SIXTH EDITION

TEXTBOOK OF PEDIATRIC EMERGENCY MEDICINE

Editors

Gary R. Fleisher, MD
Egan Family Foundation Professor
Department of Pediatrics
Harvard Medical School;
Pediatrician-in-Chief and Chair
Department of Medicine
Children's Hospital of Boston
Boston, Massachusetts

Stephen Ludwig, MD
Professor of Pediatrics and Emergency Medicine
University of Pennsylvania School of Medicine
Senior Advisor for Medical Education
John H. and Hortense Cassel Jensen Chair
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Associate Editors

Richard G. Bachur, MD
Associate Professor
Department of Pediatrics
Harvard Medical School
Chief, Division of Emergency Medicine
Children's Hospital Boston
Boston, Massachusetts

Marc H. Gorelick, MD, MSCE
Professor
Departments of Pediatrics and Population Health
Medical College of Wisconsin;
Jon E. Vice Chair in Emergency Medicine
Children's Hospital of Wisconsin
Milwaukee, Wisconsin

Kathy N. Shaw, MD, MSCE
Professor and Associate Chair
Department of Pediatrics
University of Pennsylvania School of Medicine;
Division Chief
Department of Emergency Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Richard M. Ruddy, MD
Professor of Clinical Pediatrics
Department of Pediatrics
University of Cincinnati College of Medicine;
Director
Division of Emergency Medicine
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

CONTRIBUTING AUTHORS

Michael S.D. Agus, MD
Assistant Professor
Department of Pediatrics
Harvard Medical School;
Director
Medicine Critical Care Program
Department of Medicine
Children's Hospital Boston
Boston, Massachusetts

Evaline A. Alessandrini, MD, MSCE
Professor
Department of Pediatrics
University of Cincinnati College of Medicine;
Director, Quality Scholars Program in Health Care Transformation
Divisions of Health Policy & Clinical Effectiveness and Emergency Medicine
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

Elizabeth R. Alpern, MD, MSCE
Associate Professor
Department of Pediatrics, Division of Emergency Medicine
The University of Pennsylvania School of Medicine;
Director of Research and Attending Physician
Department of Pediatrics, Division of Emergency Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Angela C. Anderson, MD, FAAP
Associate Professor of Emergency Medicine and Pediatrics
The Warren Alpert School of Medicine at Brown University
Brown University;
Physician, Pediatric Emergency Medicine
Departments of Emergency Medicine and Pediatrics
Rhode Island and Hasbro Children's Hospitals
Providence, Rhode Island

Amy M. Arnett, MD
Assistant Professor
Department of Pediatrics
The Ohio State University College of Medicine;
Attending Physician, Emergency Medicine
Pediatric Medical Director, NCH Critical Care Transport Team
Department of Emergency Medicine
Nationwide Children's Hospital
Columbus, Ohio

Paul L. Aronson, MD
Instructor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Fellow
Division of Emergency Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Magdy W. Attia, MD
Professor
Department of Pediatrics
Jefferson Medical College
Philadelphia, Pennsylvania;
Fellowship Director, Associate Director
Division of Emergency Medicine
Alfred I. DuPont Hospital for Children
Wilmington, Delaware

Jeffrey R. Avner, MD, FAAP
Professor
Department of Pediatrics
Albert Einstein College of Medicine;
Section Chief
Pediatric Emergency Medicine
Children's Hospital at Montefiore
Bronx, New York

Lynn Babcock Cimpello, MD
Associate Professor of Clinical Pediatrics
Division of Emergency Medicine
University of Cincinnati College of Medicine;
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

David Bachman, MD
Department of Emergency Medicine
Central Maine Medical Center
Lewiston, Maine

Richard G. Bachur, MD
Associate Professor
Department of Pediatrics
Harvard Medical School
Chief, Division of Emergency Medicine
Children's Hospital Boston
Boston, Massachusetts

Donald S. Bae, MD
Assistant Professor
Department of Orthopaedic Surgery
Harvard Medical School;
Attending Physician
Department of Orthopaedic Surgery
Children's Hospital Boston
Boston, Massachusetts

M. Douglas Baker, MD
Professor
Department of Pediatrics
UT Southwestern Medical Center
Dallas, Texas

Marc N. Baskin, MD
Assistant Professor
Department of Pediatrics
Harvard Medical School;
Associate Physician in Medicine
Division of Emergency Medicine
Children's Hospital Boston;
Service Chief
Short Stay Unit
Children's Hospital Boston
Boston, Massachusetts

Carl R. Baum, MD
Associate Professor of Pediatrics
Yale University School of Medicine;
Attending Physician
Section of Pediatric Emergency Medicine and Center for Children's Environmental Toxicology
Yale-New Haven Children's Hospital
New Haven, Connecticut

Louis M. Bell, MD
Professor
Department of Pediatrics
University of Pennsylvania;
Associate Chair of Clinical Activities
Department of Pediatrics
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Deena Berkowitz, MD, MPH
Assistant Professor
Departments of Pediatrics and Emergency Medicine
The George Washington University School of Medicine and Health Sciences;
Attending Physician
Department of Emergency Medicine
Children's National Medical Center
Washington, DC

Amy L. Billett, MD
Associate Professor in Pediatrics
Harvard Medical School;
Director of Safety and Quality
Department of Pediatric Oncology
Dana-Farber Cancer Institute
Boston, Massachusetts

Charles D. Blackwell, MD
Attending Physician
Department of Pediatric Emergency Medicine
Children's Hospitals and Clinics of Minnesota
Minneapolis, Minneapolis

Robert G. Bolte, MD
Professor
Department of Pediatrics
University of Utah School of Medicine;
Associate Director, Trauma Service
Division of Pediatric Emergency Medicine
Primary Children's Medical Center
Salt Lake City, Utah

Alison Brent, MD
Associate Professor
Department of Emergency Medicine
University of Colorado Health and Sciences Center
Aurora, Colorado
The Children's Hospital

Linda L. Brown, MD, MSCE
Assistant Professor of Emergency Medicine and Pediatrics
Warren Alpert Medical School of Brown University;
Physician
Pediatric Emergency Medicine
Hasbro Children's Hospital
Providence, Rhode Island

Robyn L. Byer, MD
Instructor of Pediatrics
Department of Pediatrics
Harvard Medical School;
Attending Physician
Division of Emergency Medicine
Children's Hospital Boston
Boston, Massachusetts

James M. Callahan, MD
Associate Professor of Clinical Pediatrics
Department of Pediatrics
University of Pennsylvania School of Medicine;
Director of Medical Education
Division of Emergency Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Leslie Castelo-Soccio, MD, PhD
Instructor
Department of Dermatology
University of Pennsylvania School of Medicine;
Attending Physician
Section of Pediatric Dermatology
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Laura L. Chapman, MD
Assistant Professor
Department of Emergency Medicine
Warren Alpert Medical School of Brown University;
Physician
Department of Pediatric Emergency Medicine
Rhode Island and Hasbro Children's Hospitals
Providence, Rhode Island

Vincent W. Chiang, MD
Associate Professor
Department of Pediatrics
Harvard Medical School;
Chief
Inpatient Services
Department of Medicine
Children's Hospital Boston
Boston, Massachusetts

Maryanne R.K. Chrisant, MD
Division of Gastroenterology
University of Virginia Health System
Charlottesville, Virginia

Thomas H. Chun, MD
Associate Professor
Department of Emergency Medicine and Pediatrics
Brown University;
Attending Physician
Emergency Department
Hasbro Children's Hospital
Providence, Rhode Island

Sarita Chung, MD
Instructor in Pediatrics
Department of Pediatrics
Harvard Medical School;
Assistant in Medicine
Division of Emergency Medicine
Children's Hospital Boston
Boston, Massachusetts

Theodore J. Cieslak, MD
Defense Department Liaison Officer
Centers for Disease Control and Prevention
Atlanta, Georgia

Joy L. Collins, MD, FAAP
Assistant Professor
Department of Surgery
University of Pennsylvania;
Attending Surgeon
Department of General and Thoracic Surgery
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Erika Constantine, MD
Assistant Professor
Department of Emergency Medicine and Pediatrics
Warren Alpert Medical School of Brown University;
Attending Physician
Department of Pediatric Emergency Medicine
Rhode Island and Hasbro Children's Hospitals
Providence, Rhode Island

Jacqueline Bryngil Corboy, MD
Instructor
Department of Pediatrics
Feinberg School of Medicine;
Attending Physician
Department of Pediatrics
Children's Memorial Hospital
Chicago, Illinois

Howard M. Corneli, MD
Professor
Department of Pediatrics
University of Utah School of Medicine;
Staff Physician
Emergency Department
Primary Children's Medical Center
Salt Lake City, Utah

Kathleen M. Cronan, MD
Associate Professor
Department of Pediatrics
Jefferson Medical College
Philadelphia, Pennsylvania;
Attending Physician, Emergency Department
Director of Health Content Integration, Nemours Center for Children's Health Media
Nemours A. I duPont Hospital for Children
Wilmington, Delaware

Joanne M. Decker, MD (Deceased)

Carlos A. Delgado, MD, FAAP
Attending Physician, Emergency Department
Department of Pediatric Emergency Medicine
Pediatric Emergency Medicine Associates (PEMA)
Children's Healthcare of Atlanta at Scottish Rite
Atlanta, Georgia

Robert Jay Deutsch, MD, MPH, FAAP
Attending Physician, Pediatric Emergency Medicine
Department of Emergency Medicine
Emergency Medical Associates;
Attending Physician, Pediatric Emergency Medicine
Department of Emergency Medicine
Saint Barnabas Medical Center
Livingston, New Jersey

Cinnamon Dixon, DO
Pediatric Emergency Medicine Fellow
Division of Emergency Medicine
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

Henry L. Dorkin, MD
Department of Pediatrics
Harvard Medical School;
Division of Respiratory Diseases
Children's Hospital Boston
Boston, Massachusetts

David E. Drum, MD, PhD
Clinical Associate Professor
Department of Radiology
Harvard Medical School
Boston;
Staff Physician
Department of Nuclear Medicine
VA Boston Health Care
West Roxbury, Massachusetts

Nanette C. Dudley, MD
Professor (Clinical)
Department of Pediatrics
University of Utah School of Medicine;
Attending Physician
Emergency Department
Primary Children's Medical Center
Salt Lake City, Utah

Karen Dull, MD
Instructor
Department of Pediatrics
Harvard Medical School;
Attending Physician
Division of Emergency Medicine
Children's Hospital Boston
Boston, Massachusetts

Dennis R. Durbin, MD, MSCE
Associate Professor
Departments of Pediatrics and Epidemiology
The University of Pennsylvania School of Medicine;
Director
Section of Research;
Attending Physician
Department of Emergency Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Edward M. Eitzen Jr., MD, MPH
Adjunct Associate Professor
Department of Emergency Medicine, Pediatrics
Uniformed Services University of the Health Sciences
Bethesda, Maryland;
Senior Partner
Biodefense and Public Health Programs
Martin-Blanck and Associates
Falls Church, Virginia

Lisa M. Elden, MD, CM
Associate Otolaryngologist
The Children's Hospital of Philadelphia;
Assistant Professor
Department of Otolaryngology
University of Pennsylvania;
Academic Institution Hospital or Institution
Philadelphia, Pennsylvania

Karan McBride Emerick, MD
Division of Gastroenterology
Connecticut Children's Medical Center
Hartford, Connecticut

Michele Burns Ewald, MD
Assistant Professor
Department of Pediatrics
Harvard Medical School;
Attending Physician and Medical Toxicology
Fellowship Director
Division of Emergency Medicine
Children's Hospital Boston
Boston, Massachusetts

Joanna R. Fair, MD, PhD
Assistant Professor of Radiology
Department of Radiology
University of New Mexico Health Sciences Center
Albuquerque, New Mexico

Mirna M. Farah, MD
Associate Professor of Pediatrics and Emergency Medicine
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Joel A. Fein, MD, MPH
Associate Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Attending Physician
Emergency Department
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Gary R. Fleisher, MD
Egan Family Foundation Professor
Department of Pediatrics
Harvard Medical School;
Physician-in-Chief and Chair
Department of Medicine
Children's Hospital Boston
Boston, Massachusetts

Todd A. Florin, MD
Instructor
Department of Pediatrics
University of Pennsylvania School of Medicine;
Fellow
Pediatric Emergency Medicine
Department of Pediatrics
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Janet H. Friday, MD
Clinical Professor
Department of Pediatrics
University of California, San Diego
La Jolla;
Attending Physician
Emergency Department
Rady Children's Hospital San Diego
San Diego, California

Ronald A. Furnival, MD
Professor
Department of Pediatrics and Emergency Medicine
University of Minnesota Medical School;
Medical Director
Department of Pediatric Emergency Medicine
University of Minnesota Amplatz Children's Hospital
Minneapolis, Minneapolis

Carmen Teresa Garcia, MD
Attending Physician
Department of Pediatric Emergency
Jackson Memorial and Holtz Children's Hospitals
Miami, Florida

Andrew L. Garrett, MD, MPH
Associate Research Scientist
Mailman School of Public Health
Columbia University;
Director of Planning and Response
National Center for Disaster Preparedness
Mailman School of Public Health
Columbia University
New York City, New York

Michael H. Gewitz, MD
Professor and Vice Chairman
Department of Pediatrics
New York Medical College;
Physician-in-Chief/Executive Director
Chief, Pediatric Cardiology
Maria Farari Children's Hospital at Westchester
Valhalla, New York

Javier A. Gonzalez Del Rey, MD
Professor of Clinical Pediatrics
Department of Pediatrics
University of Cincinnati College of Medicine;
Associate Director
Division of Emergency Medicine;
Director, Pediatric Residency Programs
Department of Pediatrics
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

Marc H. Gorelick, MD, MSCE
Professor
Departments of Pediatrics and Population Health
Medical College of Wisconsin;
Jon E. Vice Chair in Emergency Medicine
Children's Hospital of Wisconsin
Milwaukee, Wisconsin

Monika Goyal, MD
Department of Pediatric Emergency Medicine
Children's Hospital of Philadelphia
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Rose C. Graham, MD, MSCE
Clinical Assistant Professor of Pediatrics
Division of Pediatric Gastroenterology, Hepatology and Nutrition
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

David S. Greenes, MD
Department of Medicine
Children's Hospital Boston;
Clinical Assistant Professor
Department of Pediatrics
Harvard Medical School
Boston, Massachusetts

Karen D. Gruskin, MD
Assistant Professor
Department of Medicine
Harvard Medical School;
Director of Network Services
Department of Medicine
Children's Hospital Boston
Boston, Massachusetts

Steven D. Handler, MD, MBE
Professor
Otolaryngology: Head and Neck Surgery
University of Pennsylvania School of Medicine;
Associate Director
Otolaryngology
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Marvin B. Harper, MD
Associate Professor
Department of Pediatrics
Harvard Medical School;
Chief Medical Information Officer
Department of Medicine
Children's Hospital Boston
Boston, Massachusetts

Fred M. Henretig, MD
Professor of Pediatrics and Emergency Medicine
University of Pennsylvania School of Medicine;
Director
Section of Clinical Toxicology
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Joeli Hettler, MD
Assistant Professor
Department of Emergency Medicine
Tufts University School of Medicine
Boston, Massachusetts

Dee Hodge III, MD
Associate Professor
Department of Pediatrics
Washington University in St. Louis
Attending Physician
Emergency Services
St. Louis Children's Hospital
St. Louis, Missouri

Paul J. Honig, MD
Professor Emeritus
Department of Pediatrics and Dermatology
University of Pennsylvania School of Medicine;
Attending Physician
Section of Pediatric Dermatology
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Cynthia R. Jacobstein, MD, MSE
Clinical Assistant Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Attending Physician
Division of Emergency Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

David M. Jaffe, MD
Dana Brown Professor of Pediatrics
Department of Pediatrics
St. Louis Children's Hospital
Washington University in St. Louis School of Medicine;
Director
Emergency Services
St. Louis Children's Hospital
St. Louis, Missouri

Vaishali Jha, MD
Fellow
Department of Pediatric Emergency Medicine
University of Minnesota;
Fellow
Department of Pediatric Emergency Medicine
Children's Hospital and Clinics of Minnesota
Minneapolis, Minnesota

Mark D. Joffe, MD
Associate Professor
Department of Pediatrics
University of School of Medicine;
Director, Community Pediatric Medicine
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Howard A. Kadish, MD, MBA
Professor
Department of Pediatrics
University of Utah;
Medical Director, Rapid Treatment Unit
Department of Pediatrics
Primary Children's Medical Center
Salt Lake City, Utah

Emily R. Katz, MD
Director, Child & Adolescent Psychiatry Consultation Liaison Service
Department of Psychiatry
Rhode Island and Hasbro Children's Hospitals
Providence, Rhode Island

Ken Kazahaya, MD, MBA
Associate Professor of Clinical Otorhinolaryngology
Department of Otorhinolaryngology: Head and Neck Surgery
The University of Pennsylvania School of Medicine;
Director, Pediatric Skull Base Surgery, and Medical Director, Cochlear Implant Program
Division of Pediatric Otolaryngology & Human Communication
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Jennifer C. Kesselheim, MD, M.Ed
Instructor
Department of Pediatrics
Harvard Medical School;
Attending Physician
Department of Medicine
Children's Hospital Boston
Boston, Massachusetts

Brent R. King, MD, MMM
Professor and Chairman
Department of Emergency Medicine
The University of Texas Medical School at Houston;
Chief of Service
Emergency Department
Memorial Hermann (TMC) and Lyndon B. Johnson General Hospitals
Houston, Texas

Christopher King, MD, FACEP
Associate Professor of Emergency Medicine and Pediatrics
Department of Emergency Medicine
University of Pittsburgh School of Medicine;
Attending Physician
Department of Emergency Medicine
Children's Hospital of Pittsburgh of UPMC
Pittsburgh, Pennsylvania

Bruce L. Klein, MD
Associate Professor of Pediatrics and Emergency Medicine
The George Washington School of Medicine and Health Sciences;
Chief
Division of Transport Medicine
Children's National Medical Center
Washington, DC

Susanne Kost, MD, FAAP, FACEP
Associate Professor of Pediatrics
Thomas Jefferson University Medical College
Philadelphia, Pennsylvania
Attending Physician
Division of Emergency Medicine
Nemours/Alfred I. duPont Hospital for Children
Wilmington, Delaware

Nathan Kuppermann, MD, MPH
Professor
Department of Emergency Medicine and Pediatrics
University of California Davis School of Medicine;
Chair
Department of Emergency Medicine
University of California Davis Medical Center
Sacramento, California

Jane M. Lavelle, MD
Associate Professor
Department of Pediatrics
University of Pennsylvania;
Medical Director
Division of Emergency Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Eva Leder, MD
Clinical Fellow in Pediatrics
Department of Pediatrics
Harvard Medical School;
Clinical Fellow in Pediatrics
Division of Respiratory Diseases
Children's Hospital Boston
Boston, Massachusetts

Lois K. Lee, MD, MPH
Instructor
Department of Pediatrics
Harvard Medical School;
Associate
Department of Medicine
Children's Hospital Boston
Boston, Massachusetts

Alex V. Levin, MD, MHSc, FRCSC
Professor
Department of Ophthamology
Jefferson Medical College of Thomas Jefferson University;
Chief
Pediatric Ophtalmology and Ocular Genetics
Wills Eye Institute
Philadelphia, Pennsylvania

Jason Levy, MD
Instructor in Pediatrics
Department of Pediatrics
Harvard Medical School;
Division of Emergency Medicine
Children's Hospital Boston
Boston, Massachusetts

William J. Lewander, MD
Professor and Associate Chair of Pediatric Emergency Medicine
Department of Emergency Medicine and Pediatrics
Warren Alpert Medical School of Brown University;
Medical Director
Hasbro Pediatric Emergency Department
Hasbro Children's Hospital
Providence, Rhode Island

Lisa L. Lewis, MD
Attending Physician
Division of Emergency Medicine
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

Chris A. Liacouras, MD
Associate Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Director
Department of Pediatric Endoscopy;
Attending Physician
Department of Gastroenterology and Nutrition
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Erica L. Liebelt, MD, FACMT
Professor
Departments of Pediatrics and Emergency Medicine
University of Alabama at Birmingham School of Medicine;
Medical Director of Medication Safety
Departments of Pediatrics and Emergency Medicine
The Children's Hospital of Alabama
Birmingham, Alabama

John M. Loiselle, MD
Associate Professor
Department of Pediatrics
Jefferson Medical College
Philadelphia, Pennsylvania;
Chief
Division of Emergency Medicine
Department of Pediatrics
Alfred I. duPont Hospital for Children
Wilmington, Delaware

Stephen Ludwig, MD
Professor of Pediatrics and Emergency Medicine
University of Pennsylvania School of Medicine
Senior Advisor for Medical Education
John H. and Hortense Cassel Jensen Chair
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Dennis P. Lund, MD
Professor of Surgery & Division Chair
Department of Surgery
UW School of Medicine & Public Health;
Surgeon-in-Chief
Department of Surgery
American Family Children's Hospital
Madison, Wisconsin

James M. Madsen, MD, MPH, FCAP, FACOEM, COL, MC-FS
Adjunct Associate Professor, Preventive Medicine and Biometrics
Assistant Professor, Military and Emergency Medicine
Assistant Professor, Pathology
Uniformed Services University of the Health Sciences (USUHS)
Bethesda, Maryland;
Fellow, Medical Toxicology
Hahnemann University Hospital;
Fellow, Medical Toxicology
Division of Medical Toxicology
Department of Emergency Medicine
Drexel University College of Medicine
Philadelphia, Pennsylvania

Richard Malley, MD
Associate Professor of Pediatrics
Harvard Medical School;
Senior Associate in Medicine
Division of Infectious Diseases
Children's Hospital Boston
Boston, Massachusetts

Kenneth D. Mandl, MD, MPH
Associate Professor
Department of Pediatrics
Harvard Medical School;
Senior Associate Physician in Medicine
Department of Pediatrics
Children's Hospital Boston
Boston, Massachusetts

Shannon F. Manzi, PharmD
Adjunct Associate Professor
School of Pharmacy
Northeastern University;
Team Leader, Emergency Services
Department of Pharmacy
Children's Hospital Boston
Boston, Massachusetts

Constance M. McAneney, MD, MS
Associate Professor
Department of Pediatrics
University of Cincinnati College of Medicine;
Associate Director
Division of Emergency Medicine
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

Rakesh D. Mistry, MD, MS
Assistant Professor
Department of Pediatrics
University of Pennsylvania School of Medicine;
Attending Physician
Department of Emergency Medicine
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Matthew Mittiga, MD
Assistant Professor of Clinical Pediatrics
Department of Pediatrics
University of Cincinnati College of Medicine;
Attending Physician
Division of Emergency Medicine
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

Ameer P. Mody, MD, MPH
Assistant Professor
Department of Emergency Medicine
Division of Pediatric Emergency Medicine
Loma Linda University Medical Center
Loma Linda;
Clinical Director
Department of Pediatric Emergency Medicine
Children's Hospital of Orange Country
Orange, California

Cynthia J. Mollen, MD, MSCE
Assistant Professor
Department of Pediatrics
Division of Emergency Medicine
The University of Pennsylvania;
Attending Physician
Department of Pediatrics
Division of Emergency Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

David P. Mooney, MD
Chief, Trauma Surgery
Children's Hospital Boston;
Assistant Professor of Surgery
Harvard Medical School
Boston, Massachusetts

Fran Nadel, MD, MSCE
Associate Professor
Department of Pediatrics
University of Pennsylvania School of Medicine;
Attending Physician
Division of Emergency Medicine
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Joshua Nagler, MD
Assistant Professor
Department of Pediatrics
Harvard Medical School;
Attending Physician
Department of Emergency Medicine
Children's Hospital Boston
Boston, Massachusetts

Michael L. Nance, MD
Associate Professor
Department of Surgery
University of Pennsylvania;
Director, Pediatric Trauma
Department of Surgery
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Howard L. Needleman, DMD
Clinical Professor
Developmental Biology (Pediatric Dentistry)
Harvard School of Dental Medicine;
Senior Associate
Department of Dentistry
Children's Hospital Boston
Boston, Massachusetts

Douglas S. Nelson, MD
Professor
Department of Pediatrics
University of Utah School of Medicine;
Medical Director
Emergency Department
Primary Children's Medical Center
Salt Lake City, Utah

Linda P. Nelson, DMD, MSCD
Assistant Clinical Professor of Pediatric Dentistry
Department of Developmental Biology
Harvard School of Dental Medicine;
Senior Attending Physician
Department of Pediatric Dentistry
Children's Hospital Boston
Boston, Massachusetts

Mark I. Neuman, MD, MPH
Assistant Professor of Pediatrics
Department of Pediatrics
Harvard Medical School;
Attending Physician
Division of Emergency Medicine
Children's Hospital Boston
Boston, Massachusetts

Kevin C. Osterhoudt, MD, MS
Associate Professor
Departments of Pediatrics and Emergency Medicine
The University of Pennsylvania School of Medicine;
Medical Director
The Poison Control Center
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Bonnie L. Padwa, DMD, MD
Associate Professor
Department of Oral and Maxillofacial Surgery
Harvard Medical School;
Oral Surgeon-in-Chief
Department of Plastic and Oral Surgery
Children's Hospital Boston
Boston, Massachusetts

Jan E. Paradise, MD
Department of Pediatrics
Signature Medical Group
Brockton, Massachusetts

Ronald I. Paul, MD
Professor
Department of Pediatrics
University of Louisville;
Chief of Emergency Medicine
Emergency Department
Kosair Children's Hospital
Louisville, Kentucky

Barbara B. Pawel, MD
Clinical Associate Professor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Attending Physician
Division of Emergency Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Catherine E. Perron, MD
Assistant Clinical Professor
Department of Pediatrics
Harvard Medical School
Boston;
Attending Physician
Division of Emergency Medicine
Children's Hospital Boston
Director of Pediatric Emergency Medicine
South Shore Hospital
Weymouth, Massachusetts

Holly E. Perry, MD
Assistant Professor
Department of Emergency Medicine
Tufts University School of Medicine
Boston, Massachusetts
Attending Physician
Department of Emergency Medicine
Baystate Medical Center
Springfield, Massachusetts

Jill C. Posner, MD, MSCE
Associate Professor of Clinical Pediatrics
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Attending Physician
Emergency Department
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

William P. Potsic, MD, MMM
Professor
Department of Otorhinolaryngology, Head and Neck Surgery
University of Pennsylvania School of Medicine;
Senior Surgeon, Division of Otolaryngology
Vice Chairman for Clinical Affairs and Director of Ambulatory Surgical Services
Department of Surgery
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Carla Maria Pruden, MD, MPH
Fellow
Division of Emergency Medicine
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

Elizabeth B. Rand, MD
Division of Gastroenterology
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Mark G. Roback, MD
Professor of Pediatrics and Emergency Medicine
University of Minnesota Medical School;
Director, Division of Emergency Medicine
Department of Pediatrics
University of Minnesota Amplatz Children's Hospital
Minneapolis, Minnesota

Nancy M. Rodig, MD
Instructor in Pediatrics
Harvard Medical School;
Division of Nephrology
Children's Hospital Boston
Boston, Massachusetts

Henry D. Royal, MD
Professor of Radiology
Department of Nuclear Medicine
Mallinckrodt Institute of Radiology
St. Louis, Missouri

Richard M. Ruddy, MD
Professor of Clinical Pediatrics
Department of Pediatrics
University of Cincinnati College of Medicine;
Director
Division of Emergency Medicine
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

Richard A. Saladino, MD
Associate Professor of Pediatrics
Department of Pediatrics
University of Pittsburgh School of Medicine;
Chief
Division of Pediatric Emergency Medicine
Children's Hospital of Pittsburgh
Pittsburgh, Pennsylvania

Stephen Santora, MD
Department of Orthopedic Surgery
University of Utah School of Medicine;
Primary Children's Medical Center
Salt Lake City, Utah

Richard J. Scarfone, MD
Associate Professor
Department of Pediatrics
University of Pennsylvania School of Medicine;
Medical Director, Emergency Preparedness
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Jeff E. Schunk, MD
Professor
Department of Pediatrics
University of Utah School of Medicine;
Department of Pediatrics
Primary Children's Medical Center
Salt Lake City, Utah

Sara A. Schutzman, MD
Assistant Professor
Department of Pediatrics
Harvard medical School;
Associate in Medicine
Department of Medicine
Division of Emergency Medicine
Children's Hospital Boston
Boston, Massachusetts

Jeffrey A. Seiden, MD
Clinical Instructor
Department of Pediatrics
The University of Pennsylvania School of Medicine;
Fellow
Department of Emergency Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Steven M. Selbst, MD
Professor of Pediatrics
Department of Pediatrics
Jefferson Medical College
Philadelphia, Pennsylvania;
Vice Chair for Education
Attending Physician, Division of Emergency Medicine
Department of Pediatrics
Alfred I. duPont Hospital for Children
Wilmington, Delaware

Sonal N. Shah, MD, MPH
Instructor
Department of Pediatrics
Harvard Medical School;
Attending Physician
Division of Emergency Medicine
Children's Hospital Boston
Boston, Massachusetts

Michael Shannon, MD, MPH
Deceased
Division of Emergency Medicine
Children's Hospital Boston
Boston, Massachusetts

Kathy N. Shaw, MD, MSCE
Professor and Associate Chair
Department of Pediatrics
University of Pennsylvania School of Medicine;
Division Chief
Department of Emergency Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Stephen Shusterman, DMD
Associate Clinical Professor of Developmental Biology
Department of Pediatric Dentistry
Harvard University School of Dental Medicine;
Dentist-in-Chief, Emeritus
Children's Hospital Boston
Boston, Massachusetts

Colin A. Sieff, MD
Associate Professor
Department of Pediatrics
Harvard Medical School;
Senior Associate in Medicine
Department of Medicine
Children's Hospital Boston
Boston, Massachusetts

Benjamin K. Silverman, MD
Professor, Pediatrics
Department of Pediatric Emergency Medicine
UCLA/Harbor Hospital
UCLA School of Medicine
Torrance, California

Jonathan I. Singer, MD
Professor of Emergency Medicine and Pediatrics
Boonshoft School of Medicine
Wright State University;
Attending Physician
Children's Medical Center
Dayton, Ohio

Howard M. Snyder III, MD
Professor of Surgery in Urology
Department of Urology
University of Pennsylvania
School of Medicine;
Director of Surgical Teaching
Division of Urology
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Philip R. Spandorfer, MD, MSCE
Associate Research Director
Department of Pediatric Emergency Medicine
Children's Healthcare of Atlanta at
Scottish Rite
Atlanta, Georgia

Anne M. Stack, MD
Assistant Professor of Pediatrics
Harvard Medical School;
Clinical Chief
Division of Emergency Medicine

PREFACE

The term "innovation" has found its way into many conversations in recent times. Whether the topic is medical care, medical education, research, or advocacy—innovation is the mantra. As we bring forth the 6th edition of the *Textbook of Pediatric Emergency Medicine*, the term "innovation" is on our minds as well.

Certainly, as we look back, we note the very dramatic innovations that have taken place in our subspecialty. Prior to our first edition in 1983, there was no official subspecialty of pediatric emergency medicine either in pediatrics or in emergency medicine. Current day trainees cannot fathom that historical perspective. Many of the treatments, testing modalities, procedural techniques, technologic aids, and organized approaches to care of the ill or injured child did not exist. For example, there were no dedicated trauma centers and no attention to the elements of the emergency medical services system for children (EMSC). Certainly, there was little in the way of new knowledge being developed through research. Teaching methods were also very primitive and there were no basic training programs like Pediatric Advanced Life Support (PALS), Advanced Pediatric Life Support (APLS), or advanced fellowship training programs. We would like to think that the *Textbook of Pediatric Emergency Medicine* helped to spark the creation of a new subspecialty and stimulated the many, many innovations that have helped children across the United States and around the world. It gives a great sense of pride to think that our textbook has played some small part in the development of the now more than 1,400 board-certified Pediatric Emergency Medicine specialists, of more than 65 fellowship training programs in the United States and Canada, of the PALS and APLS courses, of the PECARN Research Network, and of the many local and regional CME courses that have helped emergency physicians and pediatricians stay abreast of the latest and most efficient therapies.

But while reflecting on the innovations of the past is satisfying, it is not as important as thinking about the innovations of the future. We hope that this 6th edition will continue to stimulate improvement. To do so, we have revised and updated each and every chapter. Suggested readings now come from the current era of publications. We have added to and expanded our table of contents by including chapters on palpitations, cystic fibrosis, travel-related emergencies, and ultrasound. In particular, there is a new chapter on practice pathways; establishing such pathways will be very important to our future, as we focus on quality and safety and gauge practice variations among our various centers. Our chapter authors formerly came from subspecialty perspectives and now they primarily are practicing PEM specialists. Many of our authors have become experts in some subfield of PEM.

In this edition we have enlisted the help of three new associate editors: Richard Bachur, Marc Gorelick, and Kathy Shaw. These individuals symbolize the new era of PEM specialists who are all fellowship trained. They represent a next generation of PEM leaders.

With this edition of the textbook, we are also offering the text on the TPEM website. This will make it possible for the owner of the text to use the book in the traditional way and also to have online access to updated information, journal articles from *Pediatric Emergency Care*, interactive practice pathways, and other helpful features. The TPEM website will transform the book into a living document always capable of growth and development.

Whether the innovation is of the past or of the future, we feel honored to be a part of this great professional movement that has helped so many children and families. Pediatric care in the Emergency Department is now more effective, safer, more pain free, and kinder and more supportive of children and families. No longer is the Emergency Department the "pit" as it was often referred to at many training centers in decades past. Now it is a great place for patient care, teaching, research, and advocacy. Many of our readers tell us—"I keep your book open in the ED." "I like it because it tells me what to do and what not to miss." "I always carry it with me on-call." Indeed, these were our motivation for writing this text in the early 1980's. Beyond all of our innovations, this feedback continues to be our constant and guiding principle.

Stephen Ludwig, MD
Philadelphia, PA

ACKNOWLEDGMENTS

As we complete the final pages of the 6th edition of *Textbook of Pediatric Emergency Medicine*, we would like to acknowledge and sincerely thank those around us who have made it all possible.

The writing and editing of this edition, like that of its predecessors, is a process that did not take place in the office between 8 a.m. and 6 p.m. Most of the work transpired during very early morning hours, nights, and weekends. When deadlines drew close, it encroached on vacations and on holidays. The precious commodity of time has been the very time that we have taken from our families. Their commitment to us and to our objectives and aspirations has been tremendous. Their donation of their own time has been magnanimous. Without their love and support our work would not have meaning. It is the treasure of our own families that drives us to help other children and their parents. To Jan and Zella, we give our love and gratitude. To Daniel, Carl, and Madeline Fleisher, to Susannah Ludwig & Mike Poppleton, Elisa Ludwig & Jesse Pires, Aubrey Ludwig and a new generation, Jack Ellis Poppleton, we offer our appreciation for sharing and understanding. Your only payback can come through the health and well-being of strangers of your generation and from those to come.

To our coeditors—our closest colleagues—we extend our greatest respect and thanks. Rich Ruddy has continued to be by our side and has been joined by a great trio of new associate editors. Unfortunately, Fred Henretig and Ben Silverman could not continue with the project as associate editors but we would not be working on the 6th edition without their dedication to the previous five versions. We also miss the contributions and positive support of the late Michael Shannon, MD. For all our closest colleagues, we hope that your level of personal satisfaction fills the void of our inability to say enough about your skills and dedication to the project.

During the years of the six editions, we have had so many associates and coworkers that it is impossible to name them all without forgetting some and thereby inadvertently offending them. They have worked by our side in the emergency department. They have taught with us in lectures, conferences, and workshops. They have served on committees, task forces, and boards. They have written and rewritten chapters based on our whims and notions. They have covered some of our nights and weekends. They have taught us, questioned us, stimulated us, and always supported us. Some remain at our sides at Children's Hospital Boston and The Children's Hospital of Philadelphia. But equally valuable are others who have moved to centers of pediatric emergency care around the United States and around the world. Those who have moved beyond the "nests" are not forgotten. We continue to appreciate and acknowledge all of you, our colleagues, both near and far.

We offer a special note of acknowledgement to our trainees. We appreciate all those we have encountered as medical students, residents, fellows, and continuing medical education students. We thank you all. It is you who have asked the questions. It is you who have longed for the information. You have held out the expectation that we provide the answers in an accurate and available form.

We have also learned from our many thousands of our patients and their parents. They too have kept the bar of expectation high, forcing us to try to meet those expectations.

In each of our offices there has been a coworker of special patience and extraordinary skills. For this edition, Cindy Chow and Carolyn Trojan have gone above and beyond the call. We have not forgotten those who were there for other editions: Rose Beato, Pat Parkinson, and Carmen Christmas. Work without these devoted colleagues would be unimaginable.

To our coworkers at Wolters Kluwer Lippincott Williams & Wilkins, we extend our thanks also. For this edition in particular, we appreciate your insight into the field of Pediatric Emergency Medicine, your consistency, and your dedication to the broad educational enterprise that we have built together over the past 20 years. In particular, we thank Julia Seto, Satvinder Kaur and Fran DeStefano who kept us moving forward.

A final note goes to our teachers, chairmen, and mentors. There are and have been many and we thank you all. To the late Jean Cortner, MD, we offer a special note of thanks. He was there when it all began. He bet on two young faculty members. I hope he knows that his bet has had adequate pay out. And for each of us, there has been a special advocate and advisor in our careers. To the late David Cornfeld and the very active David Nathan, we often think about how you would have done it. We believe that this is the highest compliment that one can offer to a mentor.

LIST OF ALGORITHMS

CHAPTER 1 ■ RESUSCITATION—PEDIATRIC BASIC AND ADVANCED LIFE SUPPORT

STEPHEN LUDWIG, MD, AND JANE M. LAVELLE, MD

The most critical and dramatic of all emergency situations is the application of cardiopulmonary resuscitation (CPR). CPR is a series of interventions aimed at restoring and supporting vital function after apparent death. The urgent and immediate goal of resuscitation is to reestablish substrate delivery to meet the metabolic needs of the myocardium, brain, and other vital organs. The overall goal is to return the child to society without morbidity related either to the underlying disease process or to the resuscitation process.

Instruction in CPR techniques has come from two widely disseminated national courses: pediatric advanced life support (PALS) and advanced pediatric life support (APLS). Both of these courses have been overwhelmingly successful in training health-care providers in the appropriate resuscitative techniques. Both courses stress the early recognition of the child who is in need of resuscitative efforts. But despite these educational efforts, the outcome of resuscitation in situations in which there has been asystolic arrest is still poor, although improving. As in many conditions we manage in pediatric patients, primary prevention, or at least early recognition, is the most successful strategy.

The paradigm for pediatric CPR has been based largely on the adult model. In 2005 the International Liaison Committee on Resuscitation (ILCOR) reviewed the science of resuscitation. There is an orderly progression through the assessment and management of the ABCs—airway, breathing, and circulation. Like its adult counterpart, pediatric CPR is best performed by a well-coordinated team of physicians, nurses, respiratory therapists, and other support personnel. Recent trends have resulted in inclusion of parents in the resuscitation room.

BACKGROUND

Incidence

There are no incidence data for pediatric resuscitations performed annually in the United States. But it is estimated that 16,000 children die annually from out-of-hospital cardiopulmonary arrests. Table 1.1 shows the childhood mortality rates and the leading causes of death in the United States for children for 2007. Table 1.2 shows the leading causes of death in the United States in different age groups and the relative rates per population. Note that there is a relatively higher mortality rate for young children. Note also that, of the causes of death listed in Table 1.1, most are potentially reversible. Trauma is the leading cause of death in childhood. Table 1.3 details the leading causes of unintentional injury by age group for the years 2000 to 2005. Special techniques of trauma management are presented in Chapters 104 and 105. We believe the techniques of basic and advanced life support, when readily available and skillfully supervised and applied, contribute to the significant reduction in childhood mortality.

