hours. Calculations of appropriate fluids must include maintenance requirements, replacement needs, and ongoing urinary losses (see Chapter 17).

If DI is strongly suspected on the basis of discrepant serum and urine osmolality, DDAVP (10 μg intranasally or 0.2 to 0.4 μg per kg subcutaneously) may be a useful adjunct to IV fluid ther-

apy. If DDAVP is not available or cannot be used for some reason, other antidiuretic agents are available. Aqueous pitressin may be administered as a continuous IV infusion starting at 1 mUnit per kg per hour and slowly (every 5 to 10 minutes) increasing the rate (maximum 10 mUnit per kg per hour) to decrease urine output to less than 2 mL per kg per hour.

DDAVP and pitressin act rapidly to promote tubular resorption of free H_2O; clinically, this response is apparent as decreased urinary output with increased osmolality within 15 minutes of administration. Once the patient has responded, however, extreme care must be used in subsequent fluid management because the patient can no longer excrete excess water. Therefore, baseline IV fluid administration must be maintained at 1 L per m^2 of body surface area per day (or roughly two-thirds maintenance fluids) using a low sodium infusate, such as 5% dextrose with one-fourth normal saline (0.23%), in addition to the fluid designed to replete the initial estimated free water deficit over 48 hours.

Failure to respond to either form of ADH suggests the possibility of tubular unresponsiveness to ADH (nephrogenic DI); however, more commonly, failure to respond results from improper administration of the medication or use of DDAVP that has lost its potency. Because of these factors, if cessation of diuresis is not noted within 2 hours of administration of the first dose, a second dose from a different bottle of DDAVP should be tried. The use of an ADH agonist generally simplifies management by reducing the quantity of fluid that must be infused; however, careful monitoring of input and output remains essential. Children who fail to respond to DDAVP are likely to have nephrogenic DI and must be acutely managed with fluid therapy alone. Hypercalcemia and renal failure are the most common causes of nephrogenic DI. Paradoxically, the thiazide diuretics have proven to be useful in the chronic control of nephrogenic DI.

The child should be closely observed for changes in level of consciousness, pulse rate, and blood pressure. Fluid input and output should be meticulously monitored. Serum osmolality and $[Na^+]$ should be determined every 1 to 2 hours until the rate of their decline can be determined. Urine osmolality should be measured every 1 to 2 hours to determine the responsiveness of the renal tubule to DDAVP. Because large volumes of dextrose-containing fluids are used, the blood glucose should also be followed closely. If the blood glucose exceeds 160 mg per dL, the concentration of dextrose in the infusate should be decreased.

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION

Background

Excessive secretion of ADH accompanying normal or low plasma osmolality or $[Na^+]$ is inappropriate because it further depresses the plasma osmolality and $[Na^+]$. Symptoms of excessive ADH secretion are not usually apparent until the plasma $[Na^+]$ falls to less than about 125 mmol per L. The overall incidence of the syndrome of inappropriate ADH secretion (SIADH) in childhood is unknown, but it is common in certain disease states. More than 50% of children with bacterial meningitis, about 20% of patients on positive-pressure ventilation, and about 70% of children with Rocky Mountain spotted fever develop some degree of SIADH.

Pathophysiology

ADH secretion is stimulated by hypertonicity of the fluid surrounding the hypothalamic osmoreceptors, volume receptors in the left atrium, and ill-defined nervous impulses from higher cortical centers. Disorders of the CNS (Table 86.8) may cause excessive ADH secretion by producing either a local disturbance of the hypothalamic osmoreceptors or some undetermined nervous stimuli. Many intrathoracic conditions are associated with SIADH, probably due to the vestigial ability of the lung to produce ADH. Physical and emotional stress, severe pain, and nausea are also potent stimuli of ADH secretion. Excessive secretion of ADH leads to water retention by the collecting tubules of the kidneys, a mechanism mediated by insertion of water channels into the luminal membrane of the collecting duct and allowing water reabsorption along the medullary concentration gradient. The retained water expands the intravascular compartment, dilutes all plasma constituents, and lowers the plasma osmolality.

TABLE 86.8

SOME CAUSES OF SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION IN CHILDREN

Disorders of Central Nervous System
Infection (meningitis, encephalitis)
Trauma, postneurosurgery
Hypoxic insults, especially in the perinatal period
Brain tumor
Intraventricular hemorrhage
Guillain-Barré syndrome
Psychosis

Intrathoracic Disorders
Infection (tuberculosis, pneumonia, empyema)
Positive-pressure ventilation
Asthma
Cystic fibrosis
Pneumothorax
Patent ductus arteriosus ligation

Miscellaneous
Pain (e.g., after abdominal surgery)
Nausea
Severe hypothyroidism
Tumors (e.g., neuroblastoma)

Drug Induced
Increased antidiuretic hormone secretion
- Vincristine
- Cyclophosphamide
- Carbamazepine
- Adenine arabinoside
- Phenothiazines
- Morphine

Potentiation of antidiuretic hormone effect
- Acetaminophen
- Indomethacin

TABLE 86.9

CRITERIA FOR DIAGNOSIS OF SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION

Hyponatremia, reduced serum osmolality
Urine osmolality inappropriately elevated (a urine osmolality <100 mOsm/kg usually excludes the diagnosis)
Urinary Na^+ concentration that is excessive in comparison to the degree of hyponatremia (usually >18 mmol/L)
Normal renal, adrenal, and thyroid function
Absence of volume depletion (euvolemic to hypervolemic state)

Clinical Manifestations

Most patients with SIADH are asymptomatic until the plasma [Na^+] falls to less than 125 mmol per L. Symptoms associated with hyponatremia range from anorexia, headache, nausea, vomiting, irritability, disorientation, and weakness to seizures and coma, leading ultimately to death. Absence of edema and dehydration are significant clinical findings.

Laboratory investigations for diagnostic purposes must include concomitant serum and urine samples (Table 86.9). Hyponatremia, hypoosmolality (serum), and low blood urea nitrogen will be present. In contrast, the urinary osmolality and [Na^+] are inappropriately elevated for the hypotonicity of the serum. Due to the euvolemic or hypervolemic state, aldosterone is suppressed and urine potassium will be low. Radioimmunoassay for ADH is now available and has been helpful in defining this syndrome; however, the results of this test are unlikely to be available on an emergency basis. The underlying cause of the syndrome should be investigated according to the physician's clinical judgment. Hyperlipidemia may falsely lower laboratory measurement of [Na^+], leading to a factitious hyponatremia. Hyperglycemia and hypoproteinemia, however, lead to true hyponatremia. Renal salt wasting, secondary to adrenal insufficiency, should be accompanied by hyperkalemia and dehydration. Cerebral salt wasting may have laboratory parameters similar to SIADH but is characterized by hypovolemia and a high urine output as long as renal perfusion remains intact. The urine osmolality in water intoxication states is usually low compared with that found in SIADH.

Management

Severely Symptomatic Children

Patients with a persistent seizure attributable to severe hyponatremia and those who are severely lethargic or comatose need urgent treatment. Hypertonic (3%) saline is the preferred treatment. Infusing small amounts of 3% saline in the range of 3 mL per kg every 10 to 20 minutes until symptoms remit is likely the safest course of treatment. One milliliter per kilogram of 3% saline should raise the serum [Na^+] by approximately 1 mmol per L. A single dose of furosemide (1 mg per kg) also can be administered intravenously. Close monitoring of fluid balance, plasma and urinary sodium, potassium, and osmolality is essential. Seizures should be treated concomitantly with a standard emergency anticonvulsant protocol (see Chapters 69 and 96). Of note, phenytoin (Dilantin®) or fosphenytoin (Cerebryx®) intravenously (5 to 10 mg per kg) inhibits ADH release and may be helpful in the patient with seizures secondary to CNS causes of SIADH. The underlying cause of SIADH, such as meningitis or pneumonia, should be treated when possible; successful treatment is usually accompanied by remission of inappropriate antidiuresis.

Asymptomatic or Mildly Symptomatic Children

Asymptomatic or mildly symptomatic patients are treated by rigorous fluid restriction. If the patient is not vascularly compromised, fluid input should be sharply limited, often below insensible loss, until the [Na^+] and osmolality begin to rise. If the initial [Na^+] is less than 125 mmol per L, all fluids must be withheld. Frequent measurements of plasma electrolytes and osmolality, as well as close monitoring of fluid input and output, are essential. As the serum [Na^+] rises and urine osmolality falls, the rate of fluid administration can be gradually increased. The child with chronic or recurrent episodes of SIADH may require treatment with demeclocycline 10 mg per kg. The underlying cause should be identified, treated, and eliminated, if possible.

HYPERPARATHYROIDISM

Background

Hyperparathyroidism is most commonly recognized during the third, fourth, and fifth decades of life. It is uncommon in children.

Pathophysiology

The parathyroid glands are derived from the third and fourth pharyngeal pouch and are usually embedded in the posterior aspect of the thyroid gland. Occasionally, a gland may be found in the anterior mediastinum. Parathyroid hormone (PTH) is the primary hormone produced by the parathyroid glands. PTH is synthesized and released constitutively; its secretion is stimulated by low and suppressed by high serum ionized calcium concentration. Prolonged hypocalcemia, most commonly in the setting of renal failure, may lead to hypertrophy of the parathyroid glands and secondary hyperparathyroidism. PTH acts on the kidney to decrease the excretion of calcium, magnesium, and hydrogen, while increasing the excretion of phosphate, sodium, and bicarbonate. Many of the effects are mediated by cyclic adenosine monophosphate (cAMP), and an increased quantity of cAMP is present in the urine of patients with hyperparathyroidism. PTH also increases the formation of 1,25-dihydroxyvitamin D in the kidneys. PTH may increase intestinal absorption of calcium, although this effect is primarily mediated by 1,25-$(OH)_2$D. Both PTH and 1,25-$(OH)_2$D affect bone. PTH acts on bone to increase the release of calcium by increasing the number and activity of the osteoclasts, whereas vitamin D decreases calcium use in bone formation by decreasing the number of osteoblasts. The net effect of the actions of PTH and vitamin D is to

increase serum calcium by decreasing renal calcium excretion, decreasing new bone formation, increasing bone resorption, and increasing intestinal absorption of calcium.

Clinical Manifestations

Hyperparathyroidism has two common presentations in children. The first presentation is the critically ill infant who is found to have severe hypercalcemia during the course of diagnostic investigations. The serum calcium level may be extremely high. The second presentation is a child in the early to midteens with nonspecific symptoms including nausea, constipation, unexplained weight loss, personality changes, and headaches. Diffuse bone pain or renal colic may be reported, although these symptoms are less common in children than in adults.

The physical findings of hypercalcemia are hypotonia, weakness, listlessness, anorexia, constipation, and vomiting, and in the neonate, respiratory distress and apnea. There may be hypertension, shortened QTc interval on EKG, polyuria (due to renal unresponsiveness to ADH), and rarely, encephalopathy with seizures. A palpable mass may occasionally be located in the parathyroid region. Certain characteristic features have been associated with idiopathic hypercalcemia in infancy, including hypertelorism, broad forehead, epicanthal folds, prominent upper lip, an underdeveloped nasal bridge, and a small mandible. Not surprisingly, these same features have been noted in infants with hyperparathyroidism.

A family history may be helpful because hyperparathyroidism has been associated with both multiple endocrine neoplasia types I and II, which are inherited as autosomal-dominant conditions. Hyperparathyroidism may also occur in infants of hypoparathyroid mothers. Radiologic findings consistent with hyperparathyroidism include evidence of demineralization and bone resorption (Figs. 86.2 and 86.3). Osteitis fibrosa cystica, although highly suggestive of the diagnosis, is unusual in children.

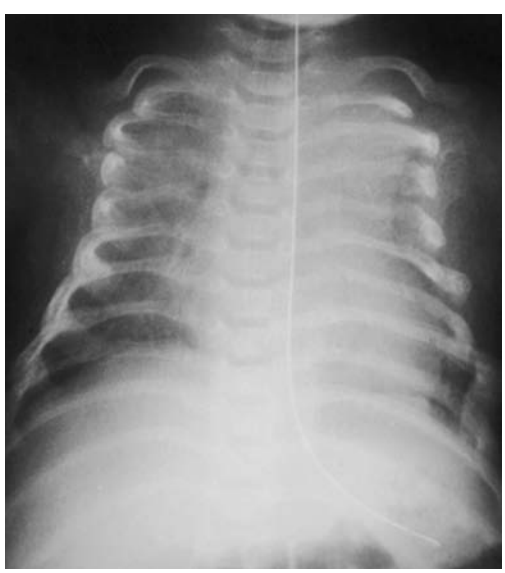

FIGURE 86.2 Primary hyperparathyroidism in a 3-day-old girl. Roentgenogram of the chest shows profound demineralization of the skeleton with loss of a well-defined cortical margin. Cystic changes in rib and subperiosteal bone resorption in humerus are seen. (Courtesy of Soroosh Mahboubi, MD, The Children's Hospital of Philadelphia.)

FIGURE 86.3 Secondary hyperparathyroidism in a 12-year-old girl with chronic pyelonephritis. There is moderate subperiosteal erosion on the radial side of the middle phalanges; note a lacy appearance of the periosteum and small-tuft erosion. Subperiosteal bone resorption is the most significant radiologic finding in hyperparathyroidism; subperiosteal bone resorption and tuft erosion are seen in both primary and secondary hyperparathyroidism. (Courtesy of Soroosh Mahboubi, MD, The Children's Hospital of Philadelphia.)

The clinical laboratory is helpful in the recognition of hyperparathyroidism. Hypercalcemia is usually present but may be subtle or intermittent in mild cases. The serum inorganic phosphate level is usually low but may be normal, especially in patients with decreased renal function. Mild hyperchloremic acidosis may be present. Alkaline phosphatase level and urinary hydroxyproline excretion may be elevated secondary to increased osteoclast activity. Because PTH causes a significant increase in cAMP in the kidney tubule, the presence of excess cAMP in the urine is strongly suggestive of excess PTH production. The determination of PTH levels is critical for diagnostic purposes, and elevated levels of PTH, when the patient is hypercalcemic, are a definitive laboratory finding.

Management

Acute management of hyperparathyroidism is essentially the same as management of hypercalcemia (see Chapter 100). The specific management of hyperparathyroidism depends on the level of calcium and on the presence of signs and symptoms. In the asymptomatic patient with serum calcium of less than 12 mg

per dL, careful follow-up with close attention to both bone mass and renal function is recommended. If the child is persistently hypercalcemic, parathyroid surgery is the preferred treatment. In the case of hyperplasia, the common reason for hyperparathyroidism in the infant, subtotal parathyroidectomy is indicated. If an adenoma is present, as is usually the case in the older child, simple removal of the involved parathyroid gland is adequate.

HYPOPARATHYROIDISM

Background

Hypoparathyroidism is rare in children. It may occur sporadically or be part of a familial syndrome consisting of combinations of several autoimmune diseases (e.g., Addison's disease, diabetes mellitus, lymphocytic thyroiditis, pernicious anemia, ovarian failure). Hypoparathyroidism is also associated with thymic aplasia and severe immunologic deficiencies (DiGeorge's syndrome). A transient form of hypoparathyroidism, lasting for as long as 1 year, has been reported in some infants. Hypoparathyroidism may also result from damage incurred during thyroid surgery or irradiation.

Pathophysiology

The basic actions of PTH are described in the preceding section on hyperparathyroidism. The lack of PTH, regardless of cause, has several deleterious effects on calcium homeostasis. Because PTH has significant effects on 1,25-$(OH)_2D_3$ formation, the absence of PTH is magnified by a consequent reduction in 1,25-$(OH)_2D_3$. The net effect of the lack of PTH (and decreased quantity of vitamin D) is a declining serum level of calcium, primarily caused by decreased intestinal absorption of calcium and decreased renal resorption of calcium.

Clinical Manifestations

The predominant historical features and clinical manifestations of hypoparathyroidism are the same as those of hypocalcemia (see Chapter 100). Unique historical information that may suggest the diagnosis of hypoparathyroidism includes other family members with autoimmune endocrine disease, recurrent episodes of serious infection in the affected child, and previous thyroid manipulations.

Most symptoms and signs of hypoparathyroidism are the same as those related to hypocalcemia. The particular symptoms and signs found depend on the age at disease onset, the chronicity of the disease, and the presence of other autoimmune or syndromic phenomena. Papilledema without hemorrhage may be seen during the initial examination and tends to resolve within several days after the initiation of therapy. Lenticular cataracts are common in hypoparathyroidism and are associated with long-standing hypocalcemia of any cause. Psychiatric and neurologic disorders occur in association with hypoparathyroidism. Subnormal intelligence occurs in about 20% of children with the idiopathic form of hypoparathyroidism, and the severity correlates closely with the period of untreated hypocalcemia. Dry, scaly skin is a common finding, as is patchy alopecia. Psoriasis or mucocutaneous candidiasis may be found on occasion. Unusually brittle fingernails and hair are often found. Hypoplasia of tooth enamel may be seen if hypoparathyroidism was present at the time of dental development. Intestinal malabsorption and steatorrhea have been reported in association with hypoparathyroidism.

In most cases, the diagnosis of hypoparathyroidism is first considered when low serum calcium is found. If an elevated phosphate accompanies low calcium, low or normal serum alkaline phosphate, and normal blood urea nitrogen, hypoparathyroidism is a likely possibility. Finding a low or nonmeasurable level of PTH in the presence of hypocalcemia and hyperphosphatemia makes the definitive diagnosis. Because PTH increases cAMP levels in the urine, the excreted amount of cAMP in the urine is low in patients with hypoparathyroidism and rises briskly with the administration of exogenous PTH. The presence of antibodies in other endocrine tissues or organs may help in delineating the cause of the hypoparathyroidism.

Management

The acute management of hypoparathyroidism is essentially the management of the hypocalcemia (see Chapter 100). Long-term management consists of treatment with vitamin D, usually with one of its more active analogs—1,25-$(OH)_2D_3$ at 0.01 to 0.05 μg per kg per day. Supplemental oral calcium is almost always necessary. The goals of long-term therapy are to maintain the serum calcium in the lower range of normal and to avoid both vitamin D toxicity and hypercalcemia. Preparations of PTH are not available for the long-term management of hypoparathyroidism.

RICKETS

Background

Rickets describes a characteristic set of clinical features delineated centuries ago, which is now known to be predominantly caused by inadequate dietary vitamin D. With this awareness and the advent of vitamin D supplementation of foods, especially milk, the incidence of rickets has fallen significantly; however, rickets is still seen among certain ethnic groups, premature infants, children with severe malabsorption problems, and patients with serious renal disease.

Pathophysiology

Rickets is caused by the failure of mineralization of bone matrix in growing bone resulting from a lack of vitamin D. Consequently, unmineralized cartilage is excessive, and bone is soft. In addition to inadequate intake of vitamin D, the other causes of rickets are inability to form the active metabolite of vitamin D, excess phosphate excretion, and excess accumulation of acid.

Vitamin D may be obtained from dietary sources (especially animal fat) or synthesized from cholesterol via a complex pathway requiring the interaction of the precursor molecule with sunlight. Further hydroxylation of vitamin D in the liver

(25-hydroxylation) and kidney (1-alpha-hydroxylation) leads to the formation of the active metabolite 1,25-dihydroxyvitamin D. Therefore, failure to form 1,25-$(OH)_2D_3$ may result from inadequate intake of vitamin D or insufficient exposure to sunlight. This is a particular problem among ethnic groups that eat small quantities of animal meat and that are extensively clothed when outdoors. Because vitamin D is fat soluble, any problem leading to prolonged fat malabsorption can result in rickets. Diseases affecting kidney or liver function may also lead to inadequate production of 1,25-$(OH)_2D_3$. An inherited deficiency of the 1-alpha-hydroxylase in the kidney (vitamin D–dependency rickets) is known. Certain drugs, such as phenobarbital and phenytoin, affect liver metabolism of vitamin D and can lead to rickets. Premature infants are particularly prone to vitamin D deficiency because of their minimal stores of vitamin D and their limited capacity for vitamin D synthesis.

Phosphate is a critical component of bone formation. Excess excretion of phosphate may lead to clinical rickets. Conditions that lead to excess phosphate excretion include primary hyperphosphaturia, Lowe's syndrome, and Fanconi's syndrome. Vitamin D–resistant rickets is a misnomer because the primary defect is in the renal tubular resorption of phosphate and not a resistance to vitamin D. Both an X-linked recessive and an autosomal-dominant form of phosphate wasting are known.

Rickets may also occur in conditions leading to chronic acidosis because bone is resorbed to buffer the acid load. This condition is seen in patients with distal renal tubular acidosis and may be partially responsible for the rachitic changes associated with Fanconi's syndrome.

Clinical Manifestations

Children with rickets may come to medical attention because of specific physical abnormalities (bowed legs), limb pain and swelling, seizures, failure to thrive (renal tubular acidosis), biochemical abnormalities (hypocalcemia), or radiographic findings (broadened, frayed metaphysis). A thorough social and dietary history is helpful in delineating the probable cause and in sparing the patient an extensive and expensive evaluation. A family history may be useful in identifying the 1-hydroxylase deficiency or renal phosphate wasting. If the child has previously been treated with vitamin D, the reported response to that treatment may be helpful in identifying the likely site of defect.

The clinical findings in rickets may vary considerably, depending on the underlying disorder, the duration of the problem, and the child's age. Most features are related to skeletal deformity, skeletal pain, slippage of epiphyses, bony fractures, and growth disturbances. Muscular weakness, hypotonia, and lethargy are often noted. Failure of calcification affects those parts of the skeleton that are growing most rapidly or that are under stress. For example, the skull grows rapidly in the perinatal period; therefore, craniotabes is a manifestation of congenital rickets. However, the upper limbs and rib cage grow rapidly during the first year of life, and abnormalities at these sites are more common at this age (i.e., rachitic rosary, flaring of the wrist). Bowing of the legs is unlikely to be noted until the child is ambulatory. Dental eruption may be delayed, and enamel defects are common.

Radiography is the optimal way to confirm the clinical diagnosis because the radiologic features reflect the histopathology. Characteristic findings include widening and irregularity of the epiphyseal plates, cupped metaphyses, fractures, and bowing of the weight-bearing limbs (Figs. 86.4 and 86.5). The clinical laboratory is often helpful in correctly identifying the cause of rickets. Frank hypocalcemia (less than 7 mg per dL) is unusual in rickets. Calcium levels in the 7 to 9 mg per dL range are common and warrant careful attention because the initiation of vitamin D treatment increases bony deposition of calcium and may lead to a fall in serum calcium. Phosphate levels are often low. An amino aciduria is often present and may lead to some confusion of simple vitamin D deficiency with Fanconi's syndrome. Alkaline phosphatase levels are significantly increased, reflecting extremely active bony metabolism. Although PTH levels are elevated, the results of this test are unlikely to be available at the time initial clinical decisions are made. Chronic acidosis, liver disease, and renal disease should be ruled out.

Treatment

Treatment depends on the nature of the underlying disease. The response to treatment may be helpful in differentiating simple dietary vitamin D deficiency from more complex causes of rickets. In the absence of chronic disease, dietary rickets may be adequately treated with daily doses of 1,200 to 1,600 IU of vitamin D (ergocalciferol) until healing occurs. Alternatively, a single high IM dose to replenish stores may be administered as ergocalciferol 50,000 to 100,000 IU. Serum phosphate usually returns to normal within 1 to 2 weeks, and radiographic improvement is generally apparent by 2 weeks. Once healing is complete, the child should continue to be treated with 400 IU per day to prevent recurrence. If the initial serum calcium is borderline low or low, supplemental calcium should be initiated 48 hours before the institution of vitamin D, especially in the young child. Otherwise, the institution of vitamin D may cause a further decrease in serum calcium and elicit frank hypocalcemia. This presentation may occur naturally if the vitamin D–deficient patient has relatively low serum calcium concentration and then has prolonged exposure to the sun. This may lead to abrupt increases in vitamin D, ultimately leading to a rapid increase in bone recalcification (hungry bone syndrome) and severe hypocalcemia with possible seizures. This syndrome is seasonally termed "spring fits." Children with symptomatic hypocalcemia or with initial serum calcium of less than 7 mg per dL on presentation warrant hospitalization and frequent calcium determinations. Failure to respond to vitamin D treatment suggests that the child has a more complex cause of rickets, and consultation with a pediatric nephrologist or endocrinologist is recommended.

THYROID STORM

Background

Thyroid storm, or thyrotoxic crisis, is a fulminating intensification of the hyperthyroid state. Because hyperthyroidism uncommonly occurs in children and because thyroid storm occurs in only 1% of patients with hyperthyroidism, thyroid

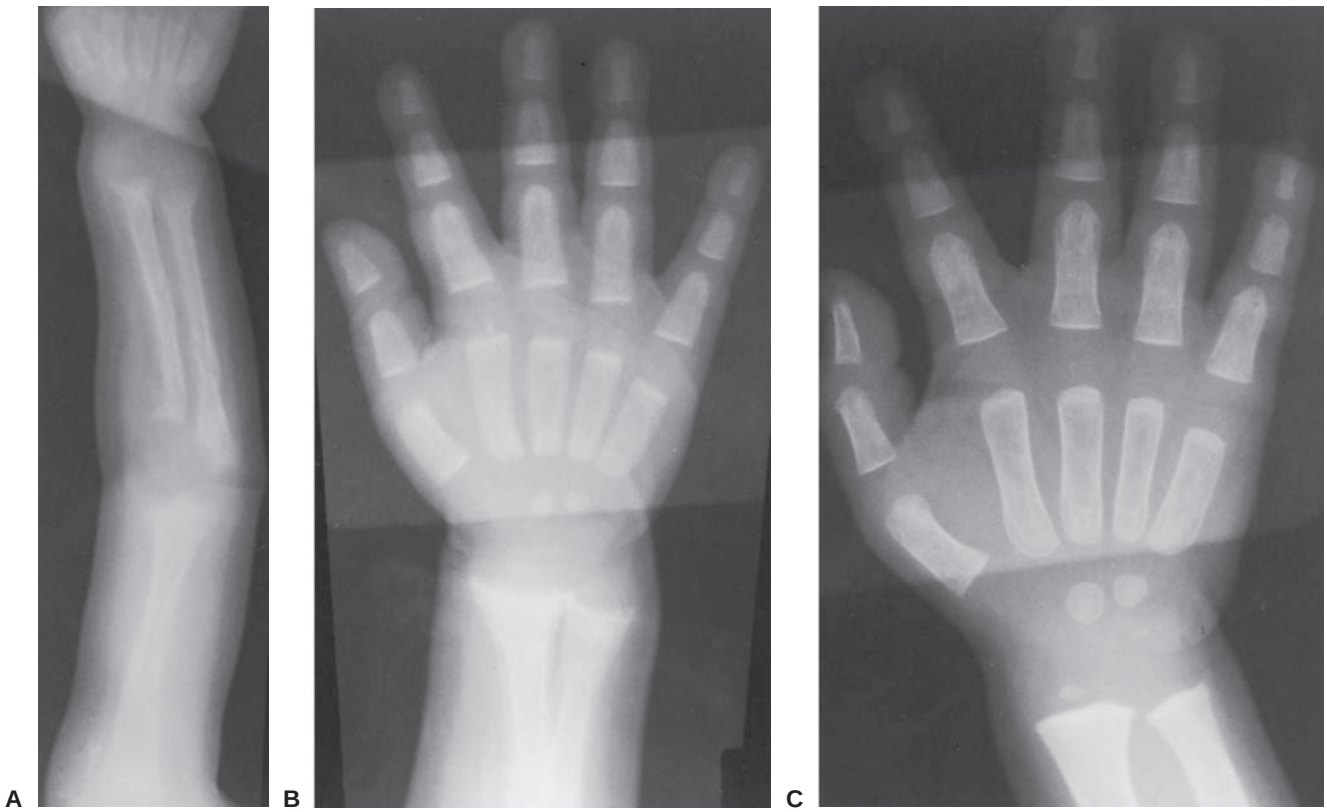

FIGURE 86.4 **A:** Rickets in an 11-month-old boy, breast-fed since birth. Roentgenogram of the upper extremity shows profound demineralization of the skeleton, with frayed, irregular cupping of the end of the metaphysis and poorly defined cortex. Note retardation of skeletal maturation. **B:** Same patient with some healing 4 weeks after supplemental vitamin D. Severe rachitic changes are noticeable. Periosteal cloaking, both of the metacarpals and of the radius and ulna, is evidence of healing. **C:** Complete healing of the rickets 8 months after treatment. Note the reappearance of the provisional zone of calcification. (Courtesy of Soroosh Mahboubi, MD, The Children's Hospital of Philadelphia.)

FIGURE 86.5 Rickets in an 11-month-old boy, breast-fed since birth. Roentgenogram of the chest shows demineralization of the skeleton with cupping of the distal end of ribs and humerus. (Courtesy of Soroosh Mahboubi, MD, The Children's Hospital of Philadelphia.)

storm is rare in children. Therefore, most information available on thyrotoxic crisis is derived from reports of this condition in adults. Precipitating factors include intercurrent infection, trauma, and subtotal thyroidectomy in an inadequately prepared patient. The mortality rate in adults may be as high as 20%; similar data are not available for children.

Pathophysiology

In thyroid storm, thyroid hormone is suddenly released into the circulation, which results in the uncoupling of oxidative phosphorylation and/or increased lipolysis, both of which contribute to excessive thermogenesis. Insensible fluid loss increases as a result of increased metabolism and sweating. Tachycardia is caused by both the hyperthermia and the direct action of thyroid hormones on the cardiac conduction system.

Clinical Manifestations

Almost all cases of thyroid storm occur in patients with known hyperthyroidism, although occasionally, a patient will

present initially with thyroid storm. Most patients will have clinical findings characteristic of hyperthyroidism, including goiter (more than 95%), exophthalmos, tachycardia, bounding pulses, and systolic hypertension. Diastolic hypotension, tremulousness, restlessness, mania, delirium, or frankly psychotic behavior may be present. A primary feature that distinguishes thyroid storm from uncomplicated hyperthyroidism is the presence of high fever, often as high as 41°C (105.8°F). The marked increase in cardiac workload may result in high-output cardiac failure, in which case hypotension and pulmonary edema may be seen, rather than more classic hypertension.

Thyroid studies including serum-free thyroxine (T_4), free triiodothyronine (T_3), T_3 resin uptake, and TSH should be obtained. Many clinical laboratories can now perform free T_4 assays on an emergency basis, alternatively total T_4 or total T_3 are adequate indices; however, in many cases, therapy must be initiated on the basis of clinical evidence. Furthermore, the T_4 and T_3 values seen in thyroid storm overlap with those found in frank hyperthyroidism without storm. Serum electrolytes should be obtained but are unlikely to reveal any characteristic abnormalities, except for evidence of modest dehydration. A chest radiograph and EKG are helpful in evaluating and following cardiac status as treatment is initiated.

Management

Initial treatment is directed toward lowering the metabolic rate and reducing the cardiac workload. Subsequent treatment is directed toward controlling thyroid hormone production. Because many of the hypermetabolic effects of hyperthyroidism are mediated by the adrenergic system, a β-adrenergic antagonist (propranolol starting at 10 μg per kg intravenously over 10 to 15 minutes; or an esmolol infusion may be initiated with a loading doses of 500 μg per kg per minute over 1 minute with maximal infusion doses of 50 to 250 μg per kg per minute) is useful in the acute management of thyroid storm. Maintenance dosing of propranolol is 2 mg per kg per day divided every 6 hours in neonates and 10 to 40 mg every 6 hours in older children. EKG monitoring for heart rate and arrhythmias is recommended. Because the metabolic rate is increased about 10% for every degree of body temperature higher than 36.5°C (86.7°F), lowering body temperature is an effective means of reducing the metabolic rate in the patient with thyrotoxicosis. Tepid sponging, use of a cooling blanket, and administration of acetaminophen can accomplish this task. Aspirin should not be used because it is a potential uncoupler of oxidative phosphorylation that may exacerbate the hypermetabolic state.

Treatment of the hyperthyroidism in thyroid storm is accomplished by the use of iodide and an inhibitor of iodine oxidation in the thyroid gland such as methimazole 0.5 to 0.7 mg per kg per day divided into three oral doses, which blocks iodine's ability to combine with tyrosine to form thyroxine and triiodothyronine (T_3); of note neither medication inactivates circulating T_4 and T_3. Propylthiouracil was a first line agent, but due to its association with pediatric liver failure has now become contraindicated in children. Iodide rapidly terminates thyroid hormone release; however, this effect is overcome after 3 to 5 days of iodide therapy. Iodide also decreases the vascularity of the thyroidal arterial supply and can be particularly useful as preoperative agent. Lugol's iodide (or SSKI) 3 to 5 drops once every 8 hours orally or sodium iodide 125 to 250 mg per day intravenously over 24 hours is the usual mode of iodide therapy. While iodide can reduce thyroid hormone secretion within 24 hours, methimazole's effects are minimally useful in acute management because the reduction in thyroid levels may take several days.

Adequate hydration is essential for effective treatment, and the estimate of fluid replacement should include a consideration of the significant increase in fluid requirements caused by fever and an accelerated metabolic rate. Glucocorticoids are useful in the acute presentation because they appear to inhibit thyroid hormone release from the thyroid and decrease the peripheral conversion of T_4 to T_3. Dexamethasone (0.2 mg per kg) or hydrocortisone (5 mg per kg) can be given parenterally during the acute phase. Because intercurrent infection may be the precipitating factor, it should be searched for and treated appropriately. Broad-spectrum antibiotics should be considered while awaiting the results of cultures, as there is a known association between thyrotoxicosis and pneumococcal bacteremia.

Improvement should be seen within a few hours after the initiation of treatment with propranolol, especially in terms of cardiovascular status. Full recovery and adequate control of the underlying thyroid disease take several days to achieve. For the patient presenting with thyroid storm, serious consideration should be given to permanent treatment of the hyperthyroidism, either by surgery or radioiodide ablation.

NEONATAL THYROTOXICOSIS

Background

Neonatal thyrotoxicosis is a life-threatening condition that may not be correctly diagnosed in the newborn nursery and that may be discovered only when the child presents in extremis in the ED. Neonatal thyrotoxicosis is found in 1% to 5% of infants born to mothers with a history of hyperthyroidism; however, the maternal disease does not have to be active during the pregnancy.

Pathophysiology

Neonatal thyrotoxicosis is caused by excessive thyroid hormone produced by the neonatal thyroid that has been stimulated by maternal thyroid-stimulating antibodies present in the immunoglobulin G (IgG) fraction that have crossed the placenta. TSH, T_4, and T_3 do not cross the placenta in significant quantities. In most cases, the disease is self-limiting, and hyperthyroidism remits within about 6 weeks. Occasionally, the disease may run a protracted course and arise in the absence of maternal thyroid-stimulating antibodies.

Clinical Manifestations

Goiter and exophthalmos are almost always present; however, a goiter may be difficult to appreciate in a small infant

with a short neck. The child usually fails to gain weight despite a ravenous appetite. The child may also be irritable and have tachycardia, as well as signs of congestive heart failure. Laboratory investigations should include estimations of serum T_4, T_3, and TSH, and thyroid-binding capacity. Increased concentration of T_4 in the presence of suppressed TSH levels is consistent with the diagnosis. If the mother is taking antithyroid medication, thyroid function tests on the infant may be unreliable in the first days of life because of suppression of the fetal thyroid by transplacental passage of maternal antithyroid medication. The bone age may be advanced. In most cases, treatment must be initiated on the basis of historical and clinical findings.

For an infant who has an elevated level of T_4 but who has few, if any, symptoms or signs, consultation with a pediatric endocrinologist is strongly recommended. T_4 levels in all infants tend to be higher than those in older children because of increased TBG induced by maternal estrogen that crosses the placenta. Also, an elevated thyroxine may be seen with defects that alter the binding of T_4 to thyroid-binding globulin (TBG) or the end-organ sensitivity to T_4.

Management

Treatment is identical to that outlined for thyroid storm in older children. The duration of treatment is uncertain and should be based on serial thyroid function tests, especially TSH. It is anticipated that treatment need be continued only for 6 to 8 weeks in most cases because the causative agent is a subclass of IgG molecules with a serum half-life of about 2 weeks.

CONGENITAL HYPOTHYROIDISM

Background

Most westernized countries routinely screen infants in the first days of life for congenital hypothyroidism. The incidence of this problem is 1 in 3,500 live births. On occasion, notification of the parents by the screening program results in significant parental anxiety and leads to a visit to the ED. Emergency physicians should be knowledgeable about congenital hypothyroidism so they can appropriately educate parents and initiate therapy. Acquired hypothyroidism rarely results in urgent clinical problems that lead to ED visits.

Pathophysiology

The causes of congenital hypothyroidism are numerous; most cases (90%) are permanent. About 20% of patients have ectopic glands, and another 50% have hypoplastic or aplastic thyroid glands. Other causes are less common and include dyshormonogenesis, maternal ingestion of antithyroid medication, hypothalamic–pituitary disorders, and defects in thyroglobulin metabolism. The dyshormonogenic disorders are inherited as autosomal-recessive conditions. Congenital thyroid deficiency may result in impaired neurologic development if not treated before 1 month of age.

Clinical Manifestations

Clinical symptoms and signs of congenital hypothyroidism may be subtle and nonspecific, especially during the first month of life. Severely affected infants may be relatively large at birth, have a large posterior fontanel, manifest hypothermia and hypoactivity, feed poorly, tend to become constipated, and have prolonged jaundice. An enlarged tongue, coarse facies, and a hoarse cry may also be noted but are unusual in the first weeks of life. An umbilical hernia may be present. If treatment is not started, the physical characteristics become more prominent as the child grows older. Thyroid function tests beyond the first 2 days of life are most useful diagnostically. The TSH level is elevated in primary hypothyroidism, and the T_4 level is low or normal for age. A thyroid ultrasound or scan (^{123}I) may be helpful in identifying the particular type of primary hypothyroidism, but treatment should not be delayed to obtain this study. A low T_4 level in the absence of elevated TSH level may result from a deficiency of TBG, a pituitary deficiency of TSH, or prematurity.