Patient Characteristics

Age

In many series of CPR cases, most children were at the younger end of the pediatric age range. In a series published from The Children's Hospital of Philadelphia, the mean age was 1.98 years and the median was 5 months. The age range was between 2 weeks and 16 years (Fig. 1.1). Although pediatric CPR education generally should be tailored to the anatomic and physiologic characteristics of the young child, emergency department (ED) staff must be prepared to cope with the full spectrum of age and size.

Etiology

The most common primary diagnoses of hospitalized pediatric patients requiring resuscitation involve the respiratory system (Table 1.4). Conditions such as pneumonia, bronchiolitis, asthma, aspiration, and respiratory distress syndrome account for the largest group of diagnoses. Cardiac diagnoses and central nervous system (CNS) disorders occur in roughly equal frequency, but half as often as respiratory diagnoses. Common cardiovascular diagnoses include congenital heart disease, septic shock, and severe dehydration. CNS diagnoses include hydrocephalus (ventricular shunt failure), meningitis, seizure, and tumor.

In the ED, the physician is more likely to encounter children whose out-of-hospital cardiac arrest deaths result from trauma (20% to 30% of cases), sudden infant death syndrome (SIDS), or unknown causes. Primary cardiac etiologies are much rarer in the pediatric population. Approximately 10% of out-of-hospital cardiac arrest patients have ventricular tachycardia (VT) or ventricular fibrillation (VF). Children with congenital anomalies, chronic sequelae of prematurity, and birth trauma, and those with chronic relapsing disease are also seen in the ED, as increasing numbers of children have survived the neonatal period, transplantation, complex surgery, and cancer therapy and have been discharged from

TABLE 1.1

DEATHS AND DEATH RATES FOR 2007 AND AGE-ADJUSTED DEATH RATES AND PERCENT CHANGES IN AGE-ADJUSTED RATES FROM 2006–2007 FOR THE 15 LEADING CAUSES OF DEATH: UNITED STATES

Rank[a]	Cause of death (based on the *International Classification of Diseases, Tenth Revision*, 2nd ed., 2004)	Number	Death rate	Age-adjusted death rate (2007)
	All causes	2,424,059	803.7	760.3
1	Diseases of heart (I00–I09, I11, I13, I20–I51)	615,651	204.1	190.7
2	Malignant neoplasms (C00–C97)	560,187	185.7	177.5
3	Cerebrovascular diseases (I60–I69)	133,990	44.4	41.6
4	Chronic lower respiratory diseases (J40–J47)	129,311	42.9	41.2
5	Accidents (unintentional injuries) (V01–X59, Y85–Y86)[b]	117,075	38.8	37.8
6	Alzheimer's disease (G30)	74,944	24.8	22.8
7	Diabetes mellitus (E10–E14)	70,905	23.5	22.4
8	Influenza and pneumonia (J09–J18)[c]	52,847	17.5	16.3
9	Nephritis, nephrotic syndrome and nephrosis (N00–N07, N17–N19, N25–N27)	46,095	15.3	14.4
10	Septicemia (A40–A41)	34,851	11.6	11.0
11	Intentional self-harm (suicide) (U03, X60–X84, Y87.0)[b]	33,185	11.0	10.8
12	Chronic liver disease and cirrhosis (K70, K73–K74)	28,504	9.5	8.9
13	Essential hypertension and hypertensive renal disease (I10, I12, I15)	23,769	7.9	7.3
14	Parkinson's disease (G20–G21)	20,136	6.7	6.4
15	Assault (homicide) (U01–U02, X85–Y09, Y87.1)[b]	17,520	5.8	5.8
	All other causes	465,069	154.2	

[a]Rank based on number of deaths.
[b]For unintentional injuries, suicides, and homicides, preliminary and final date may differ because of the truncated nature of the preliminary file.
[c]New code J09 (Influenza due to identified avian influenza virus) was added to the category in 2007.
Source: Xu J, Kochanek KD, Tejada-Vera B. *Deaths: Preliminary data for 2007*. National vital statistics reports. Vol 58, No. 1. Hyattsville, MD: National Center for Health Statistics, 2009.

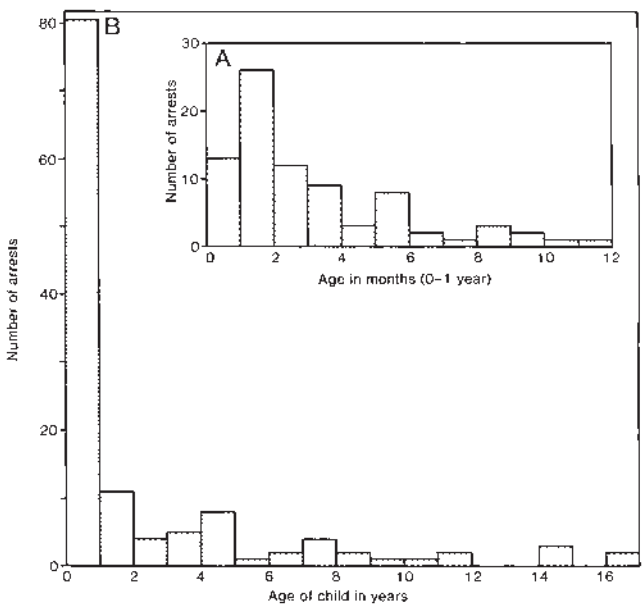

FIGURE 1.1 Histogram showing frequency of cardiac arrest as related to age in months (**A**) and years (**B**) from The Children's Hospital of Philadelphia survey.

the hospital (see Chapter 120). The broad range of diagnoses encountered in our review of resuscitation is noted in Table 1.4. This clearly differs from the adult circumstance of resuscitation, in which case most arrests are related to myocardial infarction secondary to coronary artery disease.

The PALS course teaches that the many etiologies of arrest follow one of two pathways: respiratory distress to respiratory failure to arrest or circulatory compromise to circulatory failure to arrest. In our experience, 80% of children who have arrested have followed the first pathway (Fig. 1.2). Twenty percent of patients follow the circulatory failure pathway to arrest. It is difficult in some cases to determine which mechanism was primary.

Demographics

There are no national demographic studies to identify socioeconomic, ethnic/racial, familial, or community characteristics of the pediatric patient who requires life support intervention. Such studies would be important for developing profiles of the high-risk patient population for subsequent development of surveillance or prevention programs. It is most important to study such factors on a local level, where local solutions may be implemented. Some states have begun child death review efforts that might shed light on prevention strategies.

TABLE 1.2

DEATHS AND DEATH RATES FOR THE 10 LEADING CAUSES OF DEATH IN SPECIFIED AGE GROUPS: UNITED STATES, PRELIMINARY 2007

Rank[a]	Cause of death (based on the *Intentional Classification of Diseases, Tenth Revision*, 2nd ed., 2004) and age	Number	Rate
All age groups[b]			
	All causes	2,424,059	803.7
1	Diseases of heart (I00–I09, I11–I13, I20–I51)	615,651	204.1

Treatment

Pediatric CPR presents the emergency physician with several complexities and frustrations. The first difficulty often encountered is that the patient may have received only basic life support (BLS) care (see Chapter 6). Although this is changing with enhanced development of emergency medical services for children, pediatric patients are likely to be brought to the ED without the same level of field treatment that adult patients receive routinely. Due to the fact that the overwhelming majority of cardiac/respiratory arrests occur in adults, paramedics may have limited exposure and thus a lower comfort level during pediatric arrest situations. There is controversy about how much prehospital care should be performed in other emergency situations, but cardiac arrest requires an immediate and effective response. Although paramedics are trained and equipped to provide both adult and pediatric life support, they may be forced to initiate pediatric life support at the most basic level. In other areas, paramedics are limited by laws, regulations, or negative attitudes. Absent or inadequate prehospital care leads to longer periods of hypoxia and hypoperfusion, which directly affect prognosis and CNS morbidity (see Chapter 6). Seidel documented the difference in survival rates between traumatized adults and children who require prehospital care, as well as the lack of adequate pediatric equipment in prehospital care systems. Other investigators have documented the deficiencies in emergency care provided in freestanding emergency care centers and in primary care providers' offices. Walsh-Kelly et al. documented this issue in primary care offices in one state.

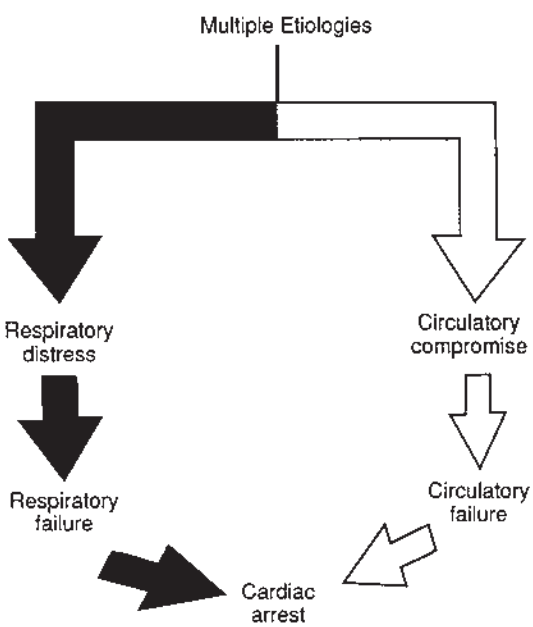

FIGURE 1.2 Pathophysiologic pathways from etiologies to cardiac arrest. (Adapted from PALS, American Heart Association.)

The wide spectrum of age and diagnoses adds additional complexity. The resuscitation team must provide an array of technical skills, drugs, and equipment. Without delay, the team must have the flexibility to adjust to the correct sizes and drug dosages for children.

Our experience shows that careful management of airway and breathing is extremely important. Because the cause of the arrest is often related to respiratory failure and because the child's myocardium is relatively resilient to hypoxemia, the rapid correction of hypoxemia may be all that is necessary to effect resuscitation.

For those patients who do not respond to airway and breathing management alone, life support will be significantly more difficult. In the ED, the lack of an immediate patient response usually predicts a need for multiple drug interventions.

One of the common frustrations when administering drugs is the establishment of an intravenous (IV) line. This technical skill continues to be the most common obstacle toward achieving successful CPR. However, the use of intraosseous (IO) technique and central line placement has been a great advance in solving the access problem. Thus far, ultrasound guidance of CVP placement has not improved outcomes but this technique may help as PEM physicians become more facile with it.

Arrhythmia management is a relatively infrequent problem in pediatric life support. The absence of atherosclerotic vascular disease makes the child's myocardium less susceptible to arrhythmia. As a result, antiarrhythmic medications and defibrillation are infrequently used. The most common cardiac rhythms to be recognized and managed are sinus bradycardia, pulseless electrical activity (PEA), and asystole. The expectations to this are those children with congenital heart disease (preoperative and postoperative) and those who have sustained direct myocardial trauma (see Chapters 84 and 118). These children may have unusual and difficult arrhythmias that require esoteric management to achieve a successful outcome.

Perhaps the greatest difficulty comes not with specific knowledge or technical skill but with attitude. Many EDs are unaccustomed to resuscitating children and will become immobilized

TABLE 1.5

when faced with the task. There is a fear that the child is somehow more fragile. In other circumstances, there is overcompensation to the point that the resuscitation of a child is prolonged beyond an optimal point for either the child or the family.

However, many pediatric emergency physicians are uncomfortable with the adult patient who may be a visitor or employee at the pediatric hospital who is brought to the ED with acute chest pain and possible myocardial infarction. Pediatric emergency physicians are encouraged to take the American Heart Association's Advanced Cardiovascular Life Support (AHA-ACLS) course.

The ED team should review the effectiveness of each individual resuscitation effort and the collective effort of the ED. This audit may be accomplished using one or more of the following approaches: (i) postresuscitation debriefing and conference; (ii) review of the videotape recording of resuscitation; (iii) monthly morbidity mortality conferences; (iv) chart audit; (v) review of resuscitation database (e.g., cross-referencing morbidity and mortality with various shifts, personnel teams, and prehospital treatment); and (vi) performance on practice codes on the use of patient simulation manikin. When the team recognizes that its efficiency and effectiveness are less than ideal (or less than they are with adult patients), specific remedial education should be undertaken.

Prognosis

The outlook for survival after CPR is very variable for pediatric patients. In our experience, if respiratory arrest is recognized rapidly and managed skillfully, immediate survival may be as high as 90%. These figures are based on a hospitalized population of children who require resuscitation within the hospital. The use of rapid response teams have improved these outcomes. For patients arriving to the ED *in extremis*, the outcome is not as good. Although this rate has been substantially improved over the last 10 years presumably due to improvements in physician education, equipment, and techniques, children who arrive in the ED in asystolic arrest still have a poor prognosis. The poorer prognosis for patients in the ED may be attributed to delayed recognition of the arrest and limited prehospital care. Several case series have documented an overall prognosis, as shown in Tables 1.5 and 1.6.

CPR research is extremely difficult to perform. Most of our information is based on retrospective studies such as those reported in Tables 1.5 and 1.6. Patient populations, characteristics, terminology, and methodology vary among studies, making it difficult to compare one investigator's work with another's. Performing a prospective study is challenged by legal and ethical considerations in enlisting patients at a time when "informed consent" is impossible. In 1997, a conference was held and a special report issued to bring uniformity to the terminology of CPR research. This important report may bring more clarity to the CPR research of the future.

CLINICAL MANIFESTATIONS

Infants and children who have experienced disruption of oxygen or glucose delivery to the brain may benefit from the various elements of basic or advanced cardiac life support. The clinical manifestations of persons requiring immediate life support are most often related to failure of oxygen delivery to the skin, brain, kidneys, and cardiovascular system. Cutaneous manifestations of oxygen deprivation include circumoral pallor, grayish hue, cyanosis, diaphoresis, mottling, and poor capillary refill. Manifestations of CNS hypoxia include irritability, confusion, delirium, seizures, and unresponsiveness. Cardiovascular manifestations include tachycardia, diaphoresis, bradycardia, and hypotension. Figure 1.3 shows the sequential development of signs and symptoms when there is failure of substrate delivery to different oxygen systems.

Good neurologic outcome	64 (67/105)	65 (154/236)	90 (19/21)

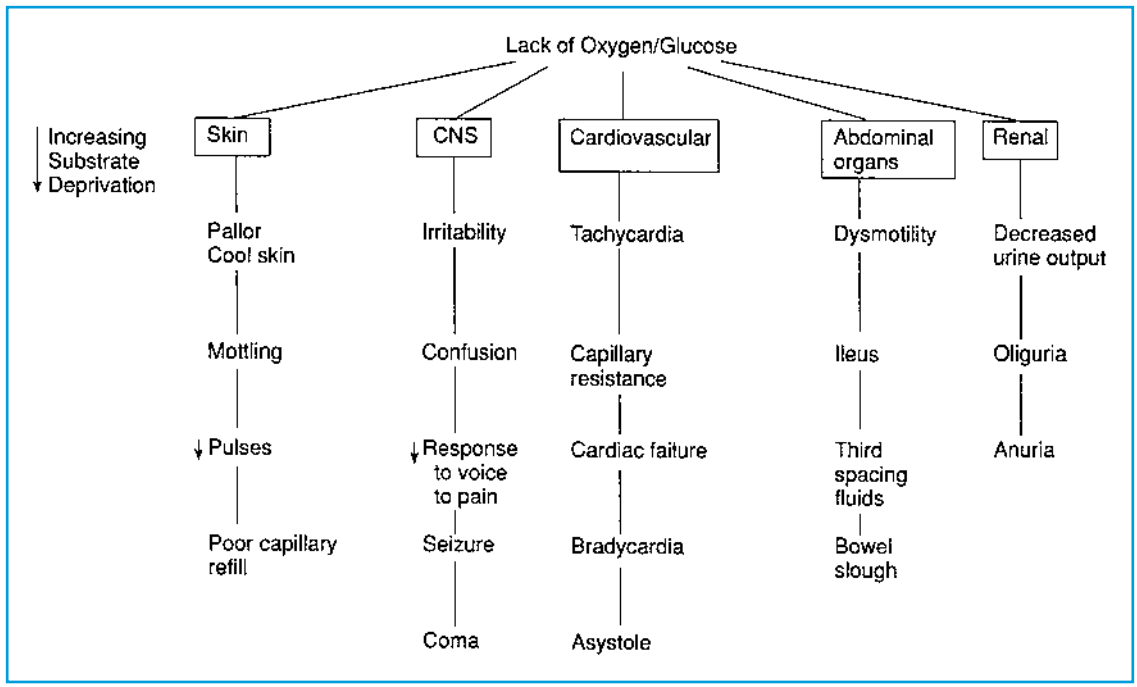

FIGURE 1.3 Signs and symptoms of lack of substrate delivery to vital organ systems. CNS, central nervous system.

Glucose is the second essential substrate necessary for maintenance of CNS integrity. Severe hypoglycemia may be just as devastating as severe hypoxemia. Clinical manifestations are often similar to hypoxemia, including seizures and coma. In addition, the effect of hypoglycemia on the cardiovascular system may lead to a secondary failure of oxygen delivery because of hypotension and related hypoperfusion.

A patient who has experienced a failure of substrate delivery to the central circulation must be resuscitated or supported until more specific diagnosis and management can be determined. It is also essential to identify patients who are *at risk* for failure of substrate delivery. This can be accomplished by a physical examination with emphasis on evaluation for airway patency, gas exchange, and cardiovascular integrity. In detecting those at risk, pulse oximetry, if available, may be useful in identifying mild degrees of hemoglobin desaturation. In addition, laboratory tests may be helpful because patients with a low partial pressure of arterial oxygen (Pa_{O_2}), pH, glucose, hemoglobin, hemoglobin saturation, or high Pa_{O_2} are at risk. Also, recognition of certain disease entities allows early intervention, careful monitoring, and prevention of cardiovascular collapse. Examples include croup, airway foreign body, meningitis, and increased intracranial pressure (ICP).

MANAGEMENT

Management Sequence

Once it is determined that a child requires life support, a sequence of evaluations and interventions should be accomplished (Fig. 1.4). Initially, CNS integrity must be evaluated: Is the patient alert? Does he or she respond to a shout or painful stimulus? If there is no response, the assumption is that the brain is no longer receiving an adequate amount of oxygen, and the three basic sequences of evaluation and management are initiated.

First, the airway is maneuvered to move the mandibular block of tissue up and off the posterior pharyngeal wall. The physician places his or her cheek next to the mouth and nose while listening and feeling for movement of air. At the same time, the physician is watching the chest for any evidence of chest wall movement. If the patient is moving air independently, the physician simply continues to support the airway and looks to provide a mechanism for delivering supplemental oxygen. If the patient is not breathing spontaneously, the work of breathing must be assumed by the care provider, using an expired air technique when a manual resuscitator is not available. As soon as advanced life support breathing technology is available, it should be used. With the recognition that the airway is open and ventilation is occurring, the third phase of oxygen delivery is evaluated by feeling for arterial pulsations. The physician should palpate the brachial, carotid, or femoral arteries. If palpable pulses are not present after a 15-second evaluation, external cardiac compression (ECC) is initiated to provide a circulation. The adequacy of ECC is initially determined by feeling for pulses. In determining whether the oxygen delivery system has been reestablished, the physician should look for improvement in the level of consciousness, a return to spontaneous breathing, or an inherent cardiac rhythm.

More specific management sequences are offered at the end of this chapter.

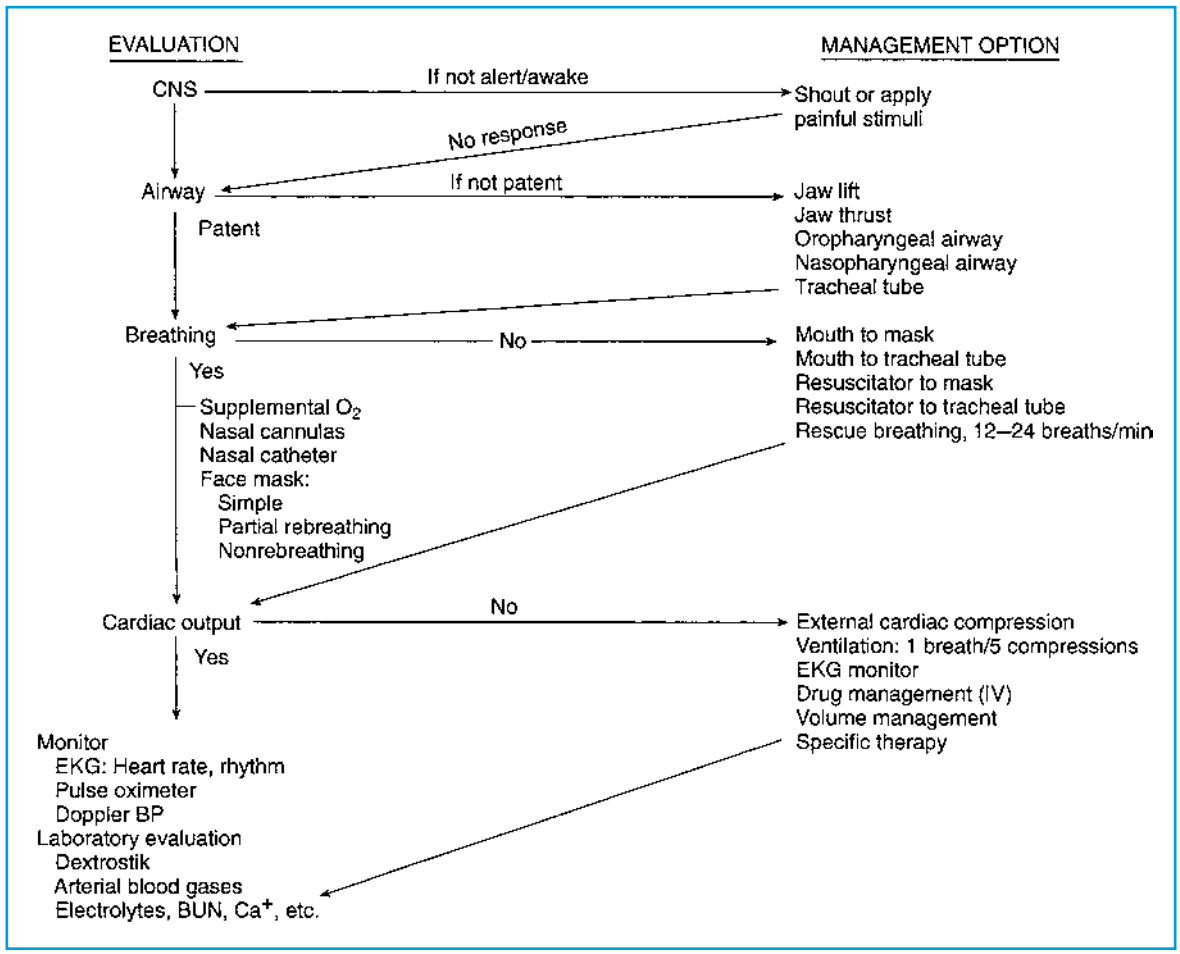

FIGURE 1.4 Management sequence for pediatric life support. CNS, central nervous system; EKG, electrocardiogram; BP, blood pressure; BUN, blood urea nitrogen.

Airway

Evaluation

The first priority in the sequential evaluation and management paradigm of basic and advanced life support is evaluation and treatment of the airway. The physician should look, listen, and feel for evidence of gas exchange. The physician should *look* at the chest to see whether there is chest wall or abdominal movement suggestive of breathing effort. The physician should *listen* over the mouth and nose for the sound of air movement. With a stethoscope, the physician should listen over the trachea and the axilla for air entry. The physician should *feel* with his or her cheek for evidence of air movement. If there is evidence of spontaneous breathing and no evidence of gas movement through the central airway, the presumptive diagnosis is that of airway obstruction.

Management

If trauma is suspected, the head and cervical spine must be stabilized during evaluation and management of the airway. Someone must be assigned to hold the head in the midline position while applying gentle cephalad traction. The most effective noninvasive maneuver for clearing an obstructed airway involves tilting the head back slightly and lifting the chin forward by pulling or pushing the mandibular block of tissue forward (Fig. 1.5). The traditional mechanism of gentle flexion of the cervical spine on the thoracic spine may open the airway, but it provides less efficient ventilation and is hazardous if cervical spine trauma has occurred.

Most airway obstruction is related to the mandibular block of tissue falling posteriorly and lying against the posterior wall of the hypopharynx. This can be relieved by physically grasping the mandibular block and pulling it forward so the lower anterior central incisors are anterior to the maxillary central incisors. The same result can be obtained by pushing the mandibular block of tissue forward. The fingers should be placed behind the angle of the jaw and the jaw pushed forward so the lower central incisors are in a plane anterior to the upper central incisors (Fig. 1.5). These noninvasive maneuvers should be attempted before any of the more invasive airway adjuncts are tried. Table 1.7 lists airway equipment and respiratory monitoring equipment that should be available for pediatric life support.

Artificial Airways

Oropharyngeal Airways. Oropharyngeal airways are used when manual manipulation of the airway cannot maintain airway patency. The purpose of the oropharyngeal airway is to stent or support the mandibular block of tissue off the posterior pharyngeal wall. There are three basic parts to this airway device (Fig. 1.6). The flange is used to prevent the airway from falling back into the mouth. It also serves as a point of fixation for adhesive tape. The bite block portion is designed to prevent approximation of the central incisors. A forceful bite may produce obstruction of an oral tracheal tube. The stent of the oropharyngeal airway is designed specifically to hold the tongue away from the posterior pharyngeal wall. Secondarily, the stent may provide an air channel or suction conduit through the mouth. The proper size oropharyngeal airway can be estimated by placing the airway alongside the face so the bite block portion is parallel to the palate. The tip of the airway should just approximate the angle of the mandible.

The primary use of the airway is in the unconscious patient. The airway should be placed by using a wooden spatula or tongue depressor to press the tongue into the floor of the mouth. The airway is then passed so the stent conforms to the contour of the tongue. If the oropharyngeal airway is not inserted properly, it may push the tongue backward into the posterior pharynx, aggravating or creating upper airway obstruction. If the airway is too long, it may touch the larynx and stimulate vomiting or laryngospasm.

Nasopharyngeal Airways. The nasopharyngeal airways stent the tongue from the posterior pharyngeal wall (Fig. 1.7). It may also be used to facilitate nasotracheal suctioning. The length of the nasopharyngeal airway is estimated by measuring the distance from the nares to the tragus of the ear. The outside diameter of the airway should not be so large that it produces sustained blanching of the skin of the ala nasae. The nasopharyngeal airway is inserted through the nares and passed along the floor of the nostril into the nasopharynx and oropharynx so it rests between the tongue and the posterior pharyngeal wall. Nasopharyngeal airways may lacerate the vascular adenoidal tissue found in the nasopharynx of children. Therefore, adenoidal

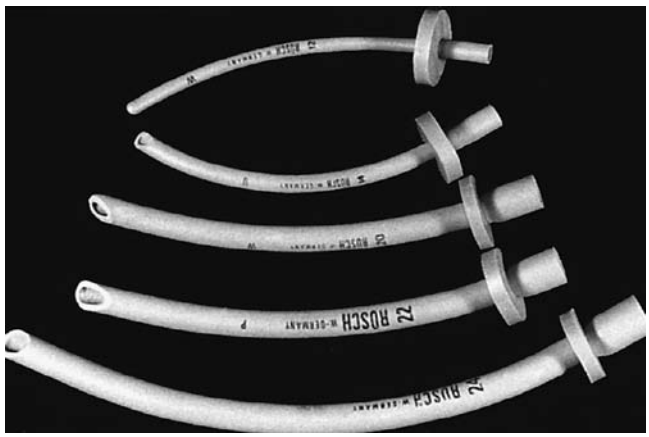

FIGURE 1.7 Nasopharyngeal airways in a variety of sizes.

hypertrophy and bleeding diatheses are relative contraindications to the use of these airways.

Endotracheal Tubes. The endotracheal (ET) tube (Fig. 1.8) supplies a stable alternate airway. ET tubes are used to (i) overcome upper airway obstruction, (ii) isolate the larynx from the pharynx, (iii) allow mechanical aspiration of secretions from the tracheal bronchial tree, and (iv) facilitate mechanical ventilation or end-expiratory pressure. The correct tube size can be approximated by using a simple formula based on the patient's age:

$$\text{Inside diameter (ID) in mm} = \frac{16 + \text{Age in years}}{4}$$

Because this is an estimate, it is prudent to have the next smaller and larger size ET tube available. Estimation of tube size based on the size of the patient's fifth finger is not accurate. Tube size may also need to be modified based on the cause of the arrest (e.g., croup). In the pediatric patient, uncuffed tubes are used and are compatible with positive-pressure ventilation. This is because in children, there is a normal narrowing of the trachea at the level of the cricoid ring (Fig. 1.9). With proper tube selection, this narrowing serves as a functional seal. In the hospital setting either cuffed or uncuffed tubes may be used for airway management. When using a cuffed tube add 0.5 mm to the tube size.

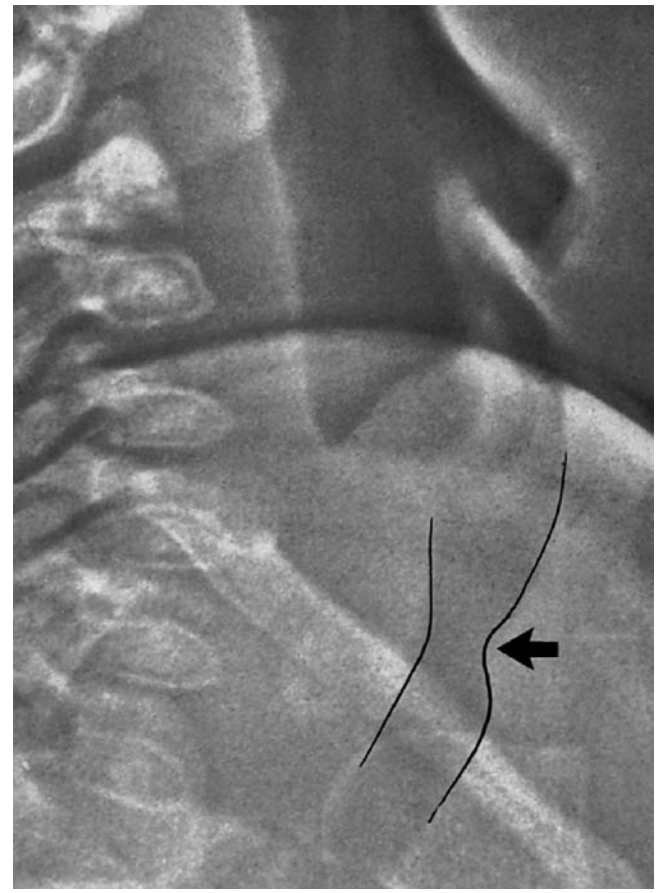

FIGURE 1.9 Lateral neck xeroradiograph showing narrowing at level of cricoid ring.

A variety of ET tubes are available. Tracheal tubes (Fig. 1.8) should be translucent to facilitate inspection of internal debris or occlusion, have a radiopaque tip marker, have the internal diameter noted proximally so it is visible after intubation, have a distal vocal cord marker so when the marker is placed at the level of the vocal cords, the tip of the tube is in a midtracheal position, have centimeter markings along the course of the tube to be used as reference points for detecting tube movement, and meet the American National Standard Institute Z-79 guidelines for tracheal tubes and cuffs. The

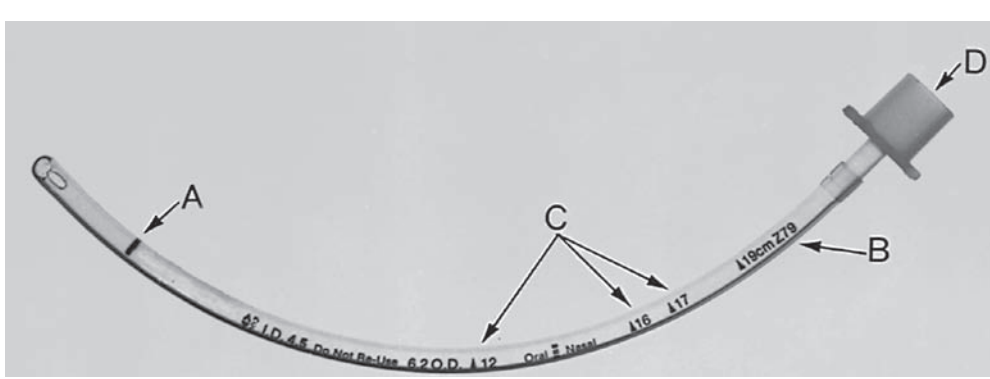

FIGURE 1.8 Oral tracheal tube: vocal cord marker (**A**), manufacturer's indication that tube meets ANSI-Z79 subcommittee standards (**B**), distance in centimeters from tip of tube (**C**), and standard 15-mm connector (**D**).

distance the tube is inserted into the trachea may be calculated by using the formula:

$$\text{Insertion distance (cm mark at teeth)} = \frac{\text{Age in years}}{2} + 12$$

Other Techniques. Alternative airway management systems, including esophageal/tracheal tubes, laryngeal mask airways, and transtracheal ventilation systems, have all been used with adult patients with varying degrees of success. All the methods have been approved by governmental agencies and professional societies, but their use in children has not been well tested or researched. There is more experience with the use of the laryngeal masks in children. This method may be used by experienced providers when ET intubation is not possible (Class 11b).

Laryngoscopy and Intubation (see Chapter 5, Procedure 8 in Chapter 135). Laryngoscopy creates a spatial plane through the mouth to the larynx through which an ET tube can be passed into the trachea. The laryngoscope consists of a blade and a handle. It is used to identify the glottis and to compress the intervening soft-tissue structures into the floor of the mouth. The three components of the laryngoscope blade are the spatula, the tip, and the flange (Fig. 1.10). The spatula may be curved or straight and is used to compress tissue. The tip of the blade is used for positioning the spatula so an optimal compression of the mandibular block or soft tissue can be achieved. The flange keeps the tongue out of the way of the intubating channel. The laryngoscope is introduced into the mouth so the tip of the blade slides down the right side of the tongue. As the tip of the blade follows the tongue posteriorly, it bumps into the anterior pillars of the tonsils. The tip is moved around the pillars of the tonsils until it bumps into the epiglottis. When using a curved spatula, the tip is placed in the vallecula, the space between the tongue and epiglottis. When using a straight spatula, the tip is placed under the epiglottis with the leading edge resting on the aryepiglottic folds. Once the tip is properly placed, the spatula is shifted from the right side of the mouth to the middle of the mouth. This left lateral movement of the spatula allows the flange to push the tongue ahead of it so the tongue eventually occupies the middle third of the mouth. The right one-third of the mouth is then available as a channel through which the tracheal tube can pass. Once the tip of the blade is properly positioned and the flange has moved the tongue into the left corner of the mouth, the full surface of the spatula is used to compress the tongue into the floor of the mouth. With compression of the soft tissue of the mouth, the glottis should be exposed and the tracheal tube can be passed. The tracheal tube should be fitted with a stylet. The purpose of the stylet is to provide some degree of curvature to the tube for those circumstances where a totally straight channel cannot be achieved. The tracheal tube is passed through the glottis so the ring marker near the tip of the tube is aligned with the vocal cords. If the tube selected is the proper size and the ring marker is placed directly at the vocal cords, the tip of the tube should be at a midtracheal position.

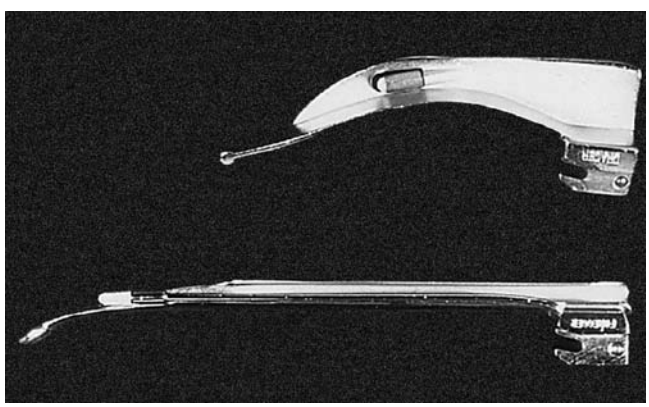

FIGURE 1.10 Laryngoscope blades—straight blade (Miller) and curved (MacIntosh).

Proper positioning of the tube is confirmed most accurately by end-tidal CO_2 monitoring (Fig. 1.11) and by auscultating for breath sounds and observing for symmetric chest movement. The child's small chest wall may transmit sounds widely and thus mislead the physician into thinking the positioning is correct. The physician should listen carefully. He or she should listen over the stomach and both axillas and look for improved color of the patient. If breath sounds are not equal or end-tidal CO_2 monitoring is not available, the tube should be withdrawn slightly and the breath sounds and chest movement reevaluated. When circumstances allow, tube position should be confirmed with an anteroposterior (AP) chest roentgenogram. On the AP film, the tip of the tracheal tube should be at a T2 to T3 vertebral level or directly between the lower edges of the medial aspect of the clavicles (Fig. 1.12).

Loss of an established airway is an unnecessary complication. The tracheal tube should be thoroughly secured with adhesive tape. The skin to which the adhesive tape is affixed should be cleansed, dried, and painted with tincture of benzoin (Fig. 1.11).

The management of airway obstruction is detailed in a separate section at the end of this chapter, and Chapter 5 covers other advanced aspects of airway management.

Breathing

Evaluation

When a clear and stable airway has been established, the patient should be reassessed. The physician should look, listen, and feel for evidence of gas exchange. In infants, adequacy of ventilation is assessed by observing free uniform expansion of the lower chest and upper abdomen. This is in contrast to older children and adolescents in whom one looks for uniform upper chest expansion as a sign of adequate ventilation. Gas exchanges should be confirmed by auscultation and by electronic monitoring of end-tidal CO_2 and pulse oximetry. First, the physician should listen over the trachea to establish quickly that gas exchange is occurring through the central airway. Then, he or she should listen to breath sounds bilaterally to assess for peripheral aeration and symmetric lung expansion.

Management

Spontaneous Ventilation. If the airway has been established and the patient is breathing spontaneously, supplemental oxygen should be administered. Although elimination of carbon dioxide is important, it is not nearly as important as delivery

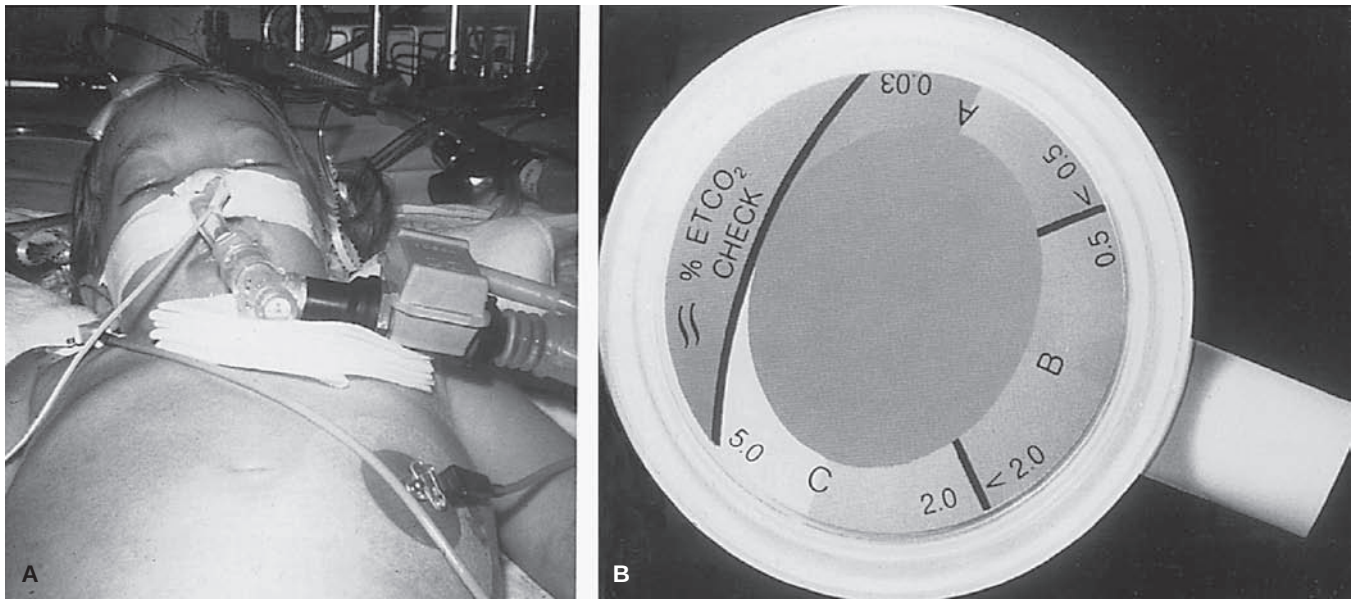

FIGURE 1.11 End-tidal CO_2 monitor. **A:** Inline on patient's endotracheal tube. **B:** Disposable-type monitor.

of oxygen. Children are quite resistant to the effects of severe hypercarbia and respiratory acidosis. However, they do not tolerate even short periods of oxygen deprivation.

Oxygen Delivery Devices. A variety of oxygen delivery devices are available for use in patients who have stable airways without ET tubes.

Nasal cannulas. Nasal cannulas have two hollow plastic prongs that arise from a flexible hollow face piece. Humidified oxygen delivered through the hollow tubing is directed to the nostrils. One hundred percent oxygen is run through a bubbler into the cannula system at a flow of 4 to 6 L per minute. Because of oropharyngeal and nasopharyngeal entrainment of air, the final oxygen delivery is usually 30% to 40%. The advantages of

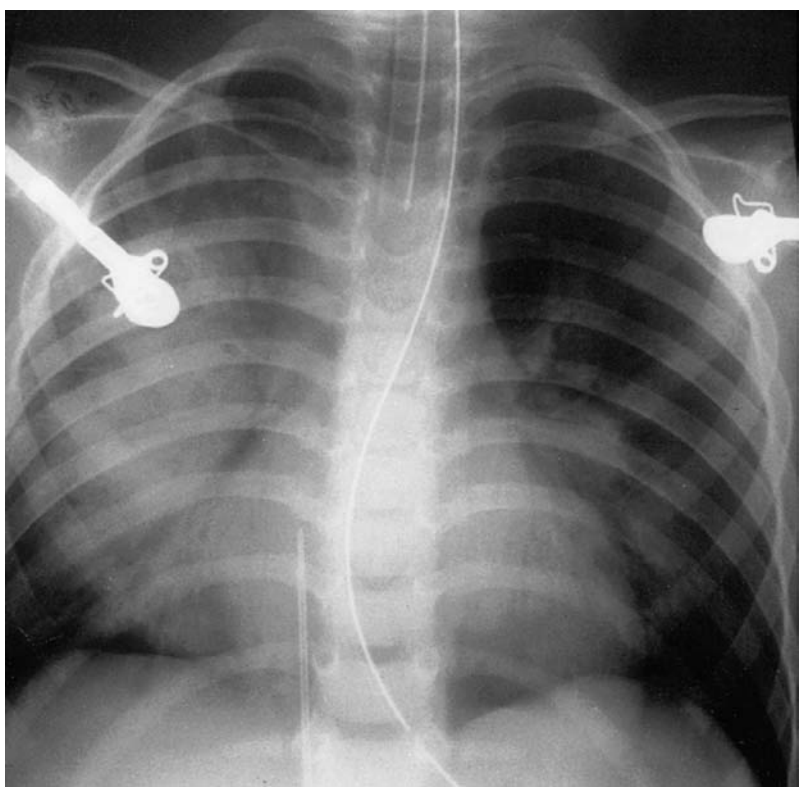

FIGURE 1.12 Chest radiograph showing proper endotracheal tube placement at T2 to T3 vertebral level.

cannulas are that they are easy to apply, lightweight, economical, and disposable. Inefficiency of the bubbler humidifier is compensated for by the fact that the normal humidification and warming systems of the upper airway are not bypassed. The use of this device presumes the patient's oxygen needs can be met with substantially less than 100% oxygen. This method of oxygen delivery is best tolerated by the older child.

Oxygen hoods. Oxygen hoods are clear plastic cylinders with removable lids (Fig. 1.13) or clear, soft, plastic tents just large enough to accommodate the infant's head. They are used for delivery of oxygen to infants and come in a variety of sizes. They usually have a gas inlet system for wide-bore tubing and a port for positioning the cylinder across the neck. Their purpose is to maintain a controlled environment for oxygen, humidity, and temperature. This can be done without producing a tight seal at the neck. Hoods are best used for newborns and infants. One can, without difficulty, deliver oxygen concentrations in the 80% to 90% range simply by increasing the oxygen flow to flood the canister. Another advantage is that the oxygen may be well humidified. Because of their potential for delivering concentrations of oxygen that may be toxic to the eyes or lungs of the infant, it is imperative to monitor both the fraction of inspired oxygen (FiO_2) and the PaO_2.

Oxygen tents. The oxygen tent provides a controlled and stable environment for humidity, temperature, and oxygen. Tents are useful for delivery of oxygen between 21% and 50%. Oxygen concentration may be variable because of a poor seal and frequent entry. Therefore, a tight fit and only necessary entry should be allowed. Tents potentially impede access to the patient, and if mist is used, the patient may be hidden in a cloud, which makes skin color difficult to evaluate.

Oxygen masks. The most often used equipment for the spontaneously breathing patient is the oxygen mask. Several types of oxygen masks can be used to offer the patient a wide range of inspired oxygen concentrations. Masks seem to be better tolerated than nasal cannula by the young child, particularly when the mask is held by a calm parent or by ED personnel. There are several mask types from which to select. As with all equipment, even masks have associated hazards. In patients prone to vomit, the mask can block the flow of vomitus and increase the risk of aspiration. The obtunded patient wearing a mask must always be observed.

SIMPLE MASKS. The simple face mask delivers a moderate concentration of oxygen. These masks are lightweight and inexpensive. They should be clear to allow observation of the child's color. They can be used in a loose-fitting fashion and are relatively comfortable. If the flow of oxygen is inadvertently disrupted, the child can breathe through side ports. A minimal flow of oxygen is necessary to flush potential dead space. This type of oxygen delivery device does not bypass the upper airway mechanisms for warming and humidification of inspired gas. The disadvantages of the simple mask lie in the fact that it is difficult to provide a known and stable FiO_2. The FiO_2 will vary with the inspiratory flow rate of the patient and with the oxygen flow into the system. The actual pharyngeal FiO_2 may be difficult to predict or measure.

PARTIAL REBREATHING MASKS. Partial rebreathing masks allow delivery of a higher oxygen concentration than simple masks do. They are also helpful in conserving oxygen. This system is a combined face mask and reservoir bag. When the flow rate into the bag is greater than the patient's minute ventilation and when the oxygen is adjusted so the bag does not collapse during inhalation, there is negligible CO_2 rebreathing. Partial rebreathing masks are usually used for midrange oxygen delivery. We use one when we are trying to maintain FiO_2 between 35% and 60%.

NONREBREATHING MASKS. Nonrebreathing masks are combined face mask and reservoir bag devices that have nonrebreathing valves incorporated into the face mask. They are useful for giving oxygen concentrations up to 100%.

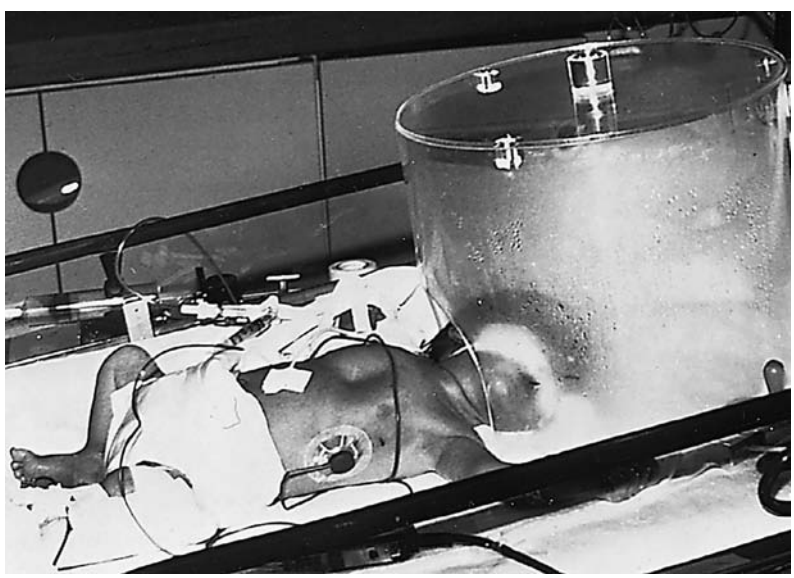

FIGURE 1.13 Infant oxygen hood. Oxygen hoods are clear plastic cylinders with removable lids or clear, soft, plastic tents just large enough to accommodate the infant's head.

Assisted Ventilation. If the airway has been established and the child is not breathing spontaneously or gas exchange is not adequate, artificial ventilation should be started. The recommended rates for rescue breathing in infants and children are 20 to 24 for an infant and 16 to 20 for an older child. Rates may need modification based on the etiology of the child's arrest (e.g., treatment of ICP may require a faster rate).

If adjuncts for mechanical ventilatory support are not available, an expired air technique may be used. Patient size, type of available airway, and trial will determine which type should be used. Because of risk of human immunodeficiency virus (HIV) transmission, mouth-to-mouth resuscitation is no longer recommended. Instead, rescue breathing should be done with a pocket mask that contains an appropriate millipore filter (Fig. 1.14). Placement of the mask over the mouth alone, over the mouth and nose, or over a tracheostomy site depends on the patient and the equipment available (Fig. 1.14). See Chapter 120 for care of the patient with tracheostomy.

Expired Air Techniques

Hand-squeezed, self-inflating resuscitators. Hand-squeezed, self-inflating resuscitators are the most commonly used resuscitators for infants and children. The elasticity of a self-inflating bag allows the bag to refill independently of gas flow. This feature makes the self-inflating bag easy to use for the inexperienced operator. Many of the self-inflating bags are equipped with a pressure-limiting pop-off valve that is usually preset at 30 to 35 cm H_2O to prevent delivery of high pressures. Self-inflating bags that are not pressure limited should have a manometer in line. For gas to flow, the bag must be squeezed. Thus, for the patient who is breathing spontaneously, the operator must time the bag compressions to the patient's efforts. These resuscitators should be adapted to deliver high concentrations of oxygen. In most cases, this involves using an oxygen reservoir adaptation with the unit (Fig. 1.15). More recent research has shown that even with an attached reservoir, only oxygen concentrations of 60% to 90% were obtainable. Units without oxygen reservoir adaptations often deliver low concentrations of supplemental oxygen and, therefore, should be avoided.

The resuscitator may be used with a mask. When selecting a family of mask sizes, select a mask type that seals a variety of facial contours. Also, the body of the mask should be sufficiently transparent so vomitus can be recognized easily through the mask. Masks with a pneumatic cuff design allow for the easiest and most efficient fit that avoids air leaks around the mask. Resuscitators, masks, and ET tubes should be standardized so any resuscitator can connect with any mask or ET tube. A recent study by Davidovic demonstrated the value of two-person technique.

Anesthesia bags. Anesthesia bags depend on an adequate gas flow to maintain a compressible unit that propels gas toward the patient (Fig. 1.16). An exit port must also be present so the bag does not become a carbon dioxide reservoir. When used

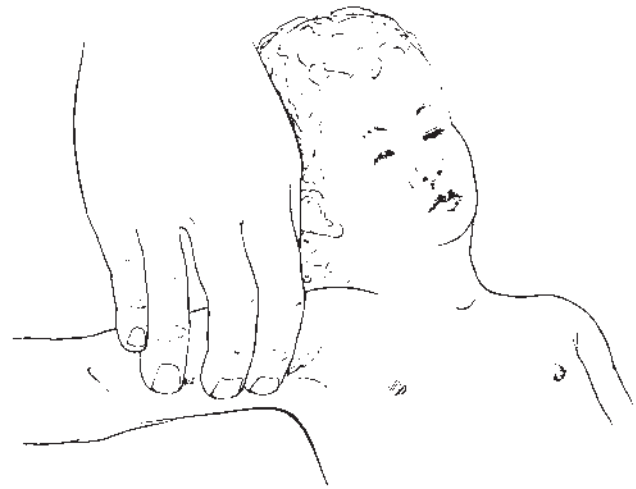

FIGURE 1.18 Palpation of brachial pulse on medial aspect of the upper arm in the subbicep groove.

with an oxygen blender, any desired concentration of oxygen may be provided for the patient because this system directly delivers the gas flowing into it. When used correctly, this device allows 100% oxygen to be delivered as well as maintaining end-expiratory pressure. However, the major disadvantage of this type of bag is that considerable experience is needed to use it effectively, which has prompted some to recommend the use of the self-inflating bag as the primary mode of ventilation. One must be able to accurately judge the rate of gas flow into the bag and the rate of gas escape from the exit port so underfilling or overfilling does not occur. If the bag is removed from a leak-tight patient application, it promptly deflates and one must wait for the reservoir to refill. Overfilling the bag is dangerous because high pressures can be transmitted to the lung and stomach (Fig. 1.17).

FIGURE 1.17 Anesthesia bag in use.

Mechanical ventilators. The ED should also be equipped with a mechanical ventilator. If the resuscitation is successful, this is important for maintenance of ventilation while the patient awaits transfer or transport to a critical care unit. A mechanical ventilator is also crucial in the event of multiple arrest victims in order to free personnel for other vital tasks.

Circulation

As with the other components of CPR, the circulation must be first assessed and then managed.

Evaluation

Once the airway has been opened and gas exchange ensured, the physician must evaluate the effectiveness of circulation by (i) observing skin and mucous membrane color, and (ii) palpating a peripheral pulse and checking capillary refill. If the patient's color is ashen or cyanotic, the circulation will need to be treated.

The palpation of a peripheral pulse and assessment of capillary refill is mandatory. Often, ineffective cardiac activity can be palpated over the child's thin chest wall. Thus, the presence of an apical pulse may not be meaningful. The palpation of a strong femoral or brachial pulse (Fig. 1.18) indicates presumptively that the cardiac output is adequate. Capillary refill should be assessed repeatedly (Fig. 1.19).

Most modern defibrillators have a "quick-look" paddle configuration that allows a rapid evaluation of cardiac rhythm to be made by placing the defibrillation paddles on the chest and using them as monitoring electrodes.

The resuscitation team will also find it helpful to have continuous blood pressure monitoring. Blood pressure measurements will help quantify the effectiveness of cardiac function. An ultrasound or portable Doppler device may be necessary to detect systolic pressure at low levels in small infants (Fig. 1.20).

As soon as possible, the team will also require continuous electrocardiogram (EKG) monitoring to assess the development of arrhythmia as the resuscitation proceeds.

FIGURE 1.19 Delayed capillary refill.

FIGURE 1.20 Portable Doppler device for determining blood pressure during resuscitation.

Management

Management may be divided into five phases: (i) cardiac compression, (ii) establishment of an intravascular route, (iii) use of primary drugs, (iv) use of secondary drugs, and (v) defibrillation.

External Cardiac Compression

The 2005 AHA Guidelines emphasize the importance of well-executed external cardiac chest compressions (CPR) as primary treatment for cardiopulmonary arrest. In the newly arrested patients, CPR should be provided immediately to establish a minimum of circulation to the brain and heart as this is associated with improvements in both survival and outcome. Importantly, several recent published reports have clearly shown that the quality of CPR administered in both out-of-hospital and in-hospital settings does not meet the standards set forth by the AHA.

In the newly arrested child, vigorous, high-quality chest compressions generate approximately one-third of the normal cardiac output. This generates a coronary artery perfusion pressure (CAPP) of approximately 10 mm Hg. This decreases over time as the myocardium becomes damaged by hypoxemia and metabolic derangements. It is estimated that CAPPs of 25 to 30 mm Hg are needed to produce forward flow through the aorta in order to reperfuse the myocardium and "jump start" the heart into a perfusing rhythm to provide sufficient blood flow to all vital organs.

The mechanism by which blood moves during CPR continues to be the subject of investigation. Techniques that augment this forward flow could potentially improve the rates of successful return of spontaneous circulation (ROSC) and neurologic survival. "Direct compression" and "thoracic pump" describe the current mechanisms that explain how blood flows during CPR. In the "direct compression" model, the heart is squeezed between the sternum and the posterior vertebrae. During compression, "systole," blood moves through the AV valves and the aorta. During relaxation, "diastole," blood fills the myocardium in preparation for the next systole. In the "thoracic pump" model, the heart is viewed as a conduit. During compression, venous valves at the thoracic inlet close preventing retrograde flow, the venous side of the circulation is compressed, and blood moves forward through the AV valves and the aorta. During relaxation, negative intrathoracic pressures suck blood into the pulmonary bed and heart in preparation for the next systole. In practice, both methods probably contribute to blood flow. Because of the compliance and elasticity of the chest wall and the intrathoracic structures, direct compression may play a larger role in the pediatric patient. Additionally, chest compressions may provide greater cardiac output because of these characteristics.

Based on the previous data, investigators have explored different techniques to increase blood flow through the aorta and the coronary arteries. These have included high-frequency compression rates (more than 100 compressions per minute), interposed abdominal compression CPR (IAC-CPR), active compression-decompression CPR (ACD-CPR), vest CPR, open chest massage, simultaneous ventilation-compression CPR, and use of automated feedback devices that monitor the quality of CPR. To date, compression rates and automated performance feedback have been the most promising.

Compression rates clearly affect the cardiac output. During CPR, CAPP rises during consecutive chest compressions and falls during pauses in compressions and with positive-pressure ventilation. Compression rates of more than 100 have been shown to improve cardiac output, CAPP, and 24-hour survival when compared with rates less than 80. Although the optimal compression rate remains unknown, compression rate of 100 per minute is now recommended for all ages beyond the neonatal period. There is some evidence in adults that compression-only CPR (no ventilation) produces similar survival rates. Because of the etiology of pediatric arrest, in addition to higher metabolic rate and lower functional residual capacity, this practice is not recommended for children.

The optimal duty cycle also remains unknown. To date, a duty cycle of 50% (compression:relaxation, 1:1) is believed to provide the highest flow rates. Leaning or incomplete decompression of the chest during the relaxation phase occurs commonly and may affect the cardiac output generated by CPR by decreasing venous return.

Other techniques such as IAC-CPR (interposed-abdominal compression CPR) and mechanical devices developed for adults and used in adult resuscitation such as ACD (active compression-decompression), vest CPR, mechanical CPR, simultaneous ventilation-compression CPR, and phased thoracic-abdominal compression-decompression CPR are not recommended for use in pediatric arrest because of lack of experience and data.

Open cardiac massage provides better blood flow to vital organs in animals and in adults when compared with CPR. Because of the compliance of the thoracic structures in children, this technique may not offer any benefit. There is inadequate data to recommend its use in the resuscitation of children regardless of the etiology of the arrest.

It is imperative that the provider assess the efficacy of CPR. Evaluating for the presence of the femoral artery pulse with compressions is helpful. Although this pulse may represent venous rather than arterial pulsations, it still provides important, easily accessible information to the provider. Continuous end-tidal CO_2 monitoring can also serve as a marker of blood flow. Exhaled CO_2 rises as pulmonary blood flow and cardiac output increases. Weil and others have worked on a method of measuring CO_2 by means of a sublingual probe. This technique offers promise for monitoring cardiac output and may be useful as a predictor of terminal hypoperfusion. One of the most innovative additions to CPR has been the development of monitors with accelerometers and force sensors that provide real-time feedback to the provider. A puck is placed on the child's chest and feedback including compression rate and force is displayed on the defibrillator screen. Verbal feedback is also provided. Currently, this technology is available for use in children older than 8 years of age.

Over the past decade there have been several reports that have demonstrated the delivery of suboptimal CPR by practitioners both in the out-of-hospital and in-hospital setting. It is now known that high-quality CPR is linked to both improved rates of ROSC, to survival to hospital admission and perhaps to better neurologic outcome. Wik et al. published a case series of paramedic practice for out-of-hospital cardiac arrest and found that chest compressions were delivered only half of the available time and were compliant with AHA guidelines only 28% of the time. Ashton et al. showed that the rate and depth of compressions decreased significantly after 2 minutes even though rescuers denied feeling fatigue. Kramer-Johansen et al. compared quality of CPR and outcome in out-of-hospital cardiac arrest in adult patients with and without automated real-time verbal and visual feedback provided by a prototype defibrillator. Compression depth, the percentage of compressions with adequate depth, and the compression rate increased when feedback was given. Increased compression depth was associated with increased survival to hospital admission. Abella et al. found that higher compression rates (greater than 80) resulted in higher rates of ROSC. Edelson et al. demonstrated that longer preshock pauses were associated with defibrillation failure. Thus, CPR quality is a critical determinant of survival after CPR. Monitoring and feedback defibrillators can enhance this quality. The AHA 2005 Guidelines recommend the following: Push hard and fast (100 per minute, IIa), ensure full chest recoil (IIb), minimize interruptions in chest compressions, avoid hyperventilation, and change rescuers every 2 minutes in less than 5 seconds. The proper technique for providing CPR is essential and all health-care emergency medicine should be familiar with this technique. The rescuer should compress the lower half of the sternum, avoiding the xiphoid process, one-third to one-half the depth of the chest. The child should be supine on a firm surface that is wider than the patient's torso and extends from the shoulders to the waist. For infants (younger than 1 year), the Thaler or two thumb-encircling hands technique is the preferred method for health-care providers (Figs. 1.21 and 1.22). The recommended rate of compressions for all ages except neonates is 100 compressions per minute. The compression and relaxation phases of each compression should be equal. Once the airway has been secured, coordination of compressions and rescue breathing is no longer necessary (Table 1.8).

Intravenous Access

The site used for vascular access depends on the patient's condition and the provider's experience. The most common sites used in the ill pediatric patient include peripheral venous access, central venous access via the femoral vein, and IO access.

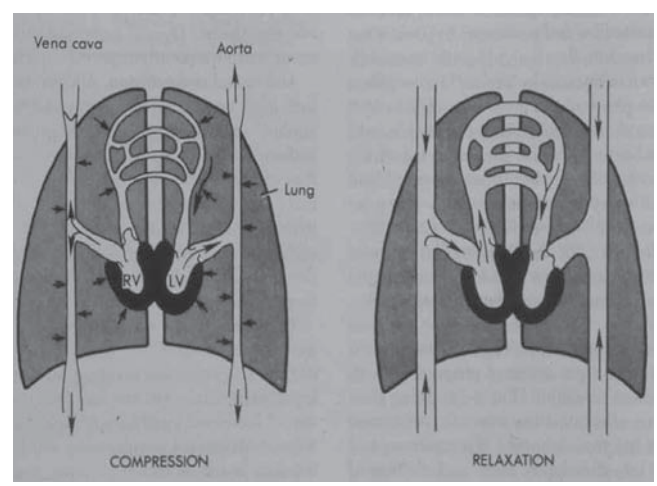

FIGURE 1.21 Movement during external cardiac compression. RV, right ventricle; LV, left ventricle.

FIGURE 1.22 External cardiac compression.

In the arrested patient, access is challenging and time-consuming. IO access is the first and best choice for this scenario because this procedure is simple and can be accomplished quickly (30 to 60 seconds). This route can be safely used for all drugs and fluids needed during resuscitation. The onset of action of drugs administered via this route is comparable to that of drugs administered into the central circulation. Manual pressure or use of a pressure bag is necessary when giving fluids to restore the vascular volume in order to overcome the resistance of the marrow venous plexus. The preferred site in children is the medial surface of the tibia 1 to 3 cm below the tibial tuberosity (Fig. 1.23). Alternative sites include the anterior surface of the distal femur, the medial malleolus, and the anterior iliac spine. There are several types of rigid, styletted needles commercially available for this procedure in infants and children. There are also some new IO devices available on the market now. The bone injection gun (BIG) is a spring-loaded device that can be used in adolescents/adults and can effectively penetrate the thicker bony cortex. The EZ-IO® (Vidacare, San Antonio, TX) a battery-powered hand-held drill, is available for use in pediatric patients. There is no data currently that supports the use of these new needles over those currently used widely. Contraindications to IO placement include recently fractured bone, osteogenesis imperfecta, and osteopetrosis. Complications are rare and have been reported in less than 1% of patients. These have included extravasation, epiphyseal injury, fracture, compartment syndrome, fat embolism, and thrombosis (see Section VII for description of procedure). Peripheral venous access provides an adequate route for resuscitation as long as it is achieved quickly. Veins of the hands, forearm, and ankle are most commonly used (see Section VII for

TABLE 1.9

SAMPLE PROTOCOL FOR INTRAVENOUS ACCESS

1. First 1.5 min
   Peripheral IV catheter, two sites
2. 1.5–5 min
   a. If intubated: give drugs via endotracheal tube (including epinephrine/atropine/lidocaine)
   b. If not intubated: intraosseous—one site
   Continued peripheral IV—one site
3. Longer than 5 min
   a. Femoral vein percutaneous
   b. External/internal jugular percutaneous
   c. Subclavian vein percutaneous
   d. Saphenous vein cutdown

Adapted from Kanter RK, Zimmerman JJ, Strauss RH, et al. Pediatric emergency intravenous access. *Am J Dis Child* 1986;140:144.

description of this procedure). There should be an established protocol for the sequence of IV access steps (Table 1.9).

The femoral vein is the easiest central vein to access in the critically ill child when many interventions are ongoing simultaneously. There are also less complications associated with this route. Central venous access provides a more secure route, allows the capability of monitoring central venous pressure, and allows for blood sampling. In adults, this route has been shown to provide more rapid onset of action and higher peak drug levels that theoretically could affect outcome. This has not been shown to be the case in the pediatric patient. In the child with uncompensated shock or arrest, this type of access may follow IO access through which initial resuscitation can occur rapidly.

The femoral vein lies medial to the femoral artery. If there is no pulse present, the artery can be found by locating the midpoint between the anterior iliac spine and the pubic symphysis. The right femoral vein is easier to access and is less likely to enter the posterior lumbar venous plexus. The Seldinger technique is preferred for catheter placement. By placing a small towel underneath the child's buttocks and slightly externally rotating the hip, the inguinal area is flattened, making venous entry easier. The needle should enter at a 45-degree angle, approximately one finger breadth below the inguinal ligament. Complications associated with this procedure include thrombosis and suppurative thrombophlebitis. See Procedure Section VII for description of this procedure and see Table 1.10 for catheter sizes.

Drugs of Resuscitation

Estimating Body Weight

Appropriate drug doses, fluid therapy, and equipment size vary depending on the size of the child in need of resuscitation. Recommended drug doses are based on kilograms of body weight. The 50th percentile weight from a standardized growth curve can be used if based on the child's known/estimated age. The "Broselow tape" allows a simple, accurate method of estimating the weight and drug doses based on the measured height. The tape is placed alongside the child in supine position and has appropriate drug dosages and equipment sizes printed on it at intervals (Fig. 1.24). Standard drugs and drug dosages are shown in Table 1.11.

Endotracheal Route of Administration

The pulmonary bed provides a surface for absorption of lipid-soluble drugs and can be used before vascular access is available. Currently, lidocaine, epinephrine, atropine, and naloxone (LEAN) can be used via this route. The optimal drug dosage remains unknown because absorption likely varies widely because of its dependence on pulmonary blood flow. Animal studies have shown that standard doses of epinephrine (0.01 mg per kg) achieve serum levels that are approximately 10% of those achieved by the intravascular route. Thus, the recommended dose of epinephrine to be given via the ET tube is 0.1 mg

TABLE 1.10

CATHETER SIZE AND LENGTH FOR FEMORAL CENTRAL VENOUS ACCESS

Age	Average weight (kg)	Average height (cm)	Average catheter length (cm)
1 mo	4.2	55	15.7
3 mo	5.8	61	17.3
6 mo	7.8	68	19.1
9 mo	9.2	72	20.1
1 yr	10.2	76	21.1
1.5 yr	11.5	83	22.9
2 yr	12.8	88	24.2
4 yr	16.5	103	28.1
6 yr	20.5	116	31.4
8 yr	26	127	34.2
10 yr	31	137	36.8
12 yr	39	149	39.9
14 yr	50	165	44.0
16 yr	62.5	174	46.3

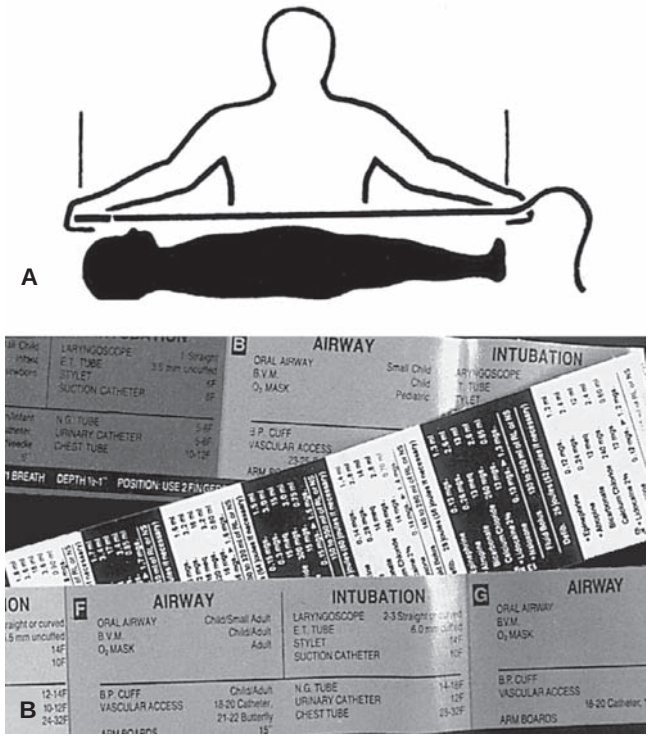

FIGURE 1.24 Broselow tape for determining drug dosage schedule based on patient length. **A:** Placement of tape. **B:** Equipment size and drug dosage schedule printed on tape.

per kg, 10 times the recommended IV dose. Larger doses of the LEAN drugs are also recommended ranging from 2 – 10x the IV dose. All drugs should be diluted up to 5 mL of saline and given with five manual ventilations to distribute it across the alveolar surface (Table 1.11).

Epinephrine. Epinephrine is the primary drug for pediatric cardiopulmonary arrest because the rhythms most commonly encountered are asystole or bradycardia (Table 1.11). Epinephrine is an endogenous catecholamine with potent alpha- and beta-adrenergic properties. At higher doses, the alpha effects are most prominent and result in intense vasoconstriction. This results in improved aortic diastolic pressure, which is associated with improved outcomes. It is also associated with increased coronary artery and cerebral blood flow. Epinephrine also augments myocardial contraction and increases the intensity of fine ventricular fibrillation that yields higher rates of successful defibrillation.

There has been much debate over the optimal dose of epinephrine. In the original AHA guidelines, the recommended epinephrine dose for adults was 1 mg to be repeated every 3 to 5 minutes. Subsequent to this, in 1986, using an animal model, Brown demonstrated significant increases in blood flow to vital organs with increasing epinephrine doses. At higher doses, however, significant side effects such as hypertension, malignant dysrhythmias, and endocardial ischemia became more prominent.

Multiple studies in both adult and pediatric populations have failed to show improved outcomes with high-dose epinephrine. In fact, a recent prospective study of children with in-hospital cardiac arrest showed that the use of high-dose epinephrine was associated with worse survival. Another study of out-of-hospital arrest in pediatric patients did not show any benefit with high dose over standard dose epinephrine.

After a decade of experience, the new guidelines recommend standard dose epinephrine (0.01 mg per kg) for initial and subsequent IV doses for unresponsive or refractory pediatric asystolic arrest. High-dose epinephrine may be considered for patients with calcium channel blocker toxicity. It is important to be familiar with the two available concentrations for epinephrine dosing to avoid error. Once ROSC has occurred, an infusion of epinephrine can be titrated to achieve the desired effects. Epinephrine should be given in a secure IV or IO to avoid ischemia-associated infiltration. Infusions are best given via a central catheter. It should not be mixed with bicarbonate solutions to prevent drug inactivation. Side effects include hypertension, tachycardia, widened pulse pressure, malignant dysrhythmias, and excessive vasoconstriction.

TABLE 1.11

DRUGS AND DOSES OF RESUSCITATION

Drug	Dose (IV/IO)
Adenosine	0.1 mg/kg, max 6 mg Repeat 0.2 mg/kg, max 12 mg
Atropine	0.02 mg/kg, min 0.1 mg ETT: 0.03 mg/kg Maximum single dose Child 0.5 mg Adolescent 1 mg
Amiodarone	5 mg/kg, repeat to 15 mg/kg, max 300 mg
Calcium chloride (10%)	20 mg/kg or 0.2 mL/kg
Dobutamine	2–20 μg/kg/min infusion
Dopamine	2–20 μg/kg/min infusion
Epinephrine	IV: Use 1:10,000 0.01 mg/kg or 0.1 mL/kg, max 1 mg 0.1–1 μg/kg/min infusion ETT: Use 1:1000 0.1 mg/kg or 0.1 mL/kg, max 10 mg
Glucose 10%	0.5–1 g/kg, 5–10 mL/kg
Lidocaine	1 mg/kg load, max 100 mg 20–50 μg/kg/min ETT: 2–3 mg
Magnesium sulfate	25–50 mg/kg, max 2 g
Naloxone	<5 yr or <20 kg 0.1 mg/kg >5 yr or >20 kg 2 mg IV
Procainamide	15 mg/kg over 30–60 min
Sodium bicarbonate	1 mEq/kg (after adequate ventilation)
Vasopressin	40 IU

IV, intravenous; IO, intraosseous.
Adapted from The American Heart Association 2005 Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care.

Vasopressin. In an effort to improve rates of ROSC, investigators have looked at a number of other vasoconstrictors, including vasopressin, norepinephrine, phenylephrine, and endothelin-1. To date, none of these has replaced epinephrine. Vasopressin is an endogenous hormone that is found in high levels in patients undergoing CPR. Levels of this hormone are higher in patients that survive the event. Vasopressin acts at V_1 receptors causing (i) intense vasoconstriction in skeletal muscle, intestine, and skin; (ii) slightly less vasoconstriction in coronary and renal vessels; and (iii) vasodilatation in cerebral vessels.

There have been several adult studies comparing vasopressin and epinephrine. None of these to date have shown clear benefit of using vasopressin over epinephrine. A few pediatric case series have appeared in the literature, these do not provide clear evidence for its use in children (2005 AHA guidelines indeterminate).

Sodium Bicarbonate. Initial AHA guidelines recommended the use of sodium bicarbonate to treat the profound acidosis associated with low or no-flow states. Subsequent to these earlier recommendations, investigations reported potential deleterious effects of its use resulting in a change in the 1992 guidelines, which stated that the use of sodium bicarbonate may be considered in the scenario of prolonged cardiopulmonary arrest. Its use remains controversial in the literature.

Adequate ventilation and restoration of pulmonary blood flow and tissue perfusion is the foundation of acid–base balance during resuscitation. This treats the respiratory component of acidosis. It is known that significant acidosis develops within minutes of cardiopulmonary arrest. Controversy exists regarding the treatment of the metabolic component. During arrest, a substantial gradient exists between central venous pH, arterial pH, and P_{CO_2}. These differences resolve once circulation is restored. Buffering with the administration of sodium bicarbonate occurs via production of CO_2, which must then be removed through ventilation. This results in an increase in intracellular acidosis when pulmonary blood flow is low or absent. Other potential detrimental effects of sodium bicarbonate therapy include hyperosmolarity, hypernatremia, leftward shift of the oxyhemoglobin dissociation curve, increased lactate production, catecholamine inactivation, and reduction of coronary artery perfusion pressure.

Several retrospective studies have failed to demonstrate improved outcomes with the use of sodium bicarbonate. However, retrospective reviews lack accurate down times, initial pH measurements, and presenting rhythms among other important data points. A single, double-blinded, randomized trial of adult out-of-hospital arrest ($n = 502$, asystole, ventricular fibrillation) comparing a mixture of bicarbonate-trometamol-phosphate with normal saline failed to show increased rates of hospital admission or survival to discharge. However, in this study, the mean response time was 5.8 minutes, 48% of cases had bystander CPR, and 44% had VF, all factors suggesting early intervention and effective resuscitation.

Animal studies have shown conflicting results. Some have shown no benefit, whereas others have demonstrated an improved resuscitation success with reduced neurologic deficit. The experimental model used may differ considerably from real clinical scenarios. In most, the arrest was less than or equal to 5 minutes and buffer is administered early in the resuscitation effort.

Current guidelines recommend that the use of sodium bicarbonate may be considered in prolonged pediatric arrest only after adequate ventilation is ensured and epinephrine and chest compressions have been instituted (Class IIa). The initial recommended dose is 1 mEq per kg. Subsequent doses should be determined by measured acidosis, or empiric 0.5 to 1 mEq per kg can be considered after every 10 minutes of persistent arrest. Half-strength (0.5 mEq per mL) solution should be used in neonates. Sodium bicarbonate is also recommended for the treatment of hyperkalemia, hypermagnesemia, tricyclic antidepressant overdose, and sodium channel blocker poisoning.

Atropine. Atropine is a parasympatholytic drug, which has peripheral and central effects. Peripherally, it is vagolytic and accelerates sinus and atrial pacemakers and increases conduction through the AV node. Centrally, it stimulates the medullary vagal nucleus, which causes bradycardia. This effect occurs when the drug is administered in low doses.

Atropine is recommended for the treatment of bradycardia that is known to be vagally mediated (such as bradycardia associated with ET intubation). It may be used in children with symptomatic bradycardia when adequate oxygenation and ventilation is not successful. Practitioners should prepare for transcutaneous pacing. The recommended dose is 0.02 mg per kg, with a minimum dose of 0.1 mg, and a maximum dose of 0.5 mg in a child and 1.0 mg in adolescents. The dose may be repeated every 5 minutes to a maximum of 1 mg in a child and 2 mg in an adolescent.

Glucose. Glucose is a major substrate for both the brain and the myocardium. Because of high metabolic rate and decreased glycogen stores, children have high requirements for glucose. Losek performed a cross-sectional study of 49 consecutive children presenting to a pediatric ED requiring resuscitative interventions for altered mental status, seizures, respiratory and cardiac failure, and cardiopulmonary arrest. Eighteen percent of these patients were hypoglycemic. Current data remains controversial as to whether or not hyperglycemia affects neurologic outcome. Therefore, it is currently recommended that glucose be monitored in the post-arrested patient. Hypoglycemia should be treated (Class IIb). Continuous infusions are most physiologic. The recommended dose is 0.5 to 1 g per kg, which can be given as 5 to 10 mL per kg of D_{10}. It may also be important to treat significant hyperglycemia.