Management

In term infants, treatment with L-thyroxine, 10 to 15 μg per kg per day should be instituted as soon as the relevant diagnostic tests are performed. In premature infants, 8 μg per kg per day can be administered. This dosage can be adjusted to maintain a TSH value that is normal for age; on appropriate replacement, the TSH will normalize within 4 weeks. Total T_4 and free T_4 concentrations should be maintained in the upper half of the normal range for age. Both undertreatment and overtreatment must be avoided. Careful follow-up on a monthly basis during the first several months, preferably by a physician who is accustomed to dealing with congenital hypothyroidism, is strongly recommended.

CHAPTER 87 ■ ENVIRONMENTAL EMERGENCIES

MICHELE BURNS EWALD, MD, AND CARL R. BAUM, MD

DROWNING

Background

Drowning is defined as water submersion with resultant asphyxiation and death within 24 hours; *drowning* implies that resuscitation has extended survival beyond 24 hours. Each term is further classified according to whether aspiration has occurred.

In 2000, drowning was responsible for the deaths of more than 1,400 U.S. children younger than 20 years. Drowning affects all age groups and males two to three times more often than females. Individuals with epilepsy have a 15- to 19-fold higher risk of drowning when compared to the general population. Drowning is the major cause of death following water-related natural disasters such as Hurricane Katrina.

In more recent years, drowning was the second leading cause of injury death in children ranging from 1 to 14 years of age. Older infants and toddlers are disproportionately represented in these accidents, and their survival rates are lower. They are vulnerable to immersion in household buckets, baths and hot tubs, swimming pools, and other bodies of water near their homes. Young teenagers are also at greater risk because adult supervision decreases and impulsive behavior increases. However, coexisting trauma, drug or alcohol use, and suicidal intent must be considered in each case. The importance of continuous adult supervision and public safety measures, such as isolation (four-sided) fences around pools and swimming lessons, cannot be overemphasized.

Pathophysiology

When a child is submerged, either breath-holding or laryngospasm occurs. If hypoxemia follows, loss of consciousness and cardiovascular collapse may occur without aspiration of fluid. Alternatively, submersion and frantic struggling may result in gasping, with subsequent aspiration. If antecedent head trauma, drug ingestion, seizure activity, or cardiac arrhythmia impair consciousness and protective airway reflexes, aspiration is more likely to occur. Although most organs may become involved, the major morbidity occurs in the pulmonary and central nervous system (CNS).

Fresh water aspirated into the lungs is rapidly taken up into the circulation, resulting in a transient rise in circulating blood volume that is quickly redistributed through the body. In a canine study of fresh-water drowning, aspiration of fresh water caused body weight to increase an average of 16.5% with concomitant hemodilution. Aspiration of salt water caused body weight to increase only 6% with hemoconcentration and diminished intravascular volume. In humans, changes in the hematocrit are not predictable, and those that occur are more closely related to coexisting trauma than to effects of hypertonic or hypotonic fluids. Occasionally, however, massive hemolysis may occur. Electrolyte abnormalities that occur after massive aspiration in laboratory animals rarely achieve clinical significance in either adult or child victims.

Even small (1 to 3 mL per kg) quantities of fresh water cause disruption of surfactant, a rise in surface tension in the lungs, and alveolar instability. Capillary and alveolar membrane damage allows fluid to leak into the alveoli with subsequent pulmonary edema.

Aspiration of salt water (osmolality greater than normal saline) does not denature surfactant but creates an osmotic gradient for fluid to accumulate in the lungs. This accumulated fluid greatly exceeds the volume that was aspirated and effectively removes surfactant from the alveolar–gas interface.

Both fresh- and salt-water aspiration decrease pulmonary compliance, increase airway resistance and pulmonary artery pressure, and diminish pulmonary flow. As nonventilated alveoli are perfused, an intrapulmonary shunt develops, leading to a drastic fall in partial pressure of arterial oxygen (PaO_2).

In other animal studies, aspiration of as little as 2.2 mL per kg of fresh water led to a fall in PaO_2 to about 60 mm Hg in 3 minutes, whereas a similar amount of sea water precipitated an even greater drop (to about 40 mm Hg). In humans, even lower levels of PaO_2 are seen; tissue hypoxia then leads to severe metabolic acidosis. The victim is usually able to correct a rise in partial pressure of arterial carbon dioxide ($PaCO_2$). Aspiration of bacteria, gastric contents, and foreign materials may cause additional trauma to the lungs.

Hypoxemia, whether secondary to upper airway obstruction (e.g., laryngospasm) or to impaired gas exchange after aspiration, results in loss of consciousness. If anoxia ensues, irreversible CNS damage begins after 4 to 6 minutes. Fear or cold may trigger the diving reflex (commonly encountered in infancy), which shunts blood to the brain and heart primarily and affords several minutes of additional perfusion. Experience with drowning victims and in cardiovascular surgery indicates that cold water is relatively protective of the CNS, but probably only if immersion hypothermia develops very rapidly or before compromise of oxygenation. Onset of hypothermia is more rapid in the victim who is younger (greater surface:volume ratio) or is struggling in or swallowing icy water. If, however, laryngospasm or aspiration occurs before a fall in core body temperature and cerebral metabolic rate, protection is probably minimal.

Cardiovascular effects are primarily those expected with myocardial ischemia, severe systemic acidosis, hypothermia,

and intravascular volume changes. After aspiration of fresh water, the transient rise in intravascular volume later contributes to problems of cerebral edema and pulmonary function.

Clinical Manifestations

In the first moments after rescue, the appearance of the child who has nearly drowned may range from apparently normal to apparently dead. Body temperature is often low, even in temperate, warm-water environments. Respiratory efforts may be absent, irregular, or labored, with pallor or cyanosis, retractions, grunting, and cough productive of pink, frothy material. The lungs may be clear, or there may be rales, rhonchi, and wheezing. Infection may develop as a consequence of aspirated mouth flora or organisms in stagnant water, but this is not usually important in the first 24 hours.

Respiratory function may improve spontaneously or deteriorate rapidly as pulmonary edema and small airway dysfunction worsen. Alternatively, deterioration may ensue slowly over 12 to 24 hours. Intense peripheral vasoconstriction and myocardial depression may produce apparent or actual pulselessness.

Neurologic assessment may show an alert, normal child or any level of CNS compromise. A child may display agitation and combative behavior, blunted responsiveness to the environment, or profound coma with stereotypic posturing or flaccid extremities. Superficial evidence of head trauma may be noted in a few children whose submersion episode was a secondary event. Head CT most typically shows diffuse loss of gray–white differentiation and/or bilateral basal ganglia edema/infarction.

Pulmonary and neurologic damage need not occur together. Although extensive pulmonary destruction and resultant hypoxemia may cause neurologic damage, all combinations of mild and severe lung and brain damage are possible.

Management

The ultimate outcome of serious immersion accidents depends on the duration of submersion, the degree of pulmonary damage by aspiration, and in some cases, effectiveness of initial resuscitative measures. When all children who experience immersion accidents are considered as a group, most are salvageable, and all should receive the benefit of excellent cardiopulmonary resuscitation without delay at the scene, according to the principles elaborated in Chapter 1. In particular, children should be given the maximum concentration of supplemental oxygen possible (100%) in transport to an emergency facility. Even those rescued with spontaneous ventilation and minimal or no neurologic dysfunction should receive the benefit of supplemental oxygen to minimize the risk of progressive hypoxemia and acidosis with secondary myocardial and cerebral damage. Physical examination is notoriously insensitive to hypoxemia; a seriously hypoxemic child may be alert and talking. Once the child has arrived at an emergency facility (and cardiovascular stability is achieved), pulmonary and neurologic assessment should guide further treatment.

Several more recent pediatric studies have attempted to predict outcome in submersion accidents. One prospective investigation devised a prediction rule for children submerged in non-icy water who presented to the emergency department (ED) in a comatose state: lack of pupillary light reflex, male gender, and hyperglycemia were variables used to predict unfavorable outcome (vegetative state or death). A retrospective study of children presenting to the ED after warm-water submersion suggested that hemodynamic, rather than neurologic, status was more highly predictive of poor neurologic outcome.

Effective therapy of drowning depends on the reversal of hypoxemia and metabolic acidosis. The pulmonary status is assessed initially with a chest radiograph (Fig. 87.1) and with measurement of arterial oxygen saturation (Sa_{O_2}) and arterial blood gas (ABG), as in Figure 87.2. If oxygenation is normal on breathing room air, the child can be assumed to have suffered drowning without aspiration. Observation for 6 to 24 hours with repeat (Sa_{O_2}) or ABG determination should be sufficient to assess the possibility of late deterioration in gas exchange.

Other initial laboratory evaluation should include complete blood cell count (CBC), electrolytes, and urinalysis. Patients

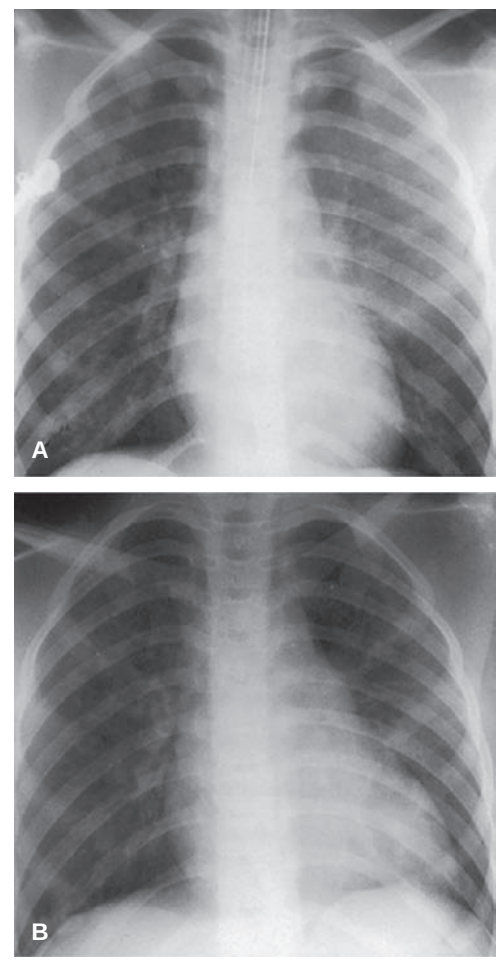

FIGURE 87.1 Drowning in a 4-month-old girl. **A:** There is bilateral disseminated alveolar pattern, more on the left than on the right, consistent with the pulmonary edema of drowning. This change may be the result of neurologic pulmonary edema rather than aspirated water. **B:** Two days later, the patient has been extubated and there is marked improvement in appearance of pulmonary edema secondary to drowning. (Courtesy of Soroosh Mahboubi, MD.)

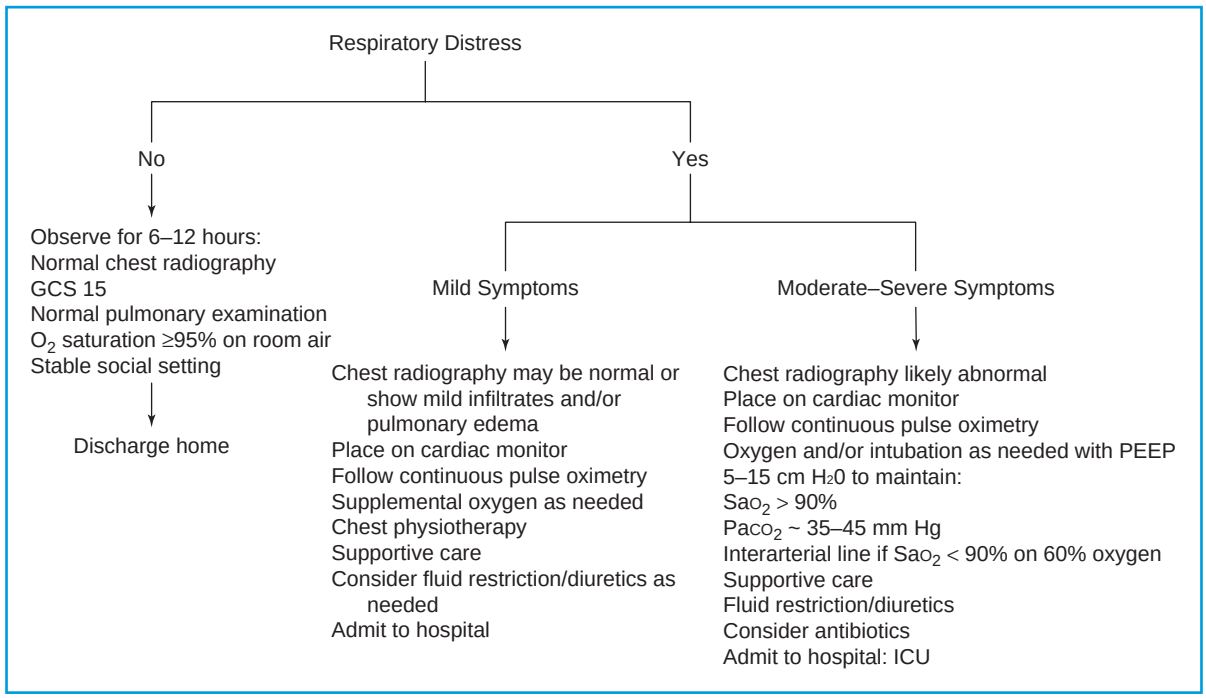

FIGURE 87.2 Algorithm for pulmonary assessment for drowning.

with abnormalities of gas exchange and acid–base status (but with normal chest radiographs) can usually be managed with supplemental oxygen, pulmonary physiotherapy, and bicarbonate therapy. Additional blood gas analysis should be done to document adequate oxygenation and reversal of metabolic acidosis. Any change in mental status or increase in respiratory distress may reflect arterial hypoxemia and should also prompt a repeat ABG determination. Continuous Sao_2 or serial Pao_2 measurements will guide the physician to continue conservative treatment or to intensify ventilatory support.

Patients with obvious respiratory distress, hypoxemia (Sao_2 less than 90% or Pao_2 less than 60 on 60% inspired oxygen), and extensive pulmonary edema or infiltration generally requires more vigorous treatment. All should be monitored for heart rate, cardiac rhythm, respiratory rate, and blood pressure (BP). Most will require frequent blood gas analysis and may be more easily monitored through arterial cannulation. Intubation, supplemental oxygen, and mechanical ventilation with positive end-expiratory pressure (PEEP; 5 to 15 cm H_2O) should be provided, as indicated.

Once BP is stabilized, fluid restriction (to approximately one-half the maintenance rate) and diuretic therapy (e.g., furosemide 0.5 to 1 mg per kg intravenously, usual maximum 20 mg/dose) may improve gas exchange. In the setting of extensive pulmonary damage, pulmonary and cardiovascular components of the disease are intimately entwined. Optimum management requires monitoring of blood gases and systemic arterial pressure.

The risk of pulmonary infection is always present, but retrospective studies have not demonstrated benefit from prophylactic antibiotics, which should be reserved for strongly suspected or proven bacterial infection. Exceptions may be made when grossly contaminated water is aspirated and, in the worst cases, when maximal ventilatory support is required to provide any margin for survival. Most studies of bronchoalveolar lavage show no improvement. Steroids have no demonstrated benefit.

Renal function must be maintained. If significant hemoglobinuria exists, diuresis is required. Maintenance of an adequate hemoglobin level (more than 10 g per 100 mL) and normal electrolytes is obviously necessary. Specific problems vary from patient to patient in an unpredictable way, and an understanding of the principles outlined in Chapters 91 and 100 is essential.

The patient's clinical condition in the ED dictates further management and may provide prognostic clues. Patients may be assigned to one of three groups (Table 87.1). Those who are awake, alert, and fully responsive have survived the episode, presumably without CNS damage. One study suggests that if the child's GCS is greater than or equal to 13 with a normal physical exam/respiratory effort and room air oxygen saturations are more than 95%, the child could be discharged with a responsible guardian after 6 hours of observation. The second group includes those who are obtunded but able to be aroused and those who exhibit a normal respiratory pattern and purposeful responses to pain. These patients have suffered certain but reversible CNS hypoxia; the goal is to prevent further hypoxic damage through intensive management of cardiopulmonary disease. Repeated neurologic evaluation is essential, and fluid restriction and diuretic therapy within the limits of cardiovascular stability may decrease the risk of cerebral edema. There is no demonstrated value in the use of steroids in this setting (see Chapter 126). In both groups, temperature normalization should be prompt. If reversal of coexisting pulmonary damage is effective, neurologic recovery should be complete.

There is controversy over patients in a third group—those who have experienced severe CNS asphyxia. These children are

TABLE 87.1

NEUROLOGIC ASSESSMENT AFTER DROWNING

Group	Description	Treatment
A (alert)	Alert Fully conscious	Observe
B (blunted)	Obtunded but arousable Purposeful response to pain Normal respiratory pattern	Prevent further hypoxic damage Monitor clinical neurologic status Therapy as required for pulmonary and cardiovascular stability Normalize temperature
C (comatose)	Comatose, not arousable Abnormal response to pain Abnormal respiratory pattern	Prevent further hypoxic damage Therapy as required for pulmonary and cardiovascular stability Maintain normocapnia or mild hyperventilation Monitor core temperature Warm to 32°C (89.6°F) Allow passive warming to 37°C (98.6°F) Avoid hyperthermia
C.1	(Decorticate) Flexion response to pain Cheyne-Stokes respiration	
C.2	(Decerebrate) Extension response to pain Central hyperventilation	Monitor temperature
C.3	(Flaccid) No response to pain Apnea or cluster breathing	Consider withdrawal of support if no protection from hypothermia

not able to be aroused and can be further divided into three subcategories according to neurologic findings: (i) those with decorticate response to pain and Cheyne-Stokes breathing, (ii) those with decerebrate response to pain and central hyperventilation, and (iii) those who are flaccid with fixed, dilated pupils and apneustic breathing or apnea. Again, reversal of hypoxemia and acidosis is critical. Fluid resuscitation should be designed to prevent hyperglycemia. Avoiding hypercapnia and resultant cerebral hyperemia is generally accepted, but hyperventilation, barbiturate coma, and other measures initially believed to provide cerebral protection and prevent or treat elevated intracranial pressure have not been helpful in these patients.

Hypothermia does appear to have some protective value. Extreme hypothermia should be corrected to at least 32°C (89.6°F) to achieve hemodynamic stability and to minimize the risk of infection. The child should then be allowed to rewarm passively. Although data in humans are limited, animal studies suggest that maintenance of mild brain hypothermia may minimize reperfusion injury. Hyperthermia, a common result of active rewarming, should be avoided.

The prognosis for this group is certainly grimmer, with a much greater risk of death or severe anoxic/ischemic encephalopathy. Risk increases with depth of coma on presentation. Patients in the third subdivision (flaccid with fixed, dilated pupils) rarely survive intact regardless of treatment, although coexistent hypothermia has provided some remarkable exceptions.

More recent studies indicate that patients with asystole on arrival in the ED have uniformly poor neurologic outcomes. In each case, consideration should be given to the possibility that continued resuscitation will salvage only the cardiovascular system; in these cases, the physician may reasonably discontinue resuscitative efforts.

SMOKE INHALATION

Background

Among unintentional injuries, fires rank fifth in the United States. Although fire has been the cause of much death and misery throughout human history, the importance of smoke inhalation has been recognized only in the last 50 years. An analysis of fire deaths among Philadelphia children younger than 15 years revealed the following epidemiologic risk factors: low-income or single-parent households, housing built before 1939, and increased numbers of children younger than 15 years. A recent study suggests that personalized parent voice smoke alarms may be more effective than conventional residential tone smoke alarms for awakening children.

Respiratory complications of smoke inhalation rank with carbon monoxide poisoning (see "Pathophysiology" section) as a major cause of early death from fire. Although serious cutaneous injury may occur in the absence of pulmonary involvement, inhalation injury dramatically increases the morbidity and mortality associated with any given percent body surface area burn.

The severity of carbon monoxide inhalation and respiratory problems is related to the duration of exposure, the occurrence in a closed space (more likely in very young or elderly

victims), the nature of materials involved, and the presence of products of incomplete combustion. Severe hypovolemic shock, massive tissue destruction, extensive fluid resuscitation, and infection further complicate direct inhalational trauma.

Pathophysiology

The relatively low heat capacity of dry air and the excellent heat exchange properties of the nasopharynx usually limit direct thermal injury to the upper airway. Dry air above 160°C (320°F) has little effect on the lower airway. The greater heat capacity of steam increases the risk of lower airway damage. In addition, continuing combustion of soot particles carried deeply into the lung may exacerbate thermal injury.

Chemical injury may occur at any level of the respiratory tract. Oxides of sulfur and nitrogen combine with lung water to form corrosive acids. Incomplete combustion of any carbon-containing material, such as wood, may produce carbon monoxide. Combustion of cotton or plastic generates aldehydes that cause protein denaturation and cellular damage. One example is acrolein, known to cause upper airway irritation at concentrations of 5.5 parts per million (ppm) and pulmonary edema within seconds at 10 ppm. Polyvinylchloride releases chlorine and hydrochloric acid, whereas polyethylene produces hydrocarbons, ketones, and other acids. Burning polyurethane may produce cyanide gas. Fire retardants that contain phosphorus may actually produce phosgene gas. The upper airway filters most soot particles, but those carried into the lung may adsorb various substances and cause reflex bronchospasm to further extend chemical damage.

Upper airway lesions include actual burns of varying severity as well as severe edema of the nose, mouth, pharynx, and laryngeal structures. A murine model of wood smoke inhalation suggests that combustion produces hydroxyl radicals in the gas phase of smoke that cause a reflex apneic response. In this investigation, a hydroxyl radical scavenger, applied to the larynx, attenuated the response. Upper airway edema increases inspiratory and expiratory resistance and causes a dramatic increase in the work of breathing. If airway narrowing is severe or complete, acute respiratory failure with hypercarbia and hypoxemia occurs and sets the stage for subsequent cardiovascular collapse.

Lower airway lesions depend on the toxin involved. A variety of features may aggravate pulmonary pathology, including circulatory, metabolic, and infectious complications, as well as therapeutic interventions such as endotracheal intubation, oxygen administration, mechanical ventilation, and fluid therapy.

Immediate effects of smoke inhalation on the lower airway include loss of ciliary action, mucosal edema, bronchiolitis, alveolar epithelial damage, and impaired gas exchange, particularly oxygenation. In addition, areas of atelectasis or air trapping worsen ventilation–perfusion mismatch and hypoxemia. Loss of surfactant activity exaggerates this phenomenon. Hours later, sloughing of tracheobronchial mucosa and mucopurulent membrane formation increase the degree of obstruction and poor gas exchange, as well as the likelihood of infection. Beyond the first 24 hours, pulmonary pathology that results from smoke inhalation is largely indistinguishable from adult respiratory distress syndrome, which arises from other insults.

Children who die from smoke inhalation may sustain serious respiratory damage in the absence of cutaneous injury. Necrosis of bronchial, bronchiolar, and alveolar epithelium; vascular engorgement and edema; and formation of membranes or casts of the airway produce small and large airway obstruction. Severe cutaneous injury increases alveolar capillary permeability, leading to pulmonary hemorrhage, edema, and hyaline membrane formation.

Clinical Manifestations

A history of exposure in a closed space should heighten concern for smoke inhalation. Need for cardiopulmonary resuscitation at the site implies significant carbon monoxide poisoning and/or hypoxia secondary to decreased ambient oxygen concentration or severe respiratory disease. The physician should also consider the types of material involved to determine the risk of poisoning from carbon monoxide or other toxins.

Physical examination that reveals facial burns, singed nasal hairs, pharyngeal soot, or carbonaceous sputum justifies a presumption of smoke inhalation. Any sign of neurologic dysfunction, including irritability or depression, should be presumed related to tissue hypoxia until proven otherwise. Signs of respiratory distress may be delayed for 12 to 24 hours, but tachypnea, cough, hoarseness, stridor, decreased breath sounds, wheezing, rhonchi, or rales may be detected on presentation.

Auscultatory findings often precede chest radiograph abnormalities by 12 to 24 hours. Radiographic changes may include diffuse interstitial infiltration or local areas of atelectasis and edema (Fig. 87.3). Acute respiratory failure may occur at any point. The cause may be asphyxia or carbon monoxide exposure and subsequent CNS depression initially, or airway obstruction or parenchymal dysfunction later. ABG analysis provides the ultimate assessment of effective respiratory function. Bronchoscopy can document the extent of inhalation injury and help remove debris but may worsen airway edema. In general, it is respiratory function, not the appearance of lesions, that guides supportive care; therefore, most patients can be treated effectively without bronchoscopy.

Management

Initial assessment and resuscitation at the scene of the fire should proceed according to the principles outlined in Chapter 1. Because of the likelihood of carbon monoxide exposure and the difficulty of assessing hypoxemia clinically, all victims should receive the maximum concentration of inspired oxygen possible in transport and in the ED until further evaluation is complete (Table 87.2).

Upon the patient's arrival in the ED, assessment of the airway and respiratory functions must proceed simultaneously with cardiovascular stabilization. Thermal injury to the nose, mouth, or face, or compromise of the upper airway (stridor, hoarseness, barking cough, retractions, delayed inspiration, or difficulty handling secretions) indicates the need for direct laryngoscopy. The presence of significant pharyngeal, supraglottic, or glottic edema mandates elective endotracheal intubation. Worsening edema over 24 hours may lead to respiratory arrest and a difficult emergency intubation through a

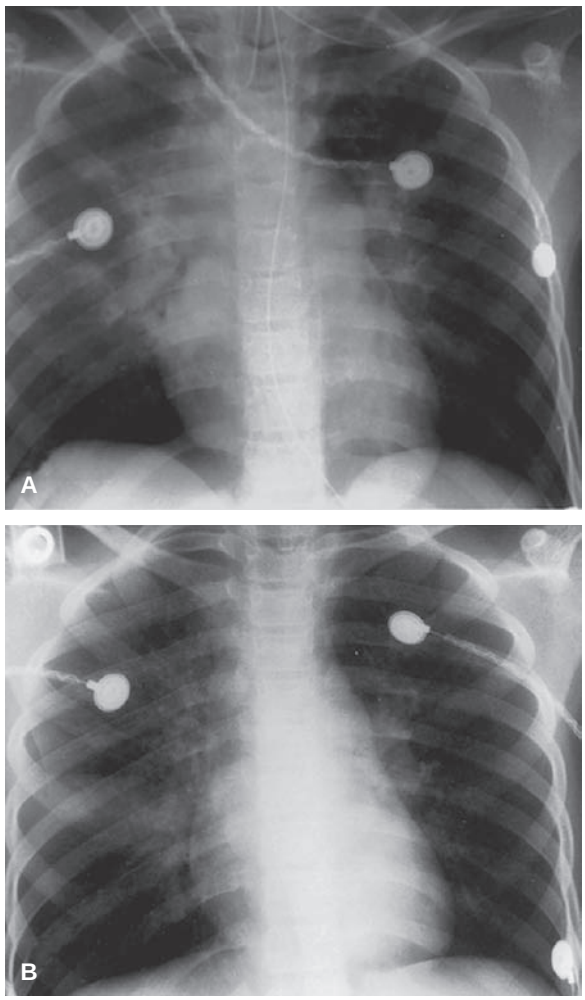

FIGURE 87.3 Smoke inhalation in a 9-year-old girl. **A:** There is bilateral central alveolar process consistent with acute smoke inhalation. **B:** A day later, the patient has been extubated and there is marked improvement in the appearance of pulmonary edema. (Courtesy of Soroosh Mahboubi, MD.)

distorted airway, and thus early endotracheal intubation can not be overemphasized. Elective tracheostomy may be considered if placing or securing the endotracheal tube will further traumatize an edematous airway or severe facial burns. However, in the presence of extensive cutaneous burns, tracheostomy dramatically increases the risk of systemic and pulmonary infection.

Cardiovascular stabilization depends on fluid replacement, which is complex when major surface burns have occurred. The details of therapy are elaborated in Chapter 108, but in general, the goals are stabilization of cardiovascular function without fluid overload and compromise of gas exchange. Pulse rate and BP should guide administration of fluid volume. Maintenance of urine output of at least 0.5 mL per kg per hour should provide adequate tissue perfusion. Decreased urine output may respond to diuretics or inotropic agents. Although adequate fluid administration is essential, careful monitoring of renal and cardiovascular systems may prevent or minimize acute pulmonary edema and delayed pulmonary dysfunction secondary to late fluid mobilization and infection.

TABLE 87.2

MANAGEMENT OF SMOKE INHALATION

Initial Management
Remove from contaminated environment
Cardiopulmonary resuscitation as needed
Provide 100% supplemental oxygen
Insure patent airway

Laboratory Determinations
Arterial blood gas analysis
Carboxyhemoglobin level, troponin
Chest radiograph

Monitor
Heart rate, electrocardiogram, respiratory rate, blood pressure, Sa_{O_2}
Consider central venous pressure
Consider pulmonary artery catheterization

Fluids
5% dextrose in normal saline at maintenance rates or less to maintain urine output 0.5–1.0/mL/kg/h
Volume expansion in presence of cutaneous burns; normal saline, lactated Ringer's solution, or 5% albumin

Respiratory Management
Intubation for:
1. Upper airway obstruction
2. $Pa_{O_2} < 60$ mm Hg on 60% oxygen
3. Central nervous system depression with loss of cough and gag reflexes. Continuous positive airway pressure 5–15 cm H_2O for $Pa_{O_2} < 60$ mm Hg on 60% oxygen

Intermittent mandatory ventilation for:
1. Hypoxia unresponsive to continuous positive airway pressure or
2. $Pa_{CO_2} > 50$ mm Hg

Humidification of inspired gases
Meticulous pulmonary toilette
Consider inhaled bronchodilators

Oxygen saturation and serial blood gas determinations should be obtained to guide oxygen supplementation and to assess adequacy of ventilation. Intubation is indicated if adequate oxygenation (Sa_{O_2} greater than 90% or Pa_{O_2} greater than 60 mm Hg) cannot be maintained with an inspired oxygen concentration of 40% to 60%, if Pa_{CO_2} rises above 50 mm Hg, or if the work of breathing appears unsustainable. In the presence of small airway edema and disrupted surfactant activity, continuous distending airway pressure may improve oxygenation. Spontaneous ventilation with continuous positive airway pressure causes less cardiovascular interference, but in the patient with severe CNS depression or severe pulmonary parenchymal damage, mechanical ventilation with PEEP will likely be necessary. Maximally humidified oxygen should be delivered by mask or artificial airway to prevent inspissation of debris and occlusion of the airway. The patient with a natural airway should also receive humidified gas mixtures and be encouraged to take deep breaths and cough frequently. If an endotracheal tube is necessary, meticulous pulmonary toilette is essential, with frequent suctioning to remove edema fluid, mucus, and sloughed epithelium that may otherwise occlude the endotracheal tube.

A more recent study of lung mechanics in children with inhalation injury compared two modes of long-term ventilation

in the intensive care unit. High-frequency percussive ventilation (hi-fi) was superior to conventional mechanical ventilation in reducing work of breathing. There is also evidence that extracorporeal membrane oxygenation (ECMO) may be useful in severely burned children.

After the first few hours, diuretic therapy (furosemide 0.5 to 1 mg per kg intravenously) within the limits of cardiovascular stability may also improve oxygenation and pulmonary compliance, leading to more effective ventilation. Chemical and particulate irritation of upper airway receptors may cause reflex bronchoconstriction and contribute to lower airway obstruction. Bronchodilators such as nebulized albuterol [2.5 mg in 2.5 mL, 0.9% sodium chloride (NaCl)] or intravenous (IV) terbutaline (load 10 *m*cg per kg per dose intravenously or subcutaneously; followed by a continuaus infusion of 0.4 to 6 *m*cg per kg per minute) may help reverse bronchospasm, but relief depends mostly on removal of secretions and debris from the respiratory tree.

Studies have not demonstrated a role for steroids in reducing airway edema or in decreasing the inflammatory response to smoke inhalation. When steroids are used, there is evidence that sodium and fluid retention increase, healing is delayed, and bacterial clearance from the lung is decreased. Little argument remains for their routine use.

Similarly, there is no value in the use of prophylactic antibiotics. Institution of antimicrobial therapy should await specific indications, which rarely occur in the first 24 hours.

CARBON MONOXIDE POISONING

Background

Each year, unintentional carbon monoxide poisoning claims about 500 lives and is largely responsible for early deaths related to fire. However, exposure may occur in a variety of other settings unrelated to accidental fires, including incomplete combustion of any carbon-containing fuel (i.e., propane-powered forklifts). Poisoning may occur with exposure to improperly vented wood- or coal-burning stoves, and to automobile exhaust in garages. In most reported cases, garage doors and windows were actually open. Passengers may be poisoned in vehicles or boats with open backs, or with faulty or blocked exhaust systems. During a 2005 snowstorm in Boston that resulted in numerous power outages, snow blocked the furnace pipes of a 7-year-old girl's home, leading to her death from carbon monoxide poisoning. Later that same year, Massachusetts passed "Nicole's Law" requiring carbon monoxide detectors in every home in the Commonwealth; other states are passing similar laws.

Pathophysiology

In the normal person, carboxyhemoglobin levels are less than 1%. In smokers, levels of 5% to 10% are common. Inhaled carbon monoxide has two important effects that conspire to cause tissue hypoxia: (i) it binds to hemoglobin with an affinity 200 to 300 times greater than that of oxygen, and (ii) it shifts the oxyhemoglobin dissociation curve to the left and changes the shape from sigmoidal to hyperbolic (Fig. 87.4). The first effect decreases oxygen content of the blood, whereas

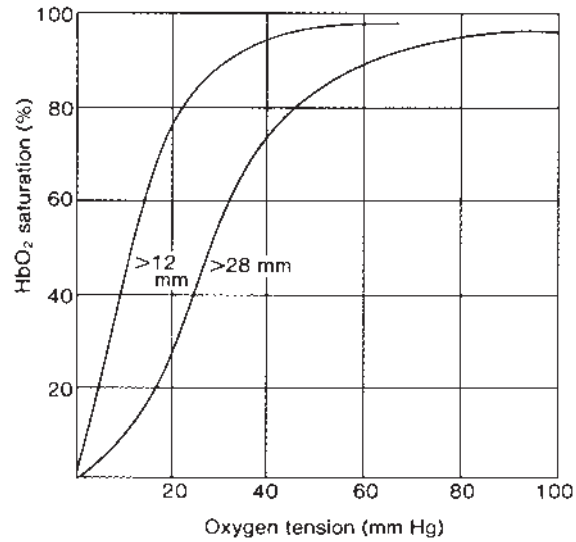

FIGURE 87.4 Carbon monoxide shifts the oxyhemoglobin dissociation curve to the left and changes its shape, making the unloading of oxygen in the tissues more difficult and provides an inadequate diffusion gradient. (*Left curve*, $P_{50} > 12$ mm; *right curve*, $P_{50} > 28$ mm.)

the second causes oxygen release at lower-than-normal tissue oxygen levels. Other endogenous (anemia) and exogenous (high altitude, or displacement of ambient oxygen during fires) factors contribute further to hypoxia. Although oxygen content of the blood is low, the Pa_{O_2} remains normal. Because carotid body receptors respond to Pa_{O_2}, respiration may not be stimulated until late, when metabolic acidosis activates other centers. Tissue hypoxia increases cerebral blood flow, cerebrospinal fluid pressure, and cerebral capillary permeability, which predispose the patient to cerebral edema.

Carbon monoxide interacts with several other cellular proteins, including cytochrome oxidase. It appears to interfere with oxidative energy production and may generate free radicals, which exacerbate CNS dysfunction. Neuronal necrosis, as well as apoptosis, is seen in animal models in the frontal cortex, globus pallidus, and cerebellum, likely contributing to delayed cognitive effects such as deficits in learning, memory, and dementia. Carbon monoxide also binds to myoglobin; individuals, particularly with preexisting coronary disease, may develop cardiac ischemia and/or dysrhythmias.

Clinical Manifestations

History provides the most valuable clue to diagnosis. Carbon monoxide poisoning should be suspected in all fire victims and considered in children exposed to other hazards noted earlier. Presence or absence of the classically described "cherry red" skin color is of no diagnostic value. In fact, patients with thermal injury may appear red, whereas those with vasoconstriction may be quite pale. Both color and respiratory rate may be deceptive and may lead the physician away from recognition of severe tissue hypoxia. Pa_{O_2} and arterial saturation as determined by pulse oximetry (Sa_{O_2}) are likely to be normal in carbon monoxide intoxication; low values reflect coexistent pulmonary dysfunction.

Determination of blood levels of carboxyhemoglobin may help document the diagnosis and may aid prognosis.

Spectrophotometric methods are most widely used clinically. Venous blood may be used because of the high affinity of carbon monoxide for hemoglobin, but an arterial sample provides more precise information about acid–base balance and adequacy of ventilation. The level of hemoglobin should also be determined.

Levels of carboxyhemoglobin as low as 5% in nonsmokers may impair judgment and fine motor skills. Mild intoxication (20% carboxyhemoglobin) produces headache, mild dyspnea, visual changes, and confusion. Moderate poisoning (20% to 40%) produces drowsiness, faintness, nausea and vomiting, tachycardia, dulled sensation, and decreased awareness of danger. At lower levels, these symptoms are noted only with exertion, but as the fraction approaches 40%, they are present at rest. Between 40% and 60%, weakness, incoordination, and loss of recent memory occur, and cardiovascular and neurologic collapse is imminent. Above 60%, coma, convulsions, and death are almost certain. Although carboxyhemoglobin levels and symptoms tend to follow the pattern just described, individual patients may be more or less symptomatic than predicted. An important caveat is that blood carboxyhemoglobin levels will fall rapidly with time and may not reflect cellular dysfunction, especially in high-demand tissues of the heart and CNS.

Patients with severe poisoning are peculiarly vulnerable to pressure trauma to skin, subcutaneous tissue, and muscle, especially at sites that support body weight or that are pinned under fallen objects. The history may suggest which sites are most vulnerable, and pain is an early symptom. Muscle breakdown and myoglobin deposition in renal tubular cells may precipitate acute renal failure.

A syndrome of delayed neuropsychologic sequelae (DNS) has been described in patients after exposure to carboxyhemoglobin. These patients develop neurologic symptoms acutely, appear to recover with treatment, and then exhibit a broad spectrum of neurologic and psychiatric abnormalities days to weeks after the exposure. Neuropsychiatric testing of children has obvious difficulties. Studies of DNS, many of which are methodologically flawed, have elucidated neither an exact mechanism nor a consensus on prevention and treatment.