Adenosine. Adenosine is a short-acting purine nucleoside that slows conduction through the AV node and blocks reentry circuits by direct action on AV nodal adenosine receptors. It depresses the automaticity of primary pacemaker cells. It is metabolized by adenosine deaminase, which is present on the surface of red blood cells, and thus has an extremely short half-life. It has proven to be very effective in the treatment of supraventricular tachycardia (SVT) in children. It is the treatment of choice for stable and unstable SVT (Class IIa). The recommended dose is 0.1 mg per kg, with a maximum of 6 mg. A second dose of 0.2 mg per kg, with a maximum of 12 mg may be given. Adenosine must be administered via rapid IV bolus during continuous EKG monitoring. A two-syringe method with stopcock is recommended; one syringe contains the drug, and the second contains a 5-mL saline flush. Its effects are seen within 15 to 30 seconds. Transient side effects

include facial flushing, chest pain, anxiety, and dyspnea. However, because of its extremely short half-life, these effects disappear within 10 to 20 seconds. Other more serious side effects include bronchospasm or apnea, accelerated ventricular rhythm, wide complex tachycardia, and brief asystole. These have been reported rarely, probably because of the short half-life of the drug. However, they emphasize the need for appropriate equipment and personnel to be available during administration of this medication.

Amiodarone. Amiodarone is a class III antiarrhythmic. Potassium channels are blocked, which prolongs phase 3 of the cardiac action potential and thus prolongs the refractory period. This is the principal effect of the drug. Amiodarone also has properties of sodium channel and beta-adrenoreceptor blockade. Amiodarone is used for the treatment of adult patients with shock refractory VT and VF/VT. The trial amiodarone versus lidocaine in prehospital VF (ALIVE) was a prospective, double-blinded, randomized, controlled trial of amiodarone versus lidocaine in 347 patients with out-of-hospital cardiac arrest resulting from refractory VF. Survival to hospital admission was 22.8% in the amiodarone group versus 12% in the lidocaine group. There was no difference between the groups in survival to hospital discharge. The widespread use of amiodarone in adults is supported by research; however, experience with its use in pediatric patients has demonstrated its effectiveness. Current guidelines recommend a loading dose of 5 mg per kg with a maximum of 15 mg per kg per day. Avoid use with class I antiarrhythmics (lidocaine, procainamide) because all these medications prolong the QT interval. It is metabolized by the liver, is highly protein bound, and is rapidly distributed and highly lipophilic. The main adverse effects include bradycardia, tachydysrhythmias, and hypotension. In the scenario of VF or pulseless VT, it should be administered as a rapid bolus; otherwise, it is given as an infusion over 20 to 60 minutes (Class IIb). The concentration should not exceed 2 mg per mL to avoid local phlebitis. No light protection is required after the drug has been reconstituted.

Lidocaine. Lidocaine is a class I antiarrhythmic and functions as a sodium-channel blocker, reducing the slope of phase 4 repolarization of the myocyte-decreasing automaticity. More recent experience has called its role in resuscitation into question. There is little evidence that lidocaine is superior to other drugs or to placebo when treating adults in the out-of-hospital setting. In fact, a recent, randomized, prospective study of adults with out-of-hospital VF compared the use of lidocaine to epinephrine after defibrillation. There was no difference in survival to hospital admission or discharge between the two groups. As discussed earlier, the ALIVE trial showed higher rates of survival to both hospitalization and discharge in adults treated with amiodarone versus lidocaine for the treatment of shock-resistant VF. The Amiodarone in Out-of-Hospital Resuscitation of Refractory Sustained Ventricular Tachycardia (ARREST) trial also suggested that amiodarone is superior to lidocaine for shock-resistant out-of-hospital VF. Thus, evidence is mounting that supports the use of amiodarone over lidocaine for resuscitation. Current recommendations state that lidocaine may be used for shock-resistant VF or pulseless VT in children. A loading dose of 1 mg per kg is given intravenously, followed by an infusion of 20 to 50 mcg per kg per minute. Side effects include myocardial depression, CNS depression, seizures, and muscle twitching.

Calcium. Calcium has an important role in vascular smooth muscle excitation–contraction coupling. Calcium enhances systolic function and systemic vascular resistance via vascular smooth muscle contraction. Calcium administration does not improve outcome in patients with out-of-hospital asystolic arrest. It has also been demonstrated that increases in intracellular calcium contribute to cell death due to reperfusion injury.

The 2005 AHA Guidelines do not recommend the routine administration of calcium in children with asystolic arrest. A recent review of pediatric patients from the National Registry of Cardiopulmonary Resuscitation revealed that calcium was used in 45% of cases. Importantly, use of calcium was associated with decreased survival to discharge. Calcium treatment is indicated for children with documented hypocalcemia, hypermagnesemia, hyperkalemia, and calcium channel overdose. Calcium should be monitored and hypocalcemia treated in ill children, particularly those with sepsis.

The most favorable dosing for calcium remains unclear. Calcium chloride 10% (100 mg per mL, 27.2 mg per mL of elemental calcium) seems to offer the best bioavailability. The current recommended dose is 5 to 7 mg per kg of elemental calcium. Therefore, 0.2 mL per kg of calcium chloride (20 mg calcium chloride/kg) can be given slow IV push during arrest or more slowly, over 5 to 10 minutes, in more stable patients. The recommended dose for calcium gluconate 10% (100 mg per mL, 9 mg per mL of elemental calcium) is 60 to 100 mg per kg or 0.6 to 1 mL per kg.

Magnesium. Magnesium inhibits calcium channels, decreasing intracellular calcium resulting in smooth muscle relaxation. Severe magnesium deficiency is associated with arrhythmias, sudden death, and congestive heart failure. Available information does not reveal any effect on outcomes for patients receiving magnesium during resuscitation. Magnesium has been shown to be effective in children with severe asthma who have persistent respiratory distress despite aggressive beta-agonist therapy. Current guidelines recommend the use of magnesium sulfate for documented hypomagnesemia, torsades de pointe, and severe asthma. A dose of 25 to 50 mg per kg (maximum of 2 g) is given intravenously over 10 to 20 minutes.

Fluid Resuscitation

Restoration of the circulating intravascular volume is an important element of successful resuscitation. Crystalloids in 20 mL per kg aliquots remain the mainstay of acute volume resuscitation. Dextrose solutions should not be used in the initial phases of fluid resuscitation.

Hypertonic saline causes an osmotic shift of fluid from the intracellular and interstitial spaces to the extracellular compartment, providing rapid volume expansion with less interstitial edema. In addition, less volume is required, which can be given over a shorter period of time. Hypertonic solutions are also believed to reduce ICP by establishing an osmotic gradient across the blood–brain barrier that draws water from the brain into the vascular space. Conversely, potential ill effects include continued hemorrhage from injured blood vessels, and increased ICP due to leakage of sodium through a disrupted blood–brain barrier. Currently, there is not enough data to support the use of hypertonic crystalloid instead of isotonic crystalloid for the resuscitation of patients.

Serum albumin concentration has been shown to be inversely related to mortality risk. Thus, its use in the resuscitation of ill patients has been explored. It is 30 times more expensive than crystalloid solutions and has limited availability. Systematic reviews have failed to show benefit its administration; in fact, its use may be associated with an increased risk of death. Albumin is believed to have some anticoagulant properties and may leak across the capillary wall promoting edema. The ongoing, prospective x trial saline vs. albumin fluid evaluation (SAFE) aims to answer this question.

Defibrillation and Cardioversion

The true prevalence of VT and VF in children with cardiopulmonary arrest is not known. In published reports the incidence varies from 9% to 10% in pediatric out-of-hospital arrest (Table 1.12A–B). The incidence of an initial rhythm of VT/VF amongst pediatric inpatient arrest is also approximately 10%. An additional 10% to 15% will develop VT/VF as a subsequent rhythm. Although the need for defibrillation is relatively uncommon, it should always be considered, particularly in older children, children with a history of congenital heart disease or dysrhythmias, or children who experience a witnessed sudden arrest.

Defibrillation is the asynchronous delivery of a shock to the myocardium in an attempt to produce simultaneous depolarization of a critical mass of myocardial cells to allow spontaneous repolarization and the resumption of a perfusing cardiac rhythm. Defibrillators can deliver monophasic or biphasic wave forms. Biphasic wave forms allow for successful defibrillation at a lower energy of 150 J. Biphasic defibrillators have largely replaced monophasic defibrillators. Standard adult paddles are 8 to 13 cm in diameter. Pediatric paddles 4.5 cm in diameter are available with most defibrillators. The correct paddle size is that which makes complete uniform contact with the chest wall. The large paddle can usually be used for infants older than 1 year of age and/or weighing more than 10 kg if placed on front and back. Larger paddle surfaces result in decreased intrathoracic impedance, which optimizes the energy reaching the myocardium. Electrode paste should be used to decrease impedance and prevent injury to the skin. Saline soaked pads should never be used because they can create a bridge between the two electrodes. Paddles should be applied with pressure on the anterior chest wall at the upper right side of the chest below the clavicle and to the left of the nipple in the anterior axillary line directly over the heart, never touching each other. Now most defibrillators have disposable adhesive pads that allow rhythm recognition through which a shock can be delivered. These can be applied to the chest, or anteriorly and posteriorly if appropriate, of the arrested child immediately at the beginning of the resuscitation and can aid in preventing delays in rhythm checks and treatment. The initial dose for defibrillation is 2 J per kg, increased to 4 J per kg if the first attempt is unsuccessful. Automated external defibrillators (AEDs) automatically interpret the cardiac rhythm and, if VF is present, advise the operator to deliver a charge. They are small, easy to use, and have batteries that last for 5 years. For patients with VF, early rapid defibrillation is the treatment of choice. AEDs have been proven to be highly sensitive and specific when used on adults, and there is good evidence that its use in the out-of-hospital setting has resulted in a dramatic improvement in survival of adults with VF. Cecchin et al. studied 696 rhythm strips from children younger than 12 years of age to test the accuracy of AEDs. There was 100% sensitivity for nonshockable rhythms, and the sensitivity for

TABLE 1.12B

[a]Children with heart disease not in the study population

VF was 96%. Since the 2005 guidelines, new information has shown that AEDs can be used to deliver shocks safely in children older than 1 year of age (Class IIb). Data is lacking to make a recommendation for or against its use in children younger than 1 year of age. Available AEDs deliver a standard adult charge between 150 and 200 J. More recently, an attenuating pediatric electrode system has become available that decreases the charge delivered to 50 J.

Synchronous cardioversion is the delivery of a charge that is timed with the patient's R wave. This reduces the risk of inducing VF by avoiding delivery of the charge during the T wave. This is indicated for treatment of rhythms in which the patient still has a pulse but has evidence of compromised perfusion, such as VT and SVT. The initial charge for synchronized cardioversion is 0.5 to 1 J per kg. This dose can be doubled to 2 J per kg if the tachydysrhythmia persists. Sedation and analgesia should be considered during this procedure.

Special Scenarios

The chain of survival includes rapid access to emergency medical services, rapid CPR, rapid defibrillation when indicated, and rapid advanced care. Once in the ED, the process of resuscitation is best accomplished with an effective leader that organizes and directs a skilled team. The American College of Surgeons divides the resuscitation into the primary and secondary surveys. During the primary survey, the life-threatening condition is identified and appropriate interventions are undertaken. These include the so-called ABCDEs of resuscitation, which includes attention to A, airway/breathing/cervical spine; B, breathing; C, circulation; D, disability, dextrose, decontamination; and E, exposure and environment. This phase of resuscitation should be completed within the first 5 to 10 minutes of arrival. Monitors (cardiorespiratory, pulse oximeter, end-tidal CO_2, blood pressure cuff) should be placed, IV access should be obtained, and a Foley catheter placed, if necessary. The secondary survey is a head-to-toe examination to determine the etiology of the illness. During this portion of the resuscitation, diagnostic studies are done, consultants are called, and arrangements for definitive care are completed. The ABCs should be reassessed frequently throughout the resuscitation.

Teamwork in Resuscitation. The new PALS and ACLS curricula have incorporated curricula on leadership, role clarity, and communication. Effective leaders and team members must have cognitive skill (fund of knowledge), technical and procedural skills, and behavioral skills. Recent information reveals lack of effective teamwork skills and their negative impact on resuscitation outcomes. Effective education includes challenging active exercises, such as high-fidelity simulation. Video-recording of resuscitation provides another venue for reviewing errors and providing constructive feedback on team management skills.

Specific Resuscitation Scenarios

In the 2005 AHA resuscitation guidelines, an international expert panel updated guidelines for pediatric prearrest/arrest scenarios. Figures 1.25 to 1.28 summarize these guidelines along with the following commentary. It is important to remember that no algorithm can cover every clinical situation; the treating team of health-care professionals must consider the many etiologies of arrest and modify therapies accordingly. Early recognition and intervention of/for respiratory and circulatory failure, vascular access, and frequent reassessment are the foundation of successful resuscitation efforts for all scenarios encountered in the pediatric ED.

Asystole/Bradycardia

The algorithms for the treatment of asystole and bradycardia adapted from the expert consensus statement are outlined in Figures 1.25 and 1.26. These are the most common prearrest/arrest scenarios encountered in the pediatric ED. As stated earlier, impending or existing respiratory failure is the most common etiology. As always, early recognition and intervention to support the respiratory system and other vital functions reduces morbidity and may be lifesaving. Other etiologies of bradycardia include heart block, heart transplant, increased ICP, hypoglycemia, hypercalcemia, drug effect, increased parasympathetic tone, and hypothermia. The first step in the treatment of children with bradycardia is airway management. Remember that increase in heart rate is the primary mechanism by which children increase their stroke volume, bradycardia readily leads to hypotension. Chest compressions should begin when perfusion is inadequate. Assess the rhythm on the cardiac monitor. If the bradycardia is believed to be due to increased vagal tone or heart block, atropine is an appropriate intervention. For most situations, epinephrine is the drug of choice. In children with heart block, cardiac pacing may be necessary.

In the pulseless child, it is important to identify the rhythm on the monitor so the correct intervention can be instituted. Asystole, PEA, pulseless VT, or VF are all possibilities, although in pediatric cardiopulmonary arrest, asystole predominates. In a witnessed, sudden arrest, primary cardiac etiologies should be considered. For asystole and PEA, SDE is the drug of choice. Always consider treatment of reversible causes such as hypovolemia, hypothermia, electrolyte abnormalities, poisonings, tension pneumothorax, and cardiac tamponade.

Tachydysrhythmias

The differential diagnosis of tachycardias includes sinus tachycardia (ST), SVT, and VT. Narrow complex morphology and beat-to-beat variability are usually present in children with ST. Rates rarely exceed 220 beats per minute (bpm) in infants and 180 bpm in children. Common causes of ST include hypoxemia, hypovolemia, hyperthermia, metabolic abnormalities, and pain/anxiety. Therapy is directed at treating the underlying cause.

SVT can be distinguished from ST by its lack of beat-to-beat variability and rate (most often greater than 220 bpm in infants and greater than 180 bpm in children). In children, aberrant conduction yielding a wide complex rhythm occurs less than 10% of the time. SVT is most commonly caused by accessory reentry pathways. The algorithm for the treatment of tachydysrhythmias appears in Figure 1.27. Patients with stable SVT have adequate oxygenation and perfusion; those with unstable SVT have inadequate perfusion and thus require rapid intervention. Chemical or electrical conversion can be used for the treatment of unstable SVT. Because of the efficacy and safety of adenosine in the treatment of SVTs, most practitioners have adopted this as first-line treatment when vascular or IO access is available. It is optimal to obtain a 12-lead EKG prior to and during treatment to aid in the diagnosis. Resuscitation equipment and drugs should be close at hand. If the patient fails to convert to sinus

rhythm after two doses of adenosine, synchronized cardioversion (0.5 J per kg) is recommended. Use of sedation analgesia should be considered. Vagal maneuvers were reintroduced in the 2000 AHA guidelines for stable SVT. In infants, ice may be applied to the face; in older children, Valsalva maneuvers, such as knee to chest or forceful blowing on an obstructed straw, may be attempted. Ocular and carotid pressure should be avoided. Use of other therapies such as procainamide, digoxin and beta-blockers may be considered after cardiology consultation.

VT is characterized by wide complex (QRS greater than 0.08 seconds) and typically has a rate ranging form 120 to 200 bpm. Etiologies of VT include prolonged QT syndrome, structural heart disease, myocarditis, cardiomyopathy, and poisonings. In children presenting with stable VT, close monitoring and immediate consultation with a pediatric cardiologist to determine etiology and definitive treatment is the best management. Chemical conversion using amiodarone, procainamide, or lidocaine is first-line therapy. In children who fail to convert, synchronized cardioversion is indicated. Treatment for pulseless VT or VF is immediate CPR and defibrillation. In the 2005 guidelines, recommendation for single defibrillation replaced the recommendation for three successive shocks. This recommendation resulted from the fact that biphasic defibrillators, which have largely replaced monophasic defibrillators, have a higher first shock success rate and that the administration of three successive shocks leads to delays in CPR is associated with decreased survival. Cardiac compressions should be interrupted only for rhythm checks and administration of the shock. If defibrillation is unsuccessful, epinephrine is the drug of choice. The use of vasopressin can be considered. Magnesium is indicated if the rhythm is torsades de pointes VT. The antiarrhythmics recommended are the same as those used for stable VT. The pattern of interventions is CPR→rhythm check→charge defibrillator during CPR→deliver single shock→

immediate CPR→brief rhythm check →resume CPR as drug is prepared and administered. Interruptions in CPR should be held to very brief periods to check the rhythm and to administer shocks. The resuscitation team should anticipate the need for the next interventions.

Extracorporeal Cardiopulmonary Resuscitation

There is now some information regarding the use of extracorporeal CPR (E-CPR) to treat refractory cardiac arrest in children presenting to an ED setting. Currently, it is an option available in large, tertiary care Children's Hospitals. The majority of the literature to date comes from the treatment of inpatients with primary cardiac disease. Use of E-CPR for these patients following a witnessed arrest seems to increase the chance for favorable outcome. The 2005 Guidelines state "Consider extracorporeal CPR for in-hospital cardiac arrest refractory to initial resuscitation attempts if the condition leading to cardiac arrest is reversible or amenable to heart transplantation, if excellent conventional CPR has been performed after no more than several minutes of no-flow cardiac arrest, and if the institution is able to rapidly perform extracorporeal membrane oxygenation (ECMO) (Class IIb). MacLaren et al. published a retrospective case series of children with septic shock who were treated with ECMO. Forty percent of the 45 cases received CPR prior to cannulation and 47% of the 45 cases survived to hospital discharge. Posner et al. presented case reports of two children treated with E-CPR in the ED, one patient with prolonged QT survived neurologically intact. Use of E-CPR can be considered for children with refractory arrest who have had a short downtime and have received high-quality CPR when the resources and personnel are available.

STABILIZATION AND TRANSPORT

Once resuscitation efforts have achieved cardiorespiratory stability, the patient should be transported to an inpatient special care unit for the critically ill. This transport may require a move of several hundred yards or several hundred miles to an appropriate pediatric hospital. In either circumstance, the patient should be transported with advanced support technology in place and qualified personnel in appropriate numbers in attendance, with options for further interventions immediately available. Medications for resuscitation, sedation, and muscle relaxation should also be available (Fig. 1.28).

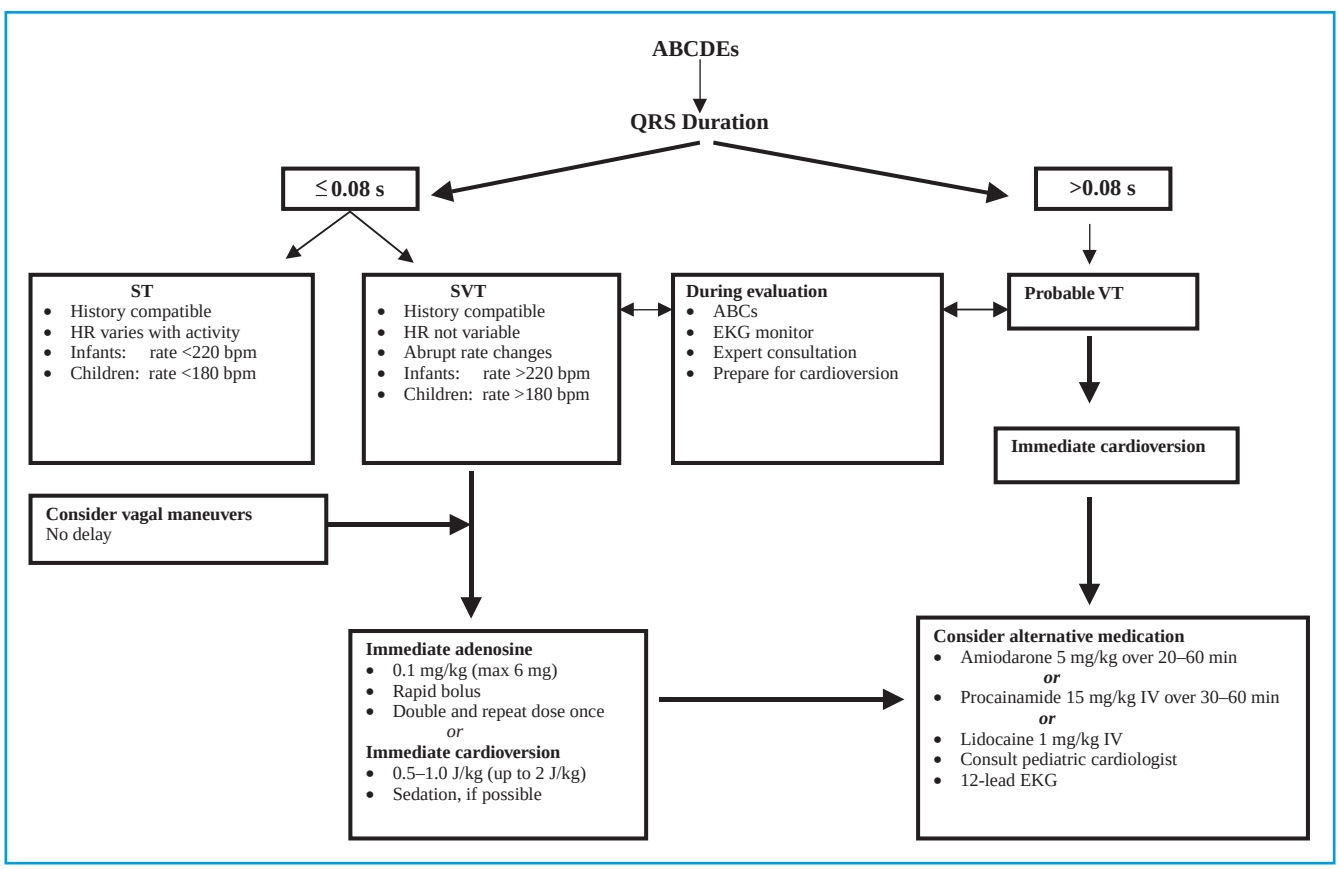

FIGURE 1.28 Management approach to tachycardia with poor perfusion. ABCs, airway, breathing, circulation; ABCDE, A, airway/breathing/cervical spine; B, breathing; C, circulation; D, disability, dextrose, decontamination; E, exposure and environment; bpm, beats per minute; EKG, electrocardiogram; HR, heart rate; IV, intravenous; ST, sinus tachycardia; SVT, supraventricular tachycardia; VT, ventricular tachycardia. (Adapted from American Heart Association Guidelines 2000 for cardiopulmonary resuscitation and emergency cardiovascular care [Supplement]. *Circulation* 2000;102(8) and American Academy of Pediatrics/American Heart Association. *PALS provider manual.* 2002.)

DISCONTINUATION OF LIFE SUPPORT

If well-executed resuscitative measures fail to achieve ROSC, resuscitative efforts should be discontinued. There is now good evidence that if cardiac muscle remains unresponsive to aggressive airway intervention, cardiac massage, and two doses of epinephrine, there is no chance for a successful resuscitation. Thus, a brief, well-executed resuscitation is indicated for the child who arrives to the ED with cardiopulmonary arrest. This includes definitive airway management; vigorous, monitored chest compressions; IO access; and one to two doses of epinephrine. During this time, the leader of the resuscitation can review the history and complete the primary and secondary survey. Prolonged resuscitation efforts past 20 minutes, without ROSC, are usually futile unless other treatable problems exist such as hypothermia, drug overdose, or VT/VF. Ultimately, the diagnosis of death and subsequent discontinuation of resuscitative efforts is a judgment that is made by the team leader. A decision not to begin resuscitation is generally not made in the ED unless there is a written do not resuscitate (DNR) document provided by the child's parent or guardian. Baren and Mahon have written about other end-of-life issues in the pediatric ED.

A well-prepared ED should consider and have a plan in place for issues such as (i) advanced directives, (ii) palliative care issues, (iii) bereavement measures and postmortem care, (iv) survivor follow-up, and (v) request for autopsy and organ donations. Proper documentation of a death is essential, as is notification of medical legal authorities, donor programs, and referring physicians and consultants.

CEREBRAL RESUSCITATION

Permanent brain damage following arrest is determined by many factors and includes arrest time (no-flow state), CPR time (low-flow state), and temperature. Cardiopulmonary–cerebral resuscitation is needed to prevent brain injury. Oxygen stores are depleted within 20 seconds following arrest, and glucose and adenosine are depleted within 5 minutes. During no-flow states, multiple complex chemical derangements occur that contribute to the death of neurons. With ROSC, there is impaired cerebral blood flow. Circulatory and pharmacologic interventions to prevent post-anoxic brain injury have yielded disappointing results to date. However, the use of hypothermia may show some promise.

Hypothermia

The use of mild hypothermia after out-of-hospital cardiac arrest due to ventricular fibrillation in adults has been associated with improved neurologic outcome and is generally tolerated without significant complication. The Hypothermia after Cardiac Arrest Study Group reported on 275 adult patients resuscitated from out-of-hospital VF cardiac arrest, who were randomized to either mild hypothermia (32°C to 24°C) for 24 hours or standard normothermic postresuscitation management. Favorable neurologic outcome at 6 months was seen in 55% of the patients in the hypothermia group versus 39% in the normothermic group, $p < 0.009$. Death occurred less frequently in the hypothermia group, 41% versus 55%, $p < 0.02$. A second study by Bernard et al. produced similar results. Seventy-seven patients were randomized to hypothermia versus normothermia; 49% of those treated with hypothermia versus 26% with normothermia were discharged with good neurologic function. A recent trial of induced hypothermia for asphyxiated neonates was associated with a significant decrease in outcomes of death or moderate disability at 18 months. A multicenter trial of induced hypothermia following pediatric arrest is now ongoing. Currently, cooling to 32°C to 34°C for 12 to 24 hours may be considered for children who remain comatose post-arrest (Class IIb).

COMMON ERRORS IN RESUSCITATION

Because of the complexity and stress of these situations, many errors are possible. Lack of effective leadership is a common problem, especially in the setting of large, tertiary care, teaching hospitals. Effective leaders assign specific roles and tasks to the members of the resuscitation team. They make clinical decisions and give specific direction without directly performing tasks or procedures. Frequent reassessment following interventions is cornerstone. Team members are queried for suggestions during the resuscitation and during termination of the resuscitation. As stated earlier, the importance of teamwork is essential to well-executed resuscitation.

Procedural errors are not uncommon. Correct ET tube placement should be continually confirmed by physical examination and end-tidal CO_2 monitoring. Adequacy of chest compressions should also be monitored by the leader, and team members should be alternated every 2 minutes to prevent ineffective compressions due to rescuer fatigue. Immediate feedback compression devices should be used for children older than 8 years of age. Team members should be skilled in IO placement and should have knowledge of the necessary equipment and procedures for peripheral and central line placement. They should also be familiar with the use of the defibrillator. Medication dosing and administration errors are also more likely to occur in this highly charged and intense situation. The leader and team members should maintain up-to-date knowledge on all necessary procedures, important equipment, and the most recent published guidelines. After the resuscitation, the team leader is responsible for debriefing the team members.

PARENTAL PRESENCE DURING CARDIOPULMONARY RESUSCITATION

Parental presence in the resuscitation room is becoming routine practice. A recent study by Dingeman et al. documented that 87% of families wanted this choice, 86% believed it was their right, and 94% said that they would choose it again. There remains a high variation of practice, 22% to 93% honor the families' request. Parents want to be with their child

during what may be the last moments of life. They also want to be certain that they and the ED staff have done all that is possible. Thus, in many centers, it is now recommended that parents be asked if they want to be in the resuscitation area. If they assent, they should be accompanied by a nurse or social worker who can serve as a support person and an interpreter. The decision to allow or not allow family presence is one that must be made by each ED, and there must be staff education, preparation, and quality assessment for this practice to be effective in easing the pain of the worst tragedy a human being can face—the loss of their child.

ETHICAL ISSUES IN PEDIATRIC CARDIOPULMONARY RESUSCITATION

Fearon, in a more recent publication, discussed many unique ethical challenges faced by the emergency physician. In providing CPR, emotions are often highly charged and, at times, a dirth of data is provided on which to base the immediate decisions that must be made. Fearon raised several important considerations: When are resuscitation attempts futile, and is the ED physician obligated to provide care at the families' insistence? How do family religious beliefs play a role in decision making? What is the role of parental presence? Should procedures be performed on the recently dead? Can resuscitation research be performed without informed consent? Some of these issues have been addressed in policy statements made by professional organizations, but each question needs to be considered in discussions that occur at the local ED level.

SUMMARY

In most circumstances, resuscitation of the pediatric patient can be approached with a sense of optimism for reversing the process that acutely threatens the child's life. Well-organized and well-qualified personnel can affect a high rate of successful resuscitation. However, organization and qualification require advanced planning, training, and preparation. Inherent in this preparation is the development of personnel disciplined to follow the sequence of evaluation and management of the ABCs. In addition, personnel must stay knowledgeable about the science of resuscitation and prevention, new interventions, new equipment, and new procedures to provide the best possible care to children.

CHAPTER 2 ■ NEONATAL RESUSCITATION

PAUL L. ARONSON, MD, AND EVALINE A. ALESSANDRINI, MD, MSCE

EPIDEMIOLOGY

More than 100 million babies are born each year worldwide, and approximately 4 million are born each year in the United States. Although more American women are seeking prenatal care in the first trimester of their pregnancies and there has been a decline in women who receive late or no prenatal care, the United States has one of the highest infant mortality rates of developed countries: 6.78 per 1,000 live births in 2004. This rate is markedly affected by birth weight. The infant mortality rate in 2004 was 2.26 per 1,000 for infants who weighed 2,500 g or more, 57.64 per 1,000 for infants who weighed less than 2,500 g, and 244.50 per 1,000 for those weighing less than 1,500 g. The infant mortality rate had declined by more than 75% between 1950 and 2004. These declines have been linked to improved access to care, advances in neonatal medicine, and educational campaigns such as the "Back to Sleep" campaign aimed at reducing sudden infant death syndrome. Still, the infant mortality rate has not declined significantly since 2004, and racial and ethnic disparities remain. Infant mortality rates are highest for infants of non-Hispanic black mothers, and lowest for infants of Asian mothers.

Amazingly, nearly 90% of neonates transition from intrauterine to extrauterine life without resuscitative needs. However, the remaining 10% require some assistance, and 1% require extensive resuscitative efforts. Resuscitative needs also vary greatly by birth weight. Approximately 6% of term newborns will require resuscitation at birth, compared with nearly 80% of infants weighing less than 1,500 g. Resuscitation of the newborn in the emergency department (ED) is an uncommon yet critical event that can cause an ED team well versed in other resuscitative scenarios to lose their usual level of confidence in critical situations. The key to a successful newborn resuscitation for the ED team includes preparedness of staff and equipment and anticipation of high-risk births.

EMERGENCY DEPARTMENT PREPAREDNESS

The best place for the birth of a newborn infant is in the delivery suite. However, because of varying circumstances, infants are born at home, in the prehospital setting, and in the ED. Most neonatal resuscitations in the ED occur without prior notice. Any knowledge that can be obtained before the arrival of the laboring mother or recently born infant will aid in the success of the resuscitation. Discussions with local prehospital providers to offer early notification to ED staff regarding anticipated or recent births will aid in more successful newborn resuscitations. Education of staff, available and functioning equipment, and familiar policies and procedures are critical for preparedness.

Staff

The American Heart Association (AHA) and the American Academy of Pediatrics (AAP) have been leaders in developing guidelines for and offering training in neonatal resuscitation since 1979. Their Pediatric Advanced Life Support course offers didactic and skills teaching for neonatal resuscitation that occurs outside the delivery room. In addition, resuscitation in the delivery room is addressed in depth in the Neonatal Resuscitation Program (NRP). In concert with the goals of the AHA and the AAP, all personnel responsible for care of newborns, including ED staff, should complete courses and maintain their skills in the area of newborn resuscitation. At least one person skilled in newborn resuscitation should attend every birth in a delivery room. Additional trained personnel must be available for high-risk deliveries, such as most of those occurring in the ED or other locations outside the delivery room. Ideally, there should be at least three members on the team that are trained to work together. Identification and training of staff is the first step in preparation for neonatal resuscitation.

Equipment

In addition to a standard obstetric tray, every ED should have a newborn resuscitation kit that is readily accessible, maintained meticulously with other emergency equipment, and rapidly restocked after use. Necessary equipment and medications are listed in Table 2.1. A medication dosing chart by weight and a radiant warmer are invaluable to a neonatal resuscitation.

Policies and Procedures

As soon as the need for neonatal resuscitation becomes evident, a prearranged plan should be activated to organize personnel and assemble equipment. Readily available policies for accessing pediatric and neonatal consultants, as well as neonatal transport teams for transfer to regional centers, are critical. Because neonatal resuscitations in the ED are uncommon, simulations, mock codes, and scavenger hunts for newborn equipment on a routine basis allow staff to remain familiar with their neonatal resuscitation skills and supplies.

TABLE 2.1

NEONATAL RESUSCITATION EQUIPMENT AND DRUGS

Equipment
Gowns, gloves, and masks for universal precautions
Radiant warmer with temperature probe
Warm towels and blankets
Bulb syringe
Suction equipment with manometer
Suction catheters (5F, 8F, and 10F)
Meconium aspirator
Oxygen with flow meter and tubing
Self-inflating resuscitation bag (500 mL) with oxygen reservoir or anesthesia (flow-inflating) bag with manometer (must be capable of delivering 90–100% oxygen and be no larger than 750 mL)
Face masks (premature, newborn, and infant sizes)
Oral airways (sizes 000, 00, and 0)
Endotracheal tubes (2.5, 3.0, 3.5, and 4.0) and small stylets
Laryngoscope handles and straight blades (nos. 0 and 1)
Extra batteries and laryngoscope bulbs
Laryngeal mask airways
Stethoscope
Tape
Scissors
Sterile umbilical catheterization tray
Umbilical catheters (3.5F and 5F)
Three-way stopcocks
Needles and syringes
Nasogastric feeding tubes (8F and 10F)
Cardiorespiratory monitor
Small electrocardiographic leads
Pulse oximeter with newborn probe
End-tidal CO_2 detector
Chest tubes (8F and 10F)
Magill forceps, small

Drugs
Weight-based resuscitation chart
Epinephrine 1:10,000 (0.1 mg/mL)
Dextrose in water, 10%
Naloxone (1 mg/mL or 0.4 mg/mL)
Sodium bicarbonate 4.2% (0.5 mEq/mL)
Isotonic crystalloid: normal saline, Ringer's lactate

HIGH-RISK BIRTHS

Most births that occur outside the delivery room have high-risk components such as trauma-induced labor and unexpected or teenage pregnancy. There is usually little time to obtain a complete obstetric history, but a brief period of questioning may reveal pertinent information that will affect a successful newborn resuscitation. Particularly important information includes prematurity, multiple gestation, meconium-stained amniotic fluid, and maternal drug use. The team can then anticipate the need for assisted ventilation, simultaneous resuscitations, tracheal suctioning, or pharmacologic interventions. Table 2.2 lists other risk factors associated with the need for neonatal resuscitation. Knowledge of many of these factors will only be available in a more controlled delivery room setting, but familiarity with this high-risk profile will benefit those involved in newborn resuscitation.

PATHOPHYSIOLOGY

Physiology of Intrauterine Development

The lungs develop over the second and third trimesters of pregnancy. Terminal airways develop by approximately 24 weeks' gestation, and the alveoli develop by 30 to 32 weeks. Surfactant is initially produced by about 23 to 24 weeks; however, sufficient amounts for opening the airways are usually not present until 34 weeks' gestation. In utero, the lung is filled with amniotic fluid, which is primarily removed by chest compression during vaginal birth. Preterm infants or those born by cesarean section tend to have more fluid in their lungs. At birth, the key physiologic change is the initiation and maintenance of respiration. Factors such as cold, touch, hypoxia, and hypercarbia help stimulate respiration. However, severe acidosis, prolonged hypoxia, maternal drugs, and moderate hypothermia depress this effort.

The heart and circulatory system begin developing during the third week of gestation. In utero, the circulation is more like a parallel circuit rather than a series circuit because of the foramen ovale and ductus arteriosus that serve as bypasses. After birth, these structures close physiologically. Severe acidosis, hypoxia, hypovolemia, and hypothermia can impair the closure. Anatomic closure of the bypasses may not occur for 2 to 4 weeks. The fetal heart is also sensitive to hypoglycemia because of the neonate's limited energy stores, and myocardial failure can occur if the infant becomes hypoglycemic.

Changes at Birth

The fetus has two large right-to-left shunts: one from the right atrium to the left atrium through the foramen ovale, and the second from the pulmonary artery to the aorta across the ductus arteriosus. The placenta is the gas-exchange organ that provides a low-resistance shunt compared with the high resistance of the fetus' pulmonary circulation. At birth, two major changes occur that eliminate these shunts: The umbilical cord is clamped, and then respirations are initiated. Expansion of the lungs increases the neonate's Pa_{O_2} and pH, which causes pulmonary vasodilation and a fall in pulmonary vascular resistance. The normal heart rate will vary between 100 and 200 beats per minute initially and then stabilize between 120 and 150 beats per minute.

The normal newborn will begin spontaneous respirations within seconds after birth. The normal rate will be between 35 and 60 breaths per minute. The initial breaths taken by the infant must inflate the lungs and effect a change in vascular pressures so that the lung water is absorbed into the pulmonary arterial system and cleared from the lung. This inflation pressure is a powerful mechanism for the release of pulmonary surfactant, which increases compliance of the lung and establishes a functional residual capacity.

The neonate oxidizes free fatty acids released from the brown fat stores for heat production and increases oxygen consumption. The neonate experiences substantial heat loss by all four heat-loss mechanisms, especially if he or she is not dried promptly and thoroughly.

TABLE 2.2

NEONATAL HIGH-RISK PROFILE

Prenatal	Natal	Postnatal
Maternal Older than 35 yr of age Younger than 16 yr of age Diabetes Hypertension Third-trimester bleeding Infection Premature rupture of membranes Drug ingestion or therapy Drug abuse Anemia Rh sensitization Cardiac, liver, or renal disease Toxemia Preeclampsia, eclampsia No prenatal care **Fetal** Fetal distress on monitor Multiple gestation Meconium-stained amniotic fluid Premature labor Postmature labor Intrauterine growth retardation	**Maternal** Hypotension Prolonged labor Placenta previa Abruptio placenta Drugs Cesarean section **Fetal** Abnormal presentation Prolapsed cord Abnormal heart rate Meconium-stained fluid Polyhydramnios or oligohydramnios Forceps delivery Asphyxia	**Fetal** Respiratory distress Asphyxia Hypotension Meconium staining Prematurity Small for dates

Asphyxia

Asphyxia is defined as the failure to provide the cell with oxygen and remove carbon dioxide, resulting in metabolic acidemia. Both ventilation and circulation are essential to avoid asphyxia. Multiple stimuli at birth initiate respirations and alter the prenatal circulation. The actual stimuli for initiating respirations are believed to include a rise in $PaCO_2$, interruption of umbilical circulation, and tactile and temperature stimulation.

Neonatal asphyxia can result from multiple factors, as listed in Table 2.3. The initial response to asphyxia will be hyperpnea for 2 to 3 minutes and sinus tachycardia. If there is no significant increase in PaO_2, respirations will stop for 1 to 1.5 minutes (primary apnea). During primary apnea, stimulation such as drying or slapping of the feet will restart breathing. If the apnea is prolonged, the infant loses muscle tone and becomes mottled, cyanotic, and then bradycardic. The infant may attempt gasping, nonrhythmic respiratory efforts of 6 to 10 times per minute for several minutes, while the heart rate continues to fall. Soon thereafter, the child ceases to gasp (secondary apnea). At this point, stimulation will not cause the infant to resume breathing, but rather ventilatory support must be initiated for the newborn to survive. Brain and other organ damage progresses rapidly beyond this point.

It is important to realize that when one evaluates a neonate in distress or full arrest, the asphyxial event may have begun in utero. It is difficult to document the beginning of the hypoxic period. Indeed, the infant may have passed through both stages of apnea in utero. Thus, there must be aggressive intervention if the infant is to survive. A rule of thumb is that for every minute of secondary apnea, the infant will require 4 minutes of artificial ventilation before rhythmic breathing is reestablished. An apneic infant must be treated as if he or she is in a secondary apneic stage, and resuscitation must begin immediately. If a rapid increase in heart rate does not occur with assisted ventilation, chest compressions and aggressive circulatory support will be required. If hypoxemia remains untreated, there may be further pulmonary vasoconstriction and increased right-to-left shunting through the ductus arteriosus and foramen ovale, as well as a persistence of fetal circulation.

ASSESSMENT OF THE NEWLY BORN

Successful resuscitation of a depressed newborn requires accurate assessment of the infant's respiratory effort, heart rate, color, and tone. In addition, attention to the newborn's temperature must accompany all resuscitative efforts.

Assessment of these critical parameters occurs simultaneously with management of any detected abnormality in a rapid and timely fashion. The evaluation of the clinical manifestations of a depressed newborn should occur along with resuscitative efforts within the first minute after birth. Complete assessment is performed after the infant is dried and placed in a warm environment, the airway is cleared, and stimulation has been provided.

Respiratory Effort

Most newborns will begin to breathe effectively in response to mild stimulation. The infant should be assessed for respiratory rate (between 35 and 60 breaths per minute is normal). Adequacy of respirations is noted by evaluating chest rise, auscultating good air movement, and confirming a heart rate above 100 beats per minute with improving color of the infant. Observation of tachypnea, retractions, or grunting warrants close evaluation and management. A gasping, cyanotic, or unresponsive infant requires immediate respiratory support with oxygenation and ventilation (see "Management" section).

Heart Rate

The newborn's heart rate is an excellent objective measurement of the success of the resuscitation and should be monitored closely with assessment of respiratory effort. The heart rate may be determined in many ways: (i) palpation of the pulse at the base of the umbilical cord, (ii) auscultation of heart tones with a stethoscope, (iii) palpation of the femoral or brachial pulse, and (iv) placement of a cardiac monitor. Auscultation of the apical heart rate is often difficult in a noisy environment, and the electrodes of a cardiac monitor may be difficult to place while vernix covers the newborn's body. The normal infant's heart rate is greater than 100 beats per minute at birth. The average awake infant's heart rate is between 120 and 150 beats per minute shortly after birth. Variations in heart rate commonly occur with hypoxia, hypovolemia, hypothermia, and maternal drug use. Trends in heart rate are followed closely during resuscitation and postresuscitation stabilization. The average mean arterial pressure of term infants in the first 12 hours of life is between 50 and 55 mm Hg.

Color

As respirations begin and pulmonary vascular pressures fall, the newborn rapidly becomes pink. Acrocyanosis, or persistent cyanosis of the distal extremities, may persist for several hours after birth. Acrocyanosis is not a reflection of inadequate oxygenation, but it may indicate hypothermia if persistent. Pallor may be a sign of decreased cardiac output, anemia, hypovolemia, hypothermia, or acidosis. Its cause should be investigated and corrected promptly. Central cyanosis that has not resolved with administration of oxygen and ventilation within the first minute of life must be emergently evaluated for heart disease, sepsis, diaphragmatic hernia, other congenital anomalies, or other causes.

Temperature

Particular attention must be paid to the thermoregulation of all infants, especially those born in a prehospital setting or ED, where the ambient temperature is lower than ideal for a newborn. As the patient is dried and placed under a radiant warmer, the temperature should be monitored via the axillary route using electronic thermometers with a disposable tip. Normal axillary temperatures fall between 36.5°C and 37.4°C. Rectal temperatures are reserved for infants whose core temperature may be in question. Recovery from acidosis is delayed by hypothermia. In addition, hypothermia increases metabolic needs and produces hypoxia, hypercarbia, metabolic acidosis, and hypoglycemia. Thus, efforts to maintain a normal body temperature are crucial to a successful resuscitation.

Apgar Score

The Apgar score is a useful guide to evaluate the newborn at specific intervals after birth. Although the Apgar score has been used as an indicator of responsiveness to resuscitative efforts, the score is not used to determine the need for resuscitation. Five objective signs—heart rate, respirations, muscle tone, reflex irritability, and color—are assessed 1 minute and 5 minutes after birth. Each sign receives a score between 0 and 2, and the points are then totaled for the final score (Table 2.4). If the 5-minute Apgar score is less than 7, additional scores may be obtained every 5 minutes until the infant is 20-minutes old. The score at 5 minutes and beyond is more predictive of survival and neurologic status. Although experienced physicians have developed these guidelines, they have not undergone rigorous clinical trials. Thus, if resuscitative efforts are needed for a newborn infant, they should be started immediately and not be delayed while the Apgar score is obtained.

MANAGEMENT

Initiation and Termination of Resuscitation

When and if to begin resuscitative efforts on a newborn is fraught with emotion and difficult to objectively address. Studies have shown that between 40% and 50% of apparently stillborn term newborns survived. Approximately two-thirds of these infants had a normal neurologic outcome. Current recommendations state that noninitiation of resuscitation is appropriate in some conditions that include gestational age less than 23 weeks, anencephaly, or known trisomy 13. Otherwise, resuscitative efforts should be performed on any term infant. There are multiple ethical issues regarding initiation of resuscitation of the very low-birth-weight infant.

TABLE 2.4

APGAR SCORE

	Score		
Sign	0	1	2
Heart rate	Absent	<100 beats/min	>100 beats/min
Respirations	Absent	Slow, irregular	Good, crying
Muscle tone	Limp	Some flexion	Active motion
Reflex irritability	None	Grimace	Cough, sneeze, cry
Color	Blue or pale	Pink body, blue hands and feet	Completely pink

However, with surfactant therapy and improved management of these infants, outcomes have improved over time and the controversy of resuscitation remains. Current recommendations note that a birth weight less than 400 g may be one criterion to not initiate resuscitation. At the stressful time of an emergency delivery, if there is any question of viability, it is probably best to initiate resuscitative efforts.

A difficult decision is when to stop resuscitation. One predictor is the Apgar score. Survival is extremely unlikely if the 10-minute Apgar score remains 0. In this circumstance, a 10-minute period of resuscitation is usually warranted; but if the Apgar score remains 0 or 1 at that time, resuscitation may be terminated because of extremely poor outcomes. It is imperative to believe that every resuscitative step has been performed correctly and repetitively prior to termination of resuscitation. In addition, emergency staff with neonatal expertise on site should be invited to participate in these resuscitative efforts and decisions to terminate resuscitation.

Initial Management Priorities

Four questions should be asked when an infant is born:

1. Is the infant term?
2. Is the amniotic fluid clear of meconium?
3. Is the baby breathing or crying?
4. Does the baby have good muscle tone?

If the answers to these questions are yes, it is likely that the newborn will do well and require routine care. However, most births occurring outside the delivery suite will have high-risk attributes and require supportive or ongoing newborn care. The initial steps of neonatal resuscitation include positioning and clearing the airway, drying and warming with prevention of heat loss, stimulating, and repositioning. These steps occur within 30 seconds and are followed immediately by an evaluation of respirations, heart rate, and color. When possible, all resuscitation equipment should be ready for use, the radiant warmer on, and a team with preassigned roles assembled. Figure 2.1 is a flow diagram of neonatal resuscitation.

Thermoregulation

The initial step of drying the infant to minimize heat loss is extremely important, and further resuscitation is continued after warming has begun. Premature infants are at greater risk of hypothermia because of their greater body surface area-to-weight ratio, minimal fat stores, and thinner epidermis and dermis. As previously stated, recovery from acidosis is delayed by hypothermia, and hypothermia is a special problem for the infant born outside the hospital. Thus, simply resuscitating the baby in a warm environment, under a prewarmed radiant warmer while drying the amniotic fluid from the infant and removing wet linens from contact with the skin will markedly decrease heat loss. These maneuvers will maximize the infant's chance of recovery. Alternative methods of warming infants, particularly while awaiting a radiant warmer in the case of an unexpected delivery, include warm blankets and towels. Placing the infant naked against the mother's body and covering both mother and infant with blankets may also warm the stable infant. Although preventing heat loss is vital, hyperthermia should be avoided because it is associated with perinatal respiratory depression and hypoxic-ischemic injury may be worsened.

Cerebral hypothermia has been advocated by some as a means to protect asphyxiated infants from further brain injury. A multicenter, randomized controlled trial showed that systemic hypothermia initiated within 6 hours of life reduced death or neurologic disability in infants with moderate or severe hypoxic-ischemic encephalopathy. Another randomized controlled trial showed improved neurodevelopmental outcomes with selective head cooling in asphyxiated infants with less severe encephalopathy. However, there remain insufficient data to recommend the routine use of systemic or selective hypothermia in asphyxiated infants until further clinical trials are undertaken. In the ED, maintenance of a normal body temperature and avoidance of hyperthermia are critical.

Suctioning

Many newborns have excessive secretions, including amniotic fluid, cervical mucus, and meconium, which may obstruct their airways. (Meconium is a special situation discussed in the following section.) These secretions can generally be removed by placing the infant on his or her side and gently suctioning the mouth and then the nose with a bulb syringe. Mechanical suction with an 8F or 10F suction catheter may also be used. To avoid soft-tissue injury, negative pressure from mechanical suctioning should not exceed 100 mm Hg. Deep suctioning of the oropharynx in a newborn is likely to cause vagally mediated bradycardia and/or apnea. Excessive suctioning may also contribute to atelectasis. Most clear fluid is resorbed by the lungs into the arterial system. Consequently, suctioning should be gentle and brief because this is usually adequate to remove secretions.

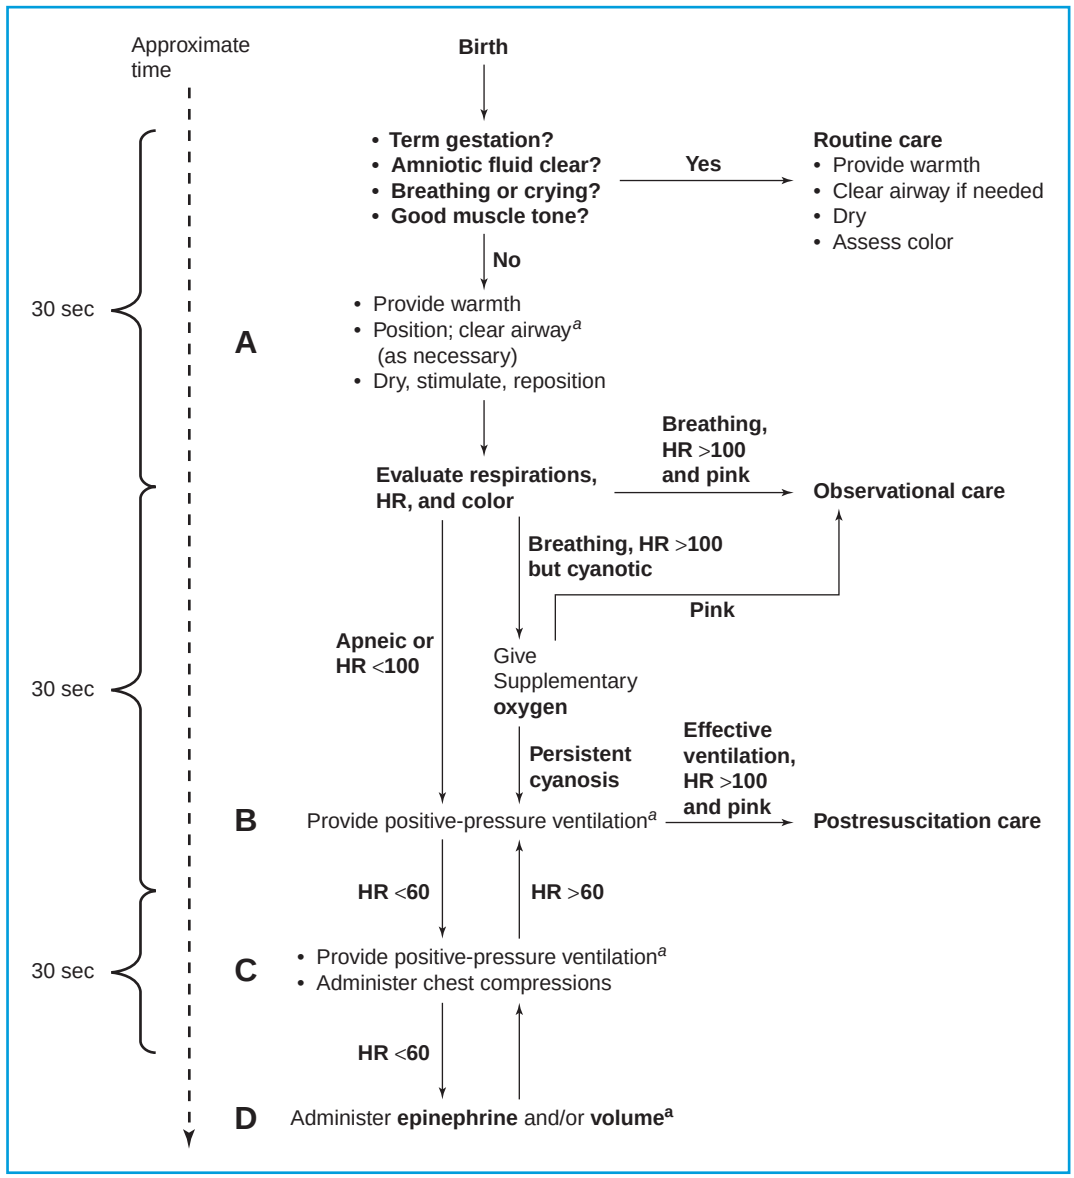

FIGURE 2.1 Overview of neonatal resuscitation. (Adapted from Kattwinkel J, Short J, Boyle D, et al. *Textbook of neonatal resuscitation*. 5th ed. Elk Grove Village, IL: American Academy of Pediatrics and American Heart Association, 2006.)

Stimulation

Most newborns will begin effective breathing during stimulation from routine drying and suctioning. Other methods of safe stimulation include flicking the heels and rubbing the back of the newborn infant. More vigorous methods of stimulation are unnecessary and may be associated with harmful consequences. If after a brief period of stimulation, suctioning, and drying (no more than 30 seconds; Fig. 2.1), effective respirations have not been established, positive-pressure ventilation (PPV) is initiated.

Airway Positioning and Oxygen Administration

Most infants require only warming, drying, stimulation, and suctioning after birth for a smooth transition to their extrauterine environment. If a newborn is exhibiting signs and symptoms of airway obstruction after routine suctioning, the airway should be repositioned. Correct positioning, with the neck slightly extended in the "sniffing position," will bring the posterior pharynx, larynx, and trachea inline and facilitate air entry. This maneuver may also be accomplished by placing a towel or blanket beneath the shoulders and upper back of the supine infant. By elevating the shoulders and upper back approximately 1 inch, the airway is again slightly extended into a neutral position, compensating for the infant's relatively large occiput. Avoid flexion or hyperextension of the newborn's neck, which is likely to exacerbate airway obstruction.

An infant who exhibits central cyanosis, yet is making adequate, spontaneous respirations and has a heart rate above 100 beats per minute, needs supplemental oxygen. It is important to deliver as close to 100% oxygen as possible, with a

flow rate of at least 5 L per minute via blow-by through tubing, a face mask attached to a flow-inflating (anesthesia) bag, or an appropriately sized simple mask. Ideally, oxygen should be warmed and humidified. Although this may not always be possible initially in an emergency setting, efforts to warm and humidify oxygen delivered to a newborn should be made as soon as possible because unheated and unhumidified oxygen at high flow rates may result in significant convective heat loss.

Further Resuscitative Interventions

Upon completion of the initial management priorities in neonatal resuscitation, personnel must assess the newborn's respirations, heart rate, and color in preparation for providing further resuscitative interventions.

Airway and Breathing

The 2005 NRP, sponsored by the AHA and the AAP, states repeatedly: "Ventilation of the lungs is the single most important and most effective step in cardiopulmonary resuscitation of the compromised newborn baby." One large observational study noted that initial management steps and ventilation were effective in establishing normal vital signs in more than 99% of newly born infants. Therefore, particular attention must be paid to providing maximal and skilled ventilation interventions for compromised newborns in the ED.

Bag-valve-mask Ventilation. Ventilation is the key to neonatal resuscitation. Adequate expansion of the lung is often the only and most important measure needed for successful resuscitation of the newborn. The fluid-filled lungs must be inflated with air. Adequate inflation stimulates surfactant secretion and also allows some gas trapping during exhalation to create a functional residual capacity. Although this is best done by negative pressure generated by a vigorous term infant with a strong chest wall, some infants require PPV to initiate lung expansion. If initial management priorities discussed previously (warming, suctioning, stimulating, positioning, and blow-by oxygen) are unsuccessful and the newborn is still not breathing or is gasping, the heart rate is less than 100 beats per minute, and/or the color remains cyanotic despite 100% oxygen, PPV must be initiated. Indications for PPV are summarized in Table 2.5.

PPV is best achieved with a well-fitted face mask, which covers the infant's nose and mouth but does not place pressure on the eyes. A cushioned rim on the face mask allows the best possible seal. A relatively high inflation pressure, between 25 and 40 cm H_2O, delivered slowly over several seconds is necessary for the infant's first breath. Subsequent ventilations typically require less pressure (15 to 20 cm H_2O for normal lungs and 20 to 40 H_2O for diseased or immature lungs), and are best judged by good chest wall rise and breath sounds. If effective ventilation does not result, the airway should be repositioned and suctioning of the oropharynx considered. An assisted ventilatory rate of 40 to 60 breaths per minute will provide effective oxygenation and ventilation.

Typically 100% oxygen is delivered via PPV for rapid reversal of hypoxia. However, some physician investigators advocate resuscitation with room air because of concerns about the generation of free radicals from high concentrations of oxygen, which may exacerbate brain injury. A 2005 Cochrane review and 2008 meta-analysis both showed a reduction in mortality in infants resuscitated with room air versus those resuscitated with 100% oxygen, without any adverse effects on neurologic outcome. However, methodologic and analytic limitations of the studies have resulted in caution in the interpretation of the results. A recent randomized clinical trial showed that room air failed to provide adequate oxygen saturation when used in the resuscitation of premature infants. The standard resuscitation algorithm continues to include the use of 100% oxygen; however, the available evidence does support the option to provide PPV with room air, especially in the preterm infant. If resuscitation with room air is undertaken, supplementary oxygen should be utilized if there is no clinical improvement within 90 seconds of birth. As ventilation remains the most important step in the resuscitation of the newborn, if supplemental oxygen is not available, PPV should be initiated with room air.

PPV may be delivered by a self-inflating bag or a flow-inflating (anesthesia) bag. Although self-inflating bags do not require a gas source to operate, they must be used with an oxygen source and a reservoir to deliver high concentrations of oxygen. They are straightforward and easy to use, but several caveats must be kept in mind. First, relatively small volumes of air (approximately 4 to 6 mL per kg) are delivered to newborns during PPV. A 450-mL self-inflating bag rather than the larger bags should be used to avoid complications from barotraumas, such as a pneumothorax. In addition, many self-inflating bags have a pressure-limiting pop-off valve set at 30 to 45 cm H_2O. In some circumstances, when an infant requires higher initial inflation pressures, the bag may not allow the resuscitator to deliver enough pressure to the newborn for an adequate first breath. Unless the valve is occluded, effective inflation may be prevented.

To inflate properly, flow-inflating bags require adequate airflow and a good mask seal. Consequently, the resuscitator must be facile at positioning the airway and mask, controlling the flow valves, and monitoring the manometer, which is needed to monitor peak ventilatory pressures delivered to the infant. Benefits of the flow-inflating bag include the ability to deliver a wide range of peak inspiratory pressures, positive end-expiratory pressure, high concentrations of oxygen compared with the self-inflating bag, and ease of determination whether there is a tight seal. Proper use requires training and practice.

If bag-valve-mask ventilation is required for longer than several minutes, an orogastric tube should be placed to decompress the stomach so further effective ventilation is not inhibited. This tube should be left in place. The infant should be reevaluated after 30 seconds of PPV for spontaneous respirations and heart rate. If the infant has begun breathing and the heart rate is

TABLE 2.5

Advanced resuscitation situations such as extreme prematurity

above 100 beats per minute, PPV may be slowly discontinued. If respirations are inadequate or the heart rate remains less than 100 beats per minute, assisted ventilation must be continued and endotracheal (ET) intubation must be considered.

Endotracheal Intubation. Most resuscitative efforts succeed with bag-valve-mask ventilation alone. In the event that there is a prolonged need for PPV or mask ventilation has not been effective in restoring vital functions, ET intubation is indicated. Indications for ET intubation are summarized in Table 2.6. Once the decision to intubate the trachea has been made, supplies from the newborn resuscitation tray are organized. Sizes of airway equipment can be determined by birth weight (Table 2.7). ET tube size can also be estimated by gestational age:

$$\text{ET tube size in mm} = \text{Gestational age in weeks}/10$$

Thus, a 35-week premature infant would require a 3.5-mm ET tube.

ET intubation is typically performed via the orotracheal route during direct laryngoscopy with a straight blade. The laryngoscope blade is inserted into the vallecula or onto the epiglottis and reveals the vocal cords during a gentle lifting movement. Laryngoscopy in the newborn is challenging because of the infant's large tongue and secretions, which may obscure airway landmarks. Attempts at ET intubation should be limited to 20 seconds per attempt. If the glottis is not visualized or the tube is not inserted into the trachea within 20 seconds, oxygenate the infant with 100% oxygen provided by bag-valve-mask ventilation, and then try again. Successful ET intubation also requires proper tube positioning. Most neonatal ET tubes have a black vocal cord line near the tip. When this guide is placed at the level of the vocal cords, the tip of the tube is likely to be positioned properly in the trachea. Another estimate for the insertion distance of the ET tube is

$$\text{Total cm at gum line} = 6 + \text{Weight of the infant in kg}$$

Proper positioning of the ET tube must be confirmed by auscultation of equal breath sounds in both axillae; good, symmetric chest wall movement; and improvement of the infant's cardiorespiratory status. Once positioning is clinically verified, the ET tube must be securely taped in place, and positioning may then be confirmed with a radiograph as indicated. End-tidal CO_2 detectors are the recommended means of confirming ET tube placement during newborn resuscitation. It is important to note that they may be associated with false-negative results, particularly in infants with extremely compromised cardiac output. Other issues, such as decreased pulmonary blood flow and small tidal volume, may influence end-tidal CO_2 detection in newborns. If ET tube positioning is uncertain and the end-tidal CO_2 detector does not detect exhaled carbon dioxide, the safest measure is to extubate, provide bag-valve-mask ventilation, and reintubate the trachea. Note that pulse oximetry is not routinely used in newborns after delivery. Some studies have shown that the readings did not correlate with blood gas values. Furthermore, the definition of a "normal" oxygen saturation immediately after birth is unknown, and aggressively attempting to increase the saturation to near 100% may cause oxygen toxicity.

More recently, investigators found laryngeal mask airways (LMAs) successful for ventilating full-term or near-term newborns, particularly in cases of ineffective bag-valve-mask ventilation or failed ET intubation. Although LMAs may be used as a secondary device to ventilate term newborns by healthcare practitioners skilled in their use, data supporting use of LMAs in preterm infants are insufficient to routinely recommend their use in this scenario. Furthermore, LMAs cannot replace ET intubation when meconium suctioning is required.

Circulation

Chest Compressions. Chest compressions are rarely needed during neonatal resuscitation. Most series have demonstrated that less than 0.1% of all births require chest compressions. Bradycardia and asystole in the newborn are virtually always a result of respiratory failure, hypoxemia, and tissue acidosis. Consequently, oxygenation and ventilation are most critical to successful infant resuscitation. Chest compressions should be started whenever the heart rate remains less than 60 beats per minute despite 30 seconds of PPV. Indication for chest compressions, which are always performed simultaneously with PPV with 100% oxygen, are listed in Table 2.8.

Current recommendations state that three chest compressions are followed by a brief pause for one ventilation. Thus, in 1 minute, the newborn should receive 90 chest compressions and 30 ventilations. This technique allows for optimal

TABLE 2.7

TABLE 2.8

INDICATION FOR CHEST COMPRESSIONS

Heart rate <60 beats/min despite 30 s of effective positive-pressure ventilation

lung expansion by not compressing the chest during PPV, and the most important aspects of reversing neonatal asphyxia, good oxygenation and ventilation, are maximized.

Two techniques of performing chest compressions in the neonate or young infant are recommended. The preferred method involves placing the thumbs on the lower third of the sternum, encircling the chest and supporting the back with the fingers (Fig. 2.2). The thumbs should be placed side by side just below the nipple line. However, if the neonate is very small or if the resuscitator is large, the thumbs may need to be superimposed. Pressure must be placed on the sternum and not the adjacent ribs. In the event that the resuscitator's hands are too small to encircle the newborn's chest or encircling the chest obstructs other resuscitative efforts such as umbilical line placement, then the two-finger technique may be used. This method entails placing the ring and middle fingers on the sternum just below the nipple line for chest compressions.

With either method of chest compression, the resuscitator should compress the chest approximately one-third of the anterior-posterior diameter of the chest to generate a palpable pulse. The compression stroke should also be somewhat shorter in duration than the relaxation phase for generation of maximum cardiac output. In addition, the fingers or thumbs should not be lifted off the chest at any time to save time with correct finger positioning; maintain control over compression depth and preserve correct finger positioning to prevent damage to underlying organs.

After approximately 30 seconds of well-coordinated chest compressions and ventilation, stop chest compressions to check the spontaneous heart rate by palpating the pulse at the base of the umbilical cord. Ventilations can be continued while using this method of pulse check. If auscultating the left chest for heart rate check, compressions and ventilations will need to be suspended. If the heart rate is at least 60 beats per minute, compressions can stop, but ventilation should be continued at the 40 to 60 breath per minute rate. If the heart rate remains below 60 beats per minute, compressions must be continued and epinephrine should be given (see below). In addition, resuscitators must be sure they are providing adequate ventilation with 100% oxygen, resulting in good chest wall movement and coordinated compressions and ventilations.

Vascular Access. A newborn requires vascular access for administration of medications or volume expansion. Bradycardia or asystole unresponsive to effective oxygenation, ventilation, and chest compressions warrant pharmacologic therapy. Infants exhibiting signs of poor perfusion, particularly those with risk for hypovolemia, such as fetal hemorrhage or maternal hypotension from placental abruption, require volume expansion.

Several methods of vascular access may be used in the newborn. The umbilical vein is often considered a preferred site for vascular access during neonatal resuscitation because it is easily located and cannulated, and medication delivery requires insertion only to the point at which blood is able to be aspirated (usually 2 to 4 cm). (See Section VII: Umbilical Vein Catheterization for methods.) A skilled resuscitator may elect to cannulate the umbilical artery to obtain arterial blood gases and monitor arterial pressures in critically ill infants; however, administration of medications is not recommended via this route. (See Section VII: Umbilical Artery Catheterization.) Vascular access may also be obtained by placing peripheral catheters in the extremities or scalp. In a newborn resuscitation

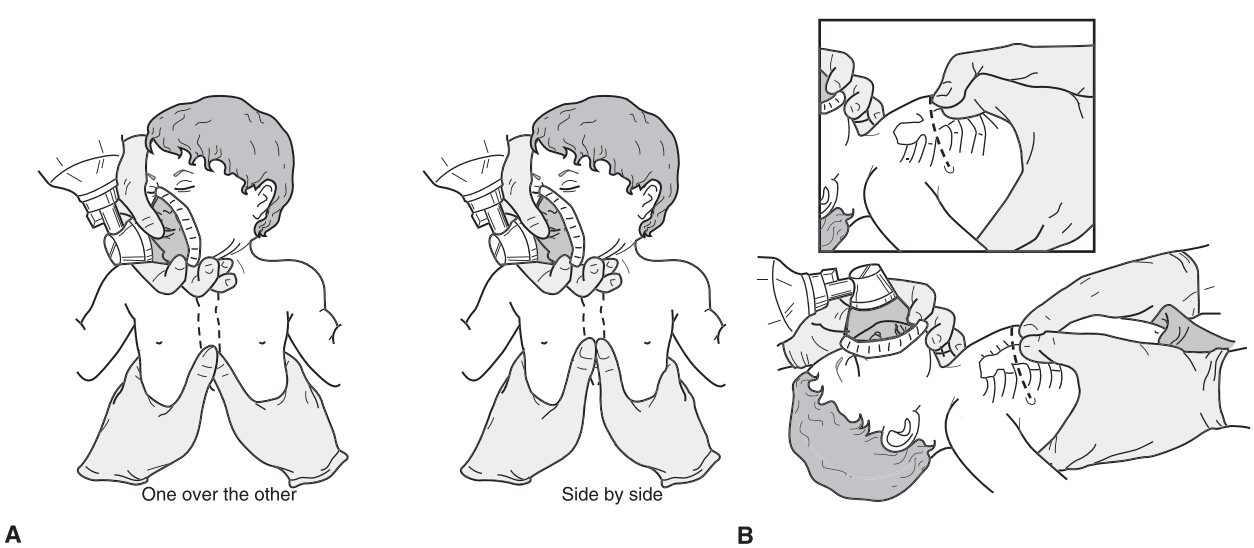

FIGURE 2.2 **A:** Thumb method of chest compressions. Infant receiving chest compressions with thumb 1 fingerbreadth below the nipple line and hands encircling chest. **B:** Hand position for chest encirclement technique for external chest compressions in neonates. Thumbs are side by side over the lower third of the sternum. In the small newborn, thumbs may need to be superimposed *(inset)*. Gloves should be worn during resuscitation.

TABLE 2.9

MEDICATIONS FOR NEONATAL RESUSCITATION

Medication	Concentration	Dosage	Route	Comment
Epinephrine	1:10,000	0.1–0.3 mL/kg	IV, ET, IO	Rapid push, dilute with 2 mL saline via ET tube
Sodium bicarbonate	0.5 mEq/mL (4.2% solution)	1–2 mEq/kg	IV, IO	Slowly over 2 min with effective ventilation
Naloxone	1 mg/mL	0.1 mg/kg	IV, IO	Rapid push
	0.4 mg/mL		IM, SC	Only in well-perfused neonate
Dextrose	10%	2–5 mL/kg	IV, IO	Correction of hypoglycemia

IV, intravenous; ET, endotracheal; IM, intramuscular; SC, subcutaneous.

scenario, peripheral venous access may be difficult. In the event that fluids and medications are required and other methods of vascular access have failed, intraosseous lines may be used (see Section VII: Intraosseous Infusion). Although experience with other infants is extensive in this arena, experience in the neonate is limited. A 20- or 22-gauge spinal needle may replace the 16- or 18-gauge larger intraosseous needles; however, the procedure for line placement in the proximal tibia is the same as for older children (see Appendix 3.8). Recall that premature infants have a small intraosseous space. Finally, the ET tube may be used for administration of epinephrine when vascular access has not yet been established.

Medications and Volume Expanders for Acute Resuscitation

Epinephrine. Although medications are rarely required for neonatal resuscitation, epinephrine is the most commonly indicated medication. Because asystole and bradycardia are usually the result of respiratory failure and tissue acidosis, epinephrine therapy is indicated when the newborn's heart rate remains less than 60 beats per minute, despite 30 seconds of effective ventilation with 100% oxygen and another 30 seconds of coordinated chest compressions and ventilation. Epinephrine works because of its α-adrenergic effects. Swine models have demonstrated that epinephrine induces vasoconstriction secondary to α-receptor agonism in infants, increases the diastolic and mean arterial pressures, and thus increases the perfusion pressure to the coronary arteries, enhancing oxygen delivery to the heart. The β-adrenergic effects of epinephrine that increase myocardial contractility and stimulate spontaneous contractions appear less important.

The dose of epinephrine therapy in neonates is 0.01 to 0.03 mg per kg of a 1:10,000 concentration, or 0.1 to 0.3 mL per kg (Table 2.9). It may be administered via an umbilical venous catheter, a peripheral IV, an intraosseous line, or the ET tube. The dose should be repeated every 3 to 5 minutes as needed throughout the resuscitation. Intravenous epinephrine should be administered as rapidly as possible and followed by a 1-mL normal saline flush. The safety and efficacy of high-dose epinephrine (0.1 to 0.2 mg per kg) has not been studied in neonates. A concern that large doses of epinephrine may lead to prolonged hypertension and subsequent intracranial hemorrhage in neonates has precluded the investigation of changing dosing recommendations. The AHA does recommend giving a higher dose of endotracheally administered epinephrine, between 0.03 and 0.1 mg per kg. However, given that there are no data from newborn infants to assess the safety of higher doses of intratracheal epinephrine, IV administration remains the preferred route. Given the need to distribute the medication throughout the lungs, ET epinephrine should be followed by 1 to 2 mL of normal saline and several positive-pressure breaths.

Volume expanders. Volume expanders are indicated for the treatment of hypovolemia. Both historical and physical examination findings suggest the need for volume expansion. Historical factors include fetal hemorrhage from an avulsed cord or trauma, or maternal hypotension from placenta previa, placental abruption, or trauma. Umbilical cord prolapse may cause hypovolemia in the newborn. Physical examination findings include pallor that persists despite oxygenation, weak peripheral pulses, persistently high or low heart rate, and a poor response to resuscitation, including effective ventilation.

Volume expanders (Table 2.10) are administered intravenously in 10 mL per kg aliquots and should be given fairly quickly (over 5 to 10 minutes), but not so rapidly as to increase the risk of intracranial hemorrhage from delicate vascular beds. The umbilical vein is the best site for administration of volume expanders, although the intraosseous or peripheral IV route may be used. After each infusion, the infant is reassessed for improvements in perfusion, blood pressure, and oxygenation. Current recommendations are to begin with a crystalloid solution, such as normal saline or Ringer's lactate. Administration of O-negative red blood cells (crossmatched with mother's blood if time allows) may be indicated for large volume blood loss or poor response to crystalloid

TABLE 2.10

Packed red blood cells	10	IV

IV, intravenous.

infusion. Albumin-containing solutions are no longer recommended because of cost, limited availability, risk of infection, and potential increased mortality.

Other Medications

Sodium bicarbonate. There are insufficient data to recommend routine use of bicarbonate therapy in neonatal resuscitation. Bicarbonate therapy may contribute to respiratory acidosis and a worsening intracellular acidosis, which may actually impair myocardial and cerebral function. Thus, its use is discouraged in brief resuscitations. In prolonged resuscitations and after establishment of adequate ventilation, bicarbonate may be given for documented metabolic acidosis or hyperkalemia using arterial blood gases and serum chemistries to guide administration. The dose of sodium bicarbonate is 1 to 2 mEq per kg administered intravenously and slowly over 2 minutes to decrease adverse effects associated with its hypertonicity. For the same reason, only the 0.5 mEq per mL (4.2%) solution should be administered to neonates. If only the 1 mEq per mL solution is available, it should be diluted 1:1 with sterile water before intravenous delivery. Because of its caustic nature, bicarbonate should never be administered via the ET route. Little research data exist to support the choice of other buffers, such as tris(hydroxymethyl)aminomethane (THAM), for documented metabolic acidosis, although many practitioners use this medication to reduce the occurrence of hypernatremia. This controversial area requires rigorous research.

Naloxone hydrochloride. Naloxone is a narcotic antagonist that reverses respiratory depression induced by narcotics. Naloxone is indicated for infants displaying signs of respiratory depression after PPV has restored a normal heart rate and color, and for those infants whose mothers have received narcotics within the 4 hours before delivery. Prompt and effective oxygenation and ventilation must be provided and the infant must have adequate perfusion before the administration of naloxone. The current dosing recommendation for naloxone is 0.1 mg per kg, which is given as 0.1 mL per kg of the 1 mg per mL concentration (Table 2.9). Caution must be used, as there are several concentrations of naloxone available. Naloxone is best administered via the intravenous, intraosseous, or intramuscular routes. ET administration is not recommended because of lack of data. Furthermore, the resuscitator must remember that repetitive doses of naloxone may be required because the duration of action of narcotics may exceed that of naloxone. Finally, do not give naloxone to the newborn of a mother suspected of narcotic addiction because this may precipitate acute narcotic withdrawal and seizures.

Atropine. Atropine is not recommended for acute neonatal resuscitation. Atropine is a parasympatholytic drug that reduces vagal tone and accelerates sinus or atrial pacemakers and atrioventricular conduction. Because vagal stimulation does not cause bradycardia in neonatal resuscitation, atropine is not indicated. Furthermore, many investigators believe that the bradycardic vagally mediated response to hypoxia is a valuable reflex to guide resuscitative efforts and should not be pharmacologically abolished by atropine.

The usual dose of atropine is 0.02 mg per kg with a minimum dose of 0.1 mg and a maximum dose of 2 mg. Because most newborns weigh less than 5 kg, their dose would require the 0.1 mg minimum. If smaller doses are given, paradoxical bradycardia and slowed atrioventricular conduction will likely occur. In conclusion, the efficacy of atropine in newborn resuscitation is unproven and anecdotal and could have deleterious consequences.

Postresuscitation Stabilization

After appropriate resuscitative efforts, continuous monitoring and anticipation of complications must occur until the patient is safely transported to a neonatal facility. Priority must be given to thermoregulation by providing the infant with a warm environment and repetitively monitoring the temperature. Measures of effective oxygenation and ventilation are assessed. Pulse oximetry and arterial blood gases are performed. ET tubes are securely taped and a chest radiograph is ordered to confirm tube and venous access placement. Vascular access is secured, and correction of metabolic acidosis and hypovolemia is continued. Glucose monitoring and the avoidance of hypoglycemia are also paramount as low blood glucose has been associated with poor neurologic outcome.

If mechanical ventilation is required while waiting transport to the neonatal facility, a pressure ventilator is used. Peak pressures are determined by clinical evaluation of adequate chest wall rise and blood gas analyses. A good starting point for peak pressure is the pressure needed for good chest wall rise and breath sounds during resuscitation as shown on the manometer. In general, this is between 15 and 30 cm H_2O. The physician should try to use the lowest pressure necessary for good clinical and laboratory response. Excessive positive pressure will decrease venous return to the heart, decrease cardiac output, and cause injury to lung tissue.