Management

Most important and obvious is the immediate need to remove the victim from the contaminated environment (Table 87.3). Resuscitation should proceed according to general principles. As soon as possible, the patient suspected of suffering carbon monoxide poisoning should be provided 100% oxygen. If the patient is breathing spontaneously, this can be accomplished with a well-fitting mask supplied with nonrebreathing valves and a reservoir bag. Entrainment of room air precludes simple masks from providing more than 40% oxygen. The half-life of carboxyhemoglobin is approximately 4 hours in a patient breathing room air at sea level and approximately 1 hour if pure oxygen is inspired. The half-life is further reduced to less than 30 minutes if the patient has access to hyperbaric oxygen (HBO) at 2 to 3 atmospheres of pressure. There is no widespread agreement on indications for HBO, and transfer to a hyperbaric chamber should not jeopardize meticulous conventional cardiopulmonary stabilization. However, HBO administration may have effects beyond the mere reduction in carboxyhemoglobin half-life. Some studies in adults suggest a role for HBO in reducing the incidence of mortality and DNS. Well-controlled studies in children would have to be undertaken to answer these questions definitively, but would have obvious ethical and methodologic difficulties. In any case, early consultation with a poison control center or an HBO facility should be considered while the patient is receiving 100% oxygen (Table 87.4).

Severe metabolic acidosis, if present, should be treated with sodium bicarbonate, although adequacy of ventilation must be assessed to prevent paradoxical intracellular acidosis. The possibility of coexistent cyanide poisoning should be considered in patients involved in closed-space fires (especially where nitrogen-containing synthetic materials have burned) who have a persistent metabolic acidosis in the context of normal carboxyhemoglobin and methemoglobin. Cyanide has high mortality but a short half-life (approximately 1 hour), so empiric cyanide levels on patients who have survived the scene are not recommended generally unless confirmation is needed.

If cyanide poisoning is strongly suspected in an early-presenting patient, the cyanide antidote kit (formerly known as

TABLE 87.3

MANAGEMENT OF CARBON MONOXIDE POISONING

Initial Management
Remove from contaminated environment
Cardiopulmonary resuscitation as needed
Provide 100% supplemental oxygen
Laboratory Determinations
Arterial blood gas analysis
Carboxyhemoglobin level, troponin
Complete blood cell count, electrolytes
Urinalysis for myoglobin
Monitoring
Heart rate, electrocardiogram, respiratory rate, blood pressure
Treatment
Correct anemia Hgb <10 g/dL
Continue supplemental oxygen until carboxyhemoglobin ≤5%
Decrease oxygen consumption with bed rest, avoid producing anxiety
Maintain urine output >1 mL/kg/h
Consider hyperbaric oxygen

TABLE 87.4

CONSIDERATIONS FOR HYPERBARIC OXYGEN THERAPY[a]

Signs of cardiac ischemia or metabolic acidosis
Pregnancy

[a]Consider early consultation with a poison control center or HBO facility.
HBO, hyperbaric oxygen.

the Lilly kit) may be considered. This two-step kit must be used with caution because the nitrite-containing first step induces methemoglobinemia. In case of doubt, the thiosulfate-containing second step, which is able to scavenge cyanide without significant additional toxicity, may be given alone. Anemia (hemoglobin less than 10 g per 100 mL) must be corrected to maximize oxygen-carrying capacity. Hydroxycobalamin (a synthetic form of vitamin B_{12}) was approved by the FDA in 2006 for use in cyanide poisoning. Its mechanism of action is that the hydroxyl group of the vitamin binds to free cyanide, forming the nontoxic cyanocobalamin. The dose is 70 mg/kg (max 5 grams) given over is minutes, with a repeat dose if necessary. The minimal side effects of hydroxocobalamin make this an attractive alternative to the traditional nitrite therapy.

If myoglobinemia or myoglobinuria is present, vigorous hydration and diuresis with furosemide (1 mg per kg intravenously) and/or mannitol (0.25 to 1 g per kg intravenously) with close attention to urine output may preserve renal function. If hydration and diuresis are ineffective, renal failure should be considered and fluids restricted accordingly (see Chapter 100).

The patient should be observed for at least 24 hours to identify other sequelae of smoke inhalation.

ENVIRONMENTAL AND EXERTIONAL HEAT ILLNESS

Background

Environmental and exertional heat illness occurs with excessive heat generation and storage. These conditions arise when high ambient temperature prevents heat dissipation by radiation or convection, and humidity limits cooling by sweat evaporation. The spectrum of illness is broad, including heat cramps, heat exhaustion, and heat stroke; the latter is an acute medical emergency with significant associated morbidity and mortality.

Heat illness is a serious tropical health hazard, but even in the United States, summer heat is responsible for significant morbidity and mortality. Heat waves, defined as more than 3 consecutive days of ambient temperatures greater than 32.2°C (90°F), may bring epidemic illness and death. During the period 1979 to 1999, more than 8,000 heat-related deaths were reported nationally, and nearly half were known to be weather related. During the California heat wave of 2006, it was estimated that for every rise in temperature by 10 degrees Fahrenheit, that there was a 9% increase in daily mortality for all counties as a whole. The elderly are most vulnerable (more than 80% of cases occur in people older than 50), but heat illness is also significant among healthy young people. Of the weather-related deaths noted previously for which the age of the decedent was recorded, 164 (4%) occurred in children younger than 15 years.

Military recruits, laborers, and athletes who work in a hot, humid atmosphere are notoriously vulnerable. Obesity, physical disability, heart disease, and alcohol and drug use increase risk. Pediatricians need to understand the special risk to children with cystic fibrosis or congenital absence of sweat glands, children receiving medications that cause oligohidrosis, infants left in automobiles on hot days, and young athletes. Heat stroke remains the third most common cause (after head injury and cardiac disorders) of exercise-related mortality among U.S. high-school athletes, despite the fact that survival following acute heat stroke has improved over the last century from an estimated 20% to more than 90%.

Pathophysiology

Under normal conditions, body core temperature is maintained constant within 0.6°C (1°F) when the environment varies from 9.4°C to 60°C (49°F to 140°F) in dry air. This represents a remarkable balance between heat production and heat loss by the body. Heat is produced as (i) a byproduct of basal metabolism, (ii) a consequence of muscle activity (including shivering), and (iii) the effects of thyroxine and sympathetic stimulation on cellular processes. Heat is lost by (i) conduction to objects and air, (ii) convection through air or liquid that surrounds tissues, (iii) evaporation, and (iv) radiation of infrared energy.

Conduction to objects represents a small fraction (about 3%) of heat lost. Conduction to air and convection represent another 12% in still air. As air movement increases, the proportion of heat lost by these mechanisms may increase to nearly 60%. Evaporative losses normally account for 25% of heat lost, and radiant heat losses account for about 60%. However, the body gains heat by conduction and radiation when ambient temperature exceeds skin temperature and loses heat only by evaporation. High ambient humidity and absence of convection currents decrease the rate of evaporation.

Heat-sensitive centers of the posterior hypothalamus control sympathetic tone. This tone regulates vasoconstriction of arterioles and subcutaneous arteriovenous anastomoses, which, in turn, controls heat conduction from the body core to the skin. Flow through these areas may represent 0% to 30% of total cardiac output. High flow provides efficient heat transfer from the body core to the skin, which is an effective radiator. Low flow to the skin prevents radiation and allows only inefficient diffusion through the insulating skin and subcutaneous tissues.

When body temperature rises, blood in the preoptic area of the anterior hypothalamus is warmer than optimal. Impulses from this area increase and are conducted through autonomic pathways to the spinal cord and then, through cholinergic fibers to the sweat glands, where sweat is released. Exercise and certain emotional states release circulating epinephrine and norepinephrine to increase sweat production.

The sweat gland is composed of two portions. The deep, coiled portion actively elaborates a precursor secretion in response to cholinergic stimulation. At low rates of sweating, much of the NaCl contained in the precursor secretion is reabsorbed before the sweat is conducted through the straight portion to the skin. At higher rates, flow exceeds the capacity of the duct to reabsorb solute, and substantial total body NaCl depletion may occur.

In the unacclimatized adult, sweating may vary from negligible amounts at rest in a cool, dry environment to 1.5 L per hour during vigorous activity in hot weather. Long-term exposure to tropical weather results in a steady increase in sweating rate over approximately 6 weeks, to a maximum of about 4.0 L per hour. Initially, enormous salt losses may occur (15 to 20 g per day). However, aldosterone secretion rises and stimulates active reabsorption of NaCl in the ducts of sweat glands (as in the kidney), and salt losses decrease to a normal 3 to 5 g per day.

In humans, behavioral control over temperature regulation is probably as important as all other mechanisms. When body temperature changes, sensations of excessive warmth or cold prompt efforts to correct the situation. One moves out of the cold or into the shade, selects warmer or cooler clothing, initiates maneuvers that warm or cool the environment, or alters levels of activity. Light-colored clothing permeable to moisture but impervious to radiant heat from the environment prevents the formation of an insulating layer of air and allows for heat loss by evaporation.

Clinical Findings

Three types of heat illness are recognized and represent different physiologic disturbances (Table 87.5). Heat cramps refer to the sudden onset of brief, intermittent, and excruciating cramps in muscles after they have been subjected to severe work stress. Cramps tend to occur after the work is done, on relaxing, or on taking a cool shower. Occasionally, abdominal muscle cramps may simulate an acute abdomen. The usual victim is highly conditioned and acclimatized. Typically, these individuals can produce sweat in large quantities and provide themselves with adequate fluid replacement but inadequate salt replacement. Electrolyte depletion is probably the cause of cramps.

Most spasms last less than a minute, but some persist for several minutes, during which a rock-hard mass may be palpated in the affected muscle. Cramps often occur in clusters. Rapid voluntary contraction of a muscle, contact with cold air or water, or passive extension of a flexed limb may reproduce a cramp. Laboratory investigation reveals hyponatremia and hypochloremia and virtually absent urine sodium. The blood urea nitrogen (BUN) level is usually normal but may be mildly elevated.

Heat exhaustion is less clearly demarcated from heat stroke than are heat cramps. In most cases, water depletion predominates because individuals who live and work in a hot environment do not always voluntarily replace their total water deficit. Progressive lethargy, intense thirst, and inability to work or play progress to headache, vomiting, CNS dysfunc-

TABLE 87.5

CHARACTERISTICS OF HEAT ILLNESS

Illness	Who	When	Characteristic	Laboratory
Heat cramp	Highly conditioned Highly acclimatized Adequate water replacement Inadequate salt replacement	After severe work stress Usually when relaxing Triggered by cold	Excruciating cramps in affected muscle occurring in clusters (may simulate acute abdomen)	↓ Serum Na^+Cl^- ↓↓ Urine Na^+ BUN nl or slightly ↑
Heat exhaustion A. Predominant water depletion	Generally unacclimatized Working in hot environment Inadequate water replacement	During periods of hot weather After physical exertion	T ≤ 39°C (102.2°F) Progressive lethargy Thirst Inability to work or play Headache Vomiting CNS dysfunction ↓ BP ↑ HR	Na, Cl ↑ Hct ↑ Urine-specific gravity ↑
B. Predominant salt depletion	Unacclimatized Inadequate salt replacement Cystic fibrosis	During periods of hot weather After physical exertion	T ≥ 39°C (102.2°F) Weakness, fatigue Headache GI symptoms exertion Prominent Muscle cramp ↑ HR Orthostatic hypotension	Na ↓ Hct ↑ Urine Na ↓↓

tion (including hyperventilation, paresthesias, agitation, incoordination, or actual psychosis), hypotension, and tachycardia. Hemoconcentration, hypernatremia, hyperchloremia, and urinary concentration are typical. Body temperature may rise but rarely to higher than 39°C (102.2°F). If unattended, heat exhaustion may progress to frank heat stroke.

Heat exhaustion may also occur secondary to predominant salt depletion. As in heat cramps, water losses are replaced but without adequate electrolyte supplementation. Symptoms include profound weakness and fatigue, frontal headache, anorexia, nausea, vomiting, diarrhea, and severe muscle cramps. Tachycardia and orthostatic hypotension may be noted.

Unlike heat cramp victims, these patients with heat exhaustion and salt depletion are typically unacclimatized. Hyponatremia, hemoconcentration, and significantly diminished urine sodium are consistent findings. Children with cystic fibrosis, particularly those who are young and unable to meet increased salt requirements, are at risk for electrolyte depletion because salt losses in their sweat apparently do not respond to acclimatization and aldosterone stimulation of the sweat gland.

Heat stroke (Table 87.5) is a life-threatening emergency. Classic signs are hyperpyrexia [41°C (105.8°F) or higher]; hot, dry skin that is pink or ashen, depending on the circulatory state; and severe CNS dysfunction. Often, but not invariably, sweating ceases before the onset of heat stroke.

The onset of the CNS disturbance may be abrupt, with sudden loss of consciousness. Often, however, premonitory signs and symptoms exist. These include a sense of impending doom, headache, dizziness, weakness, confusion, euphoria, gait disturbance, and combativeness. Posturing, incontinence, seizures, hemiparesis, and pupillary changes may occur. Any level of coma may be noted. Cerebrospinal fluid findings are usually normal. The extent of damage to the CNS is related to the time and extent of hyperpyrexia and to the adequacy of circulation. Once the body temperature is lowered, consciousness is usually restored quickly, but coma may persist for 24 hours or more.

Patients able to maintain cardiac output adequate to meet the enormously elevated circulatory demand are most likely to survive. Initially, the pulse is rapid and full, with an increased pulse pressure. Total peripheral vascular resistance falls as a result of vasodilation in the skin and muscle beds, and splanchnic flow diminishes. If hyperpyrexia is not corrected, ashen cyanosis and a thin, rapid pulse herald a falling cardiac output. The cause may be either direct thermal damage to the myocardium or significant pulmonary hypertension with secondary right ventricular failure. Even after body temperature is returned to normal, cardiac output remains elevated and peripheral vascular resistance remains low for several hours, resembling the compensatory hyperemia after ischemia noted in posttrauma, postshock, and postseptic states. Persistently circulating vasoactive substances probably account for this phenomenon.

Severe dehydration is not a necessary component of heat stroke but may play a role if prolonged sweating has occurred. Electrolyte abnormalities may occur, especially in the unacclimatized victim, if NaCl has not been replaced. In acclimatized persons, NaCl is conserved but often at the expense of a severe potassium deficit. Polyuria is sometimes noted, often vasopressin resistant and possibly related to hypokalemia. Acute tubular necrosis may be seen in as many as 35% of cases and probably reflects combined thermal, ischemic, and circulating pigment damage. Hypoglycemia may also be noted.

Nontraumatic rhabdomyolysis and acute renal failure have been described as consequences of various insults, including hyperthermia and strenuous exercise in unconditioned persons. Clinically, there may or may not be musculoskeletal pain, tenderness, swelling, or weakness. Laboratory evidence includes elevated serum creatinine phosphokinase (CPK) (300 to 120,000 units) and urinalysis that is orthotolidine (Hematest)-positive without red blood cells and shows red-gold granular casts. Typically, serum potassium and creatinine levels rise rapidly relative to BUN. An initial hypocalcemia, possibly a consequence of deposition into damaged muscle, progresses to hypercalcemia during the diuretic phase a few days to 2 weeks later.

Management

Most cases of heat cramps are mild and do not require specific therapy. Rest and increased salt intake from liberally salted foods are sufficient. In severe cases with prolonged or frequent cramps, IV infusion of normal saline is effective. Approximately 5 to 10 mL per kg over 15 to 20 minutes should be adequate to relieve cramping. Oral intake of fluids and salted foods can then complete restoration of salt and water balance.

Heat exhaustion as a result of predominant water depletion is treated with rehydration and rest in a cooled or well-ventilated place. If the child is able to eat, he or she should be encouraged to drink cool liquids and be allowed unrestricted dietary sodium. If weakness or impaired consciousness precludes oral correction, IV fluids are given as in any hypernatremic dehydration.

Exhaustion caused by predominant salt depletion also requires rest in a cool environment. Alert, reasonably strong children can be given relatively salty drinks, such as tomato juice, and should be encouraged to salt solid foods. Hypotonic fluids (e.g., water, Kool-Aid®) should be avoided until salt repletion has begun. Patients with CNS symptoms or gastrointestinal (GI) dysfunction may be rehydrated with IV isotonic saline or Ringer's lactate. Initial rapid administration of 20 mL per kg over 20 minutes should improve intravascular volume with return of BP and pulse toward normal. Further correction of salt and water stores should be achieved over 12 to 24 hours. In especially severe cases with intractable seizures or muscle cramps, hypertonic saline solutions may be used. The initial dose of 3% saline solution is 5 mL per kg by IV over is minutes for seizures, more slowly over 30–60 minutes for cramping. An additional 5 mL per kg should be infused over the next 4 to 6 hours.

Treatment of heat stroke centers on two priorities: (i) immediate elimination of hyperpyrexia and (ii) support of the cardiovascular system (Table 87.6). Clothing should be removed and patients should be cooled actively. They should be transported to an emergency facility in open or air-conditioned vehicles. Ice packs may be placed at the neck, groin, and axilla. Although immersion in ice water may be a more efficient means of lowering body temperature, it may complicate other support and monitoring. Among the most efficient but invasive and rarely used methods is iced peritoneal lavage. Iced peritoneal lavage is contraindicated in the pregnant patient and those with a history of abdominal surgery. In addition, a canine model of heat stroke suggested that an evaporative

TABLE 87.6

MANAGEMENT OF HEAT STROKE

Initial Management
Remove clothing
Begin active cooling
Transport to cool environment
Cardiovascular support

Laboratory Determinations
Complete blood cell count, PT/PTT
Electrolytes, BUN, creatinine, CPK, Ca, P
Urinalysis including myoglobin
Arterial blood gas

Monitoring
Temperature
Heart rate, electrocardiogram, blood pressure
Peripheral pulses and perfusion
Urine output
Central nervous system function

Treatment
Active cooling
Fluids
- Maintenance: 5% dextrose in normal saline at maintenance rates
- Resuscitation: ≤20 mg/kg lactated Ringer's or 0.9% sodium chloride
- Additional fluids as determined by electrolytes, output, and hemodynamic status

Inotropic support
- Dobutamine 5–20 μg/kg/min or

Diuresis for myoglobinuria
- Maintain urine output >1 mL/kg/h
- Consider furosemide 1 mg/kg
- Consider mannitol 0.25–1 g/kg

PT, prothrombin time; PTT, partial thromboplastin time; BUN, blood urea nitrogen; CPK, creatine phosphokinase.

technique in which fans blew room air over subjects sprayed with 15°C (59°F) tap water was equally efficient. Temperature should be monitored continuously with a rectal probe, and active cooling should be discontinued when rectal temperature falls to approximately 38.5°C (101.3°F). Sedation and paralysis of the patient can greatly augment the cooling process.

The severity of the patient's presentation determines the degree of cardiovascular support. If the skin is flushed and BP adequate, lowering body temperature with close attention to heart rate and BP may be sufficient. Although severe dehydration and electrolyte disturbances are uncommon, these should be assessed and corrected if necessary. Fluids cooled to 4°C (39.2°F) hasten temperature correction but may precipitate arrhythmias on contact with an already stressed myocardium. Adult patients rarely have required more than 20 mL per kg over the first 4 hours, but determinations of electrolytes, hematocrit, and urine output, and clinical assessment of central vascular volume should guide precise titration of fluids and electrolytes.

Patients with ashen skin, tachycardia, and hypotension demonstrate cardiac output insufficient to meet circulatory demand and are in imminent danger of death. Monitoring of the electrocardiogram (EKG) and arterial BP (with an indwelling arterial line) should determine support.

Inotropic support may be required after a fluid challenge (see Chapter 3). Dobutamine is probably most appropriate: its β-agonist properties increase myocardial contractility and maintain peripheral vasodilation. Isoproterenol has been used successfully in the past but may cause myocardial oxygen consumption to exceed oxygen delivery. Additional fluid resuscitation may be necessary with the initiation of either dobutamine or isoproterenol to fill the effectively increased vascular space. Normal saline or albumin should be given to maintain the arterial BP in the normal range. Dopamine may also be effective, infused at rates compatible with inotropic support without vasoconstriction (i.e. 5–15 *m*cg/kg/min). In cases of extreme hemodynamic instability, extracorporeal circulation may provide both circulatory support and a means of rapid temperature correction.

Agents with α-agonist characteristics (epinephrine and norepinephrine) are not recommended for initial management; they cause peripheral vasoconstriction, interfere with heat dissipation, and may compromise hepatic and renal flow further. Atropine and other anticholinergic drugs that inhibit sweating should be avoided.

Renal function should be monitored carefully, especially in patients who have been hypotensive or in whom vigorous exercise precipitated heat stroke. In general, BUN, creatinine, electrolytes, calcium, and urinalysis for protein and myoglobin should be obtained. Once the patient's vascular volume has been restored and arterial pressure normalized, hourly urine output should be monitored. If urine output is inadequate (less than 0.5 mL per kg per hour) in the face of normovolemia and adequate cardiac output, furosemide (1 mg per kg by IV) and/or mannitol (0.25 to 1 g per kg by IV) should be given. If the response is poor, acute renal failure should be suspected, and fluids should be restricted accordingly. Rapidly rising BUN or potassium should prompt consideration of early dialysis.

ACCIDENTAL HYPOTHERMIA

Background

Elevated body temperature is a routine concern for most physicians, especially pediatricians. However, hypothermia, defined as core temperature at or less than 35°C (95°F), is often overlooked. Reduced body temperature may be a consequence or cause of many disorders but is diagnosed only if health-care providers maintain a high index of suspicion.

Hypothermia was responsible for nearly 14,000 deaths in the United States from 1979 to 1998. Populations at high risk for hypothermia are similar to those vulnerable to heat illness. Neonates and the elderly are most often affected. Of the many risk factors for hypothermia, vehicular breakdown is most relevant to young children. Physical disability, especially immobilizing conditions, and drug or alcohol ingestion increase risk at any age. Healthy young people who work or play to exhaustion in a cold environment are also at risk. The rising popularity of cold weather sports is producing more cases of accidental hypothermia. However, environmental conditions need not be extreme, and the diagnosis should be considered even in temperate climates.

Primary CNS dysfunction, endocrinopathies, sepsis, protein–calorie malnutrition, and various metabolic derangements may also depress core temperature.

Mortality rates, reported from 30% to 80%, depend more on the underlying disorder than on the degree of temperature depression.

Pathophysiology

Human core temperature is normally maintained within 0.6 °C (1°F). As described in the "Environmental and Exertional Heat Illness" section, this represents a fine balance between heat production and heat loss. When core temperature begins to fall to less than 37°C (98.6°F), physiologic mechanisms that produce and conserve heat are activated. Cooled blood stimulates the hypothalamus to increase muscle tone and metabolism (oxidative phosphorylation and high-energy phosphate production) and to augment heat production by 50% during nonshivering thermogenesis. When muscle tone reaches a critical level, shivering begins, and heat production increases two to four times basal levels.

Although the surface temperature of the body, especially of the extremities, may drop to nearly the environmental temperature, several mechanisms work to conserve heat and to protect blood and core structures from ambient air temperature, humidity, and wind. Sweating is abolished, decreasing heat loss by evaporation (unless there is external moisture), whereas vasoconstriction of cutaneous and subcutaneous vessels reduce losses further. Piloerection, which in many animal species traps an insulating layer of air next to the skin, occurs but is ineffective in humans.

When any component of the balance between heat production and loss is altered, the risk of hypothermia increases. Neonates, with large surface:volume ratios and small amounts of subcutaneous fat, conserve heat poorly and are unable to produce heat by shivering. The capacity for nonshivering thermogenesis—primarily metabolism of brown fat—is intact, but oxygen consumption is significantly increased. Hypoxemia may result, as well as metabolic acidosis, hypoglycemia, and hypocalcemia. Therefore, minor deviations in the thermal environment may produce hypothermia in neonates. More pronounced environmental stresses are required to overcome the greater compensatory capacity of older children.

Immersion in cold water causes the most rapid fall in body temperature. Struggling or swimming movements increase blood flow to the extremities and hasten hypothermia. Death occurs in 15 minutes in water at 0°C (32°F), but significant hypothermia may occur even in water at 21°C (69.8°F). Exposure to extreme cold is an obvious risk, taxing the body's ability to conserve and produce heat maximally. Voluntary motor activity produces heat, and physically fit, acclimatized persons may be able to increase activity to balance heat loss even in exceptionally cold environments. However, the metabolic cost of physical activity increases in the cold, and less fit persons quickly exhaust muscle glycogen supplies, are unable to maintain adequate heat production, and are likely to become hypothermic quickly. Wet, windy conditions hasten loss of body heat and may precipitate hypothermia even in temperate environments. Adolescents are psychologically less likely to conserve energy and to take preventive or corrective measures, thus increasing their risk of hypothermia.

Once homeostatic mechanisms fail and core temperature falls, predictable physiologic changes take place. If shivering does not occur, basal metabolic rate decreases steadily, reaching 50% of normal at 28°C (82.4°F). As a result, oxygen consumption and carbon dioxide production decline. The oxygen–hemoglobin dissociation curve shifts to the left.

Although respiratory depression occurs late, impaired mental status and cold-induced bronchorrhea predispose the patient to airway obstruction and aspiration. Acid–base balance follows no predictable pattern. Respiratory acidosis occurs, but tissue hypoxia, increased lactic acid production, and decreased lactate clearance by the liver produce metabolic acidosis.

Decreased heart rate contributes primarily to a drop in cardiac output. Peripheral vasoconstriction and an early increase in central vascular volume cause a transient rise in BP, which later falls to become clinically significant at less than 25°C (77°F). A variety of cardiac conduction abnormalities arise, including decreased sinus rate, T-wave inversion, prolongation of EKG intervals, and the appearance of pathognomonic J waves (Fig. 87.5), which may provide the first clue to the diagnosis. Atrial fibrillation may occur at temperatures less than 33°C (91.4°F) but is usually not hemodynamically significant. At less than 28°C (82.4°F), myocardial irritability increases dramatically, and ventricular fibrillation becomes likely.

Cold-induced vasoconstriction and elevated central blood volume and pressure contribute to a diuresis, which subsequently diminishes intravascular volume. At lower temperatures, tubular dysfunction allows salt and water loss. Acidosis causes potassium to shift from cells to the urine, where it is eliminated. Increased capillary permeability results in loss of fluid into the extracellular space.

Hematologic abnormalities may also occur. Plasma loss causes an increased hematocrit level, whereas splenic sequestration may be responsible for a fall in white blood cell and platelet counts. Disseminated intravascular coagulation is sometimes seen.

CNS abnormalities are progressive. Each fall of 1°C produces a 6% to 7% decline in cerebral blood flow. Plasma loss

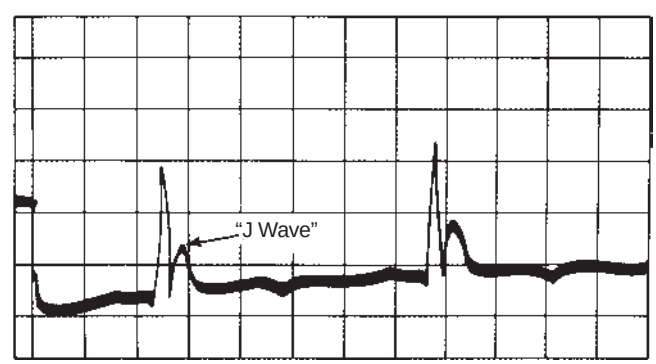

FIGURE 87.5 J wave (Osborn wave), pathognomonic of hypothermia. Rounded contour distinguishes it from an RSR′ pattern. It may also be confused with a T wave with a short Q-T interval. (Reprinted from Welton D, Mattox K, Miller R, et al. Treatment of profound hypothermia. *JAMA* 1978;240:2291–2292, with permission.)

increases blood viscosity, which further contributes to impaired cerebral microcirculation and mentation. Peripheral nerve conduction slows, and deep tendon reflexes decrease. Pupils dilate and react sluggishly, if at all, at less than 30°C (86°F). The electroencephalogram deteriorates progressively with falling temperature, from high-voltage slow waves, to burst suppression patterns, to electrical silence at 20°C (68°F).

GI motility decreases at less than 34°C (93.2°F). The liver's capacity for detoxification or conjugation of drugs and products of metabolism is poor. Insulin release abates, and serum glucose rises. Frank pancreatic necrosis may also occur, producing clinical evidence of pancreatitis.

Clinical Manifestations

The astute clinician must consider the possibility of hypothermia if the diagnosis is to be made in a timely manner. A history of sudden immersion in icy water or prolonged exposure to low environmental temperatures provides the obvious clue, but significantly low core temperatures may occur under much less suggestive circumstances. Examples include trauma victims found unconscious or immobile on a wet, windy, summer day; infants who are from inadequately heated homes or who are left exposed during prolonged medical evaluation; adolescents with anorexia nervosa; and patients with sepsis or burns. Severe hypothermia, coma, and cardiac arrest may present as the sudden infant death syndrome. Hypothermia may go undetected if the patient's temperature falls below the lower limit of the thermometer in use or if the thermometer is not shaken down adequately. Low-recording thermometers should be available in EDs and intensive care units. This diagnosis should be kept in mind for any patient with a suggestive history or coma of uncertain cause.

Physical examination reveals a pale or cyanotic patient. At mild levels of hypothermia, mental status may be normal, but CNS function is progressively impaired with falling temperature until frank coma occurs at approximately 27°C (80.6°F). BP also falls steadily at less than 33°C (91.4°F) and may be undetectable. Heart rate slows gradually unless atrial or ventricular fibrillation occurs. Intense peripheral vasoconstriction and bradycardia may render the pulse inapparent or absent. At less than 32°C (89.6°F), shivering ceases, but muscle rigidity may mimic rigor mortis. Pupils may be dilated and may not react. Deep tendon reflexes are depressed or absent. Evidence of head trauma or other injury, drug ingestion, and frostbite should be sought (Figs. 87.6 and 87.7).

Severe hypothermia mimics death. However, the significant decrease in oxygen consumption may allow life to be sustained for long periods, even after cessation of cardiac function. Signs usually associated with certain death (i.e., dilated pupils or rigor mortis) have little prognostic value. If the patient's history suggests that hypothermia is the primary event and not a consequence of death, resuscitation should be attempted and death redefined as failure to revive with rewarming.

Initial laboratory tests should include CBC, platelet count, clotting studies, electrolytes, BUN and creatinine, glucose, serum amylase, and ABGs corrected for temperature (Table 87.7). Urine should be sent for drug screening.

FIGURE 87.6 Frostbite of toes. Note the line of demarcation and ulcerative lesion.

Management

Therapy for hypothermia can be divided into two parts: general supportive measures and specific rewarming techniques (Table 87.8). Once hypothermia is diagnosed, temperature must be monitored continuously as treatment progresses.

All patients should be given supplemental oxygen. Patients with profuse secretions, respiratory depression, or impaired mental status should be intubated and mechanically ventilated. Intubation should be performed as gently as possible to minimize the risk of arrhythmias.

A decreased metabolic rate produces less carbon dioxide, and usual minute ventilation would produce respiratory alka-

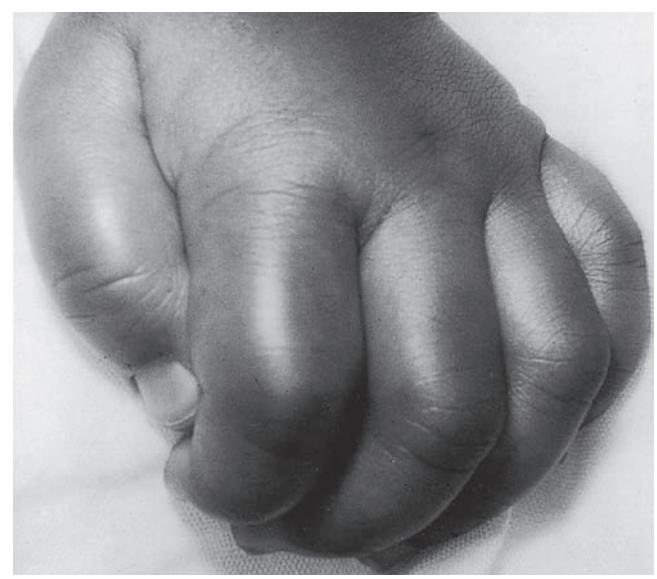

FIGURE 87.7 Swollen fingers of a child with cold exposure.

TABLE 87.7

EFFECT OF BODY TEMPERATURE ON ARTERIAL BLOOD GASES MEASURED AT 37°C (98.6°F)

	For each elevation of 1°C	For each depression of 1°C
pH	−0.015	+0.015
$Paco_2$ (mm Hg)	+4.4%	−4.4%
Pao_2 (mm Hg)	+7.2%	−7.2%

losis, increasing the risk of dangerous arrhythmias. Therefore, ventilation should begin at approximately one-half the normal minute ventilation.

Assessment of acid–base status and ventilation in the hypothermic patient is the subject of considerable confusion. Blood gas machines heat the patient's blood sample to 37°C (98.6°F) before measuring pH and gas partial pressures [thus providing theoretical values if the patient were 37°C (98.6°F)]. If the patient's actual temperature is provided with the sample, the machine can correct the values according to the nomogram of Kelman and Nunn. (Table 87.7 shows one set of guidelines for appropriate correction.) However, it is most important to understand two concepts. The first is the ectothermic principle, which relies on the following aspect of physiology: dissociation of ions and partial pressures of gases are decreased in cooled blood. In hypothermia, therefore, neutral pH is higher, whereas "normal" Pco_2 is lower than is encountered at 37°C (98.6°F). For example, hypoventilation of the hypothermic patient with a pH of 7.5 would actually induce an undesirable respiratory acidosis. A second, more practical concept is that if the patient's blood volume is restored and oxygenation maintained, acidosis will be corrected spontaneously as the patient is warmed.

TABLE 87.8

MANAGEMENT OF HYPOTHERMIA

Initial Management
Provide supplemental oxygen
Cardiopulmonary resuscitation for asystole, ventricular fibrillation

Laboratory Determinations
Arterial blood gas analysis corrected for temperature
Complete blood cell count, platelet count
Prothrombin time, partial thromboplastin time
Electrolytes, blood urea nitrogen, creatinine
Glucose, amylase
Urine drug screen

Monitoring
Heart rate, electrocardiogram, respiratory rate, blood pressure
Temperature
Consider central venous pressure

Treatment
Correct hypoxemia, hypercarbia
Correct hypokalemia
Correct hypoglycemia, 25% dextrose 1 g/kg IV
Tolerate hyperglycemia
Temperature
- ≥32°C (89.6°F): passive rewarming or simple external rewarming
- <32°C (89.6°F) (acute): external or core rewarming
- <32°C (89.6°F) (chronic): core rewarming

Fluid replacement
- (acute) 5% dextrose in normal saline at maintenance rates
- (chronic) normal saline, 5% albumin, and/or fresh-frozen plasma to maintain blood pressure

Heart rate and rhythm should be monitored continuously and the patient handled gently to avoid precipitation of life-threatening arrhythmias in an exquisitely irritable myocardium. Sinus bradycardia, atrial flutter, and atrial fibrillation are common but rarely of hemodynamic significance. Spontaneous reversion to sinus rhythm is the rule when temperature is corrected. Ventricular fibrillation may occur spontaneously or with trivial stimulation, especially at temperatures less than 28°C to 29°C (82.4°F to 84.2°F). Electrical defibrillation is warranted but frequently is ineffective until core temperature rises. Closed chest massage should be initiated and maintained until the temperature is higher than 30°C (86°F), when defibrillation is more likely to be effective. Drug therapy is rarely effective and fraught with hazards associated with decreased hepatic and renal metabolism.

Fluid replacement is essential. Relatively little plasma loss occurs in acute hypothermia (as it does after cold-water immersion), but losses may be great in hypothermia of longer duration. Normal saline or lactated Ringer's solution, warmed to about 43°C (109.4°F) in a blood-warming coil, is appropriate initially. Electrolyte determinations should guide further replacement. If clotting abnormalities occur, fresh-frozen plasma (10 mL per kg) is a useful choice for volume expansion (see Chapter 91). As temperature rises and peripheral vasoconstriction diminishes, hypovolemia is expected. Fluid volume should be sufficient to provide an adequate arterial BP.

Hypoglycemia, if present, is treated with glucose (0.5 to 1 g per kg by IV). Hyperglycemia, which may result from impaired insulin release in the hypothermic pancreas, should be tolerated to avoid severe hypoglycemia with rewarming.

A number of rewarming strategies exist (Fig. 87.8). Passive rewarming implies removal of the patient from a cold environment and use of blankets to maximize the effect of basal heat production. For patients with mild hypothermia [temperature higher than 32°C (89.6°F)], this may be adequate. As shown in the algorithm, the adequacy of perfusion and the degree of hypothermia are the major factors in the selection of rewarming strategies. For patients with an adequate pulse, passive rewarming is used as the initial strategy if the temperature is greater than 32°C and active core rewarming if the temperature is less than 32°C. Those with poor perfusion require active rewarming with a temperature greater than 32°C and ECMO, if available, with temperature less than 32°C.