SPECIAL SITUATIONS

Meconium

Management of meconium-stained amniotic fluid has changed substantially with the most recent recommendation of the NRP. Meconium staining of the amniotic fluid complicates between 10% and 20% of all pregnancies. The risk of meconium-related complications at delivery increases to nearly 30% in infants born after 42 weeks' gestation. Approximately 2% to 5% of infants born with meconium in the amniotic fluid will experience some degree of aspiration syndrome, ranging from mild tachypnea to very severe pneumonitis with persistent pulmonary hypertension (Fig. 2.3). The management of an infant born through meconium differs from that previously discussed for other depressed infants.

When meconium staining is detected during delivery, resuscitative personnel must be prepared in the event that specific interventions are needed (Fig. 2.4). In the event the delivery occurs in the ED or a setting where health-care personnel are present and there is meconium staining of the amniotic fluid, the infant should be immediately transferred to the resuscitation team without intrapartum suctioning of the infant's mouth and nose. This recommendation is a change from previous guidelines after a multicenter randomized trial showed no decrease in the risk of meconium aspiration syndrome

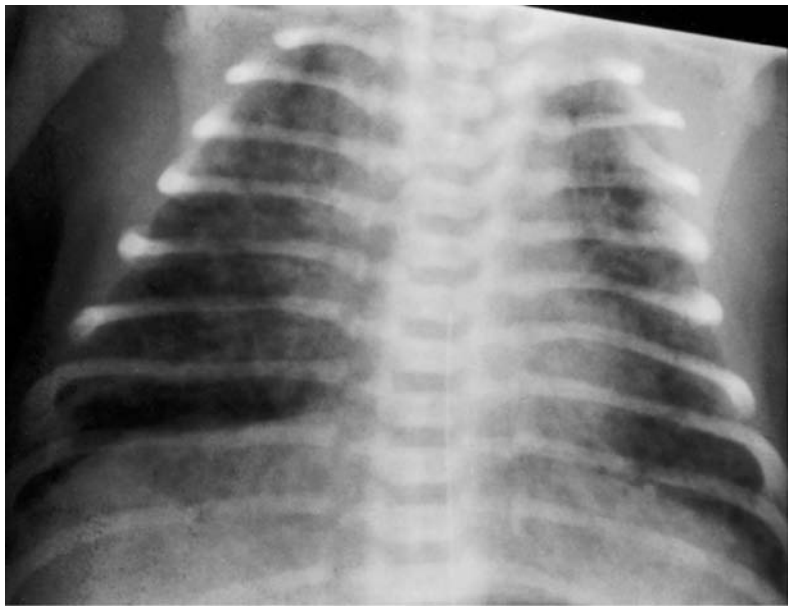

FIGURE 2.3 Meconium aspiration radiograph.

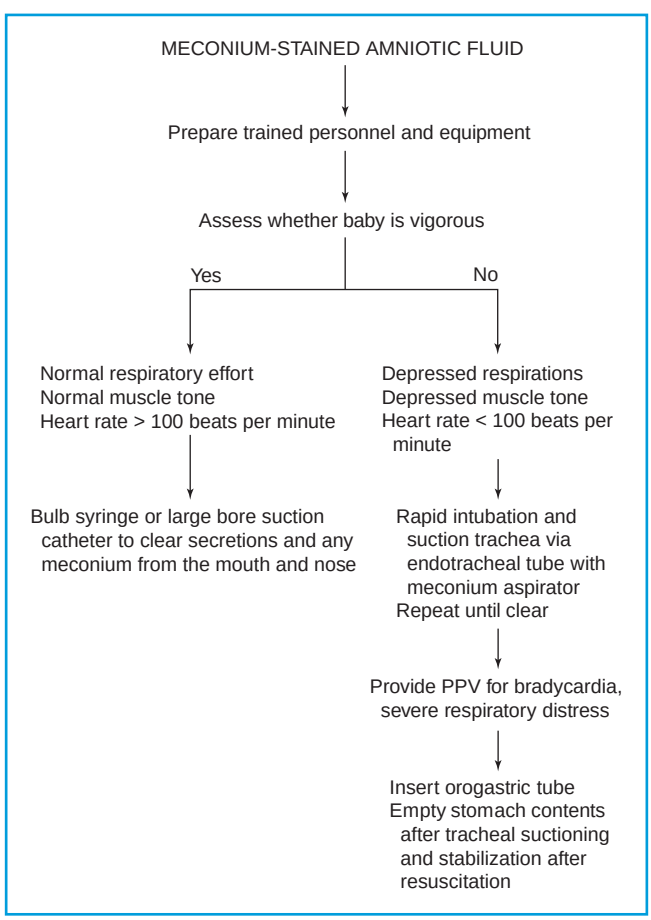

FIGURE 2.4 Management of infant born with meconium-stained amniotic fluid. PPV, positive-pressure ventilation.

when suctioning was performed after delivery of the infant's head but before delivery of the body.

Current guidelines for further management of newborns with meconium in the amniotic fluid are based on the status of the newborn rather than the consistency of the meconium. If meconium is present and the baby is not vigorous—that is, a baby with depressed respirations, depressed muscle tone, or a heart rate less than 100 beats per minute—direct suctioning of the trachea soon after delivery is indicated before many respirations have occurred. After delivery, the infant is placed in a warm environment, and before other usual resuscitative efforts, meconium suctioning is completed. First, the trachea is intubated, and suctioning of the lower airway occurs. Because the ET tube itself is the largest diameter item placed in the trachea, it is the most effective means of suctioning meconium. Thus, a meconium aspirator (Fig. 2.5) directly attached between the ET tube and mechanical suction is the preferred method of removing meconium from the lower airway. Negative pressure is applied by occluding the opening on the side of the aspirator with a finger. Mechanical suctioning should not exceed 100 mm Hg. Repeat intubation and

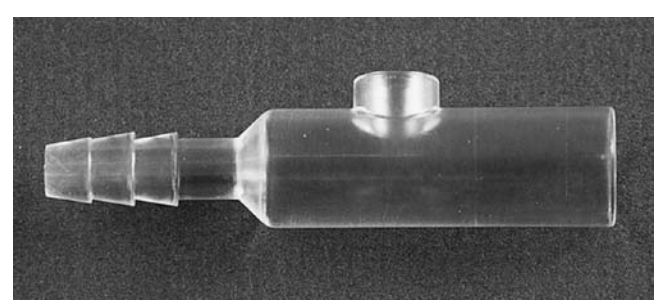

FIGURE 2.5 Meconium aspirator.

suctioning with another ET tube may be required until the aspirated material is clear. After initial tracheal suctioning, it may be necessary to begin PPV if the heart rate or respirations are severely depressed, despite persistent meconium in the airway. Wait until completion of tracheal suctioning and resuscitation to place an orogastric tube to empty meconium from the newborn's stomach, which could potentially be aspirated later.

When meconium is present and the baby is vigorous, defined as a baby with a normal respiratory effort, normal muscle tone, and a heart rate greater than 100 beats per minute, a bulb syringe or large-bore (12F or 14F) suction catheter is used to clear secretions and any meconium from the mouth and nose. Tracheal suctioning should be eliminated in vigorous infants, regardless of the consistency of the meconium. This recommendation is based on several large randomized trials that demonstrated that routine tracheal suctioning did not decrease morbidity or mortality from meconium aspiration syndrome.

Prematurity

Premature infants have an increased likelihood of needing newborn resuscitation. Early involvement of neonatologists and neonatal centers adept in the management of low-birthweight infants is crucial to improve outcome. Only 15% of hospitals have specialized neonatal units. Hospitals without neonatal units need easily available guidelines and established relationships for accessing neonatal consultation and transport. Several factors have added importance in the resuscitation of the preterm infant. These include greater risk for heat loss, greater mechanical ventilation needs, and greater risk of intraventricular hemorrhage.

Premature infants are at greatest risk for heat loss because of their higher ratio of body surface area to body mass. Premature infants require the strictest attention to maintenance of normal body temperature.

Premature infants are more likely to develop respiratory distress than term infants. As a result, assisted ventilation must be provided effectively but gently. ET intubation is usually necessary for surfactant administration and transport to a neonatal facility. Too much ventilatory pressure may result in barotrauma to the lungs and decreased cardiac output as a result of decreased venous return. Good clinical judgment should be used by watching for adequate chest wall rise and listening for good breath sounds. The physician should use the lowest pressure necessary to achieve a heart rate greater than 100 and good color; inflation pressures can generally be initiated at 20 to 25 cm H_2O and titrated to these clinical endpoints. Hyperoxia may lead to complications such as retinopathy of prematurity in low-birthweight infants, and so beginning the resuscitation with less than 100% inspired oxygen is a reasonable option. If no improvement in heart rate or color occurs by 90 seconds, the fraction of inspired oxygen should be increased. Once the infant is stabilized after initial resuscitative care, the fraction of inspired oxygen can be decreased while monitoring pulse oximetry.

The germinal matrix of the preterm infant's brain is vulnerable to bleeding. Factors contributing to subsequent intracranial hemorrhage include excessive pressure or osmolality delivered to an already maximally dilated vascular bed. Subsequently, in premature infants, hyperosmolar solutions such as 25% dextrose or 8.4% sodium bicarbonate should be avoided. Volume expanders, dextrose, and sodium bicarbonate solutions, when indicated, should be administered slowly to minimize injury to these vascular beds.

Pneumothorax

Pneumothorax is a potentially lethal problem in the neonate because it can rapidly progress to a tension pneumothorax and thereby decrease cardiac output. It is often the result of PPV, positive end-expiratory pressure, or resuscitation.

Pneumothorax is also more common in premature infants with surfactant deficiency and in infants with meconium aspiration. Signs and symptoms include grunting respirations; intercostal, sternal, and substernal retractions; elevated respiratory rate; and tachycardia followed by bradycardia and hypotension. The physical examination findings may include asymmetrically decreased breath sounds and distant heart tones. However, it often may not be possible to diagnose or localize a pneumothorax by auscultation. Transillumination by a high-intensity light in a dark room will reveal increased light transmission on the side of the pneumothorax.

If significant respiratory distress is present and pneumothorax is suspected, rapid decompression may be achieved with a large syringe, 20-gauge needle or catheter over needle, and three-way stopcock. The chest is cleansed with antiseptic solution, and the needle is advanced at the fourth intercostal space in the anterior axillary line or the second interspace in the midclavicular line. This will relieve the tension and decompress the pleural space. Subsequently, a chest tube (8F) may be placed using a standard technique (see Section VII: Insertion of a Chest Tube). If the infant is stable, an expedient portable anteroposterior chest radiograph may be taken to confirm the diagnosis.

Diaphragmatic Hernia

Diaphragmatic hernia is a true neonatal emergency and may be suspected by tachypnea, asymmetric chest wall motion, and a scaphoid abdomen. The diagnosis is confirmed by a chest radiograph showing bowel gas within the thorax (Fig. 2.6). Infants with diaphragmatic hernias must be immediately endotracheally intubated to avoid excessive amounts of air accumulation in the bowel. Since the bowel is in the thoracic cavity, distended bowel impedes ventilation. A nasogastric tube should also be rapidly placed to decompress the stomach. The infant must be rapidly evaluated by a pediatric surgeon after ventilation is stabilized and venous access is achieved.

Spina Bifida

Spina bifida (meningocele, meningomyelocele, and lipomeningocele) involves a wide array of defects. It can range from the least significant form (spina bifida occulta, nonfusion of vertebral laminar arches) to the severe form with meninges and neural tissue protruding, with poorly organized cord tissue

FIGURE 2.6 Left diaphragmatic hernia.

exposed to the surface. Neurologic deficit ranges from none to severe impairment and associated hydrocephalus. The child should receive proper supportive care, oxygen and fluid (as needed), sterile moist dressings to the exposed sac or tissues, and prompt referral to a pediatric neurosurgeon.

CHAPTER 3 ■ SHOCK

LOUIS M. BELL, MD

All physicians who care for ill children will be faced with managing the clinical syndrome of shock. Many common childhood illnesses, such as trauma, gastroenteritis, infection, and accidental drug ingestions, can lead to shock. Ultimately, without timely medical intervention, the child in shock will follow a common pathway to multiorgan system failure and death. Early recognition and appropriate therapy are vital if we hope to reduce the morbidity and mortality associated with this serious syndrome.

The first section of this chapter is devoted to early recognition, which demands a clear understanding of the definition, pathophysiology, and clinical manifestations of shock. Next, the etiologic types of shock, including hypovolemic, cardiogenic, distributive (septic), dissociative, and obstructive shock, are discussed.

Finally, the appropriate therapy and prevention of shock are discussed. Exciting developments are occurring within this area. Advances in molecular biology and immunology have led to a better understanding of the biochemical mediators involved in initiating and maintaining shock. Noninvasive methods for measurement of cardiac output are being developed for use in the emergency department (ED). Treatment modalities that antagonize or prevent the inflammatory cascade that lead to shock, multiorgan dysfunction syndrome (MODS), and death are now being studied. Combined with aggressive supportive and microbial therapies, these experimental immunotherapies may further reduce the morbidity and mortality associated with shock.

DETERMINANTS OF CARDIAC OUTPUT AND THE DEFINITION OF SHOCK

Circulation in the Child

Normal circulatory function is maintained by the complex interplay between the central pump (heart) and blood flow at the regional level, all done with the sole purpose of delivering oxygen and nutrients to the tissues.

The cardiac output is calculated by multiplying the stroke volume (volume of blood ejected by the left ventricle) by the heart rate (ejection cycles per minute). The stroke volume depends on the filling volume of the ventricle (preload), myocardial contractility (Starling's curve), and the resistance against which the heart is pumping blood into the systemic vasculature (afterload).

Heart rate is controlled through the vagus nerve and endogenous catecholamine release. Hypertension and severe hypoxemia can lead to increases in vagal tone and bradycardia. In times of flight, fright, or stress, endogenous catecholamine release increases adrenergic tone with an increased heart rate. In the infant who has relatively less myocardial contractility, in times of metabolic need, increase in cardiac output depends on an increasing heart rate rather than on an increase in stroke volume. This is also the reason bradycardia is poorly tolerated in this age group; cardiac output falls quickly because there is little ability to compensate with an increase in stroke volume. Conversely, faster heart rates are best tolerated in infants, in whom ventricular filling time is less critical in contributing to stroke volume and, ultimately, to cardiac output.

Definition of Shock

An understanding of normal physiology allows us to define *shock* as an acute syndrome that occurs because of cardiovascular dysfunction and the inability of the circulatory system to provide adequate oxygen and nutrients to meet the metabolic demands of vital organs. Note that this definition recognizes that shock can and does exist without hypotension, especially in children.

PATHOPHYSIOLOGY

Microcirculatory Dysfunction

The clinical manifestations of shock can be directly related to the abnormalities seen on the tissue, cellular, and biochemical levels. Microcirculatory dysfunction, common to all etiologic types of shock, is characterized by maldistribution of capillary blood flow. Local sympathetic, vasoconstrictor nerve activity and circulatory vasoactive substances (Table 3.1) cause smooth muscle contraction in the precapillary sphincters and arterioles. As shock continues, mechanical obstruction of capillary beds occurs by blockage with cellular debris. Normally, polymorphonuclear leukocytes undergo extensive deformation as they squeeze through the capillaries. Hydrostatic pressure within the capillary makes this possible. However, hydrostatic pressures fall by 30% to 40% during shock states. As a result, capillary beds are blocked and endothelial damage occurs. Subsequent complement activation causes still further aggregation of platelets and granulocytes. During septic shock, exposure to endotoxin directly damages vascular endothelium. Once damaged, endothelial cells can generate procoagulant activity, which may explain the mechanism by which fibrin is deposited in the microcirculation. Superoxide radicals, lysosomal metabolites, and cytokines produced by macrophages and neutrophils for bacterial killing can result in further tissue damage, especially to endothelium, adding to the vicious cycle of damage to the microcirculation.

TABLE 3.1

ENDOGENOUS (HOST-DERIVED) VASOACTIVE MEDIATORS IN SHOCK

Mediator	Stimulus	Major sources	Major actions
Norepinephrine	Hypovolemia Head trauma	Sympathetic nervous system Adrenal medullae	Vasoconstriction β_1, β_2 stimulation
Epinephrine	Hypovolemia Hypercapnea	Adrenal medullae	Vasoconstriction α, β_1 stimulation
Angiotensin II	Hypovolemia	Kidneys, brain, blood	Vasoconstriction
Arachidonic acid metabolites			
Leukotrienes	Tumor necrosis factor Bacterial antigens	Macrophages	Capillary permeability Vasoconstriction, release of lysomal hydrolases
Thromboxane A_2	Hypoxia	Platelets	Vasoconstriction, platelet aggregation
Prostaglandins F_2	Hypoxia	Platelets Vascular smooth muscle	Vasoconstriction
Prostaglandins I_2	Hypoxia	Healthy vascular endothelium	Vasodilator counterbalances thromboxane A_2
Myocardial depressant factor	Ischemia Tissue damage	Pancreas	Direct negative inotropic effects
Opiates (B-endorphins)	Hypoxia	Pituitary	Decreased myocardial contractility Decreased sympathetic tone hypotension
Inducible nitrous oxide	Inflammatory cytokines	Leukocytes	Vasodilation of vascular smooth muscle

Tissue Ischemia

Tissue ischemia is also basic to all forms of shock. The consequences of poor tissue perfusion sustain the cascade of events that occur during shock. When there is a lack of oxygen, energy production at the cellular level becomes inefficient, producing only 2 moles of adenosine triphosphate (ATP) per mole of glucose instead of the normal 38 moles of ATP produced by aerobic metabolism.

In addition, anaerobic metabolism depletes glycogen stores with an accumulation of lactate and associated acidosis. The decreasing energy and acidosis lead to an efflux of potassium and an influx of sodium and calcium with an obligate influx of water into the cell. Cellular swelling and further cellular dysfunction occur, which is seen clinically as edema.

Release of Biochemical Mediators

Biochemical mediators play an important role in the development and continuation of all types of shock. These vasoactive and inflammatory mediators are endogenous (host-derived) products primarily from cells of nervous system and hematopoietic origin. Although in septic shock these mediators are stimulated after exposure to microbial products (e.g., endotoxin) and play a primary role in initiating shock, in hypovolemic and cardiogenic shock, they are released secondarily in response to ischemic cellular injury as just described.

Vasoactive Mediators

The vasoactive mediators exert their effect primarily by induction of severe vasoconstriction and vasospasm, induction of platelet aggregation and thrombus formation, increased capillary permeability, and redistribution of blood flow away from vital tissues (Table 3.1).

Inflammatory Mediators

In the past, it was believed that invasive microbial agents were directly responsible for the cellular damage and microcirculatory dysfunction seen in septic shock. However, since the mid-1990s, it has become clear that endogenous inflammation mediators are the real culprits in the pathogenesis of septic shock and that lethal tissue injury occurs when production of these mediators escalates out of control. The concept that shock (and particularly septic shock) is an uncontrolled inflammatory response is being challenged as more is discovered about the types of cytokines that are secreted by the immune system. As we know, the CD4 T cells secrete cytokines with inflammatory properties from type 1 helper T cells (TH1s). Cytokines with *anti*inflammatory [type 2 helper T-cell (TH2)] properties, such as interleukin (IL)-4 and IL-10, are also produced. Although the factors that determine whether the T cells have a TH1 or TH2 response is unknown, it is clear that the cascade of events that lead to shock is a complicated interaction between pathogen and host immunity.

TABLE 3.2

ENDOGENOUS (HOST-DERIVED) INFLAMMATORY MEDIATORS IN SHOCK

Mediator	Stimulus	Major sources	Major action
Platelet-activating factor	TNF Bacterial antigens	Platelets Neutrophils	Thrombosis Vascular permeability
Cytokines			
Tumor necrosis factor α (TNF-α)	Bacterial antigens Severe trauma	Macrophages Monocytes	Induces other mediators Adhesion to endothelium Enhanced TNF-x production
Interferon-gamma	Bacterial antigens	T cells	
Interleukin (IL)-1 beta	TNF Bacterial antigens	Mononuclear Phagocytes	Fever Leukocytosis Acute-phase reactants Adhesion to endothelium
IL-6	TNF IL-1	Monocytes Endothelial cells	Fever Leukocytosis Thrombosis
IL-8	Endotoxin TNF	Monocytes Endothelial cells	Neutrophil activation
Complement fragments	TNF Bacterial antigens	Alternate pathway	Chemotactic activity
Toxic oxygen species	TNF Bacterial antigens	Neutrophils	Cellular damage

Septic shock starts with exposure to microbial products. Perhaps the most potent stimulator of the inflammatory cascade is the outer cell membrane of gram-negative bacteria, a lipopolysaccharide (LPS) coat, also called *endotoxin*. Once in the bloodstream, the LPS attaches to a plasma protein called *LPS-binding protein* (LBP). This complex (LPS-LBP) binds to the CD14 receptor on the surface of the monocyte/macrophage, which leads to stimulation of tumor necrosis factor alpha (TNF-α) and IL-1, and ultimately, to the entire cascade of inflammatory mediators.

As a group, these protein mediators are called *cytokines* (Table 3.2). TNF plays a pivotal role in triggering the production of not only other cytokines, but also other inflammatory mediators. TNF is one known endogenous factor that is capable of inducing a broad range of vasoactive and inflammatory mediators. Because of this, treatment of shock with anti-TNF antibodies has been attempted with mixed results (see "Initial Therapy" section). TNF in physiologic amounts has beneficial effects in tissues and promotes wound healing, tissue remodeling, and neovascularization. In pathogenic amounts, TNF and other inflammatory mediators (Table 3.2) cause severe septic shock in animal models and act primarily by inducing fever, increasing the white blood cell counts, inducing production of procoagulant and cell adhesion molecules by endothelial cells, causing aggregates of hematopoietic cells, and increasing vascular permeability.

Nitric Oxide

Although nitric oxide synthases (NOS) are absent in resting cells, it is known that the gene is rapidly expressed in response to stimuli by inflammatory cytokines. For example, after exposure to TNF-α and IL-1, a variety of cells, including macrophages, vascular endothelium, vascular smooth muscle, hepatocytes, and cardiac myocytes, are induced to increase nitric oxide (NO) production. In these pathologic amounts, NO causes vasodilation of vascular smooth muscle, vascular hyporesponsiveness, and hypotension and shock. In physiologic amounts, NO has beneficial effects that make it important in host defense against infection as a neurotransmitter and in cardiovascular homeostasis.

Complement Activation

The complement system is activated by circulating bacteria and bacterial products. The low-molecular-weight peptides that are released as a result induce both vasoactive and inflammatory effects. Vasoactive effects are seen with C3 and C5 fragments, which promote the release of histamine and other vasoactive mediators, which produce increased permeability and vasodilation. Complement fragments also stimulate an inflammatory response by promoting the activation and aggregation of platelets and granulocytes.

Myocardial Depressant Factor

Myocardial depression occurs in all types of shock. More recent investigation suggests that myocardial depression may occur as a result of mediators that act directly on myocardial tissue. Discovered in 1970, a small peptide called *myocardial depressant factor* is produced when the pancreas is ischemic and hypoperfused. Myocardial depressant factor has been shown to have negative inotropic effects in isolated heart muscle and causes constriction of the splanchnic vascular bed. In 1985, Parker, using isolated heart muscle preparation, found altered inotropic responsiveness within 1 to 2 hours of endotoxin treatment, demonstrating *in vitro* what is apparent in patients with shock syndrome. Other pathways have been implicated in myocardial depression including NO-induced cytokine production.

Intrinsic myocardial depression, either primarily as in septic shock or secondarily as in hypovolemic or cardiogenic shock, adds to other circulatory derangements that have been discussed. Understanding this intrinsic or direct cardiac depression is important in designing treatment strategies.

CLINICAL MANIFESTATIONS

Early or Compensated Shock

Regardless of the etiology, shock begins when there is absolute or functional hypovolemia. Absolute hypovolemia exists in cases of severe emesis and diarrhea, trauma with blood loss, peritonitis, and "third spacing" of fluids or increased capillary permeability, as in sepsis. Functional hypovolemia exists when vascular capacity increases, as in septic shock, spinal cord injury, anaphylaxis, and barbiturate overdose.

The signs of early shock include tachycardia, mild tachypnea, slightly delayed capillary refill (more than 2 to 3 seconds), orthostatic changes in blood pressure or pulse, and mild irritability. These earliest symptoms result from an effort to compensate for shock, increase cardiac output, and maintain perfusion of vital organs (brain, heart, kidneys). Unexplained tachycardia without other signs may be one of the earliest signs of shock. Tachycardia occurs to compensate for a diminished stroke volume (Fig. 3.1). Delayed capillary refill occurs as increases in sympathetic tone by endogenous catecholamines cause peripheral vasoconstriction. In some cases of early septic shock, the skin may be warm and dry without a decrease in capillary refill, reflecting cutaneous vasodilation in a state of increased cardiac output and increased venous capacitance—so-called *warm distributive shock*. As systemic vascular resistance falls, cardiac output must increase to maintain normal arterial pressure. Often, in this form of distributive (septic) shock (i.e., high cardiac output and low systemic vascular resistance), the pulse will be bounding and the pulse pressure widened.

Late or Uncompensated Shock

As shock continues, these early compensatory mechanisms are not enough to meet the metabolic demands of the tissue, and uncompensated shock follows (Fig. 3.1). In uncompensated shock, the effects of cellular ischemia with the associated release of vasoactive and inflammatory mediators begin to affect the microcirculation, and the child shows signs of brain, kidney, and cardiovascular compromise.

Tachycardia and tachypnea continue. Tachypnea becomes more severe because an increasing acidosis elicits a compensatory increase in the minute ventilation, resulting in a fall in $PaCO_2$ and a compensatory respiratory alkalosis. The skin may be mottled or

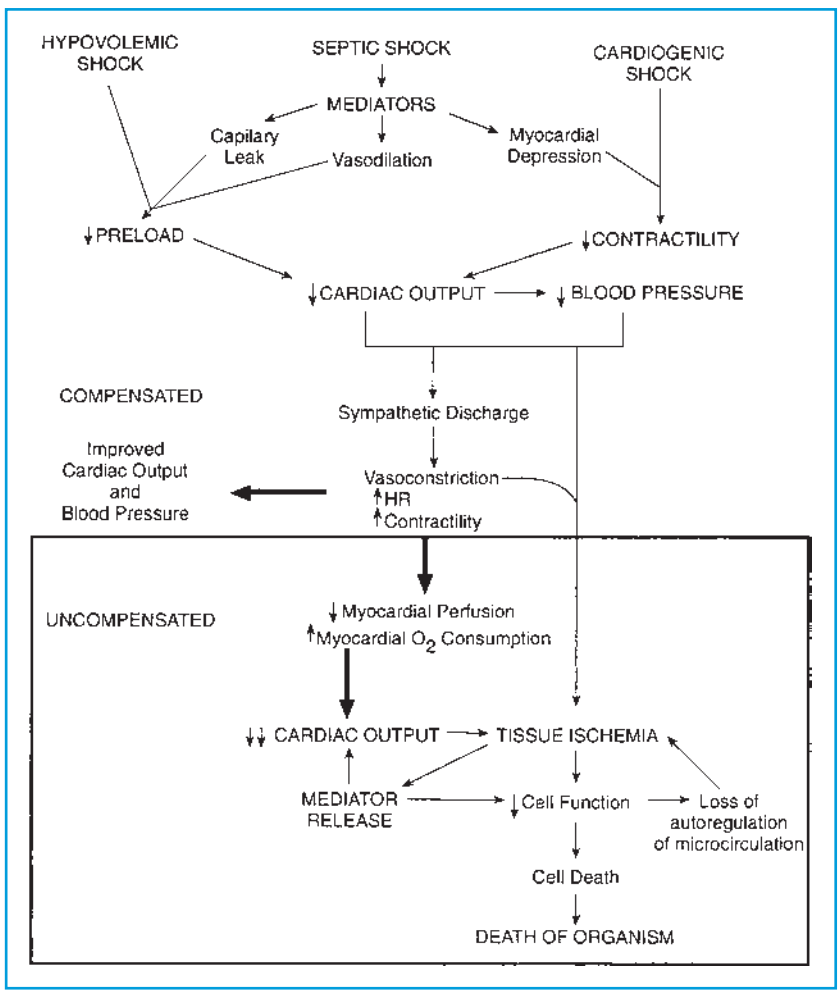

FIGURE 3.1 Sequence of pathophysiologic events in clinical shock states. (From Witte MK, Hill JH, Blumer JL. Shock in the pediatric patient. *Adv Pediatr* 1987;34:139–173, with permission.)

pale and extremities cool as vasoconstriction and diminished blood flow to the skin occur. Capillary refill becomes markedly delayed (more than 4 seconds). Hypotension is noted. Decreased cardiac output and vasoconstriction cause a decrease in renal perfusion, and oliguria is noted. The gastrointestinal tract is also underperfused and may become ischemic. Under these conditions, decreased motility, distension, release of vasoactive and inflammatory mediators, and fluid accumulation may occur. In patients with septic shock, fever (greater than 38.3°C rectally) or hypothermia (less than 35.6°C rectally) may occur.

As perfusion of the brain is compromised, irritability progresses to agitation, confusion, hallucinations, alternating periods of agitation and stupor, and finally coma. The MODS secondary to ongoing shock and exaggerated inflammatory responses is at the end of a continuum that has been termed *systemic inflammatory response syndrome* (SIRS), a syndrome that is meant to describe the nonspecific inflammatory process, which may occur after trauma, infection, burns, pancreatitis, and other diseases. (See "Distributive Shock" section.)

The effects of a dysfunctional microcirculation, tissue ischemia, and release of vasoactive and inflammatory mediators obviously affect all tissues, including the pulmonary tissues and vasculature. Damage to the capillary endothelium in the lung allows fluid to fill the interstitium of the intraalveolar septum. If the shock syndrome progresses, fluid accumulation will eventually lead to fluid leakage into the alveolar spaces, which prevents adequate gas exchange. As the damage to the lungs continues, the child demonstrates dyspnea, tachypnea, cyanosis refractory to oxygen therapy, decreased lung compliance, and diffuse alveolar infiltrates. These signs, when grouped together, represent syndromes of pulmonary injury referred to as acute lung injury (ALI) and the more severe acute respiratory distress syndrome (ARDS). Carcillo found that 11 (32%) of 34 children with septic shock developed ARDS. The incidence of ALI/ARDS is approximately 10 times more common in adults (22 to 86 cases per 100,000 persons) than in the pediatric age group (2 to 8 cases per 100,000 persons per year).

TYPES OF SHOCK

Hypovolemia

Hypovolemia (decreased circulating blood volume) is the most common cause of shock in children. The most common cause of hypovolemic shock occurs from water losses associated with diarrhea and vomiting (see Chapter 18). The World Health Organization estimates that in developing countries, 1.5 to 2.5 million diarrhea-associated infant deaths occur annually among children younger than 5 years of age, primarily because of hypovolemic shock, secondary to the vomiting and diarrhea that occurs with a variety of infectious agents, such as rotaviruses. Other causes of hypovolemic shock include blood losses (trauma, gastrointestinal, intracranial hemorrhage), plasma losses (burns, hypoproteinemia, peritonitis), and water losses (glycosuric diuresis, sunstroke).

Distributive Shock

Distributive shock occurs primarily because of vasodilation and pooling of blood in the peripheral vasculature. Causes include anaphylaxis, central nervous system (CNS) or spinal injuries, drug ingestions, and most commonly in children, sepsis. The primary derangements in septic shock results from exposure to microbial components (e.g., endotoxin, teichoic acid, viral proteins), which trigger the cascade of inflammatory and vascular mediators described. The bacterial etiology of septic shock (and meningitis) is listed in Table 3.3.

[b]Includes *Escherichia coli* and *Enterobacter* species.
Based on data from Schuchat A, Robinson K, Wenqer JD, et al. *N Engl J Med* 1997;337:970–976 and Watson RS, Carcillo JA, Linde-Zwirble WT, et al. *Am J Respir Crit Care Med* 2003;167:695–701.

SIRS in pediatrics is defined by having at least two of the following findings, one of which must be abnormal temperature or leukocyte count: (i) hyper- or hypothermia, (ii) tachycardia for age, (iii) tachypnea, and (iv) alteration in white blood cell counts, or the presence of immature neutrophils. Sepsis is defined as SIRS associated with infection. Although many children will have SIRS, the progression from SIRS (or sepsis) to severe sepsis (sepsis plus cardiovascular organ dysfunction *or* ARDS *or* two or more other organ dysfunctions), to septic shock (hypotension and need for vasoactive drugs), and/or to MODS (the presence of combinations of disseminated intravascular coagulation, ARDS, renal failure, or mental status changes) appears to be the natural history of untreated SIRS. Many patients who appear to have sepsis, severe sepsis, septic shock, or MODS have negative cultures.

Using 1995 hospital discharge and population data from seven states, Watson and colleagues estimated the incidence of severe sepsis (bacterial or fungal infection with at least one acute organ dysfunction) in children (up to 19 years old) to be 0.6 cases per 1,000 population per year. The mortality rate was 10%. The incidence was highest in infants (5 per 1,000). Half of the cases had underlying disease. In those with underlying disease, fungal infections were more common than bacterial. In some cases of septic shock, superantigenic bacterial toxins are responsible. Toxins such as staphylococcal toxic shock syndrome toxin-1 and streptococcal exotoxin-A are suspected to cause profound hypotension, leading to inflammation and multiorgan failure. Both of these superantigens have been shown to stimulate monocyte/macrophage production of TNF-α, IL-1β, and IL-6.

Cardiogenic Shock

Cardiogenic shock can usually be distinguished from other forms of shock because of associated signs of congestive heart failure, including rales auscultated throughout the lungs, a gallop cardiac rhythm, enlarged liver, and jugular venous distension.

Regardless of the etiology, cardiogenic shock leads to decreased cardiac output, in most cases as a result of a decrease in myocardial contractility. As we have seen, direct myocardial damage occurs in all types of shock as a late manifestation. Other common etiologies of cardiogenic shock in children include viral myocarditis, arrhythmia, drug ingestions, postoperative complications of cardiac surgery, metabolic derangements (hypoglycemia), and congenital heart disease. Occasionally, congenital heart disease is diagnosed in an infant, usually within the first 3 months of life, when the infant presents to the ED in congestive heart failure and shock. These infants invariably have congenital heart abnormalities, such as truncus arteriosus, transposition of the great vessels, or left hypoplastic heart syndrome, that depend on flow through the ductus arteriosum to maintain adequate oxygen delivery. The closure of the ductus precipitates congestive heart failure and eventually cardiogenic shock.

The management of obstructive shock, which is caused by mechanical obstructions to ventricular outflow and occurs with pericardial tamponade or tension pneumothorax (see Chapter 107 and Section VII), and dissociative shock, which occurs secondary to carbon monoxide poisoning (see Chapter 87) or methemoglobinemia, are discussed elsewhere.

TREATMENT

Initial Therapy

To determine proper therapy, recall the definition and pathophysiology of shock. *Shock* is defined as an acute syndrome that occurs because of cardiovascular dysfunction, as well as the inability of the circulatory system to provide adequate oxygen and nutrients to meet the metabolic demands of vital organs. Therefore, initial therapy in the ED can be applied universally, regardless of the etiology of shock, and is directed to reverse or halt further tissue injury. To underscore this, in 1991, Carcillo compared hemodynamic and oxygen use in children with either cardiogenic shock or septic shock. These data suggested that there was little difference physiologically, and therefore, initial treatment should be similar. Furthermore, the early recognition and aggressive fluid resuscitation and inotropic therapies appear to be vital in improving outcomes. The American College of Critical Care Medicine—Pediatric Advanced Life Support (ACCM-PALS) guidelines for hemodynamic support of newborns and children in septic shock recommends a therapeutic guideline (Fig. 3.2). In community hospitals (prior to transport) a retrospective cohort of 91 infants and children presenting with suspected septic shock were significantly more likely to survive if the guidelines were followed (8% vs. 38% survival). Survival was most dependent on early aggressive fluid resuscitation.

As noted previously, the basic defects are in shock hypovolemia, microcirculatory dysfunction, tissue ischemia, and cardiovascular dysfunction. Each defect becomes more severe the longer the shock state exists, so prompt and aggressive treatment is mandatory. The etiology of shock can be determined as therapy begins.

With this pathophysiology in mind, the first steps of therapy are to (i) establish an adequate airway; (ii) determine whether breathing is adequate; (iii) provide oxygen at 100% Fio_2; (iv) establish vascular access and obtain laboratory samples; and (v) provide aggressive fluid resuscitation, beginning with 20 mL per kg of crystalloid 0.9% sodium chloride or Ringer's lactate given intravenously as rapidly as possible (in minutes). Repeat intravenous boluses of 20 mL per kg (up to a total of 60 mL per kg should be done over 10 to 15 minutes. Reassessment after each therapeutic maneuver is vital (Fig. 3.3). After the initial therapy, the following questions should be addressed: (i) Is tracheal intubation needed? (ii) Should additional intravenous therapy be given? If so, blood, crystalloid, or colloid? (iii) Are positive inotropic drugs needed? If so, which one initially? (iv) What is the urine output? (v) What other drugs are needed (antibiotics)? (vi) Is the patient at risk for adrenal insufficiency? (vii) Should arrangements for admission to the ICU be initiated?

Simultaneously, a history should be obtained while the initial treatment is started. If possible, another physician can obtain a history from the caregivers. Questions pertaining to trauma, fever, diarrhea, vomiting, medication, allergies, heart disease, immune competence, and seizures should be addressed. The step-by-step initial approach to pediatric shock is outlined in Figure 3.2.

Decision and Monitoring in the Emergency Department

Oxygenation

Oxygen delivery to the tissues remains our primary focus in children with shock. While the airway and ventilatory effort is assessed, 100% oxygen should be provided via a bag-valve-mask apparatus. Assisted bag-valve-mask may be indicated. If there is any question that the airway is obstructed or that ventilatory effort is inadequate, the insertion of an artificial airway is indicated. We suggest the orotracheal intubation route initially. Measurements of the Pao_2 by an arterial blood sample or pulse oximetry should be performed throughout the decision-making process. The goal is to maintain the arterial oxygen tension above 65 mm Hg; therefore, 100% oxygen should be continued until that is achieved. It should be noted that, given a hemoglobin concentration of 10 g per dL and 100% arterial oxygen saturation, a mixed venous oxygen saturation (measured from the superior vena cava) of more than 70% is associated with improved outcome in the first 6 hours of presentation in septic shock (see "Fluid Administration" section).