Active rewarming is divided into external and core rewarming techniques. Electric blankets, hot-water bottles, overhead warmers, and thermal mattresses are simple, easily available sources of external heat. Immersion in warm-water baths is also possible but complicates monitoring or response to arrhythmias. These methods, however, cause early warming of the skin and extremities with peripheral vasodilation and shunting of cold, acidemic blood to the core. The well-known "afterdrop" of core temperature results. Severe

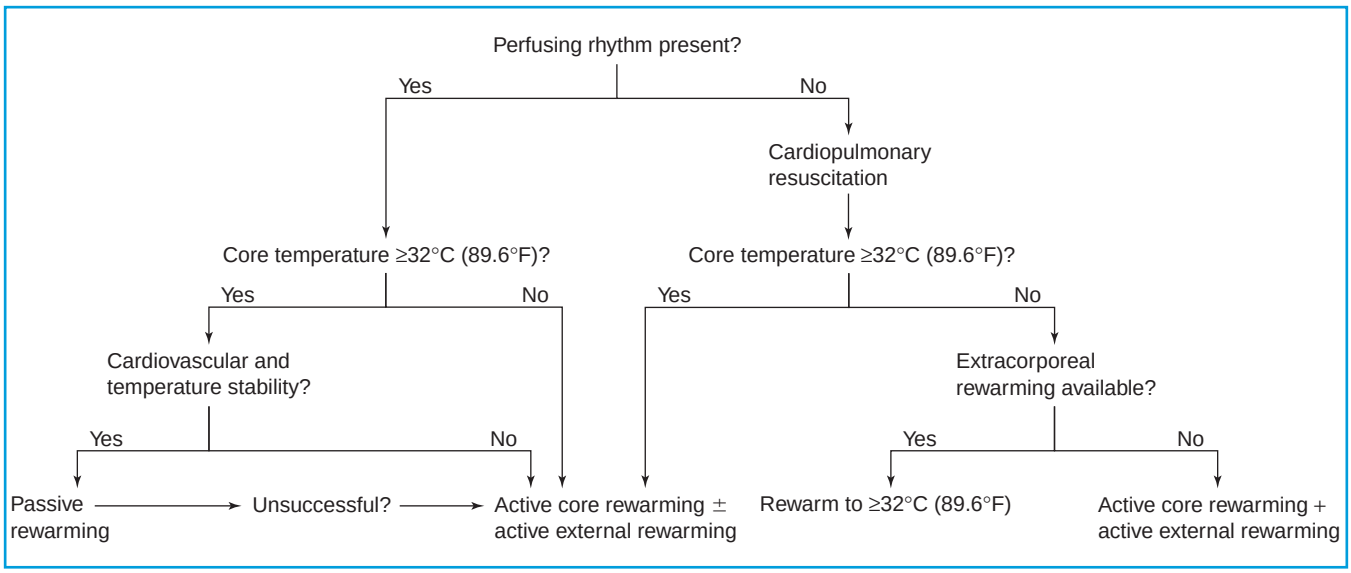

FIGURE 87.8 Algorithm for rewarming. (Adapted from Danzl DF, Pozos RS. Accidental hypothermia. *N Engl J Med* 1994;331(26):1756–1760.)

hypotension may also occur in chronic cases as vasodilation increases the effective vascular space. External rewarming techniques limited to the head and trunk may minimize vasodilation and afterdrop. In acute hypothermia, active external rewarming is appropriate, but there is some evidence that in chronic cases (more than 24 hours), mortality is higher if active external rewarming is used instead of simple passive techniques.

Core rewarming techniques are almost certainly more rapid and less likely to be associated with afterdrop, dangerous arrhythmias, or significant hypotension. These methods are especially valuable in the setting of severe chronic hypothermia [temperature less than 32°C (89.6°F)], where fluid shifts are most likely to occur. A nonshivering human model of severe hypothermia indicated that inhalation rewarming offered no rewarming advantage, whereas forced air warming (approximately 200 W) allowed a six- to tenfold increase in rewarming rate over controls. A canine study of experimental hypothermia found that heated aerosol inhalation alone contributed less heat than endogenous metabolism, but peritoneal lavage and pleural lavage had similar effect on rewarming (6°C per hour per m^2). In humans, peritoneal dialysis with dialysate warmed to 43°C (109.4°F) is effective and requires only equipment routinely available in most hospitals. Limited clinical experience suggests that pleural lavage is a relatively simple and useful measure. Gastric or colonic irrigation has also been advocated, but placement of the intragastric balloon may precipitate dysrhythmias. Hemodialysis, extracorporeal blood rewarming, and mediastinal irrigation are effective but require mobilization of sophisticated equipment and personnel. Thus, new endovascular warming catheters, introduced after cannulization of the femoral vein and advancement to the inferior vena cava, use closed-loop circuitry to maintain the patient's temperature. In one case report, a woman's temperature increased by 2.8°C per hour, with a temperature of 37°C (98.6°F) achieved after 5 hours.

Each increment in core temperature produces a "new" patient who requires reassessment and appropriate management, but most children with hypothermia have a good prognosis. In patients with mild temperature depression [greater than 32°C (89.6°F)], external rewarming techniques, and supportive care based on vital signs, ABGs, and metabolic parameters such as glucose and calcium levels, should result in prompt recovery. Patients with temperatures less than 32°C (89.6°F), and especially those in whom hypothermia developed over 24 hours or more, require meticulous attention to continuously changing vital signs and metabolic needs. More elaborate core rewarming techniques are appropriate.

Frostbite, defined as injury or destruction of the skin and its underlying tissue, may result from extended exposure to freezing temperatures; the most typical body parts affected include the fingers, toes, ears and nose. The clinical presentation can range from superficial areas of pallor and edema to more severe hemorrhagic blisters and necrosis. Treatment can be broken into three phases. The initial prethaw period, usually performed by prehospital personnel, involves getting the patient out of the cold environment and then removing wet clothing. Soft padding should be applied to protect the affected area; care must be taken not to rub any of these tissues as this may cause further damage. The second phase, the actual rewarming process, will take place over the next 15 to 30 minutes with the affected area being immersed in water that is preheated to 40°C to 42°C. Because rewarming is quite painful, IV analgesics will likely be required. The third phase, the post-thaw period, involves careful wound management and application of loose, sterile dressings. Digits are typically separated with cotton, and extremities are splinted. Tetanus prophylaxis is warranted. Prophylactic antibiotic use is controversial; however, coverage for staphylococci, streptococci, and pseudomonas should be considered if there is any indication of an early infection. If amputation becomes a reality, long-term rehabilitation and possibly psychological support may be indicated.

HIGH-ALTITUDE ILLNESS

Background

Children may be exposed to higher altitudes through participation in sporting events, family vacations, and school activities. One source defines high altitude as 1,500 to 3,500 m (4,921 to 11,483 ft), very high altitude as 3,500 to 5,500 m (11,483 to 18,045 ft), and extreme altitude as greater than 5,500 m (18,045 ft). The diagnosis of altitude illness in children can be challenging, especially in the preverbal age group.

Factors that affect whether an individual gets sick include the altitude itself, rate of ascent, the altitude where sleeping occurs routinely, and the individual's physiology. Information regarding any potential genetic basis of high-altitude illness is limited, with no specific genetic polymorphisms identified to date. However, from an anatomical perspective, those who are able to tolerate brain swelling (i.e., the elderly whose brain size diminishes with age, or infants with their immature sutures and open fontanelles) are less susceptible to altitudes illnesses. A recent study from Switzerland finds the prevalence of acute mountain sickness (AMS) in both healthy children and adolescents to be 37.5%; fortunately, the symptoms were relatively mild and responded to supportive care without the need for descent.

Pathophysiology

Physiologic changes accompanying altitude may be attributed to hypobaric hypoxia. As altitude increases, barometric pressure decreases, with a subsequent reduction in the partial pressure of oxygen. Temperature also has an inverse relationship to altitude, with hypothermia compounding these hypoxic effects. The individual's response to hypoxia is to increase ventilation, which raises alveolar oxygen while reducing alveolar carbon dioxide simultaneously. Hypocapnia produces an alkalosis that, in turn, will serve as a "check and balance" for the body by limiting further increases in the respiratory rate. The pH returns to neutral as the kidneys excrete bicarbonate in response to this alkalosis. Acetazolamide (Diamox®) is used to inhibit carbonic anhydrase so carbon dioxide is not broken down; a metabolic acidosis is then created that allows the ventilatory rate to remain high and to maintain better oxygenation.

Clinical Manifestations

The four major illnesses seen with altitude include high-altitude headache (HAH), AMS, high-altitude cerebral edema (HACE), and high-altitude pulmonary edema (HAPE). Headache is typically the initial symptom upon climbing to higher altitudes; it may occur alone as in HAH or progress to AMS. AMS is defined as having a headache in the setting of at least one of four other symptoms: nausea/vomiting, fatigue, difficulty sleeping, and dizziness. Vasogenic edema is believed to explain the pathophysiology underlying AMS, with clinical progression to encephalopathy occurring as cerebral edema, or HACE, worsens. HAPE is the most common cause of death when exposed to high altitudes; younger individuals appear to be the most susceptible, especially children with upper respiratory symptoms. Pulmonary vascular leak leads to elevated pulmonary artery pressures.

Treatment

Treatment for HAH and mild AMS includes stopping the ascent and acclimatizing at the current altitude; acetazolamide given early will hasten this process. Analgesics, hydration, and antiemetics are also given for supportive care. Once AMS worsens, low-flow oxygen should be given in conjunction with acetazolamide and/or dexamethasone, and either HBO therapy with a portable compartment or immediate descent must occur. Therapy should be even more aggressive if HACE ensues, with dexamethasone administered in addition to oxygen, HBO, and immediate descent or even evacuation. The addition of the calcium-channel blocker nifedipine will reduce pulmonary vascular pressures in patients with HAPE. Exertion should be limited, oxygen provided, and either HBO or immediate descent arranged.

Prevention efforts may minimize an individual's chance of developing altitude illness. For example, different formulas exist regarding ideal ascent rates [i.e., above 3,000 meters (9,842 ft), sleeping elevations should not exceed the previous day by more than 300 to 500 meters and rest should occur every 3 days], following the mantra of "climb high, sleep low". If physically fit individuals follow such climbing guidelines, prophylaxis with acetazolamide is not typically required. However, because of the ease of getting to high elevations via car or airplane, individuals who ascend quickly, and/or have significant underlying diseases (hepatic, renal, or cardiopulmonary dysfunction in particular) may warrant acetazolamide prophylaxis. Most sources recommend using 250 mg twice daily, with pediatric dosing extrapolated from acetazolamide dosing for edema at 5 to 10 mg per kg per dose every 6 hours, not to exceed 1 g per day. Care should be taken in the individual with a sulfa allergy given acetazolamide contains a sulfa moiety; while the incidence of cross-reactivity is low at 7% to 10% in patients with a self-reported sulfa allergy, anaphylaxis has been reported and thus use of dexamethasone may be more prudent in these cases. More in-depth discussions of altitude illness and its prevention/treatment can be found in the references provided at the end of this chapter.

ELECTRICAL INJURIES

Background

Since the beginning of time, people have viewed lightning with fear and fascination. Cloud-to-ground lightning strikes occur 30 million times each year in the United States, primarily in afternoons and early evenings of the spring and summer, and in areas around the Gulf of Mexico. Lightning that strikes individuals carries a 30% risk of mortality and claims approximately 100 lives annually in the United States. The death rate is highest among children ranging from 15 to 19 years of age.

The last two centuries have witnessed the incorporation of controlled electricity into daily life and a better understanding of its properties and physiologic effects. Availability of

electricity has also meant increased exposure to electrical hazards and accompanying injuries. Electrical injury is responsible for approximately 700 deaths per year, of which 10% are children. No federal safety standards exist for household electrical cords, the major cause of electrocution in children 12 years of age and younger. High-tension electrical injuries dominate in older children who climb on trees, buildings, or utility structures. Tasers and stun guns, which are high-voltage, low-current stimulators, cause pain due to involuntary muscle contractions. Young children may encounter them unintentionally if their caretakers are in law enforcement, or adolescents may feel their effects if they are being pursued by the police.

Pathophysiology

The spectrum of electrical injury is enormous, ranging from low-voltage household accidents to million-volt lightning strikes (Table 87.9). Appropriate management requires an understanding of the basic physical aspects of electricity, the physiologic responses to injury, and the potential for immediate and delayed damage.

The severity of electrical injury depends on six factors: (i) the resistance of skin, mucosa, and internal structures; (ii) the type of current (alternating or direct); (iii) the frequency of the current; (iv) the intensity; (v) the duration of contact; and (vi) the pathway taken by the current. Precise separation of the effect of these factors, which are interrelated, is impossible. Together, they produce either heat or current, and a variety of injuries result.

Resistance is a major factor determining the amount of current flow through tissue. Tissue injury is inversely related to resistance. Dry skin provides resistance of approximately 40,000 ohms, whereas thick, callused palms may provide up to 1×10^6 ohms. Thin, moist, or soiled skin lowers resistance to the 300- to 1,000-ohm range. The highly vascular, moist oral mucosa has even lower resistance.

Once surface resistance is overcome, current flows between points of contact, not necessarily along anatomic structures such as nerves or blood vessels. Although the resistance of various tissues is known, the voltage difference may determine the actual path taken. Low-voltage current usually follows the path of least resistance, whereas high-voltage current follows a more direct course to ground with less regard for tissue type. Assessment of the most likely current pathway does not reliably predict injury. However, current that passes through the head or thorax may cause respiratory center or cardiac injury and increases the risk of cardiopulmonary arrest. Hand-to-hand flow carries risks of 60% mortality related to myocardial injury, spinal cord transection at C4 to C8, and tetanic contraction of thoracic muscles with suffocation. Hand-to-foot current passage is associated with cardiac arrhythmias but lower mortality (20%). Foot-to-foot injuries are rarely fatal.

The type of current is another important determinant of injury. Alternating current (AC) at low voltage is able to induce tetanic muscle contraction and is, therefore, more dangerous than direct current (DC). These contractions prevent the victim from releasing his grip ("locking-on"), thus extending the duration of contact. Normal household 60-Hz current changes direction 120 times per second, a frequency that induces an indefinite refractory state at neuromuscular junctions. Higher-frequency commercial currents are less likely to induce such a state and may be less harmful.

DC is used in medical settings for cardiac defibrillation, countershock, and pacing. Currents as low as 1 mA may trigger ventricular fibrillation, and high currents may damage the heart and conducting tissues directly. Lightning is another example of DC, discharged in a single, massive bolt that lasts 1/10,000 to 1/1,000 second. The brevity of exposure makes deep thermal injury unlikely.

In general, high-voltage injury is more dangerous than low-voltage injury. A higher voltage is more likely to cause "locking-on" and associated deep-tissue injury, although its tendency to throw victims from the source of current may mitigate this effect. The possibility of head and cervical spine injuries must be considered in these cases. The value of the current, or amperage, is of even greater importance than the voltage. Flow as low as 1 to 10 mA may be perceived as a tingling sensation. Progressively higher flows may paralyze muscles and ventilation, precipitate ventricular fibrillation, and cause deep-tissue burns.

Clinical Manifestations

Electrical injury may produce a variety of clinical pictures, ranging from local damage to widespread multisystem disturbances. Typically, deceptively small entry and exit wounds mask extensive damage to subcutaneous tissue, muscle, nerves, and blood vessels. Direct effects on the heart and

TABLE 87.9

LIGHTNING VERSUS HIGH-VOLTAGE ELECTRICAL INJURY

Factor	Lightning	High voltage
Duration	Brief	Prolonged
Energy level	100,000,000 V 200,000 amps	Much lower
Type of current	Direct	Usually alternating
Shock wave	Present	Absent
Cardiac	Asystole	Ventricular fibrillation
Burns	Superficial, minor	Deep, frequently obscured
Renal failures	Rare	Common secondary to myoglobinuria
Fasciotomy and amputation	Rare	Common, early, extensive

nervous system are particularly common, and injury to all other symptoms can occur. Much of the injury is revealed immediately, but late complications are often encountered.

Victims of the most severe accidents are commonly pulseless, apneic, and unresponsive. Current that passes directly through the heart may induce ventricular fibrillation. Brainstem (medullary) paralysis or tetanic contractions of thoracic muscles may result in cardiopulmonary collapse. Lightning injury is capable of inducing asystole, from which the heart may recover spontaneously, but the accompanying respiratory failure is commonly prolonged. Unless ventilation is initiated promptly, hypoxia leads to secondary ventricular fibrillation and death.

Other cardiac disorders, including arrhythmias and conduction defects, are common among survivors. Supraventricular tachycardia, atrial and ventricular extrasystoles, right bundle branch block, and complete heart block are most common. Complaints of crushing or stabbing precordial pain may accompany nonspecific ST-T wave changes. Some patients sustain myocardial damage or even ventricular wall perforation. Despite evidence of important cardiac injuries, patients without secondary hypoxic-ischemic injury usually regain good myocardial function.

Nervous system injury is also extremely common and may involve the brain, spinal cord, peripheral motor and sensory nerves, as well as sympathetic fibers. Loss of consciousness, seizures, amnesia, disorientation, deafness, visual disturbances, sensory deficits, hemiplegia, and quadriparesis occur acutely but may be transient. Vascular damage may produce subdural, epidural, or intraventricular hemorrhage.

Additional problems develop within hours to days after injury. The syndrome of inappropriate antidiuretic hormone secretion may precipitate herniation in rare cases. Electroencephalograms reveal diffuse slowing, epileptiform discharges, or burst suppression patterns, but they may not have prognostic significance. Spinal cord dysfunction yields more motor than sensory deficit. Peripheral neuropathies with patchy distribution may reflect direct thermal injury, vascular compromise, or current flow itself. A variety of autonomic disturbances may resolve spontaneously or persist as reflex sympathetic dystrophy.

Ocular damage is common, particularly after lightning strikes. Direct thermal or electrical injury, intensive light, and confusion contribute to the presentation. Findings include corneal lesions, hyphema, uveitis, iridocyclitis, and vitreous hemorrhage. Choroidal rupture, retinal detachment, and chorioretinitis occur less often. Autonomic disturbances in a lightning victim may cause fixed dilated pupils, which should not serve as a criterion for brain death without extensive investigation of other neurologic and ocular functions. Cataracts and optic atrophy are possible late developments.

Electrical injury may induce direct or indirect complications in other organ systems. Tetanic contractions may cause joint dislocations and fractures, especially of the upper-extremity long bones and vertebrae. Fractures of the skull and other long bones may occur when high-tension shock throws the victim from the site of contact. Early cardiopulmonary insufficiency, as well as direct renal effects, may cripple renal function. Damaged muscle releases myoglobin and CPK. As in crush injuries, myoglobin may induce renal tubular damage and kidney failure. Pleural damage may cause large effusions, whereas primary lung injury or aspiration of gastric contents may lead to pneumonitis. Gastric dilation, ileus, diffuse GI hemorrhage, and visceral perforation may occur immediately or later.

In addition to burns at the site of primary contact, burns are common where current has jumped across flexed joints. Such burns are most common on the volar surface of the forearm and across the elbow and axilla. Arcing current may also ignite clothing and produce typical thermal burns. Entry and exit wounds and arc burns are notoriously poor predictors of internal damage. Tissue that appears viable initially may become edematous and then ischemic or frankly gangrenous over several days. Diminished peripheral pulses may provide immediate evidence of vascular damage, but strong pulses do not guarantee vascular integrity. Blood flow falls to a minimum at about 36 hours, but current or thermal damage may lead to vasospasm, delayed thrombosis, ischemic necrosis, or aneurysm formation and hemorrhage weeks after the injury. Viable major arteries near occluded nutrient arteries may account for apparently adequate circulation and uneven destruction of surrounding tissues.

Young children are vulnerable to orofacial burns, especially of the lips (Fig. 87.9). These full-thickness burns of the upper and lower lips and oral commissure usually involve mucosa, submucosa, muscle, nerves, and blood vessels. The lesion usually has a pale, painless, well-demarcated, depressed center with surrounding pale gray tissue and erythematous border. After a few hours, the wound margin extends and marked edema occurs. Drooling is common. The eschar separates in 2 to 3 weeks and bleeding may occur at this time; granulation tissue gradually fills the wound. Scarring may produce lip eversion, microstomia, and loss of function. Damage to facial or even carotid arteries may result in delayed hemorrhage. Devitalization of deciduous and secondary teeth may occur.

Inadequately debrided burned or gangrenous tissue provides a medium for serious infection. Staphylococcal, pseudomonal, and clostridrial species are common pathogens in the extremities. Streptococci and oral anaerobic organisms may infect mouth wounds.

Management

The first step in emergency management (Table 87.10) is to separate the victim from the current source. The rescuer must be well insulated to avoid becoming an additional casualty. If the current cannot be shut off, wires can be cut with a wood-handled ax or appropriately insulated wire cutters. Contrary to popular myth, a lightning stroke victim does not remain "electrified" and presents no risk to another person.

Any victim in cardiopulmonary arrest should be resuscitated promptly following the guidelines discussed in Chapter 1. Prolonged efforts to restore adequate cardiopulmonary and cerebral function, especially in the lightning victim, may be appropriate in the context of bizarre neurologic phenomena that inhibit ventilatory efforts, consciousness, or pupillary function. The patient who fails to respond to resuscitative efforts over hours to days and meets standard brain death criteria can be pronounced dead with reasonable certainty.

Any patient who sustains electrical injury deserves a comprehensive physical examination. Bleeding or edema from orofacial burns may compromise the upper airway. The head, particularly eyes, and neck should be examined carefully for

TABLE 87.10

MANAGEMENT OF ELECTRICAL INJURIES

Initial Management
Remove from source of current
Cardiopulmonary resuscitation as needed
Provide mechanical ventilation until spontaneous ventilation is adequate
Immobilize neck and spine

Clinical Assessment
Neurologic examination
Peripheral pulses and perfusion
Oral burns/edema
Chest wall injury
Abdominal distension
Eye or ear trauma
Cutaneous burns or bruises

Laboratory Determinations
Complete blood cell count
Blood urea nitrogen, creatinine, urinalysis including myoglobin
Electrolytes
Troponin
Electrocardiogram (EKG)
Consider skull, spine, chest, long bone radiographs
Consider computed tomography scan of brain
Consider electroencephalogram

Monitoring
Heart rate, EKG, respiratory rate, blood pressure

Management
Maintenance fluids: 5% dextrose in normal saline
Volume expansion in presence of thermal burns or extensive deep-tissue injury: 0.9% sodium chloride, lactated Ringer's solution, or 5% albumin
Fluid restriction for central nervous system injury
Maintain urine output >1 mL/kg/h
Treat arrhythmias
Treat seizures
Tetanus toxoid; consider penicillin/other antibiotics
Consider general, oral, or plastic surgical consultation

evidence of trauma. The skin should be examined carefully for burns and bruises. Limbs should be evaluated for pulses, perfusion, and motor and sensory function, as well as for soft-tissue swelling or evidence of fractures. Burns and deep-tissue injury may progress over hours to days, so repeated examination and monitoring are important.

Neurologic evaluation is especially important in all but the most minor, localized peripheral injuries. Level of consciousness and mental status should be assessed according to the child's developmental level. Cranial nerve, cerebellar, motor, and sensory evaluation are essential.

Children who have sustained minor household electrical injuries and are asymptomatic usually do not require laboratory evaluation, cardiac evaluation, or hospitalization. In one series, investigators were unable to assess the clinical significance of loss of consciousness, tetany, wet skin, or current flow across the heart, and recommended cardiac monitoring if any of these factors were present. If the history is one of a high-tension injury or lightning strike, laboratory evaluation should include EKG, CBC, CPK (with fractionation), BUN, creatinine, and urinalysis, including urine myoglobin. Physical examination that reveals evidence of bruises, bony tenderness, or distorted long bones should prompt appropriate radiographic studies.

Most children who sustain burns of the oral commissure (usually after biting an electrical cord) do not require extensive evaluation or admission. In cases of severe orofacial burns, use of an artificial airway should be considered before progressive edema leads to catastrophe. Mechanical ventilation may be necessary to overcome CNS depression or primary lung involvement.

Patients with persistent coma and loss of protective airway reflexes should be intubated to avoid aspiration. Good oxygenation and ventilation adequate to maintain a normal pH and $Paco_2$ of 35 to 40 mm Hg must be ensured. Seizure activity should be treated as indicated (see Chapters 69 and 96).

Care of the CNS is of utmost importance. The neck and back should be immobilized if the patient was thrown from the site of injury. If the mechanism of injury was severe, a cervical collar should be maintained in place despite normal

cervical spine radiographs. If a child fails to regain consciousness within a short time or shows signs of neurologic deterioration, a computed tomography scan will help exclude intracranial hemorrhage.

Any patient who has sustained cardiopulmonary arrest, loss of consciousness, or deep-tissue injury should be admitted to the hospital for evaluation and treatment. Heart rate, respiratory rate, and BP should be monitored regularly. Doppler evaluation may be helpful in cases of vasospasm, which may complicate assessment of BP and subsequent fluid management. True hypotension may require pressor support.

Cardiopulmonary support is nonspecific. Most patients resume circulatory stability unless severe hypoxia and ischemia have weakened the myocardium. Arrhythmias and acidosis should be treated along usual lines (see Chapters 84 and 100).

Patients struck by lightning require only maintenance fluids. Patients with ordinary thermal burns should be treated according to standard recommendations (see Chapter 108), although body surface area calculations may seriously underestimate fluid requirements. Extensive vascular and deep-tissue destruction may lead to extensive fluid sequestration. Isotonic fluid should be given in amounts to maintain normal pulse and BP. In all cases, fluids should be given with attention to possible CNS complications.

Cerebral edema may develop over hours to days after injury, especially after a lightning strike. If the child's neurologic status fails to improve or deteriorates, intracranial pressure monitoring and treatment, including hyperventilation, osmotic or loop diuretics, and sedation and neuromuscular blockade, may be necessary. Serum and urine electrolytes and osmolality should be followed closely to recognize promptly the syndrome of inappropriate antidiuretic hormone secretion.

Myoglobin in the urine is consistent with muscle breakdown and sets the stage for renal failure. Hydration and brisk diuresis with furosemide and/or mannitol may prevent renal damage but must be undertaken with caution if there is coexistent CNS injury. Extensive muscle damage after lightning injury is uncommon, however, and major CNS injury is common. Treatment should proceed with these relative risks in mind until definitive information is available.

Most burns associated with lightning injury are superficial. Although they may become more apparent after several hours, most remain first- or second-degree burns. Minor burns on the extremities can be treated with antibiotic ointment and should be allowed to slough and heal. Oral and plastic surgeons should evaluate children who sustain oral burns. In most cases, similar conservative management is recommended, but a removable stent may be necessary to minimize scarring.

High-voltage injuries commonly require more aggressive treatment. Fasciotomy may be necessary to restore adequate circulation to an injured extremity. The approach to debridement of wounds is controversial, but repeated examinations are considered most useful for detecting nonviable tissue. Approximately 30% of survivors of high-tension injuries ultimately require amputation of some part of an extremity.

The risk of infection in patients with deep-tissue injury is high. Any patient not clearly immunized against tetanus should be given tetanus toxoid. Prophylactic antibiotics have been recommended for oral injuries, but in general, antimicrobial therapy should be reserved for proven or strongly suspected infection.

CHAPTER 88 ■ INJURIES INVOLVING RADIATION

HENRY D. ROYAL, MD, JOANNA R. FAIR, MD, PHD, AND DAVID E. DRUM, MD, PHD

The radiation accident registry maintained at Oak Ridge, Tennessee, lists 432 accidents that have occurred worldwide from 1944 until June 2008. More than 3,000 people were exposed to significant amounts of radiation, and 127 persons died as a direct result. Most of the survivors had no permanent injury as a result of the accidents. The major issues for the survivors are a small increase in the risk of cancer and the psychological stress caused by their concerns and those of their community about the long-term effects of radiation exposure. Two hundred fifty of the accidents occurred in the United States, resulting in 26 fatalities. Worldwide, less than 10 fatalities have been reported in children. Thus, radiation accidents that result in medically significant injuries to children are quite uncommon.

Despite the rarity of medically significant radiation accidents, the emergency physician needs to be aware of the basic principles and management of radiation incidents for five major reasons. First, The Joint Commission requires plans for managing environmental events including those involving hazardous materials and terrorist events. Second, incidents in which radiation is perceived to have an important role are not rare. For instance, the discovery of a cardboard box with a radioactive label attached to it in a school play yard or public roadway is liable to cause great anxiety. Generally, the public believes radiation to be very hazardous and does not distinguish between amounts of radiation that we are exposed to every day from natural sources and amounts of radiation that have a measurable biological effect. If the emergency physician is knowledgeable about the effects of radiation, he or she can correctly counsel the patient and immediately help decrease the psychological trauma. Third, fear of radiation and lack of knowledge about its effects have led to the professional mismanagement of several individuals who were believed to be involved in a radiation accident. Fourth, the emergency physician needs to be informed about the effects of radiation because the rare radiation event is often not initially recognized. A review of radiation events that have occurred in the past should help physicians recognize situations in which radiation might be considered as etiologic. Frequent training and drills are essential to ensure that the emergency department (ED) staff have the knowledge, procedural skills, and supplies to deal with possible victims exposed to radiation accident. Finally, knowledge of radiation events will lead to better understanding of the effects of routine diagnostic radiation exposures.

PATHOPHYSIOLOGY

Types of Radiation

Radiation is a very general term used to describe energy that is emitted from a source (Fig. 88.1). Some forms of radiation may deposit a large amount of energy in a small volume of tissue. These energetic forms of radiation are called *ionizing radiation* because they deposit enough energy to strip electrons from atoms. X-rays are a type of ionizing radiation. Other types of radiation are less energetic (of longer wavelength) and are called *nonionizing radiation*. Examples of nonionizing radiation include visible light and infrared radiation. The distinction between ionizing and nonionizing radiation is important because their biological effects are very different; the latter primarily deposits heat in tissue.

Ionizing radiation can be further subdivided into types of radiation that have no associated mass (*nonparticulate*) and those that have mass (*particulate*). X-rays and gamma rays are nonparticulate types of radiation. This type of radiation can penetrate deeply into the body and affect radiation-sensitive tissues [e.g., bone marrow and the lining of the gastrointestinal (GI) tract]. X-rays are emitted by excited electrons, whereas gamma rays are emitted by excited or unstable nuclei (radioisotopes or radionuclides). Once x-rays or gamma rays have been emitted, they are indistinguishable.

Particulate radiation can be further divided into charged and uncharged particles. Neutrons, a type of particulate radiation that has no electrical charge, can penetrate the body to depths similar to x-rays and gamma rays. Because neutrons deposit their energy in a more concentrated area, they cause more biological damage than x-rays or gamma rays.

Alpha particles have a 2+ electrical charge and a large mass (two protons and two neutrons). Beta particles have a single negative charge and a small mass (one electron). Charged particles do not penetrate the body very well. Because of their larger mass and charge, alpha rays cannot penetrate even the dead layers of skin. For example, ^{239}Pu, an alpha emitter, is a biological hazard only when it is inhaled, ingested, or otherwise introduced into the body. Beta particles ("beta rays") are more penetrating and in high doses can severely damage the skin. Beta rays cannot damage the deep radiation-sensitive organs in the body unless the radioactive source is incorporated into the body. At the Chernobyl nuclear plant accident in Russia, some of the firefighters had severe skin damage due to intense beta particle exposure. This injury contributed to their deaths.

The words "radiation" and "radioactive" are often confused. An atom that is unstable spontaneously gives off energy as radiation and is radioactive. In contrast, an x-ray machine cannot spontaneously give off radiation: an external power source is needed. Therefore, an x-ray machine is not radioactive. A patient who has been exposed to radiation does not become radioactive. Patients emit radiation only if they have radioactive atoms on them (external contamination) or within them (internal contamination).

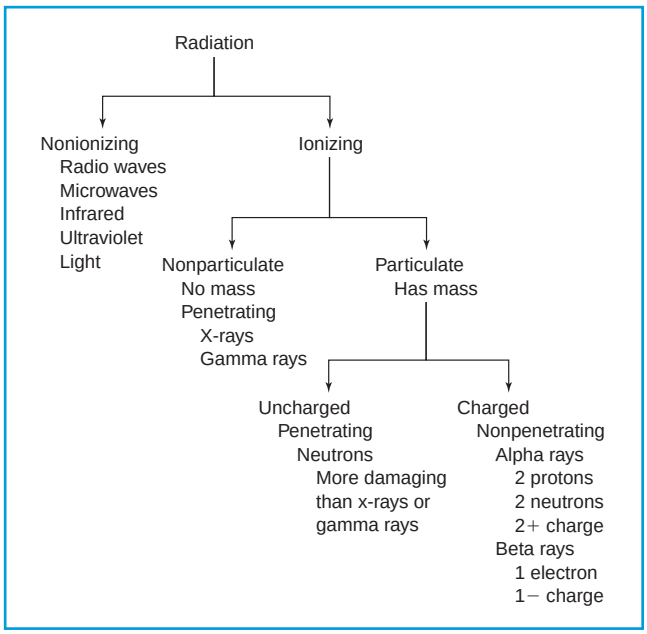

FIGURE 88.1 Types of radiation.

Amounts of Radiation

Although radiation cannot be perceived by the human senses, Geiger counters can easily measure amounts of radiation far below the levels that can be shown to have a measurable biological effect. Geiger counters are inexpensive and are readily available in the nuclear medicine department at most hospitals. Because a Geiger counter can detect and quantify immediately the radiation exposure rate, managing a radiation hazard can be easier than managing biological hazards such as bacterial meningitis or methicillin-resistant *Staphylococcus aureus* infection or managing hazardous chemical exposures.

Radiation exposure is commonly measured in three different units in the United States: roentgen, rad, and rem. However, new international units are being used by regulatory and professional organizations (Table 88.1). The roentgen (R) is a measure of radiation exposure in air. Absorbed dose in an organ is measured in grays (Gy); 1 Gy is equal to 100 rads. Effective dose, in sieverts (Sv), is a measure of overall risk to an individual when the irradiation is weighted for the sensitivity of each organ to late effects of radiation. One sievert is equal to 100 rems. Quantity of radiation is measured by becquerels (Bq), defined as 1 atomic disintegration per second. The former unit, the curie (Ci), is equal to 3.7×10^{10} Bq, and 1 mCi is equal to 37 MBq.

To put into perspective the magnitude of these units, it is helpful to recall that we are exposed to about 3 mSv of radiation each year from natural sources. During a 70-year lifetime, a person's total radiation exposure from natural sources will be more than 200 mSv, with no measurable biological effect of radiation. Typical radiation exposures that we encounter as part of our daily lives and in medicine are listed in Table 88.2.

In addition to the quantity of the radionuclide, the hazard posed by a radionuclide depends on its decay scheme, the energies of its emissions, its half-life, and on how long it stays in various organs in the body. For example, a radionuclide that decays by emitting only alpha particles is not a hazard if kept outside the body, since alpha particles cannot penetrate even the dead layers of the skin. However, some radionuclides (e.g., ^{131}I) that are readily absorbed by the body and/or are concentrated by an organ can be a hazard even when present in small amounts.

TABLE 88.1

INTERNATIONAL RADIATION UNITS

Metric	Definition
Exposure	Roentgen, R R = 2.58×10^{-4} C/kg air
Absorbed dose	Gray, Gy 1 Gy = 1 joule/kg 1 Gy = 100 rads
Effective dose	Sievert, Sv 1 Sv = 1 joule/kg, weighted for tissue sensitivity 1 Sv = 100 rems
Quantity	Becquerel, Bq 1 Bq = 1 disintegration/s 1 Ci = 3.7×10^{10} Bq 1 mCi = 37 MBq

RADIATION SAFETY

The worst radiation accident involving a commercial nuclear power plant in the United States (Three Mile Island) resulted in a radiation dose to off-site medical personnel was of 0.14 mSv. Following the Chernobyl accident, the highest radiation dose to off-site medical personnel was tens of millisieverts, similar to the dose from one computed tomographic scan examination. These doses should reassure emergency personnel that it is extremely unlikely that a radiation event involving contamination would ever threaten their safety. Patients who have been exposed only to high doses of radiation, such as a patient after radiation therapy, are not radioactive and require no special precautions from radiation exposure.

Although the radiation doses to personnel involved in the care of a victim contaminated by radioactive material are likely to be very small, simple protective measures should be employed to minimize the doses. There are three methods of protection from radiation exposure: minimizing *time* of expo-

TABLE 88.2

COMMON RADIATION DOSES

Sources	Effective dose
Roundtrip intercontinental air flight	20–30 μSv
Chest radiograph	50–100 μSv
Living in brick house	0.20 μSv/yr
Natural radiation	3 mSv/yr
Angiography	10 mSv
Abdominal computed tomographic scan	10–30 mSv

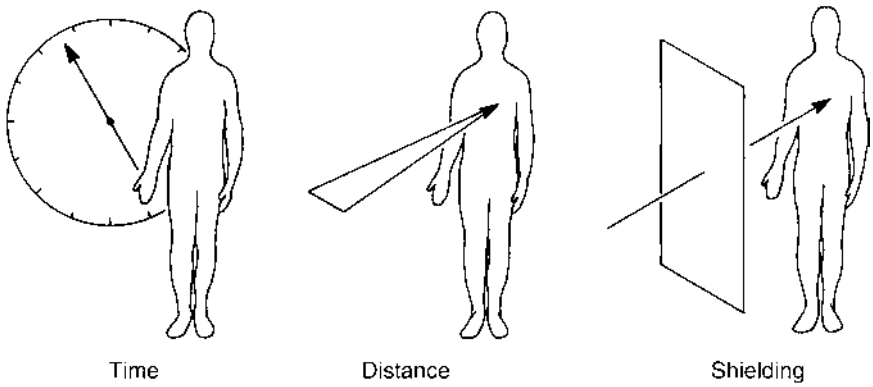

FIGURE 88.2 Three methods of reducing radiation exposure.

sure, maximizing *distance* from the material to the extent practical, and using *shielding* as appropriate (Fig. 88.2). The amount of exposure received is directly proportional to the time spent near the source of radiation. Distance is the most practical and effective method of reducing radiation exposure because the dose decreases by the square of the distance. In other words, doubling the distance from a source of radiation will reduce the dose by a factor of 4, and tripling the distance will reduce the dose by a factor of 9 (Fig. 88.3). This is known as the inverse square law. For shielding, the familiar lead aprons used in radiology departments, where the radiation comes from low-energy scattered radiation, are not generally useful in radiation event management. Lead aprons do not provide very effective protection against the higher-energy radionuclide emissions likely to be encountered with radioactive contamination.

CLINICAL MANIFESTATIONS AND EVALUATION

Recognizing Radiation Exposure

Radiation exposures can be recognized by understanding three questions: (i) Who is likely to be affected by a radiation exposure or accident? (ii) What are the likely sources of radiation? and (iii) What are the likely injuries?

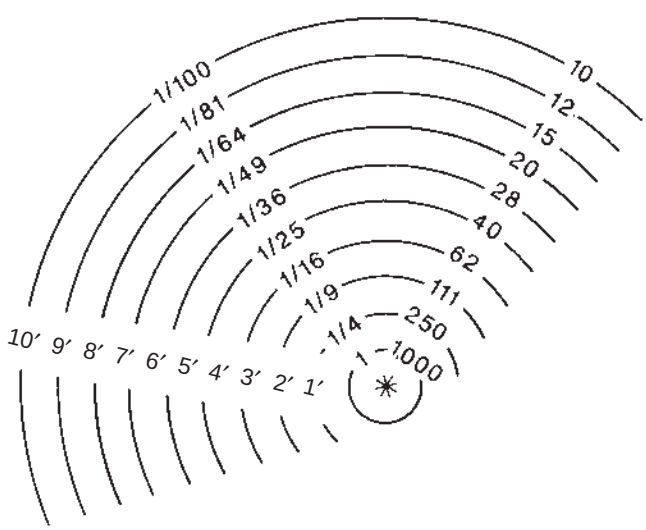

FIGURE 88.3 The effect of distance on radiation exposure from a point source of radiation.

Types of Radiation Exposures

The people most likely to be involved in a radiation exposure event are individuals whose work involves radiation. Although these exposures are usually recognized, many work-related accidents were not initially appreciated. One valuable way to determine if a radiation accident has occurred is to contact the worker's supervisor and/or the radiation safety officer for the employer. In most instances, they will immediately recognize the possibility of a serious radiation exposure.

A second group of individuals who may be involved in a radiation exposure event are members of the general public who inadvertently come into contact with a radiation hazard. An example of this kind of exposure occurred in Goiana, Brazil, in September 1987. In that incident, a ^{137}Cs radiation therapy source was stolen from an abandoned medical clinic. The poachers brought the source to their home, exposing their family and friends to large doses of radiation. The exposure worsened when the victims broke open the ^{137}Cs source, subsequently contaminating their food, their living quarters, and the area surrounding their homes. As a result of this accident, four persons, including a 6-year-old girl, died. Hundreds of other people were exposed to nonlethal amounts of radiation. The accident was not recognized until 2 weeks after the source had been opened. When the individuals first became ill, their symptoms were diagnosed as gastroenteritis.

A more recent example of this second category is the striking increase in the prevalence of thyroid cancer (more than 2,000 cases) among children in the Ukraine and Belarus after the Chernobyl accident. Radionuclides, especially ^{131}I, were deposited by fallout and incorporated into foods and milk products. Those who were youngest at exposure had the greatest increase in prevalence, whereas there was a smaller increase in adolescents and no increase in those older than 20 years at the time of exposure.

A third group of individuals who may be involved in a radiation event are persons who are unknowingly intentionally exposed to radiation by another person. A 13-year-old boy was intentionally exposed to radiation by his father on multiple occasions during weekend visitations. The son later recalled occasionally finding "shiny silver pellets" in the ear pieces of headphones he was told to wear, in a pillow he was

told to use, and in a sock he found on his bed. Other injuries suggested that he was exposed at other times while under sedation. The boy developed skin lesions, described as bruises, that gradually developed into reddish brown blisters. These lesions were attributed to infection. Subsequently, he developed lesions on the medial aspects of both thighs, right ankle, right hand, and left forehead. He also began losing hair from the left side of his head. The lesions became increasingly incapacitating, and the boy was admitted to a hospital for 3 weeks. An infectious etiology for the lesions could not be established. A psychiatrist suggested a neurodermatitis due to the conflict between the boy and his father. During a 20-month period, the boy was seen by 16 physicians. Finally, a plastic surgeon recognized the lesions as radiation necrosis.

The father, a petroleum engineer, had access to 74-GBq ^{137}Cs sources. The dose rate at contact for such a source is approximately 5 Gy per minute. However, at 1 cm, the dose rate drops to (0.3 Gy) per minute and is about 40 mGy per minute at 3 cm from the surface.

A fourth group of individuals who may be involved in a radiation exposure are patients who have undergone medical procedures (fluoroscopy or radiation therapy). Typical cases include one or more lengthy exposures to prolonged fluoroscopy, such as during an interventional cardiac catheterization. For example, a 17-year-old Spanish adolescent girl who underwent two lengthy cardiac radiofrequency ablations within 13 months developed chronic radiation dermatitis and associated limited range of motion of her right arm.

Types of Radiation Sources

To cause a significant radiation injury, an intense radiation source is needed. The four major types of possible intense radiation sources are listed in Table 88.3. Because of their various physical properties, different types of sources are likely to cause different types of radiation injuries.

Sealed sources contain a radioactive source in a leakproof container or capsule; hence, these accidents usually cause only radiation exposure. Contamination occurs only if the container is broken open. Examples of sealed sources include industrial radiography sources, some radiation therapy machines, brachytherapy seeds and devices, and industrial sterilizers.

By far, industrial radiography sources have caused the most radiation accidents. There are thousands of these highly radioactive sources in the United States. They are used in industry to x-ray metal parts such as pipe welds. When not in use, the radioactive source is shielded in a thick lead container. To take an x-ray, the source is cranked out of the shield using a cabling system. Until more recently, the source was attached to the cable by a simple mechanism that sometimes failed. If the source detached from the cable, it could be lost. The actual source is about the size of a BB pellet (Fig. 88.4); it is metallic and appears innocuous. In the past, the source was not labeled; a passerby could find the source and not recognize it to be dangerous. Because this type of source is small, it usually causes a local radiation injury involving the hands (from picking up the source) or the buttocks (from putting the source in a pocket). Strict regulatory enforcement actions have markedly decreased the occurrence of this type of accident.

Sealed sources used in radiation therapy can be small (brachytherapy "seeds") or large (cobalt therapy machine). Industrial sterilizers use large, intense radiation sources to sterilize products (e.g., packaged food, medical supplies) that would be damaged by other methods of sterilization. Large, sealed sources are more likely to result in whole-body radiation exposure.

Unsealed sources, a second type of radiation source, consist of radioactive material in a form that is dispersed easily (e.g., liquid or powder). The likely injury caused by unsealed sources involves both external and internal contamination. Unsealed sources commonly found in hospitals include the radiopharmaceuticals used in nuclear medicine (e.g., ^{99m}Tc, ^{131}I, ^{18}F). Other industries or activities may use unsealed sources of ^{32}P, ^{241}Am, or ^{239}Pu. If these radioactive materials are kept outside the body (external contamination), they would not likely cause harm. Radioactive dirt can be washed from the skin with soap and water. If properly managed, external contamination is generally a nuisance rather than a serious health threat to the patient or medical staff. If the radioactive

TABLE 88.3

INTENSE RADIATION SOURCES

Type of source	Examples	Likely injuries
Sealed	Industrial radiography Brachytherapy Some radiation therapy machines Industrial sterilizers	Contamination unlikely Local radiation injury with small source Whole-body exposure with large source
Unsealed	Medical radionuclides (e.g., ^{131}I, ^{32}P) Accidental release by a reactor Radium dial painters	External and internal contamination likely
Radiation devices	Cyclotron Linear accelerator Fluoroscopy unit	Local radiation injury likely
Uncontrolled fission	Nuclear reactor Uranium enrichment Weapons production	Large whole-body doses likely On- and off-site contamination possible for nuclear reactors

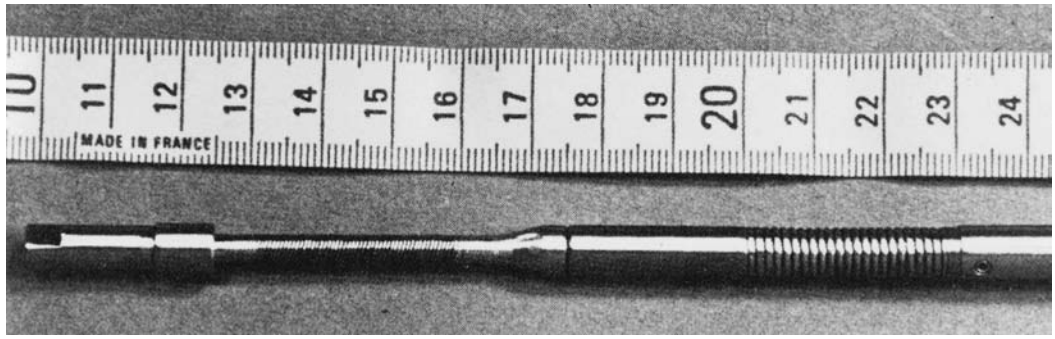

FIGURE 88.4 Source of radiation that affected two Algerian children in 1978.

dirt gets into the patient's body (internal contamination) by ingestion, inhalation, or absorption through the skin or a wound, minimizing the radiation dose is more difficult. Other examples of unsealed sources include radium ingested by radium dial painters and radionuclides such as those released during the accident at the Chernobyl nuclear power plant.

Radiation devices, the third potential radiation source listed in Table 88.3, are likely to cause a local radiation injury. Because these devices emit radiation when switched on but are not radioactive, it is highly unlikely that patients exposed to radiation from radiation devices will be radioactive should they present for treatment.

A fourth possible radiation source is an uncontrolled nuclear fission reaction (criticality accident). Usually, there is an intense radiation exposure and release of steam for a brief period of time. Criticality accidents have produced the largest whole-body radiation exposures resulting from radiation accidents. The largest portion of the dose is due to neutrons. These accidents can occur only at uranium enrichment facilities and nuclear reactors, where there is a critical mass of nuclear material. Fortunately, criticality accidents are very uncommon. Only two criticality accidents have occurred since the late 1960s; one of these was the 1986 accident at Chernobyl. The Chernobyl accident caused the deaths of 31 people who were at the nuclear power plant at the time of the accident. In addition, millions of people were exposed to low levels of radiation when hundreds of square miles of land was contaminated by radioactive fallout.

Types of Radiation Injuries

Perceived

There are three major types of radiation injury (Table 88.4). The first and by far the most common injury is the perceived radiation injury. Because of misconceptions about the possible health effects of radiation, members of the general public, fearful of having been exposed, may attribute almost any illness to radiation exposure. Unfortunately, these perceptions are often reinforced by physicians who are not knowledgeable about radiation effects. The psychological stress caused by misdiagnosis can be significant. Employers have a heavy burden to educate radiation workers to preempt such feelings. A threatened terrorist event or detonation of a "dirty bomb" could produce perceptions of radiation injury among the general public. Health care workers educated about radiation risks should be able to anticipate these concerns.

Exposure

The second major type of radiation injury is exposure to radiation. Because these patients do not have radioactive dirt on them or in them, they are not radioactive and can be treated without any additional precautions on the part of health care workers. Two types of injury from radiation exposure are possible. A high dose of penetrating radiation over a short period of time to a large portion of the body (i.e., whole-body radiation) causes the acute radiation syndrome. Exposure to alpha or beta particles of any source would never cause this syndrome because these types of radiation are nonuniformly distributed and poorly penetrating. Large doses of radiation over a short period of time to a small portion of the body cause a local radiation injury. When only a small portion of the body is exposed, much larger doses of radiation can be tolerated. Analogous medical situations would be whole-body radiation as conditioning for bone marrow transplantation and localized radiation therapy for breast cancer.

Whole-body Exposure. The signs and symptoms of the acute radiation syndrome (Table 88.5) begin to appear after whole-body radiation doses of approximately 1 Gy. Organs with rapidly dividing cells (the bone marrow and the lining of the GI tract) are the most susceptible to radiation damage. The amount of damage that occurs is dependent both on the dose and on the dose rate. For example, a dose of 1 Gy received in

TABLE 88.5

DOSE-EFFECT RELATIONSHIP AFTER ACUTE WHOLE-BODY RADIATION EXPOSURE

Whole-body absorbed dose (Sv)	Comments
0.1	Asymptomatic (minimal detectable dose using cytogenetics)
0.5	Asymptomatic (minor depression of white blood cell and platelets)
1	Nausea and vomiting in approximately 15% of patients within 2 days of exposure
2	Nausea and vomiting in most patients
4	Nausea, vomiting, and diarrhea within 48 h; severe hematologic depression; 50% mortality without medical treatment
6	100% mortality within 30 days without medical treatment; 50% mortality with medical treatment
7	Gastrointestinal syndrome; survival unlikely; death in 2–3 wk
50	Neurovascular syndrome; death in 24–72 h

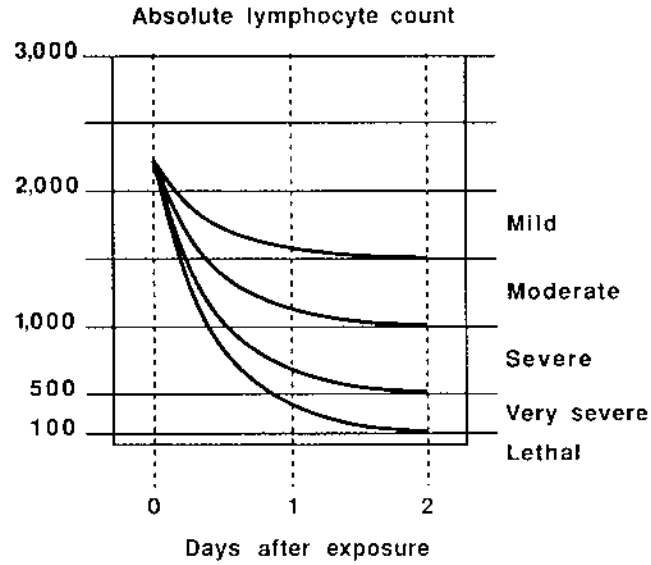

FIGURE 88.5 Effect of whole-body radiation on lymphocytes in the first 2 days after exposure.

1 minute would probably cause symptoms; however, 1 Gy received at a dose rate of 10 mGy per day for 100 days would likely be asymptomatic. Doses of about 4 to 6 Gy may be lethal in approximately 50% of people if they do not receive medical treatment. With maximum medical treatment, the dose of radiation that will kill 50% of people may be as high as 6.5 to 7 Gy.

The acute radiation syndrome consists of three distinct phases (Table 88.6). The *prodromal* phase begins minutes to hours after the radiation exposure and lasts for 2 to 3 days. During the prodromal phase, the patient may have nausea, vomiting, diarrhea, fatigue, and/or headache. The prodromal phase is followed by the *latent* phase, in which the patient is relatively asymptomatic. The latent phase generally lasts days or weeks after the exposure. The third and final phase is the *manifest illness* phase. During this phase, the patient is at greatest risk for infection and bleeding due to the bone marrow suppression and GI epithelial damage. As the radiation dose increases, the duration of the prodromal phase increases and the length of the latent phase decreases.

With doses of 2 to 4 Gy, the primary effect of the whole-body radiation is to depress the bone marrow. Although the absolute lymphocyte count (Fig. 88.5) decreases rapidly within the first 24 hours, there is no need for specific medical treatment. The patient will be at greatest risk 3 to 4 weeks after the radiation exposure when the white blood cell and platelet counts reach a nadir (Fig. 88.6). At this time, the patient is vulnerable to death from infection and bleeding. If the patient can be supported during this period of vulnerability and if the bone marrow is not irreversibly damaged, a recovery phase ensues (Fig. 88.7).

The GI syndrome occurs from absorbed doses of more than approximately 7 Gy. During the prodromal phase of this syndrome, there is prompt onset of severe nausea, vomiting, and diarrhea. There is a latent period of approximately 1 week and then recurrence of GI symptoms, sepsis, electrolyte imbalance, and likely death. The patient is susceptible to infection due to lack of granulocytes and because pathogens can readily enter the body across the damaged GI tract lining.

At dose levels of more than 50 Gy, the cardiovascular/central nervous system (CNS) syndrome predominates. There is almost immediate nausea, vomiting, prostration, hypotension, ataxia, and convulsions. The permeability of blood vessels increases. The patient suffers from CNS symptoms due to

TABLE 88.6

ACUTE RADIATION SYNDROME—SIGNS AND SYMPTOMS

[a]Days after exposure.

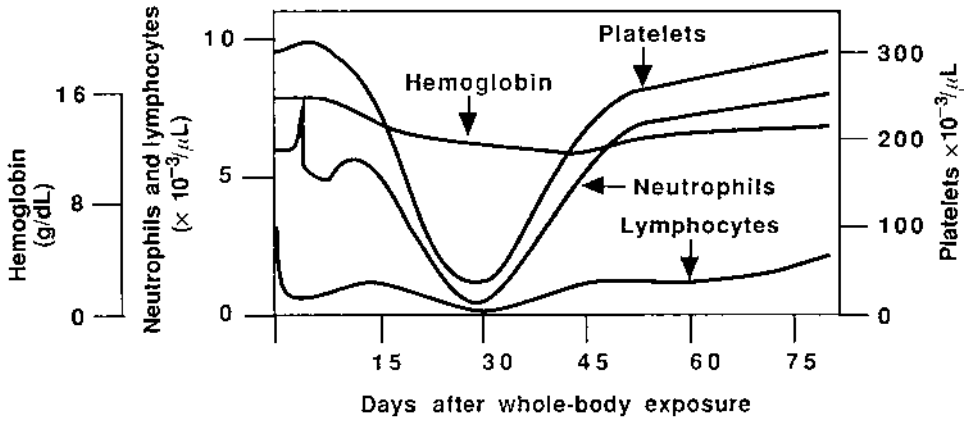

FIGURE 88.6 Effect of whole-body radiation on blood cell counts in the days after exposure.

brain edema and from hypotension caused by the difficulty of maintaining a normal intravascular space. Death usually occurs within 1 to 4 days.

Estimating the whole-body radiation dose may be difficult, especially when complicated by injuries that are not due to radiation. The signs and symptoms during the prodromal period are quite nonspecific except for a rapidly decreasing lymphocyte count. Nausea and vomiting are sensitive but nonspecific symptoms. Patients who do not have nausea and vomiting are unlikely to have been exposed to a radiation dose that is large enough to cause acute radiation syndrome. However, individuals may have nausea and vomiting for reasons other than exposure to radiation. The whole-body radiation dose from radiation accidents is rarely uniform. The nonuniform nature of the radiation dose makes it more difficult to predict the biological effects of the exposure. Chromosome analysis (cytogenetic dosimetry) may be helpful in estimating the radiation dose, but the results may not be available for about 1 week.

A radiation accident involving whole-body exposure to four young (14 to 20 years old) women occurred in Algeria in 1978. A 93-GBq ^{192}Ir industrial radiography source (Fig 88.4) fell from a truck and was found by two young boys. They played with the source for several hours before taking it home. The source was taken away by their grandmother, who hid it in the kitchen. The source remained in the room for 5 to 6 weeks, irradiating several persons, including the four young

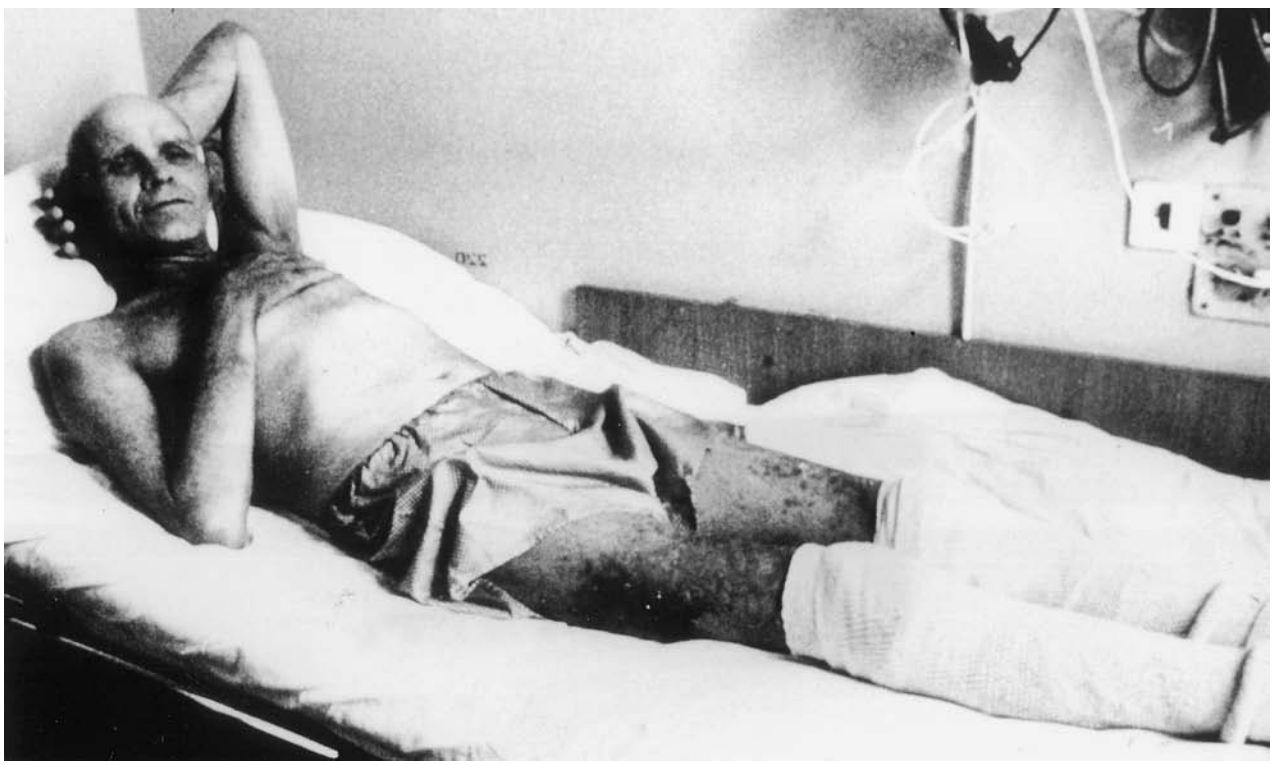

FIGURE 88.7 Chernobyl victim suffering from acute radiation syndrome a few weeks after the accident. Note the hair loss, indicating a radiation dose of 10 to 30 Gy. Also note injury to the skin of the lower extremities as a result of high, tens of grays, doses of beta (nonpenetrating) radiation. (Courtesy of A.M. Davis)

women. This accident was not discovered until the four women had severe bleeding from the mucous membranes in the mouth, anorexia, nausea, purpura, and bone marrow depression. The lymphocyte count in all four patients was less than 10% of normal. The whole-body dose over the 5 to 6 weeks was estimated to have been between 6 and 10 Gy. All four patients injured by this accidental exposure survived.

Local Radiation Exposure. The second type of radiation exposure that can occur involves a large radiation dose to a small part of the body. If only a small part of the body is exposed, much larger doses can be tolerated. Local radiation injuries do not cause bone marrow depression unless they are accompanied by a significant whole-body radiation dose. These injuries are rarely life threatening, but they are difficult to manage because they often cause a slowly progressive injury that takes months to years to fully evolve. The injury develops slowly because the radiation causes progressive fibrosis of the blood vessels, which, in turn, causes tissue necrosis. The ultimate extent of the injury may not be appreciated initially. Healing following amputation or reconstructive surgery is poor because of deficient blood supply.

The hand is the most common site for localized irradiation injuries. The next most common sites are the thighs and buttocks because individuals are likely to put things that they find into their pockets. A patient who has undergone a fluoroscopic procedure would have local radiation injury to the skin overlying the region imaged. For example, the radiation source is typically positioned posterior to a patient undergoing a cardiac catheterization and therefore a radiation burn would be on the back. Most industrial radiography sources deliver an extremely high dose on direct contact with the skin. For example, the 93-GBq ^{192}Ir source described previously has a surface dose rate of about 200 Gy per minute and will cause an absorbed dose of about 125 Gy per minute at 1-cm depth in tissue. In contrast, analytical x-ray crystallography machines, which emit x-rays of much lower energy than the photons of ^{192}Ir, are not likely to cause deep blood vessel injury.

Local radiation injuries can be readily differentiated from thermal burns. The effects of a thermal burn appear immediately, and the patient invariably knows when the painful injury occurred. If a patient presenting with a burnlike injury does not know the cause of the injury (realizing that carelessness on his or her part resulted in the injury), a local radiation injury should be suspected. Table 88.7 lists the dose-related findings expected after a local radiation exposure.

TABLE 88.7

APPROXIMATE ABSORBED DOSE TO PRODUCE SKIN CHANGES

Absorbed dose (Gy)	Findings
3	Threshold for erythema (100 keV diagnostic x-rays)
6	Threshold for erythema (10 MeV therapeutic x-rays)
15	Moist desquamation
20	Skin ulceration with slow healing
>30	Gangrenous changes

If erythema is seen within the first 48 hours, ulceration will probably occur. The erythema may come in waves, that is, appear, disappear, and then return later. With transepidermal injury, blister formation may occur at 1 to 2 weeks with doses in the range of 100 Gy and at 3 weeks after dose levels of 30 to 50 Gy. Treatment is required to prevent infection and to relieve pain. Skin grafting, especially musculocutaneous flaps, may be appropriate if the radiation exposure was localized and superficial. Progressive gangrene, due to the obliterative changes in the small vessels, will occur if the radiation exposure is large and involves deep structures. Under these circumstances, amputation may be necessary.

The two Algerian boys who found the 93-GBq ^{192}Ir radiographic source described previously suffered local radiation injuries. The younger boy was 3 years old and presented with lesions of the mouth and hands (Fig. 88.8). The boy apparently had sucked on the source, receiving an approximate dose of 25 Gy to the lip surface. The older boy (7 years old) had a necrotic deep ulceration in the hypothenar region of the right hand, apparently from using the source as a drumstick (Fig. 88.9). The estimated dose to the center of the lesion was estimated at 100 Gy, and at the periphery of the necrosis 15 Gy. Ultimately, the oral lesions in the young boy healed, whereas reconstructive surgery was required on the older boy.

Contamination

Contamination represents the third major type of radiation injury. Contamination occurs when radioactive dirt or liquid remains on the patient (external contamination) or, when inhaled or ingested, inside the patient (internal contamination).

FIGURE 88.8 Mouth lesions caused by radiation of approximately 25 Gy. The lesions healed eventually.

FIGURE 88.9 Radiation burns on the hand of the older Algerian child from a dose of 15 to 100 Gy. Reconstructive surgery was required.

Contamination is the only type of radiation injury that requires the medical staff to take any radiation-related precautions. It should be reemphasized that there is little danger to the medical staff when caring for a contaminated person once he or she has been transported to the hospital. However, medical personnel who respond to the accident site may be exposed to large, potentially life-threatening doses of radiation. For these rescue workers, 0.5 Gy is the voluntary limit suggested by the National Council on Radiation Protection and Measurements (NCRP) for lifesaving activities.

External Contamination. External contamination rarely is a significant medical problem. To prevent additional radiation exposure to the patient and unnecessary radiation exposure to the medical staff and the public, external contamination should be removed and dispersal of radioactive materials should be prevented. On the basis of the assumption that any radiation exposure is potentially harmful, the goal of the treatment of any contaminated patient is to keep radiation exposures "as low as reasonably achievable." This is called the ALARA principle and requires advance planning, specific supplies, and appropriate protective clothing. Preventing the dispersal of radioactive materials is accomplished by treating the patient in a single location, controlling access to that location, and by using standard contact precautions.

Internal Contamination. Internal contamination potentially is a more serious problem because it is more difficult to eliminate some long-lived radioactive materials from within the body than it is to remove radioactive dirt on the outside of the body. Death due to radiation from internal contamination is rare. A few deaths have been caused by medical misadministrations. Also, in the Goiana accident, a 6-year-old girl died from severe internal contamination with ^{137}Cs. Internal contamination, especially with ^{131}I, was a concern following the Chernobyl reactor accident. A familiar example of intentional, nonlethal internal contamination is the bone scan performed in a nuclear medicine department. Treatment of hyperthyroidism with ^{131}I also is, in a sense, planned internal contamination.

Metal Fragment. Another source of contamination that should be separately addressed is the radioactive metallic fragment. These could, in principle, be found if a "dirty bomb" were constructed with a radioactive metal source such as an ^{192}Ir

radiographic source. Metallic fragments can be intensely radioactive. If a radioactive metal fragment is present (e.g., embedded in the patient's skin), it should never be touched with fingers. Tongs or forceps will increase the distance between the radioactive metal fragment and the fingers and thus greatly reduce any radiation dose to the health care worker.

Hot Particles. "Hot" particles are microscopic particles that can be highly radioactive. Typically, they contain ^{60}Co or fission products. These might be found on a nuclear reactor worker after a reactor accident. These particles can be difficult to localize and remove. They may give a large radiation dose to a small volume of tissues. If the particle is trapped under a nail or is in the fold of the skin, routine washings may not dislodge it. The particle can sometimes be localized by using a thick piece of lead. If the lead is placed between the particle and the radiation detector, the exposure rate should decrease substantially. Once the particle is localized, it can usually be removed by using simple mechanical means. Rarely, a punch biopsy of the skin may be necessary.

Terrorist Events. There are several scenarios in which nuclear materials may be used in a terrorist event. An intact sealed source could be placed in a populated area, generating whole-body exposures but no contamination. A radiological dispersal device, such as a conventional explosive combined with radioactive materials, the so-called "dirty bomb," could be employed to disseminate radioactive materials over a local or wide area. For example, a conventional explosive could be used in conjunction with a large sealed source or spent nuclear fuel to spread multiple radioactive metallic fragments or radioactive dirt. Victims of such an attack would likely have contamination in addition to local radiation exposures, as well as injuries from the explosion itself. An attack on a research or commercial power reactor could produce a large-scale dispersion of nuclear material; victims could be exposed to whole-body and localized radiation, as well as internal and external contamination. Transported nuclear materials such as radiopharmaceuticals or radioactive waste could be the subject of a terrorist attack. The effects would vary depending on whether the containers were breached—intact containers would produce only external exposures, whereas destruction of the containers and dispersal of their contents could also lead to contamination. A "dud" nuclear weapon that does not undergo a nuclear reaction would still disperse radioactive materials by the associated conventional explosion, leading to contamination in addition to effects from the conventional explosion itself. A nuclear weapon effectively detonated by a terrorist group might be relatively small scale but still capable of widespread damage, including thermal and blast effects from the denotation along with contamination and exposure of affected persons and equipment.

MANAGEMENT OF RADIATION INJURIES

General Measures

The principles governing the treatment of radiation injuries are similar to the principles governing the treatment of any medical condition, especially those arising from hazardous materials. Treatment objectives must be prioritized (Fig. 88.10).

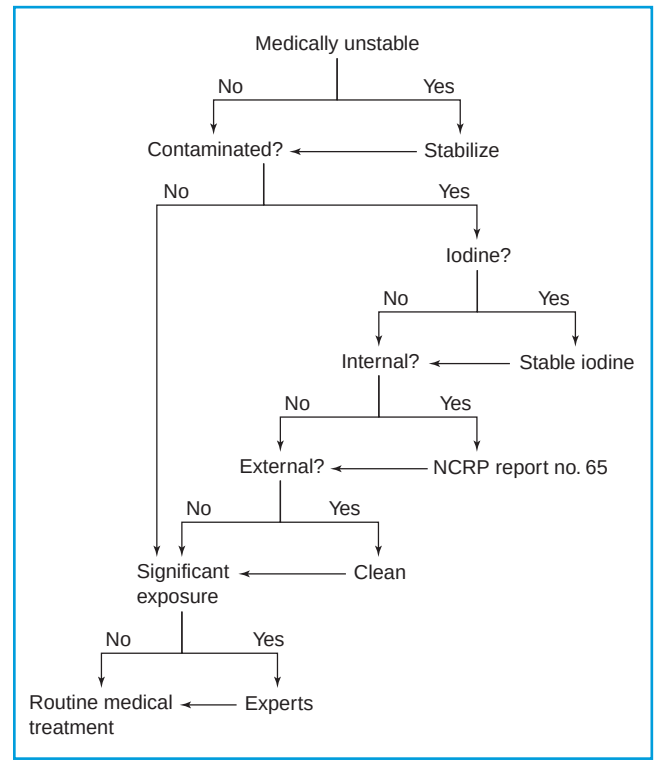

FIGURE 88.10 Treatment of radiation injuries. NCRP, National Council on Radiation Protection and Measurements.

Because no survivable radiation injury requires immediate life-saving treatment, the medical staff should focus their attention on the treatment of non–radiation-related life-threatening conditions. In the past, some medical personnel were so distracted by the radiation aspects of an accident that routine medical care was delayed.

Once the patient is stabilized, the radiation-related injuries can be addressed. Because there is no immediate treatment of radiation exposure, the problem of radioactive contamination should be addressed first. In most circumstances, a Geiger counter can be used to determine the presence of contamination. In addition, the probability of contamination can be assessed by obtaining an accurate description of the accident and the likely radiation source. If the patient is a radiation worker, finding his or her radiation badge and performing a "reenactment" of the accident may be critical for dose estimation.

Internal Contamination

Treatment of internal contamination is most effective if initiated promptly. The requirement for prompt treatment is a dilemma for the physician. First, it is difficult to determine if internal contamination is present until the external contamination has been removed. Moistened cotton Q-tips can be used to perform nasal swabs. If these show radioactivity, inhalation of radioactive materials is possible. The nature of the accident may provide clues to the possibility of internal contamination (e.g., a fire with smoke leading to the inhalation of radioactive particles). Second, the most effective treat-

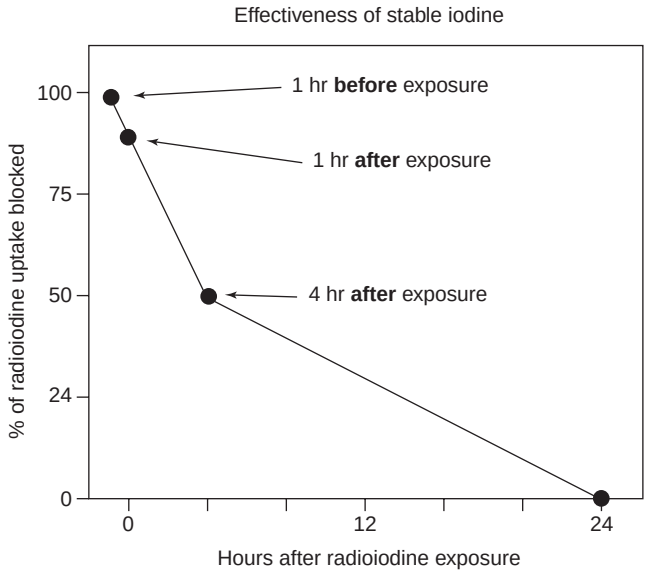

FIGURE 88.11 Stable iodine is most effective if administered as soon as possible after the ingestion of radioactive iodine. Repeated daily doses would be appropriate only if there was potentially continuing ingestion or inhalation.

ment requires knowledge of the radionuclide involved and its chemical form. This information is usually not immediately available. Fortunately, there are simple general treatment measures that can be effectively instituted before the magnitude of the internal contamination is fully known.

If given soon after exposure, stable iodine is effective for preventing the uptake of radioactive iodine by the thyroid gland. Prompt administration of stable iodine should be considered if there is a possibility of external contamination with (or ingestion or inhalation of) radioactive iodine (Fig. 88.11 and Table 88.8). Because radioactive iodine is volatile, it is likely to be inhaled. If a contaminated child were brought to the ED after an accident with a radiopharmaceutical truck carrying radioactive iodine, administration of stable iodine would be appropriate. If further investigation revealed no radioactive iodine, little harm would have been done by having administered the stable iodine. A single dose of oral iodine is highly unlikely to cause any adverse reactions, even in persons who have serious reactions to iodinated contrast agents or seafood.

After a nuclear reactor accident that results in the release of a large amount of radioactive iodine, three steps can be taken to minimize the adverse effects on the public. First, the public should be sheltered or evacuated to prevent further exposure via fallout or gaseous materials. Second, potassium iodide (KI) may be administered if available. However, it is important to note that many of nuclear reactors in the United States do not house radioactive iodine, making KI useless. Third, the food supply can be monitored carefully to prevent further ingestion of radioactive iodine or other radionuclides. If a reactor accident occurs that involves contamination of the public, understandable concern by members of the public will ensue. If this happens, emergency medical facilities should try to preserve their valuable resources for patients who need lifesaving medical treatment. Plans must be made to refer uninjured persons and persons with minor injuries to other facilities. Hospitals should not become decontamination centers.

Several simple steps can be taken to treat internal contamination nonspecifically. The goals of treatment are to prevent the absorption of the radionuclide and to enhance its excretion. Safe techniques that prevent the absorption of radionuclides include the administration of activated charcoal and alginate-containing antacids. Enhanced excretion can be achieved by hydration and administration of a purgative. Specific treatment of internal contamination depends on the radionuclide, its chemical and physical forms, and the route of internal contamination. Recommendations for many specific treatments can be found in the NCRP Report 65, titled *Management of Persons Accidentally Contaminated with Radionuclides*. This report ought to be available in every hospital ED and can be downloaded for a fee from the NCRP Web site (http://www.ncrponline.org). An updated version of this report is expected in 2009. Initiation of treatments that entail some risk to the patient (e.g., pulmonary lavage, intravenous chelating agents) should be undertaken only after consultation with experts; the benefits of the treatment should be significantly greater than the risks. The most effective treatment of internal contamination is preventing the internal contamination in the first place.

TABLE 88.8

DOSE OF STABLE IODINE (SSKI) BY AGE

Age	Dose (po)
<1 mo	16 mg
1 mo–3 yr	32 mg
3–18 yr	65 mg
>18 yr	130 mg

External Contamination

External contamination is treated in the same way as contamination by other hazardous chemical or biological agents. To make certain that the hazard is treated appropriately, it is easiest to imagine that the patient has been covered with an easily detectable noxious agent (e.g., sewage). Under this circumstance, the caregivers would wear gloves, a gown, shoe covers, and a mask. The purpose of wearing these garments is primarily to keep caregivers clean and to make cleanup easier. The garments do not decrease the exposure to penetrating radiation. The mask is recommended to prevent individuals from inadvertently touching their contaminated fingers to their nose or mouth. If available, film badges or other devices to measure radiation exposure should be worn by hospital staff who are in close contact with the patient.

If the external contamination is widespread, it may be helpful to cover the floor. If only a small area of contamination is present, spread can be prevented by simply wrapping the contaminated area until it can be cleaned. Because it is much easier to detect radioactive contamination than chemical or biological hazards, cleanup following a radiation accident will be much more effective and documentable. Precautions taken to prevent the inadvertent spread of contamination will make cleanup much easier.

TABLE 88.9

DECONTAMINATION

Remove clothes	Cover clean wounds to prevent contamination
Wash with a damp cloth and tepid water	Prevent external contamination from becoming internal
Pay special attention to skin folds and fingernails	Do not abrade the skin

External contamination is rarely a significant medical problem; however, logistic problems that must be addressed require preplanning. To minimize the chances of contaminating an unnecessarily large area of the ED, the patient should be admitted through a separate entrance. If this is not possible, the patient can be placed on a clean stretcher outside the ED and wrapped in a cloth (not plastic) sheet and then transported to the desired area of the hospital. Access to the treatment area should be controlled.