Vascular Access

Vascular access is vital in treatment. If possible, a large-bore intravenous catheter should be inserted in a peripheral vein. However, in many instances, the peripheral extremities will be

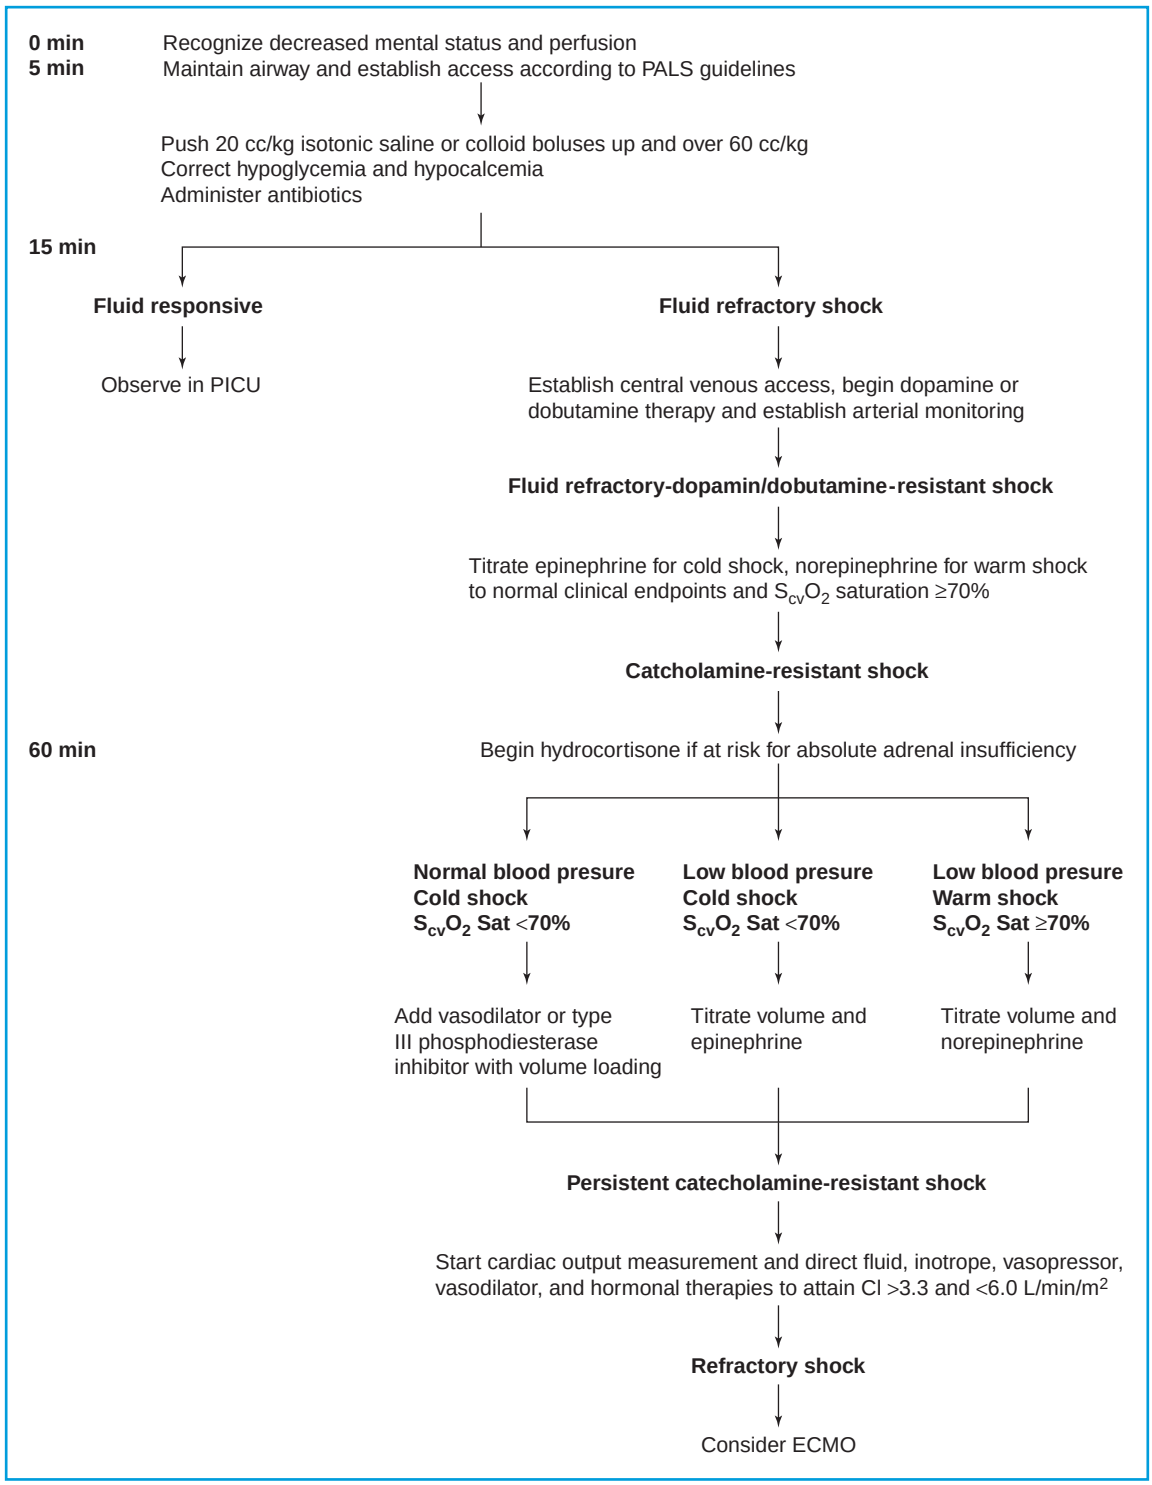

FIGURE 3.2 Approach to pediatric shock. PALS, Pediatric Advanced Life Support; PICU, pediatric intensive care unit; CI, cardiac index; ECMO, extracorporeal membrane oxygenation. (From Dellinger RP, Levy MM, Carlet JM, et al. Surviving sepsis campaign: international guidelines for management of severe sepsis and septic shock: 2008. *Crit Care Med* 2008;36(1):296–327.

cool because of vasoconstriction and no vein is found. Central vein venous placement by the Seldinger technique (see Section VII, Procedure 3.2) is the next step. Use of the femoral vein is preferred in infants and younger children. In older children and adolescents, cannulation of the internal jugular, external jugular, and subclavian veins can also be considered. If there is any delay in accomplishing prompt placement of a central venous catheter, an intraosseous line should be placed.

In children younger than 5 years of age, needle placement into the marrow space of the medial portion of the proximal

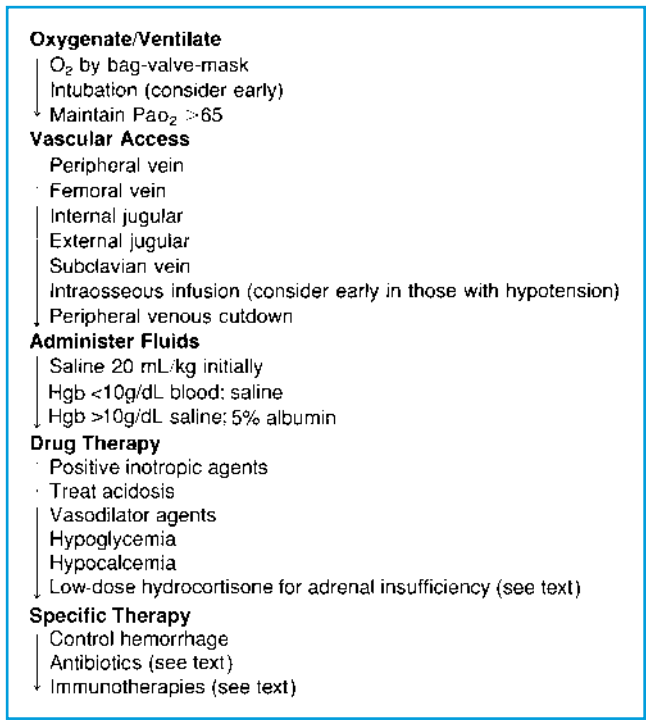

FIGURE 3.3 Management of shock—overview.

tibia, angulated away from the growth plate and 1 to 2 inches below the tibial tuberosity, is indicated (see Section VII, Procedure 3.8). In older children (older than 5 years of age) and adults, needle placement 1 to 2 inches above the medial malleolus is indicated. If central line placement is delayed, intraosseous fluid replacement is an excellent interim step in infants and children who require fluid resuscitation. In 1991, Velasco et al. found this technique to be useful in resuscitation in a hemorrhagic shock model and now it is an accepted method of achieving vascular access if reliable venous access cannot be rapidly attained. Others have commented on the safety and ease of placement. Intravenous fluid, blood products, bicarbonate, and catecholamines are among the therapies successfully given using this technique and are comparable in effect to the central or peripheral intravenous routes.

The last resort in establishing venous access would be for a venous cutdown (see Section VII, Procedure 3.1). Simultaneous with attempts at vascular access, venous blood samples can be obtained for complete blood cell count, platelets, prothrombin and partial thromboplastin times, electrolytes, blood urea nitrogen, creatinine, glucose, and blood culture (if indicated). An arterial blood sample should also be obtained.

Fluid Administration

After venous access is established, 20 mL per kg of 0.9% normal saline or Ringer's lactate is infused as rapidly as possible by push. Then reassessment should occur. The decision to give additional intravenous fluids can be based on arterial pressures, heart rate, and oxygenation. If blood pressure is normal, additional fluids will depend on urine output, heart rate, capillary refill, and mental status. If the child remains hypotensive after the initial fluid challenge, an additional 20 to 40 mL per kg should be infused and, if possible, titrated against central venous or right atrial pressures because they correlate better with intravascular volume than does systemic arterial pressure. Once in the intensive care setting, placement of a balloon-tipped, flow-directed pulmonary artery catheter or careful monitoring of mixed venous gases and central venous pressures (12 to 15 mm Hg) may be needed to assess more accurately the filling pressures of the heart, especially in children with fluid-refractory and dopamine-resistant shock.

Low cardiac output, rather than low systemic vascular resistance, is associated with increased mortality in children with septic shock. In most cases, careful monitoring of the clinical signs of perfusion, maintenance of perfusion pressures [mean arterial pressure–central venous pressure (CVP)], and maintenance of superior vena cava oxygen saturation at levels of more than 70% will ensure adequate cardiac output, thereby improving survival.

Accurate, noninvasive methods to measure cardiac output in the initial stages of fluid and inotropic support in the ED may be beneficial. One modality currently being evaluated is impedance cardiography. Using this noninvasive technique stroke volume, cardiac output and contractility can be determined. While its use in the pediatric ICU is being evaluated, it may become an important tool in the ED.

If these types of measurements are not possible in the ED or if transfer to the ICU is imminent, changes in vital signs and perfusion can be used to guide fluid management. Although we do not base fluid management on an absolute amount and are guided by the child's clinical condition, some ballpark figures for initial fluid resuscitation can be provided. In 1991, Carcillo et al. studied all children with septic shock who presented to the ED over a 6-year period and who had a pulmonary artery catheter inserted within 6 hours of presentation. Interestingly, fluid resuscitation in excess of 40 mL per kg in the first hour improved survival and was not associated with an increased risk of either cardiogenic pulmonary edema or ARDS, compared with children who received smaller amounts of fluid. Therefore in severe shock, fluid resuscitation, if indicated, up to 60 mL per kg or approximately 50% of the circulation blood volume, may be given within the initial phase of therapy (within the first 15 to 20 minutes). The important point to remember is that, in most cases of shock, not enough fluid is given and the child remains in relative hypovolemic shock. In 2002, Carcillo and Fields recommended that in the absence of rales, gallop rhythm, hepatomegaly or increased work of breathing, fluid can be administered to as much as 200 mL per kg in the first hours directed toward achieving normal perfusion and blood pressure. Monitoring such signs as heart rate, capillary refill, mental status, and urine output (at least 1 mL per kg per hour) is helpful in determining the amount of fluids needed in the initial phases of resuscitation. Monitoring of cardiac output is essential for children with cerebral damage or those in cardiogenic shock, in which case the need for adequate fluid resuscitation must be balanced with concerns over cerebral edema or cardiac disease, respectively.

Choice of Fluids and Blood Products

The initial choice of fluid should be 0.9% saline or Ringer's lactate given as described earlier, beginning with 20 mL per kg over minutes. Packed red blood cells should be given at 10 mL per kg over 1 to 2 hours to maintain a hemoglobin of 10 g per dL.

Children with cyanotic heart disease, or neonates, may require higher hematocrit percentages to ensure adequate tissue delivery.

If the hemoglobin is over 10 g per dL or if blood is not available, 5% albumin in 0.9% sodium chloride can be used in combination with crystalloid fluids. Initially, albumin can be given in 10 mL per kg doses. When colloids (albumin) are used, appropriate intravascular monitoring should be considered when possible to guard against circulatory overload.

Improving Myocardial Function and Circulation

Catecholamines (adrenergic agents) are the drugs of choice for improving myocardial contractility in patients with shock because of their very short half-life (2 to 3 minutes) and potency (Table 3.4). A brief review of adrenergic receptor physiology is important if we are to have a rational approach to their use.

There are at least three broad populations of adrenergic receptors, termed alpha (α), beta (β), and dopaminergic (DA) receptors. Although all have been subdivided further, in general, β_1-receptors mediate inotropic (contractility), chronotropic (rate), and dromotropic (increased conduction velocity) activity. β_2-Receptors mediate vasodilation and bronchial smooth muscle relaxation. α-Receptors mediate arteriole constriction systemically and bronchial muscle constriction. DA receptors, termed DA_1 and DA_2, mediate smooth muscle relaxation and increase renal blood flow and sodium excretion.

Catecholamines may stimulate some adrenergic receptors more strongly than others, providing some rationale for selection. In general, the mechanism of action for most positive inotropic agents seems to be an increased concentration of or sensitivity to intracellular calcium during systole. If the desired effect is not achieved with one agent, combinations of several agents together may be necessary. It is important to note that there may be decreased responsiveness to adrenergic stimulation in patients with congenital heart disease, after heart transplantation, or in those with bronchopulmonary dysplasia.

Currently, dopamine is the first choice to improve cardiac function and improve splanchnic and renal circulation if the patient is relatively stable but remains hypotensive after initial fluid resuscitation. At low dosages (2 μg per kg per minute), dopamine increases renal blood flow up to 50% and sodium excretion up to 100%. Cardiac output is increased with dosages of 5 to 10 μg per kg per minute. At higher dosages (more than 10 μg per kg per minute), x-adrenergic effects predominate, leading to arterial vasoconstriction and an increase in blood pressure. Improvement in perfusion as measured by increased urine output, blood pressure, and warming of the extremities can be seen early. More accurate measurements of cardiac index, arterial mixed venous difference, or left ventricular stroke work can be used to titrate the dosage in the ICU.

In some cases of profound septic shock and hypotension, epinephrine should be considered initially. A low dosage (less than 0.2 μg per kg per minute) of epinephrine stimulates both β_1 cardiac effects and β_2 peripheral vascular effects, which results in an increase in skeletal muscle blood flow and a decrease in diastolic blood pressure. Dosages higher than 0.3 μg per kg per minute are associated with increased α-adrenergic effects and increases in blood pressure. If the child is unresponsive to fluid resuscitation and dopamine, epinephrine may be useful in maintaining blood pressure and cardiac output. Experts recommend the use of low-dose norepinephrine for fluid-refractory, dopamine-resistant hyperdynamic (warm) shock.

Vasodilatory therapy should be considered in patients when epinephrine is being used and there are still signs of shock but with a normal blood pressure. Nutrient flow may be improved, left ventricular stroke work enhanced, and myocardial oxygen consumption decreased by lowering impedance to left ventricular ejections. A short-acting vasodilating drug, such as sodium nitroprusside, beginning with 0.1 μg per kg per minute, is preferred. The infusion can be increased until evidence of decreased peripheral vascular resistance exists or until the generally accepted safe dosage of between 8 and 10 μg per kg per minute is reached. Toxicity results from the accumulation of thiocyanate (cyanide), which should be monitored. The use of this therapy in the ED is rarely needed for the indication of shock, although in cases in which transfer to the ICU is delayed, it may be indicated.

TABLE 3.4

POSITIVE INOTROPIC AGENTS

Agent	Dose range (μg/kg/min)	Mechanism[a]	Considerations
Dopamine	2–20	β_1, β_2, DA stimulation	Increases renal flow 1–2 μg/kg/min, cardiac output 5–10 μg/kg/min
Epinephrine	0.1–1.0	β_1, β_2, α stimulation	Dose over 0.3 μg/kg/min associated or α effects
Dobutamine	2.5–15	β_1, β_2 stimulation	Increase cardiac output with no increase in heart rate, not as effective in those <12 mo (see text)
Milrinone	1–10	Phosphodiesterase F^{111} inhibition	Positive inotrope with smooth muscle relaxation
Isoproterenol	0.1–1.0	β_1, β_2 stimulation	Increases myocardial oxygen consumption
Norepinephrine	0.1–1.0	α, β_1 stimulation	Infrequent use due to renal vasoconstriction

[a]Adrenergic receptors: Beta (β_1) receptors mediate inotropic, chronotropic, and dromotropic activity; intestinal relaxation. Beta (β_2) receptors mediate vasodilation and bronchial smooth muscle relaxation. Alpha (α) receptors mediate arteriole constriction systemically; bronchial muscle constriction. Dopaminergic (DA) receptors mediate smooth muscle relaxation, as well as increases in renal blood flow and sodium excretion.

Dobutamine should be considered initially in patients with cardiogenic shock because it is a very selective stimulant of β_1 receptors. In patients with cardiogenic shock (elevated cardiac filling pressures and low cardiac output), it tends to increase cardiac output without increasing the heart rate. Starting dosages should be 2 to 5 μg per kg per minute. If dobutamine fails, epinephrine should be used.

Finally, milrinone represents a class of inotropic agents distinct from the catecholamines. Although the mechanism of action is not fully understood, data favor inhibition of myocardial cyclic adenosine monophosphate phosphodiesterase (cAMPase). A direct relaxant effect on vascular and vasodilation that results in smooth muscle causes afterload, and preload reduction contributes to the improved hemodynamic state. Milrinone facilitates atrioventricular conduction, relaxes smooth muscle, and dilates coronary arteries. At this time, there is seldom an indication to start this agent in the ED.

Acid–Base Abnormalities

It is clear that unless perfusion and ventilation are adequate, infusion of sodium bicarbonate rarely maintains arterial pH. There is increasing concern that the use of sodium bicarbonate may be detrimental at worst or of no benefit at best. The 2005 American Heart Association guidelines for CPR no longer recommend therapy with buffers during cardiac arrest in adults. The use of sodium bicarbonate to treat metabolic acidosis in children and neonates is also under scrutiny. Some experts have concerns about the effects of bicarbonate with respect to hemodynamics, left ventricular function, intracellular pH, and oxygen delivery and consumption. It seems most prudent that when treating shock in the pediatric patient that the focus be on correcting the underlying cause of acidosis, rather than the use of bicarbonate. Ultimately, improved blood flow will result in a decrease in acid products of anaerobic metabolism and only then will pH concentration remain normal.

Steroids

Bone, in a prospective, randomized, double-blind, placebo-controlled study of adults, concluded that high-dose corticosteroids provided no benefit in the treatment of septic shock. Patients in this study who exhibited serum creatinine levels above 2 mg per dL and who received steroids experienced a significantly higher mortality rate than the placebo group. Furthermore, patients who received high-dose methylprednisolone died as a result of secondary infection more often than their placebo-treated counterparts. Therefore, high-dose corticosteroids are of no therapeutic value in patients with septic shock. More recently, however, there have been several studies in adults with septic shock (most requiring ongoing vasopressor therapy) given physiologic doses of corticosteroids. The results suggested that this supplemental therapy may benefit some patients with vasopressor-dependent septic shock. A multicentered trial in France revealed that adults with catecholamine refractory septic shock who received low-dose hydrocortisone had a reduced risk of death. Currently, hydrocortisone therapy in children is only indicated for catecholamine resistance and suspected or proven adrenal insufficiency (defined as a total cortisol level between 0 and 18 mg per dL). Children at risk for adrenal insufficiency include those with purpura fulminans and associated Waterhouse-Friedrickson syndrome, those who have previously received steroids for chronic illness, and those with known pituitary or adrenal abnormalities.

Disseminated Intravascular Coagulation

As we have seen, microcirculatory dysfunction, tissue ischemia, and cardiovascular dysfunction, regardless of etiology, leads to shock and consumption of coagulation factors and platelets. This consumption is characterized by thrombocytopenia, an increase in fibrin split products, a decrease in fibrinogen, and abnormally prolonged prothrombin time and partial thromboplastin times (see Chapter 91). Management includes platelet transfusions (if indicated for bleeding or platelet counts less than 50,000 per mm^3) with infusion of 0.2 unit per kg. Fresh frozen plasma, 10 mL per kg intravenously, may be given for prolonged prothrombin and partial thromboplastin times.

Antibiotics

Antibiotics are given presumptively in most cases of severe shock when the etiology is unclear. Antibiotics are chosen based on age and suspected bacterial pathogens. If the child is younger than 4 weeks of age and there is no suspicion or evidence of meningitis, ampicillin and gentamicin is one effective combination. From 4 to 12 weeks of age, ampicillin and cefotaxime are favored by many pediatric infectious diseases specialists when meningitis is ruled out.

In some cases, the infant or child is too unstable to tolerate a lumbar puncture. Presumptive antibiotics should not be delayed in these cases. After resuscitation, the lumbar puncture can safely be performed and the cerebrospinal fluid (CSF) profile will still indicate a bacterial etiology. Latex agglutination tests can be obtained on urine plus CSF if the CSF culture and blood culture are negative. Presumptive antibiotics in children with shock and meningitis or when meningitis cannot be ruled out would include vancomycin and ceftriaxone or cefotaxime for the possibility of a strain of *Streptococcus pneumoniae* that is resistant to penicillin or cefalosporins. Vancomycin should be considered in the patient with suspected sepsis in an area that has increased methicillin-resistant *Staphylococcal aureus*. In children with underlying disease that affect the immune system, fungal infections should be considered. Invasive candidiasis would be most likely and amphotericin B or voriconazole would be a reasonable presumptive choice.

An Approach to Pediatric Shock

Considering all of the above, an approach to pediatric shock has been suggested by Carcillo and others (Fig. 3.2). The guideline includes a timeline underscoring the importance of early recognition of shock and prompt fluid resuscitation as the vital first steps in management.

Experimental Therapies

Over the last several years, identification of the mediators of septic shock has led to a better understanding of how these mediators cause and contribute to the pathophysiology of shock. Coincidentally, the use of monoclonal antibody techniques has allowed for the production of large quantities of antibody that are free from human infection and are of known isotype and epitope specificity. This new knowledge has led to the development of a number of investigational therapies aimed at different components of the inflammatory cascade.

TABLE 3.5

EXPERIMENTAL THERAPIES[a] FOR THE TREATMENT OF SEPTIS SHOCK (SELECTED)

Category	Product and mechanism of action
Antimicrobial	
E5	Murine IgM monoclonal antibody; binds to lipid A of endotoxin
HA-1A	Human IgM monoclonal antibody; binds to lipid A of endotoxin
Soluble CD14	Blocks binding of endotoxin to macrophage
Anti-CD14 antibody	Blocks binding of endotoxin to macrophage
Anticytokine	
Anti-tumor necrosis factor (TNF) antibody	Blocks inflammatory cascade
TNF soluble receptor	Binds TNF, inhibits inflammatory cascade
Interleukin (IL)-1 receptor antagonist	Blocks IL-1 binding
Nitric Oxide (NO) Inhibitors	
L-NMA	L-*arginine* analogs; inhibits NO synthase and decreases NO production, thereby preventing vasodilation
L-NAA	Same as above
Anticoagulation/ Antiinflammatory	
Recombinant human activated protein C	Antithrombotic; antiinflammatory and profibrinolytic activity, modulates and improves microcirculatory dysfunction
Antithrombin III	Glycoprotein; reduces interactions between endothelial cells and neutrophils, decreases cytokine production
Antioxidant	
N-acetylcysteine	Antioxidant; reduces proinflammatory factors, IL-8

[a]The safety and efficacy studies of these agents in humans and animals have been mixed. In some cases, use of these products has resulted in an increased mortality as compared with controls. Further research is needed.

These therapies can be divided into four broad categories (Table 3.5): (i) agents aimed at blocking the effects of circulating microbial products, (ii) agents that block cytokines, (iii) agents that reduce or prevent NO production, and (iv) agents that act as anticoagulants.

Although initially there was much optimism as to whether these products would reduce mortality by blunting the proinflammatory effects of cytokines or the vasodilatory effects of NO or thrombus formation, subsequent animal and human studies have revealed mixed results. In fact, some of these studies have been associated with an increased mortality. One potential useful agent is activated protein C [drotrecogin alfa (activated)] because procoagulation and subsequent thrombus formation are always components of the pathophysiology of shock. Reduced levels of activated protein C, an endogenous protein that promotes fibrinolysis and inhibits thrombosis and inflammation, are associated with an increased risk of death in septic adults. Randomized, double-blind, placebo-controlled trials in adults with sepsis determined that administration of activated protein C was associated with improved survival, with the potential for bleeding during the infusion as a risk. In November 2001, the U.S. Food and Drug Administration approved this agent for use in adults with severe sepsis. In adults, the incidence of serious bleeding was higher in those receiving protein C than the placebo group (3.5% vs. 2.0%) in a 2001 study. Protein C levels in children reach adult values at the age of 3 years. There is interest in studying this therapy in children. In a safety study in 83 children with severe sepsis, serious bleeding was seen in 2.4% to 4.8%. Currently, protein C should be considered for use only in adults with sepsis-induced organ dysfunction with a clinical assessment of high risk of death.

The use of these agents needs further study in children. If proven effective, we can almost certainly expect to use these agents in the ED. Therefore, emergency medicine physicians will need to understand the indications and risks of these agents as new data are made available for review.

Laboratory Indications of Improvement in Shock

The initial phase of treatment for shock is directed to improve oxygen delivery to the tissues by ensuring adequate ventilation, correcting hypovolemia, and improving cardiac function.

The success of the initial resuscitation is usually reflected in signs of improved perfusion (skin, kidneys, brain, heart rate) and indications of normal CVP if invasive monitoring is required. However, other laboratory parameters may be useful, if monitored sequentially, in determining whether the shock syndrome is persisting despite early clinical improvement. Sequential measurements of serum lactate levels, and expired CO_2 gas (end-tidal CO_2) and cardiac output measurement may indicate that continued aggressive resuscitation is needed despite signs of improvement.

In 1983, Vincent et al. found that a 5% reduction in serum lactate in the first hour was a good prognostic sign for patients presenting in circulatory shock. Lactate should fall over time as perfusion and oxygen delivery to the tissue improves. High serum lactate levels (approximately 4 mm per L) or serum lactate levels that continue to rise despite therapy are indications of severe shock. Aggressive therapeutic maneuvers to reverse the shock should be redoubled in this setting.

In addition, end-tidal CO_2 is a noninvasive laboratory value that may indicate continued hypovolemia. In hypovolemia and poor perfusion of the peripheral tissues and pulmonary tissues, CO_2 is not excreted in the lungs. Subsequently, there is a reduction of expired CO_2 gas, which is measured as a decreased end-tidal CO_2. As perfusion improves, end-tidal CO_2 increases. Investigators hope to correlate whether sequential end-tidal CO_2 measurements can be used to titrate the amount of intravenous fluid needed during resuscitation of the patient in shock. These measurements are noninvasive and may be a valuable adjunct in accessing improvements in perfusion in children with severe hypovolemia in the ED.

The feasibility of using a noninvasive technique to determine cardiac output by continuance wave Doppler ultrasound is being studied in ED settings in Australia. This technique was used in 30 children with suspected fluid-resistant septic shock in England as well. Determining the hemodynamic patterns (high cardiac index with low systemic vascular resistance vs. low cardiac index) was helpful in management. This technique may help to direct therapy in the treatment of severe sepsis in the future.

CHAPTER 4 ■ SEDATION AND ANALGESIA

JOEL A. FEIN, MD, MPH, AND STEVEN M. SELBST, MD

The relief of pain and suffering is one of the most common reasons for seeking care in an emergency department (ED). Injuries and painful medical conditions are common among children, and ED physicians are morally obligated to manage pain appropriately. Pain is defined as an unpleasant sensory and emotional experience usually characterized in terms of tissue damage, which is signaled by some form of visible or audible behavior. Acute pain serves a useful function and is necessary for survival; it alerts us to avoid certain painful stimuli, and it warns us that some body tissues may be damaged. However, pain must be relieved as quickly as possible; chronic pain serves no useful function and it has been noted that even acute pain can inhibit healing.

BACKGROUND

Historical Undertreatment of Pain in the Emergency Department

There have been great advances in recognition, assessment, and management of pain in children in recent years. The care of infants and children who undergo painful procedures in the ED has also improved considerably. Unfortunately, pain control is still not always addressed satisfactorily. Some recent studies still show that children, especially children younger than 2 years of age, still often fail to receive analgesia for painful conditions. Pain experienced by children in the ED is often poorly assessed and documented. Inadequate dosing of medications for children upon discharge from the ED is a significant problem. Emergency physicians and pediatricians are equally unlikely to give analgesics to children.

Barriers to Treatment of Pain in Children

Many theories try to explain why pediatric pain is not successfully managed in the ED. Physicians expect babies to cry, so this nonspecific response to pain is often tolerated instead of controlled. Moreover, because young children and infants cannot describe or localize their pain, it is often ignored or presumed not to exist. Adult patients who clearly indicate that they are in pain generally get a direct response from a physician, whereas a young child who is crying or whimpering may not. In addition, some ED physicians avoid giving adequate analgesics to children because they fear it will lead to drug addiction. This is fear unfounded, however, because narcotic addiction is extremely rare when medications are used appropriately to manage acute pain. Hypotension and respiratory depression are other feared consequences of narcotic use with children, and although these fears may be legitimate, respiratory depression and hypotension are unlikely to occur if proper protocols are adhered to. These unlikely occurrences should be manageable in the ED, and they should not inhibit the attempt to control pain. Furthermore, it is likely that ED physicians are often forced to concentrate on other aspects of resuscitation and care before managing pain. Plans for pain control, therefore, may be forgotten because of other priorities. Some physicians avoid analgesics because they do not want to mask symptoms. Also, in some cases, pain is ignored because it is inconvenient to wait for topical analgesics to take effect. This can delay care, so some physicians may underuse analgesics and convince a young child that a painful procedure or repositioning of an extremity will hurt only for a minute. Brute force (instead of medication) is then used, and more pain is inflicted on an already uncomfortable child.

Pain control may not be properly addressed with children because some physicians are unfamiliar with sedative and analgesic agents for children. In some EDs, these agents are not available. Also, children are often unable to cooperate or provide good verbal descriptions of pain, so it may be difficult to assess or quantify pain or to measure success in treating it. However, great progress has been made lately in the assessment of pain in children. Table 4.1 summarizes some reasons for inadequate pain control with children.

ASSESSMENT OF PAIN IN CHILDREN

The clinical evaluation of pain may be accomplished through physiologic measurements, behavioral assessment, or self-report. Infants and preschool children (younger than 5 years of age) cannot understand the nature of self-report scales, and their assessment, therefore, relies on observer report. *Physiologic* indicators of pain include heart and respiratory rates, blood pressure, and palm sweating. Of interest, but not yet of practical use in the emergency setting, is the correlation between an individual's pain and the acutely measured levels of stress hormones, such as cortisol, catecholamines, and glucagon.

Observational *behavioral pain assessments* can, however, measure behavioral distress experienced by the child. For example, the Behavioral Pain Score categorizes facial expressions (positive, negative, or neutral), crying (laughing, not crying, moaning, sobbing), and movements (playing, not moving, withdrawal, complex agitation). The Children's Hospital of Eastern Ontario Pain Scale is a widely used instrument that measures crying, facial expression, verbal expression, torso position, touch, and leg position. The scale has been found to be valid and reliable for assessing pain in younger children and

TABLE 4.1

POSSIBLE REASONS FOR INADEQUATE PAIN CONTROL IN EMERGENCY DEPARTMENT

Inability of young children to talk
Misconception that infants cannot feel pain
Misconception that children will not remember pain
Misconception that children will get addicted to narcotics
Fear of respiratory depression and hypotension
Unfamiliarity with analgesics and dosages
Other conditions taking priority

infants. Some observational pain scales use a combination of behavioral and physiologic measurements.

Self-report pain scales are the best indicators of pain and are the gold standard for assessing pain in children. Standard self-report assessment tools, such as visual analog scales (VASs), are more reliable indicators of pain when completed by the patient rather than by observers. Young children (between ages 4 and 7 years) can reliably use picture scales with faces in different phases of happiness and crying. The Wong-Baker FACES Pain Rating Scale (Fig. 4.1A) is one example of this type of ordinal scale.

For older children and adults, a VAS consists of a 10 cm (100 mm) horizontal line with end points marked as "no pain" (0) to "worst possible pain" (10) (Fig. 4.1B). Patients indicate the level of their pain by marking the line. A decrease in the VAS by 10 mm has been noted to correlate with the patients reporting "a little" improvement in their pain. Another study in adults demonstrated that patients who are in more pain to begin with require up to 30 mm decrease before considering their pain "a little better." The VAS has been further enhanced for children by allowing them to use multiple modalities for pain rating. These more versatile instruments allow the child to determine changes in height, thickness, and color as the pain intensity increases, as well as capitalize on the child's ability to discriminate his or her pain using at least one of these dimensions.

Impact of Pain on Children and Families

Emergency physicians must understand that pain is an individual experience and many factors contribute to the degree of pain that a child experiences for any given condition. Children of all ages can experience pain; it is believed that even neonates by 26 weeks' gestation respond to tissue injury with specific behavior and with autonomic, hormonal, and metabolic signs of distress. Newborns feel pain and react to painful stimuli (e.g., circumcision) with wiggling motions and crying. Young children often exaggerate the size and power of needles, while older children may be better able to understand the need for a painful procedure; they are usually less anxious and better able to tolerate the inflicted pain. However, an older child may have a better understanding of the significance of an injury or an illness that could cause depression, anxiety, and more pain. Similarly, parental response (anxiety or reassuring calm) may affect a child's perception of pain. Caregivers can experience elevated heart rate, blood pressure, and anxiety during the child's IV cannulation. Not surprisingly, parental distress-promoting behaviors increase childhood distress during IV cannulation. Other psychological factors, such as the child's emotional state, personality traits, gender, or cultural background, may impact his or her anxiety, and this can also alter the degree of pain. Some children seem to have a hypersensitivity to pain, whereas others tolerate it well. Recent work has demonstrated that certain genotypes, such as the CYP2D6 polymorphisms and opioid receptor OPRM1, can mediate the metabolism and efficacy of certain opiate medications. The context of the situation also plays a role; children who are hit during play may not complain of pain, yet may experience pain if the injury was meant as an attack or as punishment. A child's past experience with painful stimuli is also meaningful. One study showed that inadequate analgesia for one painful procedure might diminish the effect of adequate analgesia in subsequent procedures. Of course, the painful stimulus itself is important, and a stimulus that causes a great deal of tissue damage may hurt more than one that causes minor injury. Figure 4.2 summarizes the components of a pediatric patient's pain experience.

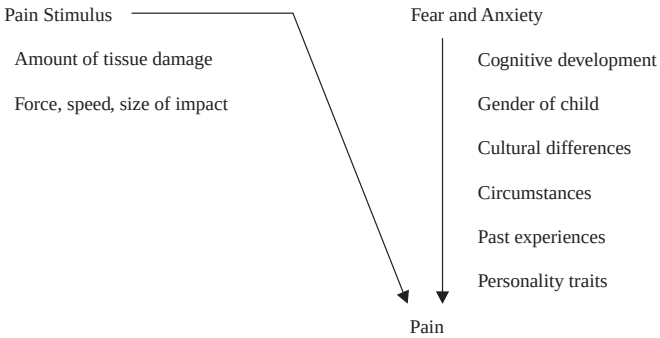

FIGURE 4.2 Components of pain. (Adapted from Schecter NL. Pain and pain control in children. *Curr Probl Pediatr Adolesc Health Care* 1985;15:4–67.)

Importance of Successful Pain Management

Realistically, pain in the pediatric patient who presents to the ED may never be eliminated completely. Efforts must be made, however, to relieve pain as much as possible. Several means are available for managing pain in children, and various medications and techniques can be used, depending on the type of pain that requires treatment.

Successful pain management is extremely important. Uncontrolled pain may lead to hyperalgesia, a state where the painful stimulus causes more pain than normally expected. Infants who undergo a painful experience develop an altered response to future episodes of pain. For instance, infants circumcised without anesthesia show increased distress during routine immunizations at 4 to 6 months of age, compared with those who received topical local anesthetic at the time of circumcision. This has also been demonstrated in neonates who had repeated heel sticks. Furthermore, surveys of patients, parents, and families show that satisfaction with the ED experience is highly dependent on the degree of pain a patient experiences and the efforts made to alleviate the pain. One study demonstrated that more than 75% of caregivers would be willing to pay $15 and more than one third would pay $100 to make an IV cannulation procedure painless. The Joint Commission has specific guidelines stating that patients have the right to pain assessment and treatment. This pain must be frequently reassessed, and the pain must be appropriately addressed with adequate analgesia.

NONPHARMACOLOGIC METHODS FOR PAIN CONTROL

Regardless of the procedure performed or the medications used during procedural sedation and analgesia (PSA), the patient's developmental level and acute level of anxiety will directly impact the success of a procedure and the patient's eventual subjective experience. There are many nonpharmacologic methods used to decrease the child's fear and incorporate the family into the therapeutic objectives. In general, these methods are low cost, consume very little time, and have few, if any, side effects. Thus, nonpharmacologic techniques can be used alone or as "adjuncts" to sedation drug therapy.

Children need gentle reassurance and carefully chosen words to reduce fear and pain. One should keep in mind that young children understand more than they say. Avoid casual teasing, condescension, or talking about the child while excluding him or her. As many choices as possible should be offered, but only if they are real choices. Do not tell a child that something will not hurt unless you are sure that it will not. It is important to be honest with the child about any pain or discomfort that he or she will experience. Once a child is surprised by a painful stimulus, he or she will become more vigilant and less amenable to distraction or relaxation techniques. In general, the time between informing the child about potential discomfort and the actual procedure performance should be brief. Long delays between the explanation and the actual procedure increase anticipatory distress prior to the procedure. One study showed that an empathic (age-appropriate) explanation of an upcoming needle stick reduced crying among patients compared with a group of children who received impersonal instructions. Fassler showed that allowing an older child to read about a procedure and then allowing role-playing and discussion was helpful in reducing pulse rates, as well as other physiologic and behavioral responses to pain. Such explanations and role-playing are time consuming, and it is helpful to enlist the child's parents to assist in these techniques. In some EDs, child life specialists help children with preparation and distraction for procedures, and they help educate the staff (and sometimes even families) about the most appropriate language to use for a specific child.

Most pediatric centers advocate family member presence during painful procedures. Recent research demonstrates that family presence does not increase the pain or distress of the parent or child, nor does it adversely affect the clinicians' abilities to provide safe and effective care. Giving the family the option to remain in the room during procedures and resuscitations increases the family's overall satisfaction with the visit, and should be incorporated into the plans for PSA.

Distraction of a child during a painful procedure may help reduce pain and distress. This includes having the child perform rhythmic breathing or blowing bubbles. A recent meta-analysis showed that music therapy is effective in reducing anxiety and pain for children undergoing procedures. Music can be used as adjunctive therapy in some clinical situations involving pain in the ED. Age-appropriate distraction has been demonstrated to reduce self-reported anxiety and parental perception of pain in children during laceration repair. For younger children, parents can also help with singing and storytelling. Visually intriguing toys, paintings on the walls or ceiling of a procedure room, and music or videotapes may also distract a young child. *Guided imagery*, in which children are coached to imagine a pleasant memory or scenario, may also be helpful. For example, one could ask the child to think of the funniest movie he or she has ever seen and to imagine the pain getting less intense with each laugh. Or, the child could be asked to imagine the pain as a color that is fading away and is painted over with the child's favorite color. *Hypnosis* has been used to treat pain in children for several years, and it has been successful in children as young as 2 years of age. Some physicians believe that the technique better serves children than adults because children have vivid imaginations and can more easily intertwine fantasy and reality. Hypnosis is of proven value for chronic pain syndromes such as migraine headaches

or long-term illnesses. Hypnosis has also been recommended for the acute management of burns, fractures, and other injuries; however, its use for painful procedures in a busy ED has not been rigorously evaluated.