Removal of the patient's clothing will usually eliminate up to 90% of the external contamination (Table 88.9). Contaminated articles should be placed in labeled plastic bags. Residual contamination is likely to be on the hands, face, hair, and wounds. These should be washed with lukewarm water and soap. Cleaning the skin with damp washcloths is much better than cleaning with running water. The radioactive dirt on the damp washcloth can be contained by placing the cloth in a plastic bag. Radioactive dirt in wash water is much more difficult to control but, when necessary in the course of patient care, may be discharged to the sewer system by flushing. Shaving should not be performed because this may make small cuts and increase absorption through the skin. Excessive rubbing of the skin may also increase transdermal uptake.

Open uncontaminated wounds should be covered to prevent them from becoming contaminated. Contaminated wounds should be cleaned like any other dirty wound. All samples from the patient should be saved and labeled if there is any question about the identity of the radionuclides.

A Geiger counter should be used to monitor and document the progress of the decontamination efforts. If contamination persists, the source may be fixed to the skin or may be internal. Radiation experts should be consulted before more aggressive decontamination attempts are made. Some residual contamination may be acceptable.

Exposure

Other than symptomatic measures, there is no immediate treatment to reverse whole-body or local radiation exposure.

TABLE 88.10

APPROPRIATE LABORATORY TESTS FOR PATIENTS INVOLVED IN A SIGNIFICANT RADIATION ACCIDENT

In the emergency department
Complete blood cell count; repeat every 6 h for 24 h
Nasal swabs
Collect all excreta
Later
Cytogenetics
Sperm count
Eye examination (baseline for cataracts)
Human leukocyte antigen typing

Medically significant whole-body radiation exposure is unlikely if the patient does not have nausea and vomiting. Serial complete blood cell counts are also helpful in excluding the diagnosis of a recent large whole-body exposure to radiation (Table 88.10). In the absence of other major trauma, the absolute lymphocyte count will rapidly fall in patients who have been exposed to a large radiation dose. If a patient has been exposed to a large dose of radiation, there is little in the way of specific medical treatment that needs to be done in the ED. The threat to the patient's life will occur within days to weeks after the exposure.

The diagnosis of a local radiation injury requires vigilance. The physician should consider the possibility of a local radiation injury whenever there is an unexplained painless "burn." A complete blood cell count to exclude an accompanying whole-body exposure is indicated. The prognosis of a local radiation injury depends on the dose. The dose can be estimated only by having a qualified physicist reconstruct the accident that led to the exposure.

CHAPTER 89 ■ GASTROINTESTINAL EMERGENCIES

DENNIS R. DURBIN, MD, MSCE, CHRIS A. LIACOURAS, MD, AND JEFFREY A. SEIDEN, MD

GASTROINTESTINAL BLEEDING

Gastrointestinal (GI) bleeding is a common and occasionally life-threatening condition in infants and children. An orderly approach to this problem is essential and is outlined in Chapter 29. One of the most important initial steps in establishing the cause of GI bleeding in children is determining whether the source of bleeding is the upper or lower intestinal tract. The following discussion of general principles of management, as well as specific diagnoses, is therefore organized accordingly. Only those conditions most appropriately classified as medical diagnoses are described in this chapter. Additional causes of GI bleeding that are more appropriately classified as surgical diagnoses, including intestinal malrotation with volvulus, intestinal duplications, intussusception, and Meckel's diverticulum, are discussed in detail in Chapter 121.

General Principles of Management

In contrast to the adult experience, most children presenting to the emergency department (ED) with either upper or lower GI bleeding have not experienced significant blood loss. Many patients can be managed successfully with judicious laboratory investigation, conservative supportive care, and follow-up with a primary care provider or an appropriate subspecialist. A detailed discussion of pertinent laboratory evaluation and initial management of each of the most common causes of GI bleeding in children is provided in the following sections.

Severe GI bleeding should be considered a potentially life-threatening emergency that may require the cooperation of a team, including the emergency physician, surgeon, and gastroenterologist. Similar to the management of all potentially life-threatening conditions in children, the initial approach to the child with significant GI hemorrhage begins with an assessment of the child's airway, breathing, and circulation. A child with overt hemodynamic instability or suspected significant volume loss should have cerebral perfusion and oxygenation optimized by patient positioning, fluid resuscitation, and supplemental oxygen. For patients with hematemesis, airway protection is paramount to prevent pulmonary aspiration of blood. Positioning may be all that is needed, but in massive upper intestinal bleeding, endotracheal intubation may be lifesaving. The next priority is the insertion of two large-bore intravenous (IV) catheters (14 to 20 gauge in the child and at least 22 gauge in small infants). An intraosseous or central venous catheter should be placed if there is difficulty obtaining adequate peripheral venous access.

Immediate laboratory studies in any patient with severe GI bleeding should include (i) type and cross-match, (ii) complete blood cell (CBC) count, (iii) platelet count, (iv) prothrombin time (PT), and (v) partial thromboplastin time (PTT). Additional laboratory studies may be indicated on the basis of the differential diagnosis of the most likely cause of the patient's bleeding and are discussed later in this section. Arterial blood gases are also important parameters to follow in severe blood loss associated with shock. The hematocrit is an unreliable initial index of acute blood loss because it may be normal or only slightly decreased. Its subsequent fall will depend on (i) the rate and type of fluid replacement and (ii) the body's own hemostatic mechanisms, resulting in renal conservation of fluid and electrolytes and gradual shifts of fluid from extravascular to intravascular compartments.

IV therapy has two major objectives: (i) restoration of intravascular volume (reflected in blood pressure or pulse) and (ii) restoration of oxygen-carrying capacity (reflected in hemoglobin and hematocrit values). The former objective can be accomplished by both crystalloid and colloid solutions, whereas the latter can be accomplished solely by the infusion of blood. The practical limitations of time required to properly type and cross-match blood make crystalloid solutions the mainstay of early resuscitation. In the rare circumstance of massive, ongoing hemorrhage in which low oxygen-carrying capacity is believed to be an important factor at the onset of resuscitation, O-negative blood may be used. In most cases, proper type and cross-match can be performed whereas intravascular volume is restored by nonsanguineous solutions. The exact type of solution to be used is controversial. Studies in both animals and humans have shown a reduction in intravascular and extravascular volume in acute blood loss; therefore, the preferred method is manual infusion of crystalloid solutions, such as normal saline or Ringer's lactate, in 20 mL per kg boluses until intravascular volume is minimally restored as indicated by a decrease in the pulse rate, a rise in blood pressure level, and/or disappearance of clinical signs of peripheral vasoconstriction. Colloid solutions, such as albumin, plasma, or hetastarch, should be used only when blood loss is massive and continuous because in this situation, respiratory insufficiency or shock lung may develop with a fall in plasma oncotic pressure. Dextran is to be avoided because it may affect platelet function. Patients who are in shock at the time of admission should have the urinary bladder catheterized in the ED to accurately measure urine output and to allow for early detection of acute tubular necrosis.

Overexpansion of intravascular volume is potentially dangerous, particularly not only in bleeding varices but also in bleeding gastric or duodenal ulcers. Therefore, after correction of shock and restoration of urine flow, further IV volume replacement should be titrated to match continuing blood loss. The decision to begin transfusion depends on the

hematocrit taken at the time of restoration of blood volume and on evidence of ongoing bleeding. For a patient who has stopped bleeding, blood transfusion may be given to allow some reserve in case of rebleeding. Under most circumstances, slow transfusion to return the hematocrit to approximately 30% is recommended to achieve this objective. In this case, packed red blood cells (10 mL per kg) are used to reduce the volume load for the patient. In addition, packed red blood cells contain considerably less ammonia than whole blood, an important factor for patients who have severe liver disease. For a patient who has continuous bleeding, ongoing blood transfusion is the only means of maintaining adequate oxygen-carrying capacity. In this case, the rate of bleeding determines the rate of transfusion. A sustained rate of transfusion is recommended and is best achieved with an electrical infusion pump, not by gravity. Potential complications of massive transfusions include hypercitrinemia, hyperlacticacidemia, hypocalcemia, decreased levels of clotting factors, and thrombocytopenia. The risks inherent in massive transfusions are definitively lowered by using packed red blood cells, fresh frozen plasma, proper filters, and blood warmers. Any patient with or without a history of liver disease who presents with GI bleeding associated with an abnormal PT should receive 5 to 10 mg of vitamin K (subcutaneously for non–life-threatening bleeding, intravenously for life-threatening bleeding) as soon as possible.

UPPER GASTROINTESTINAL BLEEDING

Background

Upper GI bleeding is generally regarded as originating proximal to the ligament of Treitz. Hematemesis or bloody gastric aspirates from a nasogastric (NG) tube may originate from the mouth, nasopharynx, esophagus, stomach, biliary tree, or duodenum. The most common causes of upper GI bleeding in children are mucosal lesions including esophagitis, gastritis, Mallory-Weiss tear, peptic ulcer disease, and duodenitis. Less common but important causes include bleeding esophageal varices and vascular lesions. Endoscopy, when performed by a well-trained physician, is the most sensitive and specific diagnostic procedure for determining the cause and site of upper GI bleeding. Specific diagnosis should be pursued in patients who have (i) active bleeding documented by NG lavage; (ii) evidence of severe hemorrhage (hemodynamic instability or equilibrated hemoglobin level less than 10 g per dL); (iii) conditions that affect healing or clotting, such as catabolic state or serious chronic disease; (iv) a history of unexplained gross or occult bleeding or unexplained iron deficiency anemia; or (v) a history of chronic dyspepsia (vomiting, abdominal pain, nausea, oral regurgitation, heartburn, dysphagia).

The pathophysiology, clinical manifestations, and specific management issues related to each of the most common causes of upper GI bleeding in children are discussed. As noted in Chapter 29, an upper tract source of GI bleeding is often indicated either by a history of hematemesis or by obtaining fresh (red) or old (coffee ground) blood via gastric lavage after the placement of an NG tube.

General Principles of Nasogastric Lavage

Not every child with a history of possible upper GI bleeding requires NG lavage. Patients who have acute, self-limited hematemesis of streaks of blood or a small amount of coffee-ground material in the context of forceful emesis, recurrent gastroesophageal reflux (GER), symptoms of infectious gastroenteritis, or epistaxis can often be managed presumptively without gastric lavage. However, lavage should be performed in all patients suspected of having significant GI bleeding that is indicated by either history or physical examination (e.g., pallor, unexplained tachycardia, poor perfusion). The purpose of gastric lavage is to confirm the level of bleeding and to estimate the rate of bleeding. There is no evidence that gastric lavage has any therapeutic role in controlling hemorrhage. It is important to realize that a clear NG aspirate does not exclude major bleeding from the upper GI tract.

Most patients can be effectively lavaged with an NG sump tube (12F in small children, 14F to 16F in older children). Verification of the location of the tube in the stomach by injection of air and auscultation over the stomach is essential. The recommended volume for each saline infusion depends on age: 50 mL for infants and 100 to 200 mL for older children. With the patient's head elevated to 30 degrees, the solution, at room temperature, is rapidly infused into the stomach, allowed to stand for 2 to 3 minutes, and then aspirated by gentle suction. Return volumes should approximate input volumes, and discrepancies should be recorded. If aspiration meets with significant resistance, the physician should reposition the tube, reposition the patient, or increase the amount of solution introduced. Saline lavage of the stomach should be performed ideally by two people. One person fills and empties the stomach, while the other person empties and fills the syringes.

Blood-flecked gastric aspirate or coffee-ground material indicates a low rate of bleeding. In contrast, bright red blood, especially if it does not clear with repeated lavage for 5 to 10 minutes, suggests a significant or ongoing hemorrhage. No benefit is derived from continuous lavage longer than 10 minutes if return is not clearing. The tube can be left to gravity or low suction and irrigated every 15 to 30 minutes to assess the activity of the bleeding. The presumed lesion causing the bleeding determines the subsequent management of the patient.

Nonspecific Mucosal Lesions

Background

GI bleeding may be a complication of all acute and chronic nonspecific upper GI mucosal lesions [esophagitis, gastritis, prolapse gastropathy (PG), Mallory-Weiss tears, and duodenitis].

Regardless of the cause, upper GI bleeding usually stops spontaneously, often by the time the patient arrives in the ED. Esophagitis as a result of GER is being diagnosed more often with improved pediatric fiber-optic endoscopes. The use of endoscopic biopsy has allowed physicians to document esophagitis as the cause of bleeding in many patients with clinically significant GER. Exposure to aspirin and nonsteroidal antiinflammatory drugs (NSAIDs; e.g., ibuprofen, naproxen) has also been associated with gastritis and mucosal ulceration. A more recent study suggests that clinically apparent upper GI

bleeding from esophageal, gastric, and duodenal erosions and/or ulcerations may occur in as many as 1% of healthy, full-term newborns. Mallory-Weiss tears are mucosal lacerations of the gastric cardia or gastroesophageal junction induced by retching or vomiting. These lesions, however, are quite rare in children. While accounting for approximately 5% of cases of upper GI bleeding in adults, there are very few case reports of upper GI bleeding in children. On the other hand, PG is the more common postemetic condition that causes hematemesis in children. In one series, PG was found in approximately 25% of children undergoing upper endoscopy for hematemesis.

Pathophysiology

The upper GI mucosa bleeds when an ulcerating process erodes into a blood vessel, usually an artery in the base of the ulcer. In most cases, normal mechanisms of thrombosis and healing stop the bleeding and prevent recurrent bleeding. Erosion of larger arteries, however, in which blood flow exceeds the capacity of normal hemostasis, results in continuous hemorrhage. A more common scenario is that thrombosis temporarily stops the bleeding, but aneurysmal dilation of the artery in the recanalization process or continuing arteritis from the chemical irritation of acid digestion facilitates recurrent hemorrhage. Acid and pepsin also produce profound adverse effects on platelet aggregation and plasma coagulation. The pathogenesis of Mallory-Weiss tears involves the production of transient large gradients between the intragastric and intrathoracic pressures at the gastroesophageal junction as a result of forceful retching. The gradient results in dilation of the gastroesophageal junction and, thus, tears. PG is caused by repeated forceful emesis, in which the stomach prolapses through the lower esophageal sphincter causing mucosal injury.

Clinical Manifestations

Diagnosis of mucosal lesions is usually suspected by an antecedent history of vomiting and/or abdominal pain and the absence of physical findings suggestive of chronic liver disease or portal hypertension. Reflux esophagitis is suspected in infants, usually younger than 1 year, who have a history of recurrent nonprojectile emesis, "wet burps" after feeding, or a documented diagnosis of GER. Infants presenting with emesis that is blood streaked or contains a small amount of coffee-ground material. They may be fussy but consolable and may have been previously diagnosed with colic. Reflux esophagitis should also be suspected in infants with guaiac-positive stools or iron deficiency anemia. A history of repeated aspirin or NSAID use for control of fever and/or pain should also prompt suspicion for gastric mucosal lesions as the cause of upper GI bleeding. Clinical features of Mallory-Weiss tears and PG are similar, though bleeding in PG tends to be less severe. These entities should be suspected in children with a history of protracted forceful vomiting and streaks of hematemesis appearing after several episodes of nonbloody emesis.

Management

For patients who have significant bleeding and for whom NG lavage was initiated, if gastric contents clear following initial saline lavage and immediate endoscopy is not planned, gastric irrigation should be performed every 15 minutes for 1 hour and then every hour for 2 to 3 hours. If the patient is hemodynamically stable and gastric return remains clear for the aforementioned period, the tube is electively removed. Persistent nausea or vomiting or the presence of ileus points to the need for continued drainage.

Patients with nonspecific mucosal lesions theoretically should benefit from neutralization of intragastric acidity by antacids, as well as reduction in gastric acid and pepsin secretion by H_2-receptor antagonists. For patients with significant symptoms or blood loss, H_2-antagonists may be given initially by the IV route, switching to the oral route when the NG tube is removed. Ranitidine (1.0 mg per kg per dose intravenously three times a day or 2 to 4 mg per kg per dose orally two times a day initially) is an appropriate choice. IV proton pump inhibitors, such as pantoprazole (0.5 to 1 mg per kg per day once daily), have been prescribed for adults with good success. Studies are limited, but proton pump inhibitors appear to be safe and effective in children as well. In addition, sucralfate (40 to 80 mg per kg per day) in two or three divided doses may be prescribed for patients with mucosal lesions. Finally, children with acute discomfort may be given antacids via the NG tube. For patients who have acute, self-limited bleeding and who are not considered candidates for endoscopy, oral H_2-antagonists are continued for 2 to 4 weeks, at which time they are empirically discontinued if the patient is asymptomatic.

In general, all patients with a history suggestive of significant upper GI bleeding should be admitted to the hospital for observation. A clear NG aspirate should never be used as an indication to discharge a patient from the ED if the history suggests significant bleeding. The main reason for admission is the unknown incidence of rebleeding from these lesions in children.

Esophageal Varices

Background

Portal hypertension may result from either extrahepatic presinusoidal obstruction (50% to 65% of cases in children) or hepatic parenchymal disorders. Extrahepatic obstruction (e.g., portal or splenic vein obstruction) is associated with omphalitis, dehydration, sepsis, and umbilical vein catheterization. Hepatic parenchymal disease may result from biliary cirrhosis associated with biliary atresia, cystic fibrosis, hepatitis, α_1-antitrypsin deficiency, or congenital hepatic fibrosis. Persons with either type of portal hypertension are susceptible to GI hemorrhage both from bleeding esophageal varices and from congestive or hemorrhagic gastritis. After development of portal hypertension, the onset of esophageal varices can vary from a few months to many years.

Pathophysiology

Portal hypertension results from relative obstruction of portal venous blood flow, leading to the development of either portal systemic collateral veins or varices. Portal systemic collaterals develop in any area where veins draining the portal venous system are in close approximation to veins draining into the caval system (i.e., submucosa of the esophagus, submucosa of the rectum, and anterior abdominal wall). Esophageal and gastric fundal varices, connecting branches of the coronary veins with branches of the azygous vein, are the most likely site of spontaneous hemorrhage (Fig. 89.1).

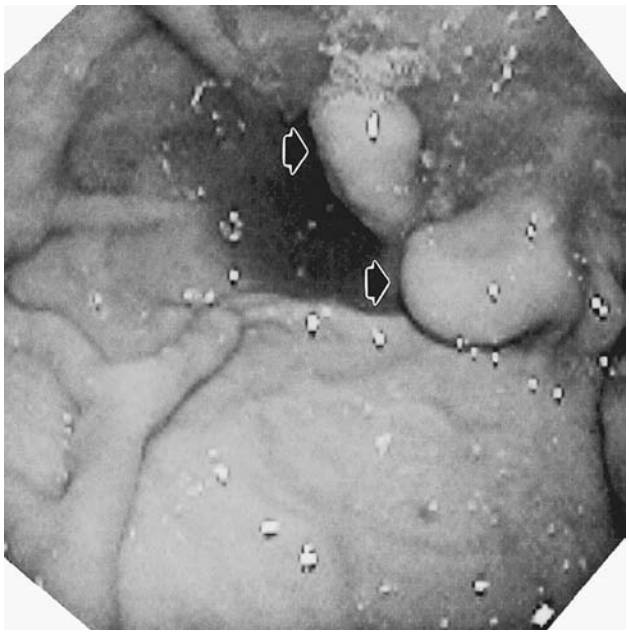

FIGURE 89.1 Gastric varices. The *arrows* represent two large blood-filled varices in the gastric cardia.

Clinical Manifestations

Patients with portal hypertension may have occult bleeding, but more commonly, the bleeding is brisk and patients will have melena and/or hematemesis. The possibility of bleeding esophageal varices should be considered in any patient with a history of jaundice (beyond the newborn period), hepatitis, blood transfusion, chronic right-sided heart failure, pulmonary hypertension, omphalitis, umbilical vein catheterization, or one of the hepatic parenchymal diseases previously noted. Accordingly, the physical examination may reveal stigmata of the underlying disease leading to portal hypertension, including jaundice, ascites, rectal hemorrhoids, and hepatosplenomegaly.

Management

The initial management of suspected variceal hemorrhage is identical to that of massive upper GI bleeding from any source. Fluid resuscitation to maintain adequate perfusion is warranted, but overexpansion of the intravascular volume should be avoided because it contributes to rebleeding. Coagulation abnormalities should be managed aggressively with IV vitamin K, fresh frozen plasma, and platelets. Bleeding varices may be the initial sign of sepsis in patients who have cirrhosis; therefore, any patient who has fever should be started on broad-spectrum antibiotics such as ampicillin (200 mg per kg per day) and gentamicin (5 to 7.5 mg per kg per day), pending results of blood cultures.

Suspicion of variceal bleeding is not a contraindication to pass an NG tube. An NG tube should be placed in a patient suspected of having upper GI bleeding. If bleeding ceases during the initial gastric lavage, the tube should be managed as previously described. Antacids and H_2-antagonists are given in the doses used for mucosal lesions. Pharmacologic therapy of acute variceal hemorrhage includes the splanchnic arterial constrictor vasopressin or somatostatin. Emergency flexible endoscopy should be arranged if the patient remains hemodynamically unstable and should be performed as soon as possible once deemed safe. Alternatively, endoscopic treatment may be delayed until hemorrhage has been controlled by pharmacologic agents, especially if the endoscopist has difficulty obtaining a clear field of vision.

Vasopressin administration has been well documented to decrease blood flow and pressure through the portal circulation. The physician should begin infusing 0.002 units per kg per minute and titrate to effect up to 0.01 units per kg per minute. Adverse effects can be significant; thus, the child must be monitored carefully. Major complications include myocardial ischemia, life-threatening arrhythmias, and limb vasoconstriction or ischemia. Minor complications include water retention with sodium depletion, benign arrhythmias, and acrocyanosis. The vasopressin is usually given in 5% dextrose in water; the exact dilution is based on overall volumes of fluids being infused. Infusing vasopressin through a large-bore, preferably central venous, catheter is the safest method. The reported success rate of vasopressin infusion in adults is 50% to 70%. Because of the high rate of rebleeding, the drug should be continued at the dosage that controls bleeding for a minimum of 12 to 24 hours after all bleeding has stopped. This management plan stems from studies showing sustained vasoconstrictive effects of vasopressin on splanchnic vessels in dogs for more than 24 hours. However, this point is controversial because tachyphylaxis reportedly also develops with prolonged use of vasopressin.

Endoscopic techniques available for acute management of variceal bleeding include endoscopic variceal sclerotherapy, whereby a sclerosing agent such as sodium morrhuate is injected into the varix. In addition, endoscopic variceal ligation using an elastic band ligature device has also been widely used to control bleeding from varices and to prevent recurrences.

Gastroesophageal balloon tamponade is a high-risk procedure. It should be considered only for previously proven gastric or esophageal varices unresponsive to pharmacotherapy and when the patient cannot undergo endoscopic management in a timely fashion. Either a Sengstaken-Blakemore (S-B) tube or a Linton tube may be used. The S-B tube has both gastric and esophageal balloon tubes, whereas the Linton tube has a single lavage gastric balloon. A pediatric tube is used for children younger than 11 to 13 years; the adult tube can be used in adolescents. Gastroesophageal tamponade is reported to arrest bleeding initially in 50% to 80% of cases. However, the reported incidence of major complications from the use of the S-B tube ranges from 9% to 35%; such complications include rupture or erosion of the esophageal or gastric fundal mucosa, occlusion of the airway by the balloon, and aspiration of secretions resulting from inadequate drainage of the occluded esophagus. Death directly attributed to the use of the tube has been reported in 5% to 20% of patients in whom the tube was used.

Miscellaneous Causes of Upper Gastrointestinal Bleeding

In the first few days of life, or in breast-fed infants, *swallowed maternal blood* may be the cause of hematemesis or melena in an infant who otherwise appears healthy. Performing a guaiac test on expressed breast milk may suggest the diagnosis. An Apt-Downey test may be performed on a sample of emesis or

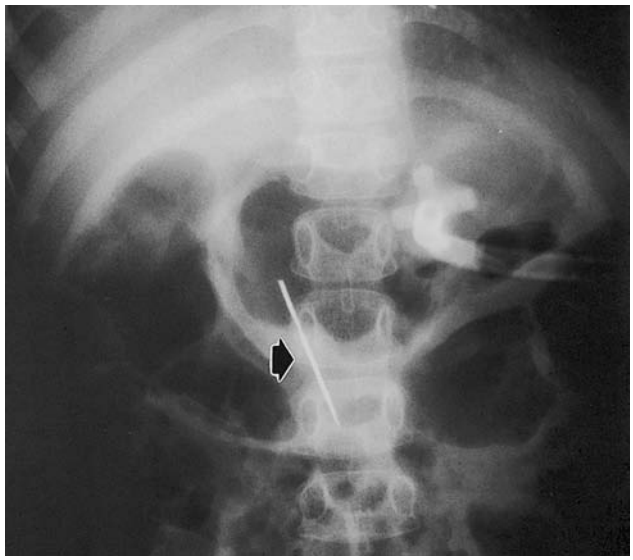

FIGURE 89.2 Gastric foreign body. This 6-year-old developmentally delayed patient ingested a large straight pin that caused bleeding of the gastric antrum. The *arrow* represents the foreign body. An opaque gastrostomy tube is also radiographically present.

NG aspirate to definitively diagnose the condition. Blood from the aspirate is placed on a filter paper and mixed with 1% NaOH. Adult hemoglobin will be reduced to give a rusty brown or yellow color. Fetal hemoglobin is resistant to denaturation and will retain a bright pink or red color.

A *Dieulafoy lesion* is an unusual cause of GI bleeding, in which massive hemorrhage occurs from a pinpoint nonulcerated arterial lesion, usually high in the fundus of the stomach. The bleeding results from an unusually large submucosal artery that travels a tortuous course through the submucosa and may erode through a mucosal defect. Its characteristic presentation is one of recurrent, massive hematemesis, usually without any prodromal symptoms. This diagnosis is primarily performed in adults, but patients as young as 20 months have been diagnosed with a Dieulafoy lesion, and most series contain a number of teenagers. Management is similar to that for any patient with a significant GI hemorrhage. Diagnosis can be made by endoscopy, during which the Dieulafoy lesion can usually be located.

Finally, swallowed foreign bodies can cause significant trauma and GI bleeding. Most swallowed foreign bodies, even those with sharp edges, will pass spontaneously and require no specific therapy. However, on occasion, a sharp foreign body may be the cause of GI bleeding (Fig. 89.2). Removal by endoscopy is indicated if significant bleeding occurs.

LOWER GASTROINTESTINAL BLEEDING

Background

Rectal bleeding is a relatively uncommon but worrisome complaint in the ambulatory or ED setting. A case series of children presenting with rectal bleeding to an urban, tertiary care ED indicated that rectal bleeding was the chief complaint of 0.3% of all ED visits during a 1-year period. The average age of patients was approximately 5 years, with nearly half of the patients younger than 1 year. No patient in the series was judged hemodynamically unstable in the ED, nor did any patient require a blood transfusion. The most common presentation was for hematochezia (98% of patients), with 10% of patients presenting with melena (some patients presented with both complaints). Diarrhea (37% of patients), abdominal pain (43%), and constipation (22%) were the most common associated symptoms, with only 2% of patients presenting with fever. Presumptive diagnoses were made in two-thirds of patients, most of which (81%) did not change with follow-up. Potentially life-threatening disorders (intussusception and Meckel's diverticulum) were found in 4% of cases.

The cause of lower GI bleeding varies with age. Among infants younger than 6 months, the most common diagnoses are milk-protein sensitivity (allergic colitis), anorectal fissures, and infectious gastroenteritis. Children 1 to 5 years of age are most likely to have infectious gastroenteritis, intussusception, Meckel's diverticulum, colonic polyps, and anorectal fissures. Older children typically have infectious gastroenteritis, inflammatory bowel disease (IBD), and hemorrhoids/rectal varices. The pathophysiology, clinical manifestations, and specific management indicated for the most common conditions causing lower GI bleeding in children are discussed in the following sections.

Anorectal Fissures and Hemorrhoids

Anal fissures are the most common cause of rectal bleeding in the first 2 years of life. Most occur in infants younger than 1 year. Anal fissures (pleural) may result from diarrhea, which causes perineal irritation, but it is more commonly associated with constipation. The fissure usually starts when passage of a hard stool tears the sensitive squamous lining of the anal canal. Subsequent bowel movements are associated with pain and/or bleeding. Bright red blood is seen coating the stool. The infant begins to withhold stool, leading to increasing constipation and a vicious cycle of hard stools, bleeding, and pain. Anal fissures (pleural) can be seen by spreading the perineal skin to evert the anal canal. Simply spreading the buttocks to view the anal opening is not sufficient. Treatment consists of local skin care combined with stool softeners. Malt extract (Maltsupex 1 to 3 tablespoons per day) or lactulose (1 to 4 tablespoons per day) can be given to soften the stool. Local care involves sitz baths four times a day, a perianal cleansing lotion (Balneol) after bowel movements, and an emollient protective ointment (Balmex) after each bowel movement.

Small varicosities of the external hemorrhoidal plexus (i.e., hemorrhoids) may occur in the healing process associated with anal fissure. They rarely cause pain or bleeding. Therapy is directed at the treatment of the anal fissure. The presence of external hemorrhoids does not imply associated internal hemorrhoids. The latter may develop in response to portal hypertension and may be a cause of painless rectal bleeding.

All patients with perianal excoriation, multiple anal fissures, recurrent anal fissure, or fissure resistant to conservative management should have perianal cultures for β-hemolytic

streptococci. If this organism is recovered, the patient should receive a 7-day course of oral penicillin.

Polyps

There are two major types of polyps that may be diagnosed in infancy or childhood: hamartomatous and adenomatous. Hamartomatous polyps are generally benign and are the usual type of polyp found in juvenile polyps, juvenile polyposis coli, and Peutz-Jeghers syndrome. Adenomatous polyps are potentially premalignant and are found in a number of syndromes including familial adenomatous polyposis and Gardner's syndrome.

Juvenile polyps are the most common of the polyp syndromes in children, found in 15% of patients in one series who had colonoscopy for rectal bleeding (Fig. 89.3). More than one polyp may be found in more than 50% of cases of juvenile polyps. Most (75%) of the polyps are rectosigmoid or in the descending colon, 15% are found in the transverse colon, and 10% in the ascending colon. Autoamputation of juvenile polyps, especially in the rectum, occurs spontaneously in most cases. In juvenile polyposis coli, multiple juvenile polyps are found throughout the colon. Peutz-Jeghers syndrome is the association of mucocutaneous pigmented lesions and hamartomatous polyps. It has autosomal-dominant inheritance with a high degree of penetrance. The macular, melanin-containing pigmented lesions characteristically occur on the buccal mucosa, lips, face, arms, palms and soles, and perianal region. The polyps are typically located in the small intestine but can also be found throughout the GI tract.

Familial adenomatous polyposis is an autosomal-dominant inherited syndrome consisting of multiple adenomatous polyps that are generally confined to the colon but can also be found throughout the GI tract. A 6% incidence of malignant transformation of these lesions is present by 15 years of age, prompting recommendations for total proctocolectomy by 18 years of age. Gardner's syndrome is an autosomal-dominant inherited syndrome consisting of hereditary adenomatous polyps of the small and large intestine and soft tissue, as well as bony tumors. The tumors are often epidermoid cysts, fibromas, or osteomas of the skull and mandible and are often the initial manifestation of the disease.

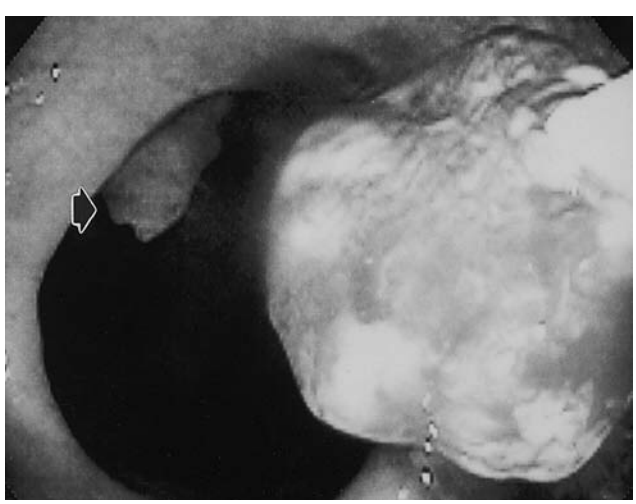

FIGURE 89.3 Juvenile polyp. The *arrow* demonstrates the cauterized polyp stalk.

Pathophysiology

Juvenile polyps are proliferations of mature colonic epithelium, with aggregates of lymphoid tissue and cystic dilation of normal glandular elements. This histopathology has prompted the use of other terms such as *retention*, *inflammatory*, or *hyperplastic polyps*. The surface epithelium is often ulcerated, with a loss of mucosal surface. Adenomatous polyps may appear grossly similar to juvenile polyps, although on microscopic examination, adenomatous polyps are distinguished by the amount of cellular atypia seen within colonic epithelial cells. More recently, detailed descriptions of the histology of juvenile polyps have indicated the presence of areas of dysplasia, typically associated with polyps larger than 1 cm in diameter. In addition, the presence of more than two colonic polyps raises concern about the possibility of juvenile polyps being capable of malignant transformation.

Clinical Manifestations

The most common presentation of juvenile polyps is painless rectal bleeding, often with blood streaking the outside of the stools. Most juvenile polyps occur in the first decade of life, with the peak incidence of presentation in preschool children, although they can also occur in older children and adolescents. The most common presenting manifestation is rectal bleeding, although prolapse of the polyp through the rectum may occur as a presenting symptom. The polyp may also form the "lead point" of an intussusception. All patients with rectal bleeding should have a careful rectal examination because 30% to 40% of polyps are palpable by rectal examination.

As noted, polyps may be a part of various inherited syndromes; therefore, a complete physical examination should be performed in any patient with rectal bleeding. A careful search for pigmented lesions or soft tissue and bony tumors may aid in the diagnosis of inherited polyposis syndromes as previously described.

Management

The initial ED management of patients who have suspected polyps is aimed at assessing the amount of blood loss and arranging the appropriate diagnostic study. Blood loss is rarely life threatening, but significant losses may be noted from chronic intermittent bleeding. All patients should have a CBC count performed, and if the history of blood loss is significant, a blood type and cross-match may also be indicated. Patients with suspected polyps should undergo elective colonoscopy. Only rarely will these patients require inpatient admission. Endoscopic removal of a polyp is safe and effective therapy even in a young child. For patients with brisk, painless hematochezia associated with a drop in hemoglobin level or vital sign instability and for whom rectal examination is negative for a palpable polyp, other causes for bleeding (e.g., Meckel's diverticulum) need to be considered. This possibility should prompt a decision to perform either red cell–labeled bleeding scan or a ^{99m}Tc radionucleotide (Meckel's) scan in an effort to identify the possible location of bleeding.

Dietary Protein Sensitivity Syndromes ("Allergic Colitis")

Dietary proteins are capable of inducing significant bowel injury and may be the cause of several different types of enterocolitis presenting throughout childhood. Each condition, by definition, is induced by a dietary protein and resolves completely after the protein is eliminated from the diet. Immunologic responses may vary from classic allergic mast-cell activation to immune complex formation. The development of proctocolitis in response to cow's milk-protein exposure was among the first to be described. Subsequently, a similar condition has been described in response to soybean-based formula and among exclusively breast-fed infants, presumably in response to maternal dietary protein intake.

Pathophysiology

The appearance of the rectum and colon on colonoscopic examination characteristically consists of diffuse inflammation, friability, edema, and frequent focal ulcerations. Rectal biopsies demonstrate both acute and chronic inflammatory changes and eosinophilic infiltration is often present.

Clinical Manifestations

The typical presentation of milk-protein sensitivity colitis is that of acute onset of blood-streaked, mucoid diarrheal stools in an otherwise well-appearing infant younger than 6 months. Mean age of onset among 35 infants in one series was 4.3 ± 4.1 weeks. It is unusual to present within the first week of life. Blood loss is typically limited, so infants do not appear acutely ill or dehydrated. They are afebrile, and weight gain has typically been within normal limits since birth. The differential diagnosis includes anal fissures and infectious enterocolitis. External anal fissures can be ruled out by careful physical examination. Appropriate viral and bacterial cultures of stool may be indicated to rule out infectious causes.

Management

These patients are rarely hemodynamically unstable or seriously ill; therefore, initial ED management is focused on making a presumptive diagnosis based on history and physical examination, initiating appropriate dietary therapy, and arranging adequate follow-up with the patient's primary care physician or a pediatric gastroenterologist. One might consider basic laboratory testing to support the diagnosis, including a CBC count with white blood cell (WBC) differential to assess the hemoglobin level and check for leukocytosis and eosinophilia. Patients with histologically proven milk-protein sensitivity colitis have higher mean peripheral eosinophil counts than age-appropriate normal values. However, in the individual patient, a higher than normal eosinophil count is actually an insensitive marker (sensitivity = 10%) for histologically proven colitis. In addition, a serum albumin level should be considered because hypoalbuminemia has a sensitivity of approximately 80% for histologic colitis. Examination of stool for blood, fecal leukocytes, and routine bacterial culture should be performed on all infants. Infants who have milk-protein sensitivity colitis will characteristically have leukocytes seen on fecal smear, although eosinophils may not be present in the stool.

Treatment consists of elimination of the offending protein from the infant's diet. The diagnosis is typically confirmed by the resolution of symptoms within 72 hours of the dietary change, although histologic improvement may take 4 to 6 weeks. Infants receiving cow's milk-based or soy protein formulas should be changed to a formula containing casein hydrolysate as the protein source. Nutramigen®, Pregestimil®, and Alimentum® are currently available in the United States. Occasionally, in patients with severe allergic colitis, an amino acid–based elemental formula, such as Neocate® or Elecare®, is required. Gross symptoms of allergic colitis respond within a few days to elimination diet therapy, although guaiac-positive stools may persist for several weeks. In exclusively breast-fed infants, elimination of the offending protein from the mother's diet also leads to clinical improvement and breast-feeding can usually be continued. Persistent evidence of gross bleeding for 5 to 7 days following formula change is an indication for flexible proctosigmoidoscopy. Most infants who present for endoscopy have nodular lymphoid hyperplasia. Infants who respond to dietary elimination should not be rechallenged with a milk- or soy-based formula until 1 year of age. Parents should be counseled that symptoms of allergy might change with increasing age such that a positive challenge may evoke vomiting, diarrhea, or GI signs of allergy rather than recurrent rectal bleeding.

Infectious Enterocolitis

Infectious causes of GI bleeding are predominantly a result of bacterial pathogens including *Campylobacter*, pathogenic *Escherichia coli*, *Yersinia*, *Salmonella*, and *Shigella*. Less commonly, infection with *Giardia* or rotavirus is associated with heme-positive stools. A detailed discussion of the pathophysiology, clinical manifestations, and management of bacterial gastroenteritis can be found in Chapter 92.

Pseudomembranous colitis is a form of inflammatory colitis characterized by the pathologic presence of pseudomembranes consisting of mucin, fibrin, necrotic cells, and polymorphonuclear leukocytes. The entity develops as a result of colonic colonization and toxin production by the gram-positive obligate anaerobe *Clostridium difficile*, in most cases after normal bowel microflora have been altered by antibiotic therapy. All classes of antibiotics have been associated with pseudomembranous colitis. Patients usually present with profuse diarrhea, tenesmus, and crampy abdominal pain, usually beginning during the first week of antibiotic therapy. Frank hematochezia is rare. The diagnosis and management of pseudomembranous colitis are further discussed in Chapter 92.

Miscellaneous Causes of Lower Gastrointestinal Bleeding

Henoch-Schönlein purpura (HSP; see Chapter 100) is a systemic vasculitis that may cause edema and hemorrhage in the intestinal wall. Peak age of onset is between 3 and 7 years and the male:female ratio is 2:1. The presentation consists of the onset of a purpuric rash, typically confined to the buttocks and lower extremities, followed by arthralgias, angioedema, and diffuse abdominal pain. GI symptoms may precede the usual cutaneous symptoms and include abdominal pain (60% to 70%), occult

bleeding (50%), gross bleeding (30%), massive hemorrhage (5% to 10%), and intussusception (3%). In a more recent series, thickening of the duodenal wall was noted by ultrasonography in 82% of children who had HSP, with multiple hemorrhagic duodenal erosions noted by endoscopy in two patients. All children with suspected HSP and GI symptoms should have a stool guaiac test performed, as well as a urinalysis to monitor for the onset of renal involvement (nephritis). Children with HSP limited to the involvement of the skin and joints can often be managed as outpatients. However, severe abdominal pain or GI hemorrhage is an indication for admission.

Hemolytic-uremic syndrome (HUS; see Chapter 100) is a disorder characterized by the triad of acute microangiopathic hemolytic anemia, thrombocytopenia, and oliguric renal failure. The disease is heralded by a prodrome of intestinal symptoms ranging from diarrhea (100%) to hemorrhagic colitis (80%). Fever (20% to 30%), vomiting (75% to 80%), and abdominal pain (60%) are also commonly seen. Acute infectious gastroenteritis or colitis secondary to infection with *E. coli* O157:H7 is now considered the most important initial causative event in both sporadic and epidemic cases of HUS.

All children with HUS require admission to the hospital. Laboratory studies should be obtained, including a CBC count, platelet count, PT, PTT, electrolytes, blood urea nitrogen (BUN), and creatinine. IV access needs to be secured immediately for the correction of dehydration and the administration of blood products. As with HSP, the GI manifestations of HUS resolve, usually without sequelae or the need for antibiotic treatment of the initial intestinal infection.

GI *vascular malformations*, including hemangiomas, angiodysplasia, and arteriovenous malformations (AVMs), are rare causes of GI bleeding in children and are often seen as a part of congenital syndromes. GI hemangiomas may be part of the Klippel-Trenaunay-Weber syndrome, which consists of a capillary or large vessel hemangioma on an extremity with hypertrophy of that limb. Diffuse visceral hemangiomatosis is rare, often fatal, and is always associated with cutaneous vascular lesions. GI hemangiomatosis should be suspected in any child with unexplained anemia and a syndrome of cutaneous hemangiomata.

Intestinal AVMs are rare in the pediatric age group, may occur both as solitary and as multiple AVMs, and are typically part of a congenital syndrome (e.g., Osler-Weber-Rendu disease). Many GI vascular malformations, particularly cavernous hemangiomas and AVMs, can be detected using computed tomographic (CT) scans with IV contrast. Intestinal angiography or tagged red blood cell scans are often used to identify the source of bleeding during an acute hemorrhage. ED management of patients with GI bleeding from vascular malformations is the same as for any patient with potentially significant blood loss. After initial stabilization, referral to an appropriate subspecialist for diagnosis and definitive treatment is warranted.

INFLAMMATORY BOWEL DISEASE

Background

IBD is used to designate two chronic intestinal disorders of unknown origin: (i) ulcerative colitis, characterized by inflammation and ulceration confined to the colonic mucosa; and (ii) Crohn's disease, manifested by transmural inflammation and frequent granulomas that may affect any segment of the GI tract. The incidence of IBD has increased over the past few decades. In a recent study of IBD in California, the overall incidence of IBD among children younger than 18 years was 5.9 cases per 100,000 population. The incidence of Crohn's disease (3.0 per 100,000) was similar to that of ulcerative colitis (2.9 per 100,000). Other studies have reported higher rates for Crohn's disease than for ulcerative colitis. In a population-based survey of IBD in Wisconsin children, the median age at diagnosis was 15 years for both conditions and only 20% of diagnoses were made in children younger than 10 years. In this study, the incidence of IBD did not vary by population density or by race/ethnicity. Most (89%) newly diagnosed cases were nonfamilial.

Many clinical features are common to both disorders, including diarrhea, GI blood and protein loss, abdominal pain, fever, anemia, weight loss, and growth failure. Extraintestinal manifestations involving the joints (arthritis), skin (erythema nodosum), eyes (uveitis), and liver (chronic hepatitis and sclerosing cholangitis) are seen with both disorders, although they are generally more common with Crohn's disease.

Ulcerative colitis typically involves the rectum and extends proximally without skip areas (Fig. 89.4). In contrast, Crohn's disease has discontinuous, patchy involvement of the GI tract. In the study of IBD in Wisconsin, 25% of children had isolated ileal involvement, 32% had colonic disease, 29% had ileocolonic disease, and 14% had significant upper GI disease (Fig. 89.5). The onset of both ulcerative colitis and Crohn's disease is usually insidious, consisting of growth failure, weight loss, diarrhea, and occult rectal bleeding but may be more dramatic and extensive. The average time from onset of symptoms to diagnosis is typically 3 to 4 months.

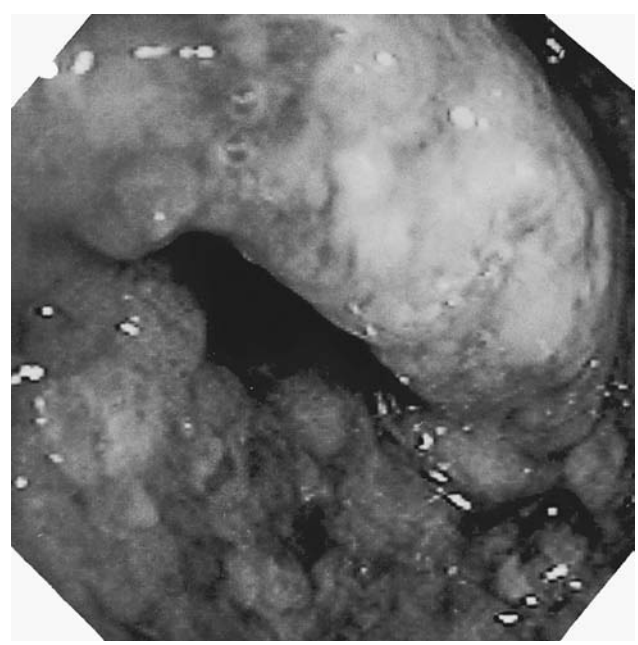

FIGURE 89.4 Severe ulcerative colitis. The mucosa appears granular, nodular, and edematous and is actively bleeding.

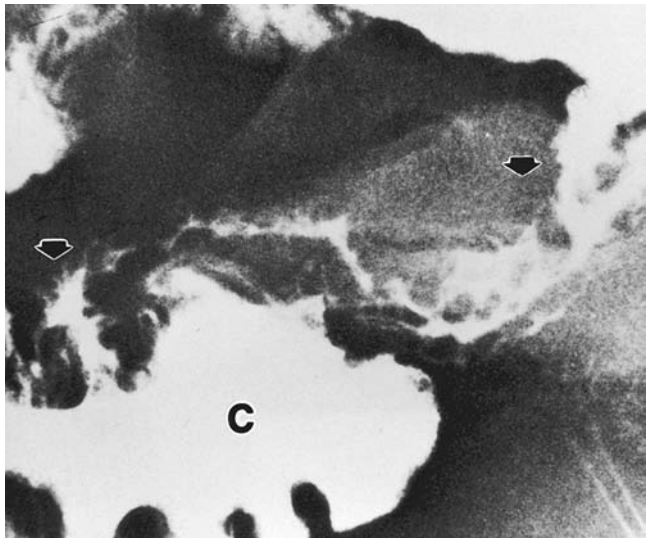

FIGURE 89.5 Crohn's disease of the terminal ileum demonstrated by severe narrowing of the terminal ileum (as shown between the two *arrows*). The cecum is represented by the "C."

Pathophysiology

IBD likely results from the inappropriate and ongoing activation of the GI mucosal immune system driven by the presence of normal bacterial flora. It is a disease that, for many patients, likely results from the interplay of an environmental precipitant affecting a genetically susceptible person. The cause of growth failure in patients with IBD is multifactorial, but inadequate nutrient intake is most likely the final common pathway. Growth failure is twice as likely in children who have Crohn's disease as it is in those who have ulcerative colitis. Malabsorption, especially with small bowel involvement of the disease, may lead to reduced assimilation of fats, vitamins, and minerals. Hematochezia, protein-losing enteropathy, and increased fecal losses of cellular constituents result from chronic inflammation and damage to the intestinal mucosa. The cause of diarrhea is also multifactorial, resulting from extensive mucosal dysfunction, bile acid malabsorption in terminal ileal disease, bacterial overgrowth secondary to strictures and disordered motility, and protein exudation from inflamed surfaces. Extraintestinal manifestations of the disease are often partially the result of a breakdown in the normal barrier and immunoregulatory functions of the GI tract as a result of chronic inflammation. This reaction enables bacterial products and inflammatory mediators (e.g., cytokines) to enter the circulation and subsequently to be deposited in various sites such as the eyes, skin, and joints, leading to localized inflammatory responses.

Clinical Manifestations

Clinical manifestations of IBD can be varied and related to either GI inflammation or the development of either GI tract or extraintestinal complications. Severe abdominal pain is among the most common complaints prompting an ED visit by the patient with IBD. Abdominal pain and diarrhea with or without occult blood are the most common symptoms at presentation. The pain is often colicky and, in Crohn's disease, may localize to the right lower quadrant or periumbilical area, prompting a consideration of acute appendicitis in the differential diagnosis. The abdominal examination may elicit guarding and rebound tenderness. Frank rectal bleeding occurs in fewer than 25% of all cases but is more common in ulcerative colitis. Interestingly, patients younger than 6 years are more likely to have rectal bleeding as the initial symptom of Crohn's disease. On the other hand, abdominal pain, weight loss, and/or fever are more common in older children and adolescents who are ultimately diagnosed with Crohn's disease. Perianal disease, including fissures, skin tags, fistulae, and abscesses, occurs in 15% of children with Crohn's disease. Perianal disease may precede the appearance of the intestinal manifestations of Crohn's disease by several years.

A low-grade fever and mild leukocytosis commonly occur. Approximately 10% of children with ulcerative colitis and a lesser percentage of those with Crohn's disease present with a fulminant onset of fever, abdominal cramps, and severe diarrhea with blood, mucus, and pus in the stools. A fulminant episode may also occur in the patient who has a known disease. There may be associated anemia and dehydration. IBD occasionally causes massive lower GI bleeding. Rarely, Crohn's disease causes complete intestinal obstruction. The patient always gives a history of antecedent abdominal pain, diarrhea, and weight loss. The presence of abdominal distension, accompanied by diminished or absent bowel sounds, should raise the suspicion of actual or impending perforation, even in the absence of severe pain. Perforation may occur even after minor abdominal trauma and must be ruled out when patients with known IBD complain of abdominal pain after trauma.

The development of massive colonic distension is a rare complication of both ulcerative colitis and Crohn's disease. Toxic megacolon represents a life-threatening emergency that has a reported mortality rate of as high as 25%. Although rare in children, nearly half of the cases occur with the first attack of IBD; another 40% are seen in patients receiving high-dose steroid therapy for fulminant colitis. Toxic megacolon almost always involves the transverse colon. The pathophysiology is believed to be an extension of the inflammatory process through all layers of the bowel wall, with resulting microperforation, localized ileus, and loss of colonic tone. The result is imminent major perforation, peritonitis, and overwhelming sepsis. Antecedent barium enema, opiates, or anticholinergics may all precipitate toxic megacolon. Clinical features include (i) a rapidly worsening clinical course usually associated with fever, malaise, and even lethargy; (ii) abdominal distension and tenderness usually developing over a few hours or days; (iii) a temperature of 38.5°C (101.3°F) or higher and a neutrophilic leukocytosis; and (iv) an abdominal radiograph showing distension of the transverse colon of more than 5 to 7 cm. In a recent case-control study of children with toxic megacolon, fever, tachycardia, dehydration, and electrolyte abnormalities were significantly more common than in age-matched controls with ulcerative colitis alone. The differential diagnosis of acute fulminant colitis includes acute bacterial enteritis, amebic dysentery, ischemic bowel disease, and radiation colitis.

Other potential clinical manifestations of IBD related to extraintestinal complications include thrombosis of cerebral, retinal, or peripheral vessels that may lead to coma, seizures, or

focal visual or motor deficits; renal calculi leading to hematuria; and pancreatitis.

Management

The initial ED management of IBD is determined primarily by whether the patient is known to have been previously diagnosed with ulcerative colitis or Crohn's disease and by an assessment of the severity of GI symptoms and systemic toxicity. Several clinical classification systems are used, but in general, mild disease is associated with less than six stools passed per day and an absence of systemic signs such as fever and severe anemia. Moderate disease is characterized by more than six stools passed per day, fever [higher than 38°C (100.4°F)], hypoalbuminemia (serum protein concentration less than 3.2 g per dL), and anemia (hemoglobin concentration less than 10 g per dL). Severe disease is indicated by more than six stools passed per day, marked abdominal cramping and tenderness, fever, significant anemia (hemoglobin concentration less than 10 g per dL), leukocytosis (WBC count more than 15,000), hypoalbuminemia (3.0 mg per dL), and toxic megacolon.

Initial blood studies most commonly needed to evaluate patients who have known or suspected IBD include a CBC count, serum electrolytes, BUN, serum albumin and total protein, transaminases [alanine aminotransferase (ALT) and aspartate aminotransferase (AST)], and depending on the amount of suspected blood loss, a blood type and cross-match. The erythrocyte sedimentation rate can be a useful marker of inflammation; it is elevated in up to 80% of patients with newly diagnosed Crohn's disease and in 60% of those with newly diagnosed ulcerative colitis. A recent study of the utility of screening laboratory tests for IBD in children demonstrated that normal values do not rule out the diagnosis. Among children with newly diagnosed IBD, 21% of those with mild Crohn's disease and 54% of those with mild ulcerative colitis had a normal hemoglobin level, platelet count, serum albumin level, and erythrocyte sedimentation rate. These values were more likely to be abnormal in those with moderate or severe disease. The diagnostic yield of plain supine and upright or decubitus abdominal radiographs is relatively low (10% or less) in terms of positive findings of clinical relevance. Nevertheless, plain films can be useful in establishing the diagnosis of toxic megacolon, bowel obstruction, or perforation and should be strongly considered in the initial management of any patient with known or suspected IBD and who presents to the ED with abdominal pain or tenderness.

Stool examination for occult blood and fecal leukocytes may indicate the presence of active inflammation. For patients who have not been previously diagnosed with IBD, as well as during flare-ups in patients with a known diagnosis, stool should be obtained for culture to rule out infectious colitis, which may often either mimic IBD or complicate a known case. Noninfectious causes of rectal bleeding, including polyps, Meckel's diverticulum, HSP, and HUS, as discussed further in this and other chapters (see Chapters 100 and 121), may also be considered in some instances, with appropriate diagnostic evaluation tailored accordingly.

Patients with known or previously undiagnosed IBD, those who have mild manifestations of disease, and those whose initial laboratory and radiographic studies do not reveal significant abnormality can be discharged from the ED after arranging follow-up with an appropriate specialist (pediatric or general gastroenterologist). Further diagnostic studies such as sigmoidoscopy, colonoscopy, or air-contrast barium enema, as well as the institution of medical management with corticosteroids, immunomodulators such as 6-mercaptopurine, or ASA compounds (mesalamine or sulfasalazine), can be arranged on an outpatient basis.

The goal of initial management of patients with moderately severe disease is supportive, and IV hydration with crystalloid solutions is often necessary to correct acute dehydration. Normal saline may be given as a 20 mL per kg bolus infusion and repeated as necessary to achieve hemodynamic stability. An infusion of a dextrose-containing electrolyte solution may then be initiated on the basis of initial serum electrolytes. When severe abdominal pain occurs in a patient who is not known to have IBD, surgical consultation is indicated if diagnoses such as acute appendicitis or bowel obstruction are likely possibilities. Hospitalization of patients with moderately severe disease is often indicated to initiate or modify specific therapy such as systemic corticosteroids or immunosuppressive agents such as azathioprine or 6-mercaptopurine. More recently, infliximab (Remicade®; Centocor, Malvern, Pennsylvania), a genetically engineered monoclonal antibody against tumor necrosis factor-α, has demonstrated effectiveness in reducing the need for steroids among children with Crohn's disease. Finally, improved nutritional intake, preferably via enteral means, is often necessary.

All patients with acute fulminant colitis should be admitted to the hospital. Oral intake should be discontinued and an IV infusion begun with normal saline until electrolyte and BUN levels are known. Opiate or anticholinergic drugs should be avoided because they may precipitate toxic megacolon. A fever, significant leukocytosis, or an ill-appearing child may suggest an abdominal abscess. In these cases, an abdominal/pelvic CT scan is warranted. If toxic megacolon is suspected, arrangements should be made for admission to an intensive care unit (ICU). The patient should discontinue all antidiarrheal and anticholinergic medicines. The first priority in the management of children with toxic megacolon is the treatment of intravascular dehydration and shock. Intensive IV therapy with normal saline, albumin, or blood must be sufficient to correct hypotension and ensure adequate urine flow. An NG tube, or preferably a Miller-Abbott tube for small bowel decompression, should be placed. Patients should be started on broad-spectrum antibiotics such as ampicillin (200 mg per kg per day), gentamicin (5 to 7.5 mg per kg per day), and clindamycin (40 mg per kg per day) in combination. Suitable alternative therapies include ampicillin/sulbactam, piperacillin/tazobactam, or cefoxitin in combination with gentamicin.

Management of significant GI bleeding should be performed as described earlier in this chapter. Emergency management of suspected intestinal obstruction includes gastric decompression with NG drainage and IV rehydration, initially with normal saline. Patients with fulminant colitis, suspected toxic megacolon, significant GI bleeding, or suspected intestinal obstruction should all receive prompt surgical consultation as part of their initial ED evaluation.

ULCER DISEASE

Background

The term *ulcer disease* describes a group of disorders, consisting of primary and secondary gastric and duodenal ulcers, as well as nodular gastritis. With increasing use of endoscopy in

children, peptic ulcer disease is a more commonly recognized disorder, although it is still far less common than in adults. Reliable incidence data in children are generally lacking, although several studies have suggested that large pediatric referral centers diagnose approximately five new cases per year or 1 case per 2,500 hospital admissions.

In children younger than 10 years, ulcer disease is more common because of the use of noxious agents such as corticosteroids or NSAIDs or after major stresses such as burns, sepsis, or other systemic illness. Stress ulcers account for 80% of peptic disease in infancy and early childhood. These ulcers often present as medical emergencies as a result of perforation or hemorrhage and can be either gastric or duodenal in origin. In older children and adolescents, the clinical presentation and natural history of ulcer disease are more similar to those seen in adults, with duodenal ulcers far more common than gastric ulcers (Fig. 89.6). A family history of ulcer disease is typically present in 50% or more of children with duodenal ulcers.

The role of the bacterium *Helicobacter pylori* in the etiology of ulcer disease in children has been vigorously investigated. *H. pylori* infection is usually acquired in childhood, with earlier acquisition noted in developing countries. For example, infection rates among Bolivian children approach 70% by 10 years of age, with virtually everyone infected by 20 years of age. In contrast, seroprevalence rates in the southeastern United States are estimated at 12% to 15% by 9 years of age. Similarly, the prevalence of *H. pylori* infection diagnosed by urea breath test was 13.7% among healthy European preschool-aged children. There are higher prevalence rates among family members and institutionalized populations, suggesting person-to-person transmission via either an oral route or a fecal-to-oral route. Most children with *H. pylori* infections are asymptomatic. Available evidence to date shows a strong association between *H. pylori* infection and antral gastritis and duodenal ulcer disease in children. However, little to no evidence has been presented for an association with gastric ulcer or recurrent abdominal pain in children. The specific role of *H. pylori* in the pathogenesis and treatment of ulcer disease is discussed in the next section.

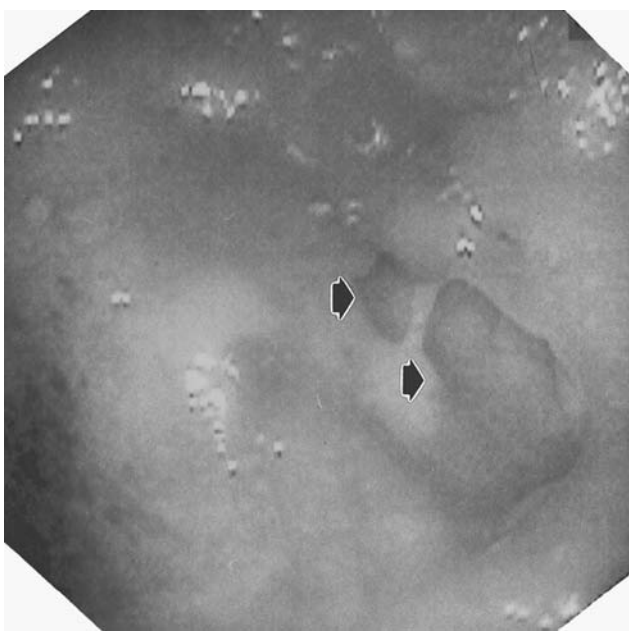

FIGURE 89.6 Duodenal bulb ulcers. The *arrows* show two individual duodenal nonbleeding ulcers.

Pathophysiology

The pathogenesis of ulcer disease results from an imbalance between cytotoxic factors, such as acid, pepsin, medications such as NSAIDs, and infection with *H. pylori*, and cytoprotective factors, including the secretion of mucus and bicarbonate by superficial epithelial and mucus cells in the upper GI tract. Gastric acid is produced by parietal cells in the stomach and is controlled primarily by histamine, acetylcholine, and gastrin. The final common pathway for all acid secretion is the proton pump (H^+/K^+ ATPase). All agents that stimulate gastric acid secretion also stimulate pepsin secretion. Pepsins are enzymes that hydrolyze proteins, as well as gastric mucus glycoproteins, in an acid pH environment. They are secreted by gastric chief cells as pepsinogens and are converted to active pepsin by gastric acidity. The underlying mechanism of gastric ulcer formation is less well understood. Local blood flow, delayed gastric emptying, duodenal reflux, and other factors have all been suggested as important predictors of gastric ulceration. The exact interplay of gastric acid, *H. pylori*, local blood flow, and other factors in the pathogenesis of ulcer disease is the subject of intensive investigation but currently remains unclear.

H. pylori possesses a number of virulence factors that render it particularly pathogenic in the acidic gastric environment. *H. pylori* normally adheres only to gastric mucosa in vivo. It is a flagellated organism with the capacity for active motility, giving it the ability to penetrate the mucous layer overlying the gastric mucosa. It also possesses potent urease activity, converting urea, which is abundant in gastric epithelium, to ammonia and bicarbonate. This capacity has been proposed as both a survival mechanism for the organism (the bicarbonate may moderate the pH of the local environment of the organism) and a pathogenic mechanism (the ammonia functions as a gastric irritant). *H. pylori* invariably produces a localized inflammatory reaction that may contribute to epithelial damage either by direct toxic effect or via immunopathologic means (Fig. 89.7).

Clinical Manifestations

Symptoms of ulcer disease vary with the patient's age. Nonspecific signs and symptoms predominate among infants and preschool-aged children, with boys and girls affected equally. The older the child, the more specific (and similar to adult patterns of presentation) the signs and symptoms become. Among teenagers with ulcer disease, a male predominance is seen, with boys outnumbering girls nearly 4:1. Infants with ulcer disease (usually secondary to some other condition) may present either with nonspecific feeding difficulties and vomiting or more fulminantly with upper GI bleeding or perforation. Preschool-aged children often complain of poorly localized abdominal pain, vomiting, or GI hemorrhage and manifest as either hematemesis or melena. Older children and adolescents present almost invariably with abdominal pain, which is described as waxing and waning, sharp or gnawing, and localized to the epigastrium. It may awaken the child at

FIGURE 89.7 A large duodenal bulb ulcer secondary to *Helicobacter pylori* infection.

night or in the early hours of the morning. The presence of nocturnal pain may assist in distinguishing recurrent abdominal pain as a result of ulcer disease from functional abdominal pain, which rarely occurs at night. A careful history of the pain and a family history of ulcer disease will often suggest the diagnosis of peptic ulcer disease in the older child. History should also be obtained regarding the presence of predisposing factors such as smoking or regular use of NSAIDs.

Physical examination may reveal abdominal tenderness, poorly localized in young children and more commonly localized to the epigastrium or to the right of the midline in older children and adolescents. A rectal examination should be performed to evaluate the patient for the possible perianal disease that might suggest Crohn's disease in the differential diagnosis. Stool should be tested for occult blood, and the remainder of the physical examination should include an oral examination looking for dental enamel erosion, which would suggest chronic GER or recurrent emesis, and an examination of the lungs for wheezing, which also might suggest bronchospasm due to or exacerbated by reflux. Weight loss may be noted. If occurring in adolescent girls, it should also prompt suspicion for an eating disorder.

Differential Diagnosis

A number of conditions may mimic the presentation of ulcer disease. Abdominal pain is a common symptom during childhood, occurring in 10% to 15% of school-aged children. Most children with recurrent abdominal pain have a "functional" cause. These patients typically do not have any weight loss or vomiting and report that their pain is localized to the umbilical area. Further discussion regarding the differential diagnosis of abdominal pain can be found in Chapter 49. It should be noted that the prevalence of *H. pylori* infection in children who have recurrent abdominal pain varies widely in the literature, with most patients in published studies selected from among those presenting to tertiary hospital gastroenterology clinics. Children with *H. pylori* infection are characteristically asymptomatic, and there does not appear to be an association between *H. pylori* infection and an increased prevalence of recurrent abdominal pain. Therefore, routine evaluation for *H. pylori* in patients without symptoms of acid-peptic disease is not indicated.

Gastritis, distal esophagitis, *giardiasis*, and pancreatitis may all cause epigastric pain and tenderness. Biliary tract disease and ureteropelvic junction obstruction may cause right upper quadrant tenderness. Children who have IBD, HSP, or diabetes mellitus may also present with abdominal pain, tenderness, or GI bleeding.

Diagnosis

Radiologic examination, with either single- or double-contrast (with air) barium upper GI series, is not an effective diagnostic tool to either confirm or rule out the presence of ulcer disease in children. These studies often do not detect superficial ulcers, and, conversely, barium trapped in a gastric or duodenal fold may falsely give the impression of an ulcer. However, radiologic examination may be used to rule out other conditions, such as malrotation with volvulus, or other structural anomalies of the GI tract.

Flexible fiber-optic esophagogastroduodenoscopy with mucosal biopsy is the most accurate method of diagnosing peptic ulcer disease in children. In most tertiary care referral centers, this procedure can be performed safely even on infants. It is typically not performed in the presence of active hemorrhage, although some centers are gathering experience with the use of therapeutic endoscopy to control significant bleeding. When performed, biopsy specimens should routinely be obtained from any area of endoscopic abnormality and from the distal esophagus, antrum, and second part of the duodenum. No clear guidelines exist to indicate which pediatric patients should undergo endoscopy for the evaluation of ulcer disease. Suggested guidelines include any child with chronic abdominal pain (longer than 3 months) associated with any of the following signs and symptoms: (i) hematemesis, (ii) a history of peptic ulcer disease in a first-degree relative, (iii) nocturnal pain, (iv) pain occurring within 1 hour of eating or relieved by eating, (v) recurrent vomiting, (vi) weight loss, or (vii) abdominal tenderness localized to the epigastrium (particularly in older children). In addition, endoscopy should be strongly considered in any patient presenting with significant acute upper GI bleeding or with any concern that *H. pylori* may be present.

All patients for whom an obvious cause of secondary gastric or duodenal ulceration (e.g., stress, sepsis, burns) does not exist should undergo diagnostic evaluation for the presence of *H. pylori* infection. *H. pylori* infection can be confirmed in a variety of ways in patients with primary ulcer disease. Histologic examination of biopsy specimens obtained during endoscopy should routinely be performed because *H. pylori* is readily seen with a variety of staining techniques. This is the diagnostic method currently recommended by the American Academy of Pediatrics for children with symptoms consistent with acid-peptic disease. In centers with appropriate facilities for culturing the organism, biopsy specimens may also yield growth of the organism, which can assist in the choice of appropriate antibiotic

therapy, particularly in recalcitrant infections. A variety of commercially available assays take advantage of the urease activity of the organism for diagnostic purposes. A biopsy specimen is mixed with the assay, which typically contains urea and an indicator dye that changes color when the urea is converted to ammonia by the organism. The urease activity can also be detected through the use of breath tests, in which radiolabeled (^{13}C or ^{14}C) urea is ingested by the patient. Degradation of the urea by *H. pylori* results in the release of the radiolabeled carbon, which can be detected in the expired air. Finally, enzyme-linked immunosorbent assays are available for the detection of immunoglobulin G (IgG) antibodies to *H. pylori* in serum. Noninvasive tests, such as serology and breath tests, are useful but should not be promoted as the sole method of diagnosing *H. pylori*–associated ulcer disease in children because they cannot distinguish between incidental infection and the presence of ulceration. At this time, therefore, the presence of suspected ulcer disease should be confirmed by endoscopic examination according to the guidelines previously suggested.

Management

The focus of ED management of patients with suspected ulcer disease should be on the detection and stabilization of life-threatening complications such as perforation and major GI hemorrhage and on ruling out other potential serious or life-threatening conditions that may require urgent intervention. Depending on the suspected amount of blood loss, all patients with GI bleeding should have a CBC count and blood type and screen obtained. If vomiting has been prominent, electrolytes, BUN, creatinine, serum amylase, and lipase should also be determined. If physical examination findings suggest significant abdominal tenderness with guarding or rebound tenderness, plain radiographs of the abdomen should be obtained to rule out a perforation or bowel obstruction. IV access should be obtained in all patients who have significant emesis, dehydration, weight loss, or concerning abdominal examination findings. An initial bolus of normal saline (20 mL per kg) should be given and vital signs monitored frequently, with additional boluses given as needed to achieve hemodynamic stability.

A number of approaches are available for the treatment of ulcer disease in children. Therapies can be categorized as those that neutralize acid (i.e., antacids), block acid secretion, are cytoprotective, or are antiinfective. Antacids are a low-cost, safe, and effective means of treating peptic ulcer disease in children and can be prescribed for patients of any age. Adverse effects of antacids are related to the cation present in the preparation: magnesium-containing products cause diarrhea, whereas aluminum-containing products cause constipation. Some products are available combining the two to minimize these effects. The usual dosage for children is 0.5 mL per kg, given 1 hour after eating and before going to the bed. Patients with food-related or nocturnal abdominal pain without associated signs of serious illness can be started on empirical therapy with antacids, assuming good follow-up with a primary care physician. Referral to a pediatric gastroenterologist can then be made if the patient fails to respond to 2 weeks of therapy.

H_2-receptor antagonists are the most common agents used to block acid secretion and treat ulcer disease. Patients with significant GI bleeding, vomiting, or abdominal tenderness should be admitted to the hospital and begun on IV therapy with an H_2-receptor antagonist. Currently, most physicians with pediatric experience use ranitidine (2 to 4 mg per kg per day IV q6 to 8 h) or famotidine (1 mg per kg per day IV bid) for initial treatment. Both agents are competitive H_2-receptor antagonists that reduce gastric acid output, thereby raising gastric pH. Patients for whom initial outpatient therapy is appropriate can be prescribed an H_2-receptor antagonist following an ED visit, but this therapy is best done in consultation with either the patient's primary care physician or a pediatric gastroenterologist, who will establish appropriate follow-up for the patient. The proton pump inhibitors, omeprazole (0.6 mg per kg per day po qd) and lansoprazole (1 mg per kg per day po qd), are irreversible inhibitors of H^+/K^+ ATPase. Their potential adverse effects include headache, diarrhea, nausea, and vomiting. When initiating therapy, the emergency physician should arrange appropriate follow-up.

Sucralfate (40 to 80 mg per kg per day po q6h) is an aluminum salt that "coats" damaged gastric mucosa, effectively insulating it from further damage by acid, pepsin, or bile. It is typically given as a slurry and can be used with H_2-receptor antagonists, provided the drugs are given at least 1 hour apart.

Recurrences of *H. pylori*–associated ulcer disease are markedly reduced—from 65% to 5% at 1 year of follow-up—by treatment that includes eradication of the infection and acid suppression therapy. Most children with *H. pylori* infection are asymptomatic, and no convincing evidence that *H. pylori* causes symptoms in the absence of ulceration has been presented. Therefore, antimicrobial therapy is currently not recommended for children without ulcers or gastritis who harbor the organism. Current recommended protocols for first-line therapy include a proton pump inhibitor (for 1 month) plus two antibiotics (choosing two of the following: amoxicillin, clarithromycin, or metronidazole for 7 to 14 days). Compliance is an important consideration because it is a major determinant of the success of treatment.

REYE'S SYNDROME

Background

Reye's syndrome is a distinct, reversible, clinicopathologic syndrome occurring after an antecedent viral infection, characterized by severe noninflammatory encephalopathy and fatty degeneration of the liver. The incidence of Reye's syndrome peaked at 400 to 600 cases per year in the 1970s and early 1980s, when a series of case-control studies established a link between antecedent aspirin exposure and the onset of Reye's syndrome. The incidence has since declined to about two cases per year. Isolated case reports continue to be described, indicating the need to continue to consider Reye's syndrome when evaluating patients with the typical clinical presentation described in the next section.

Pathophysiology

The precise pathogenesis of Reye's syndrome remains unclear, but there is a primary mitochondrial injury in all tissues of the body, which results in disturbances of fatty acid and carnitine

metabolism. Most of the clinical features of Reye's syndrome, including lactic acidosis, elevated fatty acids, nitrogen wasting, hyperammonemia, cellular fat accumulation, and cytotoxic cerebral edema, may be explained in the context of primary mitochondrial damage.

Clinical Manifestations

Reye's syndrome affects children of all ages. No gender difference is apparent. A biphasic clinical history is remarkably constant. First, the child has a history of a recent, usually febrile, illness that is waning or has resolved. Approximately 90% of the children have an antecedent upper respiratory tract infection. Varicella virus or influenza B infections have been characteristically associated with Reye's syndrome. The abrupt onset of protracted vomiting usually starts within 1 week following the prodromal illness. The vomiting is unresponsive either to restriction of oral intake or to antiemetic therapy.

Coincident with the onset of vomiting (or shortly thereafter), signs of encephalopathy appear. At first, encephalopathy may be manifested by unusual quietness or disinterest. However, a rapid sequential progression to irritability, combativeness, confusion, disorientation, delirium, stupor, and coma may occur. Seizures are a late sign in older children but may occur during early stages of encephalopathy in infancy (usually secondary to hypoglycemia).

In the ED, patients are usually afebrile. Tachycardia and hyperventilation commonly occur. At the initial presentation, only 50% of patients have hepatomegaly. The liver usually increases in size during the first 24 to 48 hours after the diagnosis is made. The absence of jaundice and scleral icterus is characteristic and is the major mitigating clinical sign against hepatic encephalopathy secondary to acute fulminant hepatitis. Despite evidence of encephalopathy, no focal neurological signs or signs of meningeal irritation are apparent.

The diagnosis of Reye's syndrome is suggested by the clinical presentation, supported by characteristic biochemical findings and confirmed by characteristic histologic findings on liver biopsy. The hallmark of the acute encephalopathy of Reye's syndrome is the associated evidence of liver abnormality. The levels of transaminases (ALT and AST) and blood ammonia are almost always elevated at the time of the onset of protracted vomiting. The range of transaminase elevation is highly variable and has not been shown to correlate well with severity of the disease. Ammonia levels more than 300 g per L have been shown to be an indicator of a poor prognosis. The PT is more than 50% of control in at least one-half of the patients, although clinical bleeding is rare and evidence of disseminated intravascular coagulation is absent. The level of serum bilirubin rarely exceeds 2 mg per dL. Hypoglycemia is rare, except in children who present in coma and in infants younger than 1 year, in whom the incidence is reported to be as high as 70% to 80%. Azotemia and ketonuria are common, secondary to starvation and dehydration from vomiting and poor oral intake. Patients most often have a mixed respiratory alkalosis and mild metabolic acidosis. The metabolic acidosis correlates with the level of ammonia elevation and reflects the degree of mitochondrial dysfunction.

Management

Once the diagnosis is made, immediate plans to admit the child to an ICU should be made, because the progression of the encephalopathy may be rapid, resulting in increased morbidity and mortality.

Despite the generalized nature of the mitochondrial insult in Reye's syndrome, the brain is the principal organ affected by the syndrome. Increased intracranial pressure (ICP) secondary to cerebral edema is the major factor contributing to morbidity and mortality in Reye's syndrome. With the ability to monitor ICP, numerous different invasive therapies have been introduced in an attempt to rapidly reduce and control cerebral edema. However, none of these therapies, including hyperventilation and muscle paralysis using neuromuscular-blocking drugs, hyperosmolar agents, high-dose barbiturates, exchange transfusions, or hypothermia, have been clearly proven to protect the brain from progressive ischemic insult. Ultimately, the management of Reye's syndrome is supportive because no specific curative therapy is currently available.

ACUTE BILIARY TRACT DISEASE

Background

Acute biliary disease occurs occasionally in children (more often in adolescents) and is associated with a wide spectrum of clinical manifestations. Acute cholecystitis is typically a complication of cholelithiasis, which is primarily associated in younger patients with hemolytic anemias (pigment stones) such as sickle cell disease and hereditary spherocytosis. Adolescent girls develop cholecystitis more often than do boys (cholesterol stones). Gallstones may be asymptomatic, and their prevalence increases with age. Acalculous cholecystitis, or acute inflammation of the gallbladder in the absence of gallstones, in children is actually more common than cholelithiasis and has been associated with bacterial enteric infections such as typhoid, shigellosis, and *E. coli* infection, parasitic infections, and other conditions such as leptospirosis, scarlet fever, pneumonia, Kawasaki disease, hepatitis, and polyarteritis nodosa. Acute cholangitis resulting from an ascending biliary infection or obstruction is seen primarily in the pediatric patient who has had surgical correction of congenital biliary tract obstruction (biliary atresia, choledochal cyst). Finally, hydrops of the gallbladder, causing jaundice and a right upper quadrant mass effect with pain, is a complication of Kawasaki disease.

Pathophysiology

Biliary colic results from acute transient obstruction of the cystic duct or common bile duct by gallstone(s). Cholecystitis is an aseptic inflammatory process that develops as a reaction to chemical injury triggered by obstruction to the cystic duct by a gallstone. This inflammation is mediated by (i) lysolecithin, which is formed from biliary lecithin by refluxed pancreatic enzyme phospholipase A; (ii) refluxed proteolytic pancreatic enzymes; and (iii) unconjugated bile salts. The cause of acalculous cholecystitis is unknown. The condition is commonly

associated with gallbladder distension, called acute hydrops of the gallbladder. In infectious syndromes, inflammation of the cystic duct and/or enlargement of mesenteric lymph nodes may result in obstruction to bile flow. In vasculitis syndromes, such as mucocutaneous lymph node syndrome (Kawasaki disease) or polyarteritis nodosa, there may be a reactive serositis or vasculitis with increased mucus secretion by the gallbladder, which, when coupled with factors that contribute to bile stasis such as fever, prolonged fasting, ileus, or dehydration, may result in gallbladder distension that in turn may kink the cystic duct. Cholangitis results from secondary bacterial infection by enteric organisms in the face of biliary tract obstruction or after surgical manipulation of the biliary tract. Acute cholangitis may be mild and superficial, producing only short-lived symptoms, or it may be severe, causing suppurative cholangitis with septic shock and formation of hepatic abscesses.

Clinical Manifestations

The pain of biliary colic is acute in onset, often follows a meal, and is usually localized to the epigastrium or right upper quadrant. Some children may localize the pain to the periumbilical area. Characteristically, the pain increases to a plateau of intensity over 5 to 20 minutes, typically after meals, and persists for a variable duration, usually less than 4 hours (although less than 1 hour in 50% of patients). In contrast to the colicky pain of intestinal or ureteral origin, biliary colic does not worsen in relatively short cyclic paroxysms or bursts but instead is characterized by its sustained, intense quality. Unlike pancreatitis, the patient tends to move about restlessly and the pain is not improved by changes in position. In addition, referred pain is common, particularly to the dorsal lumbar back near the tip of the right scapula. Nausea and vomiting are commonly associated with biliary colic but are not severe and protracted as seen with pancreatitis. Mild jaundice occurs in 25% of patients, but the serum bilirubin rarely exceeds 4 mg per dL. An attack of acute cholecystitis begins with biliary colic, which increases progressively in severity or duration. Pain lasting longer than 4 hours suggests cholecystitis. As the inflammation worsens, the pain changes character, becoming more generalized in the upper abdomen and increased by deep respiration and jarring motions. The temperature is usually mildly elevated, ranging from 37.5°C to 38.5°C (99.5°F to 101.3°F).

In contrast, acute cholangitis should be suspected in the patient who has right upper quadrant abdominal pain, shaking chills with spiking fever [temperature higher than 39°C (102.2°F)], and jaundice (Charcot's triad). These patients usually have a history of abdominal surgery. A dangerous aspect of this disorder is that overwhelming sepsis can develop rapidly. Listlessness and shock are characteristic of advanced or severe cholangitis and usually reflect gram-negative septicemia. Cholangitis can evolve rapidly before the development of significant jaundice. Clinically apparent jaundice may be absent even in postsurgical biliary atresia patients. Hydrops of the gallbladder is associated with a palpable right upper quadrant mass and pain. Fever and jaundice generally do not occur.

In addition to scleral icterus, nonspecific physical findings that suggest gallbladder disease include right upper quadrant guarding, Murphy's sign (production of pain by deep inspiration or cough when the physician's fingers are depressing the abdomen below the right costal margin in the midclavicular line and abrupt cessation of inspiration because of pain), and production of pain or tenderness by a light blow applied with the ulnar surface of the hand to the subcostal area. In about one-third of patients with cholecystitis, the gallbladder is palpable as a sausage-shaped mass lateral to the midclavicular line. A rigid abdomen or rebound tenderness suggests local perforation or gangrene of the gallbladder.

Laboratory tests are typically nonspecific in cholecystitis. A CBC count and blood smear may show evidence of hemolysis. The leukocyte count averages 12,000 to 15,000 per mm^3 with a neutrophilic leukocytosis. Higher leukocyte counts suggest cholangitis. The level of serum bilirubin may be elevated but rarely exceeds 4 mg per dL. Higher values are more compatible with either complete common bile duct obstruction or cholangitis. The levels of serum transaminases (ALT and AST) and alkaline phosphatase may be mildly elevated but are often normal. Marked elevation in the levels of transaminases may occur with acute, complete common duct obstruction. Serum amylase levels may be mildly elevated without other evidence of pancreatitis. Abdominal flat and upright radiographs may show right upper quadrant calcification of gallstones, particularly in patients with hemolytic anemia (pigment stones), or a right upper quadrant mass. Abdominal radiographs are particularly important to rule out perforation. The erythrocyte sedimentation rate is often elevated in children with cholangitis, and organisms may be recovered from blood cultures.

Abdominal ultrasound is the most commonly used test to confirm gallbladder disease. This test is noninvasive, easily performed, and provides information on the surrounding organs such as the liver, pancreas, and kidneys. Ultrasound can determine the presence of most gallstones, dilated bile ducts, a thickened gallbladder wall or hydropic gallbladder, sludge, and hepatic abscesses. Other radiographic tests, such as cholecystograph or radionuclide testing, are not typically used in the emergency setting.

Other conditions to be considered in the differential diagnosis of biliary tract disease include perforated peptic ulcer, pneumonia, intercostal neuritis, pancreatitis, hepatitis, and hepatic and abdominal sickle cell crises. Therefore, evaluation should also include stool guaiac test, chest radiograph, amylase: creatinine ratio, and a peripheral blood smear.

Management

All patients with suspected acute biliary tract disease and acute symptoms should be admitted to the hospital. The exception is a patient with biliary colic that has resolved spontaneously, in which case an urgent outpatient evaluation by ultrasound can be pursued. Conditions associated with acalculous cholecystitis should be evaluated and treated if identified. General ED management includes discontinuation of oral intake, support with IV fluids, and surgical consultation. Cholecystitis and cholangitis associated with gallstones are general indications for surgery. The patient should be made NPO (nothing by mouth) and given IV fluids, pain medication, and antibiotics, if cholangitis is considered. Antibiotic coverage should include gram-negative organisms and enterococci. Ampicillin (200 mg per kg per day) and gentamicin (5 to 7.5 mg per kg per day) provide good coverage; ampicillin/sulbactam (dosed on ampicillin at 200 mg per

kg per day) can also be used. Narcotics are useful to alleviate the pain and to reduce gallbladder mucosal secretion.

In all patients with suspected cholangitis, blood cultures should be drawn before antibiotics are administered. When possible, antibiotics should be withheld pending a liver biopsy for definitive culture. However, the exception is the clinically septic children in whom antibiotic coverage should be immediately instituted. In these cases, a liver biopsy performed after the institution of antibiotics may still show histologic evidence of cholangitis.

ACUTE PANCREATITIS

Background

Although uncommon, the diagnosis of pancreatitis is often overlooked because no specific pathognomonic symptoms are associated with the condition. Pancreatitis should be considered in any child with acute or chronic epigastric abdominal pain and vomiting, ascites of obscure origin, or following upper abdominal trauma. Table 89.1 lists the causes of pancreatitis. In 30% of cases, the precipitating factor is unknown. Approximately 50% of cases are associated with an infectious agent or blunt trauma. Mumps pancreatitis is seldom severe and rarely occurs in children younger than 5 years; clinical mumps is present in only 50% to 60% of cases. Most blunt injuries to the pancreas are the result of automobile crashes or falls from bicycles; however, because the pancreas is a fixed retroperitoneal structure, mild trauma from small pointed objects, such as sticks, handlebars, or fence posts, may transmit injury directly to the organ.

Pathophysiology

Regardless of the initiating event, the pathophysiology of acute pancreatitis is probably similar. Activation of the numerous pancreatic enzymes, including proteolytic enzymes, lipase, amylase, elastase, and phospholipase A, produces autodigestion of the gland. The process may be focal or diffuse. In mild cases, there is interstitial edema and inflammatory infiltrate without significant cell necrosis. This type of pancreatitis, called *acute edematous pancreatitis*, is by far the most common form seen in children; it is usually self-limiting and associated with complete recovery. When the autodigestive process intensifies with increased inflammation, fat necrosis, and hemorrhagic changes, it is called *necrotic* or *hemorrhagic pancreatitis*. This type of pancreatitis is associated with a 20% to 40% mortality rate and significant morbidity. It is unclear why the autodigestive process is arrested in some cases and not in others, but one factor may be the magnitude of the initial triggering mechanism.

The morbidity and mortality associated with pancreatitis is related to complications from the autodigestive process. Fat necrosis of neighboring tissue and saponification of calcium often result from the release of pancreatic lipase. Released proteolytic enzymes may extend the inflammatory process into the retroperitoneum and the peritoneal cavity. Proteolytic enzymes may activate kallikrein, a potent vasoactive polypeptide that may mediate systemic vasodilation and increase vascular permeability, producing severe hypotension, shock, and renal and/or pulmonary insufficiency that may prove fatal. Secondary infection may lead to abscess formation, and walling off the autodigestive process may result in pseudocyst formation.

TABLE 89.1

CAUSES OF ACUTE PANCREATITIS IN CHILDREN

I	Trauma: blunt, penetrating, surgical
II	Infectious: mumps, coxsackievirus B infection, hemolytic *Streptococcus* infection, *Salmonella* infection, hepatitis A and B
III	Obstructive: cholelithiasis, ascaris infection, congenital duodenal stenosis, duplications, tumor, choledochal cyst
IV	Drugs: steroids, chlorothiazides, salicylazosulfapyridine, azothiaprine, alcohol, valproic acid, tetracyclines, borates, oral contraceptives
V	Systemic: systemic lupus erythematosus, periarteritis nodosa, malnutrition, peptic ulcer, uremia
VI	Endocrine: hyperparathyroidism
VII	Metabolic: hypercholesterolemia, cystic fibrosis, vitamin A and D deficiency
VIII	Hereditary
IX	Idiopathic

Clinical Manifestations

Epigastric abdominal pain is the most consistent symptom of pancreatitis and may vary from tolerable distress to severe incapacitating pain. Symptoms may be chronic and insidious, but they typically progress rapidly, building to a crescendo over several hours. The pain is usually localized to the epigastrium and may radiate to the back (left or right scapula) or to the right or left upper quadrants. The pain is usually described as knifelike and boring in quality and is aggravated when the patient lies supine. Classically, the pain of pancreatitis is constant, as opposed to colicky pain, which waxes and wanes. Anorexia, nausea, and vomiting are the most common associated symptoms. Vomiting may be severe and protracted. Low-grade fever [temperature lower than 38.5°C (101.3°F)] is present in 50% to 60% of cases. In cases of severe necrotic pancreatitis, patients may complain of dizziness. Mental aberrations are common in necrotic pancreatitis; patients may act overtly psychotic or present in coma.

Early in the course of the disease, there may be a discrepancy between the severity of the patient's subjective pain and the objective physical findings. During the examination, patients are usually quiet and prefer sitting or lying on their side with knees flexed. The abdomen may be distended but is usually not rigid. There may be mild to moderate voluntary guarding in the epigastrium. A palpable epigastric mass suggests pseudocyst. Ascites is rare. Bowel sounds may be decreased or absent. Associated physical findings may include signs of parotitis, mild hepatosplenomegaly, epigastric mass, pleural effusions, and mild icterus. Although rare, rebound tenderness or a rigid abdomen is a poor prognostic sign if present. Similarly, a bluish discoloration around the umbilicus (Cullen's sign) or flanks (Grey Turner's sign) is rare in children but portends a poor prognosis and a diagnosis of hemorrhagic pancreatitis. Signs of overt hemodynamic instability are rarely

evident at initial presentation. It is particularly important to evaluate patients for clinical signs of hypocalcemia (Trousseau and Chvostek signs).

The clinical diagnosis is often tentative because the same constellation of symptoms (abdominal pain, vomiting, and low-grade fever) and signs (abdominal tenderness and guarding) may be mimicked by several other conditions including ulcer disease, gastritis, esophagitis, biliary colic, acute cholecystitis, intestinal obstruction, and appendicitis.

Currently, two easily attainable laboratory tests are used to make a diagnosis of pancreatitis: serum amylase and serum lipase. The combination of the aforementioned clinical symptoms and an elevation of the level of one or both of these enzymes strongly point to pancreatitis. In acute pancreatitis, the serum amylase increases hours after the onset of the autodigestive process. Generally, because amylase is rapidly cleared by the kidneys, serum amylase levels may return to normal after 3 to 5 days, even though pain persists. Elevated serum triglyceride levels may interfere with the assay and result in false-normal values. The degree of serum amylase elevation rarely corresponds to the severity of pancreatic inflammation. Although controversial in the past, lipase assays are now accurate and commonly used to diagnose pancreatitis. Serum lipase levels may remain elevated for up to 14 days after the onset of acute pancreatitis.

Elevated serum amylase and lipase levels are not pathognomonic for pancreatitis. Many situations, including penetrating or perforated ulcer, intestinal obstruction or infarction, Crohn's disease, pneumonia, hepatitis, liver trauma, acute biliary tract disease, salpingitis, salivary adenitis, renal failure, diabetic ketoacidosis, and benign macroamylasemia, can cause an amylase elevation. Other causes for an elevated serum lipase level include perforated peptic ulcer and bone fracture with pulmonary fat embolism.

Radiographically, the abdominal ultrasound provides a noninvasive, direct view of the pancreas and is probably the most useful test in diagnosing pancreatitis in the emergency setting. Ultrasound can assess pancreatic size, contour, and the presence of calcifications and pseudocyst formation. Ultrasound should be considered in all cases of suspected pancreatitis. Abdominal CT scan and endoscopic retrograde cholangiopancreatography (ERCP) are being used more often to assess the severity of pancreatitis and pseudocyst formation and to determine possible causes of pancreatitis. ERCP has the additional advantage of providing the option for therapeutic maneuvers such as stone removal or sphincterotomy. However, ERCP should not be performed in the acute phase or in patients with acute pseudocyst formation or pancreatic abscess formation but should be reserved for patients with chronic, recurrent pancreatitis. Rarely, ERCP may be indicated in acute pancreatitis if an obstructing gallstone is present in the common bile duct. More recently, magnetic resonance cholangiopancreatography has been considered equivalent to ERCP for the diagnosis of many pancreatic and biliary conditions. It is less invasive than ERCP, with reported sensitivity to detect common bile duct stones of 70% to 100%.

Management

All patients with evidence of pancreatitis or suspected pancreatitis should be admitted to the hospital. Treatment, however, should begin in the ED. The goals of medical treatment include suppression of pancreatic secretion and relief of pain. Morbidity and mortality in pancreatitis are directly related to complications that may already be present at the time of initial presentation. Therefore, aggressive early maintenance of intravascular volume and treatment of hypocalcemia, respiratory distress, and suspected infection are mandatory.

IV fluids should be immediately started, and the patient's oral intake should be discontinued. The patient should be assessed for hypotension. When the patient is judged stable, IV fluids should be administered at 1.5 times the maintenance rate. Vital signs and urine output should be monitored frequently. Continuous NG suction should be started; aspiration of gastric contents is based on the premise that the prevention of delivery of gastric acid into the duodenum will diminish hormonal stimulation of the pancreas. NG suction also relieves pain and prevents development of ileus. The use of anticholinergics or H_2-receptor antagonists to reduce gastric secretion is controversial and is not recommended in the initial management of patients. A crucial part of management is the treatment of abdominal pain. Traditionally, meperidine has been the analgesic of choice since morphine may increase spasm at the sphincter of Oddi. However, there is no evidence to support the assumption that morphine administration worsens pancreatitis, and repeated doses of meperidine may lead to neuromuscular irritation and seizures in rare instances.

Laboratory studies that should be performed in the ED include amylase, lipase, CBC count, electrolytes, BUN, calcium, glucose, AST, ALT, bilirubin, alkaline phosphatase, triglyceride, PT, and PTT. Arterial blood gases should be determined in patients with tachypnea. A chest radiograph should be obtained and evaluated for pleural effusion, interstitial pneumonic infiltrates, and basilar atelectasis. A flat and upright abdominal radiograph is needed to rule out perforation, ascites, and pancreatic calcifications. In severe cases or in cases of questionable diagnosis, an abdominal ultrasound should be performed.

In most cases, discontinuing enteral intake while maintaining intravascular volume and providing adequate analgesia will result in a rapid resolution of symptoms. Prognostic indicators of necrotizing or hemorrhagic pancreatitis include hypocalcemia (less than 8.0 mg per dL), hyperglycemia (more than 200 mg per dL), clinical shock, elevated hematocrit or BUN, ascites, and oxygen partial pressure of less than 60 mm Hg. Such patients should be admitted to an ICU, given sufficient colloid (e.g., albumin) to maintain normal intravascular volume, and have more extensive monitoring with an arterial catheter and a urinary catheter. A Pa_{O_2} lower than 60 mm Hg is an indication for elective intubation. Early peritoneal dialysis should be started if rapid clinical deterioration occurs.

Antibiotics are not indicated in the initial management of pancreatitis. Pancreatic abscess should be considered if the patient's temperature is higher than 38.5°C (101.3°F). In those cases, broad-spectrum antibiotic coverage with ampicillin, gentamicin, and either clindamycin or metronidazole is indicated pending the results of blood cultures and diagnostic ultrasound. Emergency surgery is rarely necessary in acute pancreatitis; however, indications for surgery include active intraperitoneal bleeding, suspected abscess, biliary duct obstruction, and suspected traumatic transection.

FULMINANT LIVER FAILURE

Background

Fulminant liver failure occurs when the vital functions of the liver fail, including the development of a coagulopathy, hypoglycemia, hyperbilirubinemia, hypoproteinemia, and encephalopathy. Liver failure can develop acutely, or it may be chronically progressive. The causes of liver failure are diverse and include infectious processes (e.g., viral hepatitis), metabolic diseases (e.g., Wilson's disease), pharmacologic agents, ischemia, and malignancy. Acute liver failure can be a life-threatening problem that causes a severe coagulopathy, hypoglycemia, and encephalopathy. Aggressive supportive medical management is required in most cases.

Pathophysiology

The pathogenesis of fulminant liver failure requires the progression of several key steps that lead to irreversible hepatocyte injury. The initiating step is the exposure of the susceptible person to the inciting agent, which leads to widespread hepatocyte injury. Hepatocyte necrosis may occur secondary to an infectious agent (viral hepatitis), a toxin (various pharmacologic substances), or a metabolic by-product.

Following hepatocyte death, the potentiation of the responsible agent is necessary to continue the hepatic destructive process. Normally, the liver is capable of regeneration; however, the regenerative process is inhibited in patients who develop liver failure. These steps may lead to terminal hepatic failure in which the liver becomes incapable of supporting those events required for life.

Although infectious agents (e.g., hepatitis A to E viruses) are responsible for most proven cases of liver failure (approximately 80% in most series), in many cases, no cause is determined. Common drugs and toxins that cause liver failure include acetaminophen, salicylates, solvents, valproic acid, amiodarone, isoniazid, NSAIDs, tetracycline, and chlorinated hydrocarbons. Rarely, metabolic diseases can lead to liver failure. These diseases include galactosemia, tyrosinemia, Wilson's disease, neonatal hemochromatosis, disorders of fatty acid oxidation, bile acid synthetic disorders, and hereditary fructose intolerance.

Clinical Manifestations

Many patients do not exhibit serious clinical features of acute liver failure. Typically, pediatric patients who develop acute liver failure were previously healthy and had no prior medical problems. Patients may initially complain of fatigue, nausea, vomiting, and diffuse abdominal pain. Occasionally, right upper quadrant pain may be severe. Commonly, a history of a prodromal viral illness can be elicited. The presence of jaundice usually initiates the first visit to the physician. As liver failure progresses, patients become more jaundiced and lethargic and develop tremors. In a short time, they become confused or somnolent and may have problems with easy bruising or bleeding.

The onset of encephalopathy occurs in conjunction with the severity and progression of liver failure. Encephalopathy is graded on a scale from I to IV. Grade I is manifested by a coherent individual who shows mild or episodic drowsiness, poor concentration, and impaired intellect. In grade II, the patient not only continues to be coherent and conversant but also becomes disoriented and fatigued. Agitation and aggressive behavior in conjunction with extreme drowsiness are manifested in grade III encephalopathy. Unresponsive patients who respond only to painful stimuli and who have evidence of cerebral edema are labeled as having grade IV encephalopathy. The clinical features of increased ICP include systemic hypertension, "decerebrate posturing," hyperventilation, abnormal pupillary responses, and impairment of brainstem reflexes. Cerebral edema is associated with increased mortality and requires aggressive supportive management. Finally, bleeding esophageal and gastric varices and ascites may rapidly develop secondary to increased portal hypertension.

Laboratory Findings

Because it may be difficult to diagnose patients clinically, biochemical evidence that provides evidence of liver failure may be collected. The liver plays an important role in hemostasis because the liver synthesizes a number of coagulation factors. An uncorrectable coagulopathy is usually the first laboratory manifestation of liver failure. Other factors may have a shorter half-life, but the PT is the most commonly used marker of the severity of liver disease. A prolonged PT despite IV supplementation of vitamin K should alert the physician to impending liver failure. Other laboratory markers suggestive of liver failure include evidence of increasing cholestasis manifested by a rising serum bilirubin level, hypoalbuminemia, and hypoglycemia.

It is also important to monitor serum transaminase levels. Falling transaminase levels usually indicate resolving liver disease, though in the setting of increasing jaundice and coagulopathy, this trend indicates hepatocyte death rather than hepatocyte repair. Serum fibrinogen is usually decreased in patients with liver failure. In cases in which the patient has splenomegaly, thrombocytopenia and leukocytopenia may be present.

Hypoglycemia almost always accompanies acute liver failure because the liver is the primary organ for gluconeogenesis, and this may complicate the signs of encephalopathy. Hepatorenal syndrome occurs in approximately 75% of patients who reach grade IV encephalopathy. The cause of hepatorenal syndrome is unclear; however, the result is oliguria in the presence of near normal intravascular pressures. Metabolic acidosis occurs in approximately 30% of patients who have liver failure, and the risk of sepsis is increased secondary to the patient's compromised immune function.

Management

All patients suspected of having liver failure should undergo a complete physical examination, including a thorough neurologic evaluation. Laboratory testing should include serum glucose, transaminases, total and direct bilirubin, albumin, PT, γ-glutamyl transpeptidase, CBC count with differential, electrolytes, blood culture, and fibrinogen. Patients with hypoglycemia

should be administered IV fluids with 10% dextrose and should undergo frequent blood glucose monitoring (every 1 hour) until their blood glucose level stabilizes. Metabolic acidosis should be corrected; however, correction of hyponatremia should be gradual in patients with ascites. Patients who have a life-threatening coagulopathy should be given IV vitamin K (2.5 mg in infants; 5 mg in older children and adolescents). If the case of non–life-threatening coagulopathy, vitamin K should be given subcutaneously because of the risk of infusion reactions. A repeat PT should be performed 6 to 8 hours after administration. An uncorrectable PT is suggestive of severe hepatocyte damage. The management of bleeding esophageal varices has been previously discussed in this chapter. Therapeutic management of ascites should occur only in the face of respiratory distress or renal failure. In these cases, either direct paracentesis or IV 25% albumin (1g per kg) followed by IV furosemide can be used. Otherwise, the introduction of a diuretic (e.g., spironolactone) to achieve a slow, gradual change in ascites is all that is initially required.

Patients with encephalopathy should be frequently monitored for changes in neurologic function. In cases in which the patient has developed cerebral edema, management consists of an intensive care setting, insertion of a subdural transducer, mechanical ventilation (hyperventilation), and administration of mannitol to maintain near normal levels of ICP.

ACUTE VIRAL HEPATITIS

Background

The existing alphabet of viral hepatitis is now up to E, with new variants awaiting discovery. Hepatitis A (HAV), the cause of "infectious" or epidemic hepatitis, is transmitted by the fecal-oral route. On a worldwide scale, fewer than 5% of cases are clinically recognized. HAV is a rare cause of fulminant hepatitis. No chronic carrier state exists. The virus is maintained in the human population through person-to-person transmission. Hepatitis B (HBV) is endemic in the human population. Although predominantly transmitted by the parenteral route or sexual contact, the high incidence of infection in family contacts suggests that the virus may also spread by saliva or breast milk. The ability of HBV to produce a chronic carrier state in 5% to 10% of infected subjects allows maintenance of an infectious pool without serial transmission. Hepatitis C (HCV) accounts for about 95% of hepatitis infections in recipients of blood transfusion and 50% of cases of sporadic non-A, non-B hepatitis. Most of these patients will progress to chronic hepatitis, and about 20% will develop cirrhosis. Hepatitis D (HDV) requires hepatitis B helper functions for the propagation in hepatocytes and may occur either simultaneously with hepatitis B infection (coinfection) or as superinfection in chronic hepatitis B carriers. Hepatitis E is an enterically transmitted virus responsible for large epidemics of acute hepatitis in Asia, the Middle East, and parts of Africa.

Clinical Manifestations

Most childhood cases of acute hepatitis produce minimal symptoms, are anicteric, and, unless suspected by palpation of tender hepatomegaly, are usually confused with a GI flu-like illness. Clinical hepatitis classically consists of a 5- to 7-day prodrome of variable constitutional symptoms (low-grade fever, anorexia, nausea, vomiting, malaise, fatigue, and epigastric or right upper quadrant abdominal pain), followed by acute onset of scleral icterus, jaundice, and passage of dark urine. Pruritus and diarrhea are rare. Physical examination after the onset of jaundice may reveal tender hepatomegaly. Mild splenomegaly is present in 25% to 50% of patients. HBV patients may also present with extrahepatic signs and symptoms such as arthralgia, arthritis, or papular acrodermatitis (on face, buttocks, and extensor surfaces of arms and legs). When the rash is associated with lymphadenopathy and fever, it is called the Gianotti-Crosti syndrome. Onset of the icteric phase of acute hepatitis most commonly is temporarily associated with improvement in the constitutional symptoms. In up to 15% of cases, severe fatigue, anorexia, nausea, and vomiting persist. The icteric period usually lasts 1 to 4 weeks. Occasionally, the jaundice is prolonged for 4 to 6 weeks, with increasing pruritus at 2 to 3 weeks.

Differential Diagnosis

A number of infectious agents may mimic a viral hepatitis-like illness. The most common are Epstein-Barr virus (EBV; infectious mononucleosis) and cytomegalovirus (CMV). Both agents rarely produce clinical jaundice, and high fever and diffuse adenopathy are more characteristic. Less common agents include herpes, adenovirus, coxsackievirus, rheovirus, echovirus, rubella, arbovirus, leptospirosis, toxoplasmosis, and tuberculosis.

Diagnostic Evaluation

The following laboratory tests are usually performed in all cases of suspected viral hepatitis: serum transaminases (AST and ALT), alkaline phosphatase, total and direct bilirubin, CBC count, PT, electrolytes, BUN, glucose, total protein, albumin, globulin, and, in patients who are older than 5 years, ceruloplasmin. AST and ALT are the best indicators of ongoing hepatocellular injury. Alkaline phosphatase levels are usually less than two times the upper limit of normal for age. Levels greater than three times normal should raise suspicions of EBV or CMV hepatitis or biliary tract disease. Hepatitis classically produces direct fractions of serum bilirubin in excess of 30% of total, indicating definite liver disease. Hyperbilirubinemia may be present in the absence of scleral icterus or jaundice because these signs usually cannot be appreciated until levels of total bilirubin exceed 3 to 4 mg per dL. Serum bilirubin levels peak 5 to 7 days after the onset of jaundice. The initial biochemical screen may reveal several indicators of severe hepatocellular injury, including (i) total bilirubin level more than 20 mg per dL, (ii) serum transaminase levels that exceed 3,000 units per L, (iii) WBC count more than 25,000 per mm^3, (iv) elevated PT, and (v) hypoglycemia.

Serum albumin and globulin are usually within normal levels. Decreased albumin or increased globulin levels should suggest an acute flare of chronic liver disease. Serum ceruloplasmin levels should be drawn in all patients older than 5 years who have suspected hepatitis to rule out Wilson's disease. A chest

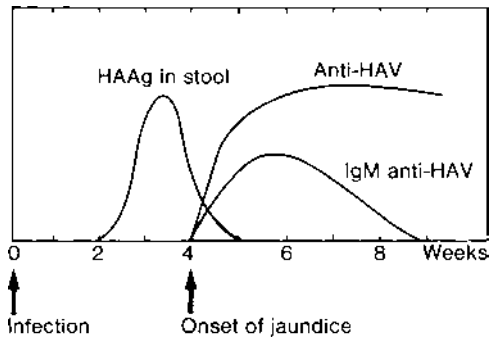

FIGURE 89.8 Serologic changes in hepatitis A. HAAg, hepatitis-associated antigen; HAV, hepatitis A virus.

radiograph may reveal cardiomegaly if any suspicion of low cardiac output states exists. Figures 89.8 and 89.9 contrast the sequence of clinical, biochemical, and serologic events in typical HAV and HBV infection. The serodiagnosis of acute hepatitis is best approached by first testing for anti-HAV IgM, HB surface antigen, HB e antigen, HB serum DNA (quantitative), anti-HB core Ab, anti-HCV, hepatitis C serum polymerase chain reaction (PCR) (quantitative), anti-CMV, and EBV serology. The finding of serum IgM anti-HAV is diagnostic of acute HAV infection because the antibody is present at the time of clinical symptoms. A positive HB surface antigen suggests the diagnosis of HBV in a symptomatic patient. A positive HB e antigen or anti-HB core Ab is helpful in the rare patient who rapidly clears HB surface antigen from the serum. It is also important to note that in long-term HB surface antigen carriers who have HDV superinfection, the suppression of HBV replication may lead to a transient absence of HBV markers in the serum; unless HDV markers in the serum are sought, the diagnosis may be missed. Anti-HCV does not appear in the patient's circulation until 1 to 3 months after the onset of acute illness, and in rare cases, detectable levels may not be demonstrated for up to 1 year. Thus, unless the acute presentation is actually a flare of chronic HCV, serodiagnosis of an HCV infection (Hep C PCR) will await long-term follow-up.

Management

No specific treatment of acute viral hepatitis is available. Most patients can be managed at home. No restrictions in diet or ambulation are necessary. The traditional recommendations of a low-fat, high-carbohydrate diet and bed rest are now recognized to have no effect on the symptoms or duration of the disease. Parents should be told that anorexia and fatigue are common symptoms. Small, frequent feedings may be helpful. Drugs should be strictly avoided. The key for both the patient and other household contacts is personal hygiene. Infants and children should avoid contact with the patient even after they have received immunoprophylaxis. In HAV, shedding of the virus may occur for up to 2 weeks after the onset of jaundice. Patients should be kept at home during this time. After this, they may return to school. Indications for hospitalization of a patient who has acute hepatitis include (i) dehydration secondary to anorexia and vomiting, (ii) bilirubin levels more than 20 mg per dL, (iii) abnormal PT, (iv) WBC count more than 25,000 per mm^3, or (v) levels of transaminases more than 3,000 units per L.

Patients who have acute hepatitis and who are hospitalized should be isolated. Follow-up studies of all patients with acute hepatitis should be performed to document biochemical resolution. Follow-up serology may also establish a specific cause in cases of apparent non-A, non-B hepatitis (fourfold increase in CMV serology, development of anti-HCV). Reevaluation of patients with HBV is especially important either to ensure clearance of HB surface antigen or to recognize the development of the HB surface antigen carrier state.

Postexposure Prophylaxis

Hepatitis A

The mean incubation period for HAV infection is about 4 weeks (range = 15 to 45 days). Conventional immune serum globulin (ISG; 0.02 mL per kg IM) confers passive protection against clinical HAV infection if given within 2 weeks of exposure. Seventy-five percent of this group will develop detectable levels of anti-HAV IgM, suggesting passive-active immunity. Postexposure immunoprophylaxis is suggested for (i) household and close personal contacts, (ii) institutionalized contacts, and (iii) contacts within a day care facility. Grade school classroom contacts of an isolated case and routine play contacts do not require ISG. However, a second case within a class is an indication for immunoprophylaxis of the rest of the class. An alternative method for determining who should receive ISG is to test high-risk contacts for anti-HAV IgG. Importantly, current guidelines recommend preexposure prophylaxis via routine HAV immunization for all children. Recently, studies have shown that immunizing patients postexposure with the hepatitis A vaccine is as effective as providing immune globulin.

Hepatitis B

Prophylactic treatment to prevent infection after exposure to HBV should be considered in the following situations seen in the ED: (i) sexual exposure to the HBV surface antigen–positive patient, (ii) inadvertent percutaneous or permucosal exposure to HBV surface antigen–positive blood, and (iii) household exposure of an infant younger than 12 months to a primary caregiver who has acute HBV. Before treatment in the first two situations, testing for susceptibility is recommended if it does not delay treatment beyond 14 days postexposure. Testing for anti-HBV core Ab is the most efficient prescreening procedure. All susceptible persons should receive a single dose

of hepatitis B immunoglobulin (0.06 mL per kg) intramuscularly and hepatitis B vaccine in recommended doses.

CELIAC DISEASE

Background

Celiac disease (also known as celiac sprue and gluten-sensitive enteropathy) is an immune-mediated enteropathy triggered by the ingestion of gluten-containing grains such as wheat, rye, and barley in genetically susceptible persons. Nearly all patients with celiac disease carry either the human leukocyte antigen (HLA)-DQ2 or HLA-DQ8 haplotype. More recent prevalence data generated on large, population-based samples of subjects from the United States and Europe indicate that the disease is far more common than originally thought. Data from 32 U.S. states suggest that the prevalence among asymptomatic, not-at-risk persons is 1 in 133. Among at-risk groups such as first- or second-degree relatives or symptomatic patients, the prevalence varied from 1 in 56 to 1 in 22. The protean clinical manifestations with which celiac disease may present, as well as increasing recognition of its prevalence, require emergency physicians to maintain a high degree of suspicion for the disorder when evaluating patients with a variety of complaints.

Pathophysiology

Celiac disease is a classic disorder in which the interplay of genes and environment (gluten) leads to disease. There is undisputed evidence regarding the role of gluten as the triggering agent. It abnormally passes into the lamina propria in susceptible persons and is then deamidated by tissue transglutaminase and subsequently recognized by antigen-presenting cells bearing the HLA-DQ2 or HLA-DQ8, thereby triggering the autoimmune reaction of celiac disease. The hallmark findings resulting from autoimmune damage are crypt hyperplasia, epithelial lymphocytosis, increased plasma cells, and villous atrophy. In the continued presence of gluten, celiac disease is self-perpetuating.

Clinical Manifestations

In its classic form, the disease is characterized by malabsorption and failure to thrive. Other common GI symptoms include diarrhea, constipation, and recurrent abdominal pain. However, more recently, several non-GI symptoms have been increasingly appreciated as presentations for celiac disease. Anemia, joint pain, arthritis, chronic fatigue, irritability, and other behavioral changes can all be the presenting symptoms of celiac disease. These nonspecific signs and symptoms in part explain the observation that the average time from onset of symptoms to diagnosis in U.S. children is typically several years.

Laboratory Findings

The gold standard for making the diagnosis of celiac disease is the typical pattern of villous atrophy and crypt hyperplasia demonstrated on a small bowel biopsy specimen. Villous height and crypt depth are measured and a ratio of villous height to crypt depth is calculated. A ratio of less than two is considered indicative of celiac disease.

The advent of new serologic tests has dramatically changed the way celiac disease is initially diagnosed. Serum antigliadin antibodies, antiendomysial antibodies (EMAs), and tissue transglutaminase antibodies can now be measured. They have been used to evaluate symptomatic patients and in large-scale screening of asymptomatic persons. Currently, EMA is the most sensitive test. A CBC count should also be considered in the evaluation of patients with suspected celiac disease to check for anemia. In the ED setting, it is more likely that a physician may suspect celiac disease and initiate this workup but not have results of serologic tests available in a timely fashion. Proper referral to the patient's primary care physician and/or gastroenterologist is paramount for any patient suspected to have celiac disease.

Management

The only effective treatment of celiac disease is the complete avoidance of gluten-containing grains. Early diagnosis of the disease and dietary elimination of gluten are currently the only ways to avoid complications of the disease that may manifest in adulthood, including intestinal lymphoma and diabetes mellitus. Beside the obvious sources of gluten—wheat, barley, rye, and oats—many processed foods contain gluten as a stabilizer or thickener. Gluten content of foods is not typically provided on product labels, complicating the already challenging task of providing a gluten-free diet.