Counterstimulation is a technique by which someone repetitively and persistently rubs or touches an area of the body close to the area that is being hurt. This technique is based on the gate theory of pain. Transmission of pain information from dorsal horn cells occurs through a "gate," which opens in response to signals from the affected small fibers. The gate can be "closed" by large neurons that are stimulated by nonpainful touching or pressing of the skin. The theory explains why we rub our elbow when we hit it against something: The rubbing stimulates these large fibers and suppresses the anticipated painful sensation.

Restraint should not be used in lieu of appropriate sedation and analgesics for the pediatric patient. Although proper *restraint* of a child for a painful procedure does not always reduce fear or anxiety, it does allow the physician to perform the task better. This indirectly reduces pain because fewer attempts may be necessary to accomplish the task. One should never attempt a painful procedure on a moving subject! The need for restraint should be explained to the parents, who should not be involved in the actual process. Instead, the child might be wrapped in hospital sheets or papoose boards with Velcro straps, with the parents attempting to calm the child afterward. Experienced clinicians using papoose boards often use sheets between the child and the Velcro straps to avoid skin abrasion by the Velcro itself. The technique should be monitored carefully to avoid the uncommon complications of minor bruising, edema, or transient vascular compromise.

SPECIFIC AGENTS

Analgesics for Mild to Moderate Pain

Conditions such as headache, myalgia, chest pain, pharyngitis, otitis media, arthralgia, sunburn, strains, and sprains often produce mild pain in children. For treatment of less intense pain, aspirin, acetaminophen, ibuprofen (nonnarcotics), and codeine (narcotic) are excellent oral analgesic medications. *Aspirin* is one of the oldest analgesic medications, but it is rarely used now because of the better side effect profile of other analgesics and the perceived risk of Reye's syndrome.

Acetaminophen acts centrally on nonopioid receptors in the brain to inhibit prostaglandin synthetase. Acetaminophen is a good choice for pain associated with minor trauma or otitis media because it is well tolerated and comes in liquid form, making it easy to give to young children. One study showed that 1,000 mg of acetaminophen is equal to 60 mg of codeine for postpartum pain. In addition, acetaminophen does not cause bleeding and is unlikely to cause bronchospasm in asthmatics. It is dosed at 10 to 15 mg per kg per dose every 4 hours and takes effect in 20 to 40 minutes, with a peak effect in 2 hours. Rectal administration produces delayed and variable uptake. Higher doses may be needed, but clearance may be prolonged so the rectal dose interval should be extended to 6 or 8 hours. Single rectal doses of 20 mg per kg produced safe plasma concentrations in preterm neonates. In general, high dosages of acetaminophen are usually well tolerated, but therapy in children should not exceed 75 mg per kg day (60 mg per kg per day in infants and newborns). Updated guidelines and product labeling are anticipated from the FDA in the near future, decreasing the total daily dosage that is considered safe. Acetaminophen has no antiinflammatory effects, and therapeutic doses rarely are associated with side effects in children; overdose, however, can cause liver toxicity. Addition of codeine may enhance the analgesic effect in a subset of children.

Nonsteroidal antiinflammatory drugs (NSAIDs) (e.g., ibuprofen) are potent inhibitors of the COX pathway and they prevent the formation of prostaglandin, a known mediator of pain, fever, and inflammation. NSAIDs are excellent choices for treating minor pain, such as headache, dysmenorrhea, or musculoskeletal injuries. Some studies show that NSAIDs provide better analgesia than acetaminophen, and others show no difference. NSAIDs have a longer half-life than acetaminophen. The recommended dosage of ibuprofen is 8 to 10 mg per kg given every 6 hours. The recommended dosage for ibuprofen in older children is 200 to 400 mg per dose given every 6 hours (maximum 40 mg per kg per day) for mild to moderate pain. Ibuprofen is available in liquid form, making it suitable for use in very young children. Ibuprofen and the other NSAIDs, such as naproxen and ketorolac, are nonaddictive and does not cause respiratory or cardiac depression. NSAIDs may cause gastrointestinal bleeding, but this risk is very small. These agents also cause renal and hepatic dysfunction; therefore, they should be used with caution in children with renal or hepatic disease. They may prolong bleeding time, but their effect on platelets (inhibition of aggregation) is reversible. NSAIDs are subject to a ceiling effect, in which a maximum dose is achieved, beyond which there is no additional analgesic effect.

A newer group of NSAIDs, the COX-2 inhibitors, may have fewer side effects than ibuprofen in children. There is concern in adults that COX-2 inhibitors may result in a greater number of cardiac adverse events, but this has not been shown to be true in children without underlying cardiac disease. These agents do not impair platelet function and are less likely to cause gastritis. Currently, these medications are recommended for those who require long-term NSAID administration for chronic pain syndromes. They should be used with caution, as recent evidence links some of these medications with heart disease and stroke in adult patients.

Furthermore, *codeine* is a narcotic analgesic that can be given orally (even to young children) to control minor pain. Codeine usually is given orally because it maintains two-thirds of its effectiveness in oral form compared with parenteral use. It is believed to be more potent than aspirin but less potent than meperidine; thus, it is valuable for moderate pain (dental abscess, severe otitis media, or stomatitis) in some children and has a low addiction potential. Significant effort has been invested in uncovering the pharmacogenetic effects of codeine in children. When given the same dose, some children will have a suboptimal response, others will respond well and still others will have toxic manifestations. The recommended dosage is 0.5 to 1 mg per kg per dose every 4 to 6 hours (maximum 60 mg per dose). Codeine can be ordered as a liquid form for use in young children, and it can be combined with acetaminophen to produce an even greater analgesic effect than when either is used alone. Codeine can cause respiratory depression, but this occurs very rarely. It has little renal or hepatic toxicity and does not alter platelet function, but

TABLE 4.2

ANALGESICS FOR MILD PAIN

Analgesic	Advantages	Disadvantages
Acetaminophen	Well tolerated, safe	Liver toxicity if overdosed
Ibuprofen	Long duration of action	Gastrointestinal irritation
Codeine	Good safety record	Nausea, constipation
Sucrose	Maybe useful for infants for procedural pain. No adverse effects.	Not always affective for babies older than 30 days.

it can cause the same gastrointestinal side effects (e.g., nausea, vomiting, constipation) as noted for other narcotics.

Finally, sucrose has been shown to be safe and effective in managing pain, especially for procedural pain, such as heel sticks and injections, for infants younger than 6 months of age. The effect of sucrose is strongest in the newborn and decreases gradually over the first 6 months of life. It is recommended to use a 25% sucrose solution and administer 2 mL orally by allowing the infant to suck on a pacifier. Alternatively, use a syringe and apply 1 mL orally to each cheek. The sucrose should be administered no more than 2 minutes before beginning the painful procedure.

The benefits of using codeine and the other analgesics described here for mild pain far outweigh the few side effects involved with their use in young children. Table 4.2 summarizes the advantages and disadvantages of these analgesics for treating minor pain in children.

Analgesics for Moderate to Severe Pain

Opioid medications are extremely important for treating patients in the ED with moderate to severe pain (burns, fractures, sickle cell vasoocclusive crises). Most opioids can cause important adverse effects (primarily respiratory depression and hypotension) that are dose related and may be reversed with naloxone if necessary, remembering that with reversal of the narcotic induced side effect will also reverse pain control. For this reason, naloxone may be dosed according to level of reversal needed (e.g., mild respiratory depression can be reversed with 1 – 10 mcg/kg) to preserve some level of pain control. Because of pharmacokinetic differences in young infants that may predispose them to respiratory depression, these drugs should be used with caution and with reduced doses in infants younger than 3 months of age who are not ventilated mechanically. Opioid analgesics can be given by various routes of administration. In general, the intramuscular (IM) route should be avoided because the injection itself is painful, it causes delayed drug absorption, and the dosage of drug given cannot be titrated. The intravenous (IV) route is more advantageous because titration is possible, although some pain is involved in starting the IV line. Subcutaneous administration can also be an option in patients without IV access. Some physicians choose to deliver the opioids with a patient-controlled analgesia device that allows the patient to self-administer the drug at a safe dosage as it is needed. This allows patients to have some control over their own pain while relieving the ED nurse of time needed to administer the drugs.

For severe pain from a significant burn, sickle cell crisis, fracture, or other injury, *morphine* is an excellent choice. The usual dosage of morphine is 0.1 to 0.2 mg per kg per dose, titrated to effect and given intravenously over a few minutes. The maximum dose is generally 10 mg for opioid-naive subjects, and the medication may be repeated every 2 to 4 hours. The higher dosage, and a dosing interval of every 1 to 2 hours, is suggested for those who take narcotics often (e.g., those with sickle cell disease or cancer) because they may have some tolerance to the drug. If needed, a subsequent dose is reduced to 0.05 mg per kg if the patient is moderately sedated. Young infants should receive 0.05 mg per kg every 4 to 8 hours and they should be closely monitored. Morphine can also be given as a continuous infusion at 0.01 mg per kg per hour for infants younger than 6 months of age and 0.025 to 0.04 mg per kg per hour for children older than 12 months of age. It can be titrated, if needed (increase 25% every 3 hours). When given intravenously, its effect is almost immediate, with the peak effect occurring in 20 minutes. Morphine can cause pooling of blood by decreasing peripheral vascular resistance and histamine release, both of, which may result in hypotension. This is more often a concern in the patient with a severe injury who may be hypovolemic or those experiencing histamine release. Certainly, the fluid status of an injured child requires careful attention from the ED staff, but pain control should not be withheld after IV fluids have corrected volume depletion. If the child is awake, alert, and screaming in pain, morphine can be given safely as long as the patient is monitored carefully. If the patient has persistent hypotension, other agents such as fentanyl can be used to control pain.

Meperidine is another opioid agent that can be used to treat moderate to severe pain. It can be given intravenously at a dose of 0.5 to 1 mg per kg, or intramuscularly at a dose of 1 to 1.5 mg per kg given every 3 to 4 hours. The maximum recommended dose for opioid-naive patients is 100 mg. It has no significant advantages over morphine, and there can be problems with its use. For example, it may cause nervousness, tremors, disorientation, and even seizures when used intravenously because of accumulation of its metabolite normeperidine. Meperidine should be used with great caution, if at all, in patients with head trauma or increased intracranial pressure as it has the potential to decrease respirations and increase intracranial pressure. Likewise, it should be used with great caution in infants, as it may decrease respiration. In general, morphine may be a better opioid for severe pain unless a patient indicates that meperidine works best.

Fentanyl is a synthetic opioid that should be given at a dose of 1 to 3 μg per kg per dose intravenously *slowly* over 3 to 5 minutes. It has a rapid onset of action (almost immediately) and a short duration of action (30 to 60 minutes), which makes it useful in the ED. Fentanyl also appears to be

effective when used intranasally or via nebulizer. It is an excellent agent for severe pain from fractures. Fentanyl also has several other advantages. It is a relatively safe drug and rarely causes hypotension, making it an excellent choice for injured children in severe pain. Respiratory depression can occur within minutes of fentanyl administration, but this is reported in only 0.7% of adult patients, some of whom were intoxicated with alcohol. There is a greater risk of respiratory depression when coadministered with other sedatives and in infants younger than 3 months of age. Apnea occurs even less often, and this may be related to a rapid rate of infusion of fentanyl rather than the dosage. Although these adverse effects are serious, they can be reversed with naloxone and avoided if the dosage guidelines are followed and the drug is given slowly. Individualized dosing titrated to effect may reduce these side effects. Also, equipment and personnel who can manage an obstructed airway should be nearby when fentanyl is used.

An uncommon event caused by fentanyl is neuromuscular blockade, with severe thoracic and abdominal muscle rigidity. However, this "wooden chest syndrome" has not been reported during procedural sedation in which lower doses are used, and when the drug is administered slowly. Most often, this side effect is reversible with naloxone, but succinylcholine and manual ventilation may be required. Despite the problems already noted, fentanyl remains a valuable analgesic that can be used in the ED when a child has severe pain. Fentanyl has been used for safe repair of complicated facial lacerations that might otherwise have required general anesthesia. It should be noted that fentanyl causes an unusual tendency for children to reach up and scratch their faces. If fentanyl is used for repair of lacerations, restraints may be needed to prevent a child from contaminating a sterile field. Even better, the parent can be assigned to scratch the child's nose if so requested. Fentanyl can also be given in the form of a transmucosal lozenge, but this is contraindicated in patients who are not opioid tolerant and in the management of acute pain.

Ketorolac tromethamine is a parenteral NSAID that has been used to treat moderate to severe pain. IV ketorolac has been found to be as effective as morphine for postoperative pain in children with fewer side effects. Some studies show that ketorolac is comparable to narcotic agents for treatment of musculoskeletal pain, headaches, sickle cell crises, and orthopedic injuries with less sedation and fewer side effects. Other studies show that children with sickle cell disease and fractures do not have a narcotic-sparing effect with ketorolac. It is often the drug of choice for patients with acute renal colic. However, some believe the drug is comparable to oral ibuprofen and there is little advantage of injectable NSAIDs over oral administration. Ketorolac does not cause respiratory depression or nausea or vomiting. Dosing guidelines are not well established, but many pediatric centers use ketorolac with a dose of 0.5 mg per kg intravenously to a maximum of 30 mg IV every 6 hours for a maximum of 5 days.

Other Agents

Hydromorphone (Dilaudid) is a semisynthetic agent used for management of moderate to severe pain for children in the ED, as a substitute for morphine and codeine. This is often given orally, rectally, or parenterally, and the analgesic effects last 4 to 5 hours. It is less sedating than morphine. Serious errors have occurred when hydromorphone dosing is confused with morphine dosing. No more than 0.015 mg/kg (max 4 mg/dose) should be given intravenously for initial dosing. Likewise, oxycodone and hydrocodone are oral analgesics that are more potent than codeine with less associated nausea and vomiting. Oxycodone and hydrocodone are about equal to morphine as analgesics and respiratory depressants. Like codeine, they retain about 60% of their efficacy when given orally. Oxycodone is often combined with nonopioid medications such as aspirin (Percodan), acetaminophen (Percocet, Tylox), or ibuprofen. One recent study found that oxycodone was no more effective than ibuprofen in reducing pain related to orthopedic injuries in children and combining oxycodone with ibuprofen did not add further pain relief. Sustained-release oxycodone should not be used for acute pain management.

Table 4.3 summarizes the advantages and disadvantages of several analgesics used to treat moderate to severe pain.

LOCAL ANESTHETIC AGENTS FOR WOUND REPAIR

Lidocaine

Lidocaine is an excellent local anesthetic that has been used frequently in the ED for wound repair, foreign body removal, insertion of IV infusion lines or lumbar puncture needles, drainage of abscesses, and arterial puncture. Lidocaine is usually administered as a 1% solution (10 mg per mL) at a maximum dosage of 5 mg per kg. A 0.5% solution is used for infiltration when large volumes are needed or in smaller patients when it is desirable to limit the total number of milligrams per kilograms given. When vasoconstriction is desired for suturing, lidocaine can be used in combination with epinephrine, at a

ANALGESICS FOR MODERATE TO SEVERE PAIN

Analgesic	Advantages	Disadvantages
Morphine	Rapid onset, potent analgesia	Respiratory depression, hypotension
Meperidine	Potent analgesia	Respiratory depression, seizures
Fentanyl	Potent analgesia, less hypotension	Respiratory depression, apnea
Ketorolac	Nonnarcotic NSAID	Use for more than 5 days can result in renal damage

dosage of (lidocaine) 7 mg per kg. Slightly lower doses should be used in neonates (4 to 5 mg per kg). Lidocaine should not be combined with epinephrine for use in areas supplied by end arteries, such as the digits, penis, or pinna of the ear. Lidocaine is advantageous because it provides excellent local anesthesia and takes effect quickly (within a few minutes). The effect lasts long enough to complete most procedures (about 1.5 to 2 hours). It is generally a safe drug because few people have a true allergy to it. Serious toxicity, such as seizures and cardiac arrest, can occur, but only when large amounts are injected inadvertently or when the drug is injected directly into a blood vessel.

The major disadvantage of using lidocaine as a local anesthetic is that a painful injection is required for administration. This pain can be reduced, however, if a long, small (27- or 30-gauge) needle is used to produce a "fanning" effect of the anesthetic. To avoid inadvertent injection into a vessel while injecting deep into tissue, a larger needle is needed to aspirate blood. Otherwise, the small needle is recommended, and only a small amount of lidocaine should be injected to avoid tissue distortion. Some physicians recommend using a syringe with a thumb ring during infiltration for better control. It is best to inject lidocaine slowly, perhaps over 30 seconds. This may cause less rapid distension of local tissue and activation of fewer nerve endings. Warming the lidocaine by storing the medication and syringes in fluid warmed to 98.6°F seems to reduce the pain of infiltration. It may also hurt less to inject the lidocaine into the damaged tissue inside the wound instead of into the intact skin. The needle should be pulled out to the tip and the injection given again at 90-degree angles to minimize the number of punctures. Subsequent injections to extend the area of anesthesia should be given through anesthetized tissue when possible. It is helpful to rub the skin near the site of injection first because this reduces pain by stimulating other nerve endings according to the gate theory of pain. Buffered lidocaine, prepared by mixing lidocaine and sodium bicarbonate in a 9:1 ratio, which is more alkaline and subsequently less painful when administered. Buffered lidocaine can be made as needed in the ED or in advance, and it will remain stable for approximately 2 weeks. In all cases, a few minutes should be allowed for the anesthesia to take effect. Table 4.4 summarizes some hints to reduce the pain of lidocaine infiltration.

Other Injectable Local Anesthetics

Bupivacaine 0.25% is similar to lidocaine but may have a longer duration of action and may help reduce pain for 6 hours after a wound is repaired. To avoid toxicity, inject no more than 2 to 2.5 mg per kg of bupivacaine. Diphenhydramine, 0.5% and 1%, has been used and studied as a local anesthetic in adult patients. However, it seems to cause more pain on infiltration than lidocaine and has resulted in tissue necrosis. Therefore, it is not recommended as an injectable anesthetic. Benzyl alcohol has been shown as a reasonable alternative to lidocaine for subcutaneous anesthesia in the rare patient that has a history of allergy to amide anesthetics. Multidose vials of physiologic saline solution that contain 0.9% benzyl alcohol can be mixed in a 1:100 dilution with epinephrine 1:1,000 strength to create a solution that has comparable effectiveness to 1% lidocaine for laceration repair and IV insertion. Note that the duration of action of benzyl alcohol is shorter than that of lidocaine and may not be as effective for prolonged procedures. Benzyl alcohol should never be used in infants.

TABLE 4.4

HINTS TO REDUCE PAIN OF LIDOCAINE INFILTRATION

1. Do not allow child to see needles involved in preparing lidocaine.
2. Warm and buffer lidocaine with sodium bicarbonate.
3. Use a long, small needle for infiltration.
4. Rub skin around injection site before infiltration.
5. Infiltrate through devitalized tissue or anesthetized areas.
6. Inject slowly, only what is needed.
7. Wait for anesthetic effect.

Topical Anesthetics for Wound Repair

LET is a solution of 4% lidocaine, 0.1% epinephrine, and 0.5% tetracaine. It can be made in gel form with hydroxyethyl cellulose. LET has been used successfully and safely for repair of uncomplicated facial and scalp lacerations in children. The major advantage to using LET for suturing is that the anesthetic can be applied painlessly, without the use of a needle. This reduces the fear and anxiety involved in wound repair and may help the suturing go more smoothly. Even in the small number of children who have inadequate anesthesia from LET, the application of this topical anesthetic will reduce the pain of subsequent administration of lidocaine by injection. The gel can be applied directly to the wound and allowed to remain for approximately 20 to 30 minutes, the solution can be "painted" onto the wound with a cotton-tipped swab, or a saturated cotton ball can be applied to the wound and held in place manually or with tape. Subsequently, the surrounding skin will be well blanched, indicating adequate local anesthesia. Like lidocaine, LET should not be applied to body parts where vasoconstriction is contraindicated. LET has essentially replaced TAC (tetracaine, adrenaline, cocaine compound) as the preferred topical anesthetic for wound repair because it is much less costly and has reduced toxicity. TAC carries the risk of cocaine toxicity and can lead to seizures and death, especially if used near mucous membranes where rapid absorption can occur. TAC should no longer be used as an anesthetic for wound repair in children.

TOPICAL ANESTHETIC AGENTS FOR IV PLACEMENT AND VENIPUNCTURE

A plethora of products are currently available for topical anesthesia through intact skin and have been found helpful in relieving pain associated with IV catheter placement and venipuncture in children. Studies have shown that decisions about IV line placement can often be made at triage. If preparing for IV line placement, one should prepare multiple sites in case the first attempt is unsuccessful, which occurs between 50% and 75% of the time, depending on whether or not the child is dehydrated. These products are also useful for draining

an abscess or paronychia, arthrocentesis, lumbar puncture, or access for fully implantable central venous catheters.

All topical anesthetics currently available contain lidocaine either alone or mixed with another anesthetic and have variable mechanisms of delivery and onset times. The delivery mechanism must traverse the stratum corneum, which contains highly ordered lipid bilayers that block the entry or exit of water or water-soluble substances. Products can traverse this barrier using direct injection below the skin, using needle-less injection using pressurized gas by passive diffusion, or by interrupting or bypassing the barrier using heat, ultrasound, or electricity.

Multiple studies have demonstrated that intradermal injection of lidocaine, or saline with benzyl alcohol, can reduce IV insertion pain; although this technique requires an additional needle stick, most patients prefer it to no anesthesia at all. Anesthesia is almost immediate, offering a distinct advantage over other modalities. Newer products using pressurized helium or CO_2 to achieve needle-less subcutaneous infiltration of 1% or 2% powdered lidocaine achieve anesthesia within 1 to 3 minutes. One pediatric study that showed good efficacy did not find that this method caused pain on administration, contrary to the adult studies using the same method. Ethyl chloride vapocoolant spray applied to the puncture site has demonstrated variable effectiveness in multiple studies. Perhaps because the needle stick needs to follow the topical application almost immediately, vapocoolants have been found more effective for IM injection than for IV insertion.

Passive diffusion can be time-consuming, and during the time required for onset of anesthesia, young children may become agitated, perspire, and have difficulty keeping the anesthetic in the correct skin location. The oldest and most studied of these products, topical EMLA cream, is a eutectic mixture of lidocaine and prilocaine. EMLA is applied with an occlusive dressing directly to the skin for 60 minutes before it is effective, so it is not practical for some situations in the ED. A newer topical anesthetic cream, LMX-4, has been shown to be a very effective topical skin anesthetic. This is a topical formulation of 4% lidocaine in a liposomal delivery medium. An occlusive dressing is ideal but not required for application. In contrast to EMLA cream, LMX4 does not contain prilocaine and, therefore, does not increase the risk of methemoglobinemia in neonates. The 20-minute onset of action makes this a better topical anesthetic choice for use in the ED, but still requires some ability to predict who will need these procedures. Although there have been no safety studies in children younger than 2 years of age, there have been no reports of lidocaine toxicity in any age group with this medication.

Heat, ultrasound, laser, and iontophoresis have all been used to disrupt or more effectively bypass the lipid bilayers in the stratum corneum, thereby decreasing the anesthetic onset time for topical agents. Many of these products have proven efficacy and work efficiently; however, most require an additional mechanical apparatus attached to the skin. One more recently tested product is a self-contained topical patch containing lidocaine and prilocaine that generates heat once removed from its airtight pouch, allowing for a 20-minute onset of action. This product offers the advantage of keeping the medication where it is placed, without the potential for leakage; however, it must also be applied well in advance of the procedure, requiring accurate site choice and potentially higher cost for application at more than one site.

NERVE BLOCK

Lidocaine can be used for peripheral nerve block if the physician has appropriate knowledge of anatomy and the nerve supply to the wound is superficial. The skin at the nerve site should be anesthetized, and then lidocaine (5 mg per kg) should be infiltrated more deeply into the nerve in the same manner as the local anesthesia. During this infiltration, the physician should aspirate to ensure a blood vessel has not been penetrated inadvertently.

Some EDs use lidocaine for regional nerve block. The preferred technique for fracture reduction at some institutions is a Bier block or "mini-Bier" block. With this technique, a double pneumatic tourniquet or two blood pressure cuffs are placed above the elbow and IV lines are started in the child's upper extremities. One of these lines is for administration of lidocaine, and the other is reserved for other medications, if needed. Diazepam, midazolam, and thiopental should be available in case seizures result from lidocaine infiltration, and the child should be attached to a cardiac monitor during the procedure. Newer literature suggests the utility of intralipids in local anesthetic overdose or inadvertent IV administration, particularly with bupivacaine. The affected limb is elevated for exsanguination as the upper cuff is inflated to occlude the arterial blood supply. Then lidocaine (without epinephrine) is infused into the affected extremity at a dosage of 3 mg per kg (Bier block) or 1.5 mg per kg (mini-Bier block) (maximum 100 mg). This should be given slowly, and tourniquet pressures must be maintained so the drug does not escape under the tourniquet. Once the injured extremity has local anesthetic in an isolated compartment, the lower cuff, which should be wrapped around an anesthetized area, can be inflated. The upper cuff can be deflated. This lower cuff can be deflated very slowly after the procedure but not less than 15 minutes after the lidocaine infusion was given. The child should be observed in the ED for at least 1 hour. The Bier block has been found to be slightly more effective than the mini-Bier block. There are risks to this procedure, including seizures, coma, confusion, and cardiac arrest, if the child were to unintentionally receive a massive amount of lidocaine rapidly. Three randomly controlled trials involving Bier blocks, found no adverse effects among more than 500 procedures. Still some physicians prefer to perform the Bier block or mini-Bier block in the operating room, where circumstances can be better controlled.

PROCEDURAL SEDATION AND ANALGESIA (PSA)

PSA has replaced *conscious sedation* in the lexicon of emergency medical treatment of ill or injured patients. The American College of Emergency Physicians (ACEP) defines PSA as "techniques of administering sedatives or dissociative agents with or without analgesia to induce a state that allows the patient to tolerate unpleasant procedures while maintaining cardiorespiratory function." This definition eliminates the confusion that results when rendering a patient *less* conscious during "conscious sedation" and allows for the attainment of different levels of sedation depth dependent on the specific patient needs. The Joint Commission accepts the continuum of depth of sedation proposed by the American Society of Anesthesiologists (ASA) in 1999 (Table 4.5).

TABLE 4.5

DEFINITIONS OF FOUR LEVELS OF SEDATION AND ANESTHESIA

Level	Respond purposefully (not reflexively) to	Airway and breathing maintained	Cardiovascular function maintained
Minimal sedation	Verbal commands	Yes	Yes
Moderate sedation/analgesia	Light tactile stimulation	Yes	Yes
Deep sedation/analgesia	Painful stimulation	Potentially not	Yes
Anesthesia	None	No	Potentially not

Adapted from American Academy of Pediatrics, American Academy of Pediatric Dentistry, Coté CJ, et al. Guidelines for monitoring and management of pediatric patients during and after sedation for diagnostic and therapeutic procedures: an update. *Pediatrics* 2006;118:2587–2602.

The regimens used for PSA can provide anxiolysis, sedation, dissociation, analgesia, or any combination of the four. As clinicians involved in this decision, our selection of medication is informed by knowing details about the procedure, the patient, and the particulars about the available medications (Table 4.6). The terminology assigned to a particular episode of PSA is most accurately determined by the intended effects, rather than by the specific medications used. For example, the clinician can decide that a child needs some assistance in keeping still, an increased receptiveness to distraction techniques, or amnesia for the procedure. This child requires anxiolysis rather than sedation, and will receive a relatively smaller dose of a medication that will not require cardiorespiratory monitoring. However, a child who needs to be still during a delicate procedure may require a larger dose of the same medication, after which he or she has some risk of cardiorespiratory compromise that requires more intensive monitoring.

It is best to obtain information about the procedure from the person performing it. It is important to know the length of time that the procedure will take to complete, and the time that the child may need to remain immobile. For example, one may decide to use morphine rather than fentanyl if a procedure is expected to last longer than 10 minutes. It is equally important to know the duration and severity of pain usually involved in this procedure. Some procedures, such as fracture reduction, are only brief but very painful and also require the child to remain immobile during the casting portion of the procedure. The same is true for procedures in which the administration of regional anesthesia is painful, but the remainder of the procedure is not. Finally, one must consider the level of distress that visualization of the procedure may cause for patient and family members. Agents that provide an amnesic effect may be desirable in the case where a child could be frightened by the sight of blood or other body fluid.

The child's reaction to the procedure can be estimated from his or her current pain rating, developmental level, and initial reaction to health-care providers. Parents are often the best source of information about the child's expected reaction to the procedure. Some parents may know that, despite a pain-free procedural technique using topical anesthetic for a facial laceration, their child will be so fearful of strangers that non-pharmacologic techniques will not suffice. Conversely, a mother may express that her child was calm throughout his or her last laceration repair and believe that she can adequately distract him or her during the procedure.

SEDATION PROTOCOLS

Progression from mild sedation or analgesia to general anesthesia cannot be simply divided into discrete stages. In general, as the dose of analgesic and sedative agents increases, consciousness decreases and the risk of cardiorespiratory depression increases. A child may continue to advance along the sedation continuum until protective airway reflexes are lost and he or she is effectively under general anesthesia. It is not always possible to predict how a child will respond to medications. Although the ED physician may intend to achieve mild sedation, moderate or deep sedation may result. Thus, individuals administering moderate or deep sedation and anesthesia should be qualified (and have appropriate credentials) to manage patients at whatever level of sedation or anesthesia is achieved, either intentionally or unintentionally.

TABLE 4.6

INFORMATION THAT CAN ASSIST CLINICIAN IN DETERMINING TYPE OF AGENT NEEDED FOR PROCEDURAL SEDATION AND ANALGESIA

Procedure	Patient	Agent
Expected pain severity	Current pain rating	Onset
Expected pain duration	Prior experiences	Duration
Required duration of immobility	Developmental age	Desired effects
Distressful or frightening appearance of procedure	Initial reaction to provider	Unwanted effects
	Parental expectation	

Because of the potential for respiratory depression with the sedative and analgesic agents discussed in this chapter, it is imperative that EDs develop protocols for their use. Several organizations, such as the American Academy of Pediatrics (AAP), the ACEP, and the ASA, have prepared guidelines for sedation in children. These protocols differ in certain fine points, but there is general agreement on major issues. The specifics of the ED protocol should be modified at each individual institution.

Evaluation and Preparation of Patient Prior to Sedation

The ASA recommends that clinicians administering sedation/analgesia should be familiar with aspects of the patient's medical history that may relate to the medication about to be given. This includes abnormalities of any major organ system; previous adverse experience with sedation analgesia; drug allergies; current medications; time of last oral intake of solids and liquids; and use of alcohol, tobacco, or drugs of abuse. Patients should have a focused physical examination before sedation is administered. This should include vital signs, auscultation of the heart and lungs, and evaluation of the airway. Conditions that may make endotracheal intubation more difficult (such as short neck, small mandible, large tongue, or trismus) should be noted.

For moderate and deep sedation, the ASA recommends providing patients and parents with information on the risks, benefits, and alternatives to sedation and analgesia before a procedure. The importance of preprocedure fasting is controversial, and it is not known whether preprocedure fasting results in decreased incidence of adverse outcomes. That said, the AAP recommends several dietary precautions before sedation: Infants should not have milk or solids for several hours before elective sedation (not within 4 hours for infants younger than 5 months, 6 hours for those 6 to 36 months, and 8 hours for older children). Intake of clear liquids may continue, but should cease in all cases within 2 hours of the scheduled sedation. ACEP publications have noted that there is insufficient evidence to fully support these time intervals, and offers a "level B recommendation" (moderate clinical certainty) that "procedural sedation may be safely administered to pediatric patients who have had recent oral intake." Those at risk for aspiration of gastric contents (such as those with history of gastroesophageal reflux, extreme obesity, pregnancy, or previous esophageal dysfunction) may benefit from appropriate pharmacological treatment to reduce gastric volume and increase gastric pH. For the emergency patient, sedation should still be preceded by an evaluation of food and fluid intake. It is prudent to assume that patients in the ED have full stomachs when planning the use of sedatives or analgesics. The increased risks of sedation must be weighed against the benefits and the lightest affective sedation used. Some patients may benefit from delaying the procedure or administration of appropriate pharmacological treatment to reduce gastric volume and increase gastric pH. Consider airway protection before emergency sedation.

Personnel

Personnel who are trained in pediatric life support should be available, and at least one additional support personnel should be on hand to monitor the patient. Personnel must understand the pharmacology of the sedatives they use. For deep sedation, the AAP recommends that a third person trained in pediatric resuscitation should be available to assist the patient.

Equipment

For children who are undergoing moderate sedation, emergency equipment should be available for children of all ages and sizes. This should include a suction device and a positive-pressure oxygen delivery system capable of delivering at least 90% Fio_2. In areas where moderate and deep sedation are being administered, endotracheal tubes should also be available. Reversal agents such as naloxone and flumazenil should be immediately available in the ED. Additional equipment recommendations include a nearby defibrillator and medications that might be needed for resuscitation.

Monitoring

A designated person must continuously observe the child's face and chest wall motion. Unless truly unavoidable, equipment and special drapes must not block this observation. Patients should have continuous monitoring of oxygen saturation, respiration, and heart rate with (at least) intermittent monitoring of blood pressure during and after the procedure. Continuous electrocardiographic monitoring has not been proven to affect outcome; however, it is simple, readily available, and should be routine. Monitoring with pulse oximetry is essential because of the proven difficulty in recognizing hypoxemia even by experienced personnel. Measurement of exhaled carbon dioxide ($EtCO_2$) is another modality that has been used extensively in anesthetized patients and has recently been introduced into the emergency medicine arena. Noninvasive capnography by nasal cannula is available for pediatric patients; some units combine this nasal cannula device with an oxygen delivery component as well. The visualization of the "sidestream" $EtCO_2$ waveform over time can offer the clinician insight into the ventilatory status of a nonintubated patient who has normal baseline lung function. Studies have demonstrated that monitoring of $EtCO_2$ provides earlier detection of respiratory depression than traditional monitoring techniques. Although it is not yet clear which patients require $EtCO_2$ monitoring, it would clearly be a helpful adjunct for patients receiving deep sedation, for those whose ventilation cannot be observed while receiving moderate sedation, and for those who are receiving supplemental oxygen empirically thus blunting the already limited ability of the pulse oximeter to detect hypoventilation or apnea.

The bispectral index (BIS) monitor is an electroencephalographic device that is attached to a patient's forehead and has been introduced as a potential marker of a patient's sedation level. The device has been widely used for monitoring patients receiving general anesthesia in the operating room. A patient with a BIS value of 0 has no electrical activity, and a patient with a score of 100 is wide awake. Unfortunately, specific numerical BIS values may not correlate well with other observational measurements of sedation in children undergoing ED procedures, and can be highly variable at lighter levels of sedation. Further research is needed to determine how BIS monitoring can be effectively used in pediatric emergency patients.

If a patient is expected to have deep sedation, it is recommended that an IV line be established before sedation and maintained throughout the procedure and until a patient is no

longer at risk for cardiorespiratory depression. If a patient is receiving an IM agent, the clinician should determine the need for an IV based on the risk for cardiovascular compromise or the potential need for rapid sequence intubation.

Vital signs should at least be measured at baseline, after drug administration, after the procedure is completed, during early recovery, and at the completion of recovery. If deep sedation is anticipated or the child has an underlying illness, the frequency of measurement of vital signs should be increased (e.g., to every 5 minutes). Patients are at highest risk for complications from sedation during the 5 to 10 minutes after administration of the medication and during the period immediately after the procedure when stimuli are discontinued. After the procedure, appropriate staff should continue to observe patients who received sedation and continuous pulse oximetry, and monitoring of heart rate should continue until the patient has met discharge criteria. Before discharge, any child who has received moderate or deep sedation should be awake enough to sit and speak without assistance and preferably able to ambulate. Younger children should be able to perform age-appropriate functions. The child should also have adequate hydration status, documentation of stable cardiovascular function, and an adequate airway.

CHOICE OF TECHNIQUES AND MEDICATIONS

Taking the previous information into consideration, clinicians must first decide whether the child requires anxiolysis, sedation, analgesia, or some combination of the three. Patients who undergo nonpainful procedures, such as computed tomography (CT) scans or magnetic resonance imaging (MRI) scans, or those receiving regional analgesia, may be best served by receiving an agent that provides anxiolysis or sedation alone. The following sections discuss the onset, duration, effects, and potential adverse consequences of these agents.

Anxiolysis and Sedation

Children who are undergoing painless procedures may be too young, anxious, or emotionally labile to remain still enough for the procedure to be successful. Examples include CT scans, echocardiography, and electroencephalography. Benzodiazepines can be used to provide the appropriate level of anxiolysis or sedation. It is important to remember that these agents do not provide any analgesia and should not be used alone for painful procedures. In addition, the sedative/hypnotic agents include chloral hydrate, pentobarbital, etomidate, propofol, and nitrous oxide (N_2O). Barbiturates include pentobarbital, thiopental, and methohexital. The relative advantages and disadvantages of these agents are listed in Table 4.7.

Benzodiazepines can provide anxiolysis, sedation, muscle relaxation, and amnesia during frightening or painful procedures. Benzodiazepines, such as midazolam, depress all levels of the central nervous system by binding to the gamma-aminobutyric acid (GABA) receptor complex and modulating GABA, which is a major inhibitory neurotransmitter in the brain. The dosage, routes, onset, and duration of action of the commonly used benzodiazepines are presented in Table 4.8. Of these, midazolam is considered the most efficacious during PSA, offering the advantage of rapid onset, rapid offset, and relatively wide therapeutic range. It is important to remember that the higher doses used in the transmucosal administration of benzodiazepines render the medication just as potent as if administered intravenously. The other distinct advantage of midazolam is the multiple potential routes of administration. Parenteral administration is the fastest and more reliable method; however, it requires another painful procedure (IV

TABLE 4.7

AGENTS USED FOR SEDATION OF CHILDREN IN EMERGENCY DEPARTMENT

Agent	Advantages	Disadvantages
Benzodiazepines	Multiple routes of administration Short acting Amnestic	Potentiates respiratory depression when used as adjunct
Chloral hydrate	Oral or rectal routes Pure sedative	Slow onset Long duration Paradoxical hyperactivity
Pentobarbital	Pure sedative effects Wide therapeutic range Rapid onset	Cardiorespiratory depression if given rapidly or at high dosage
Thiopental	Very rapid onset and offset	Circulatory depression
Methohexital	Very rapid onset and offset Rectal route possible	Circulatory depression Respiratory depression Twitching
Propofol	Short duration Deep sedation, amnesia	Narrow therapeutic range Respiratory depression
Etomidate	Short duration Deep sedation, amnesia	Myoclonus Possible adrenal suppression

TABLE 4.8

FEATURES OF BENZODIAZEPINES

Drug	Dosage (mg/kg)	Route	Onset (min)	Duration (h)
Midazolam (Versed®)	0.05–0.1	Intravenous (IV)	2–3	1–2
	0.1–0.2	Intramuscular (IM)	10–20	1–2
	0.5	Oral	15–30	1–1.5
	0.3–0.5	Rectal	10–30	1–1.5
	0.2–0.5	Intranasal	10–15	1
Diazepam (Valium®)	0.2 (max 10 mg)	IV, IO	1–3	0.5
	0.5 mg/kg	Rectal	10	1
Lorazepam (Ativan®)	0.05 mg/kg (max 2 mg)	IV, IO, IM	15–30	8–12

placement or IM injection). Children tolerate oral midazolam well; younger children find it less caustic than the intranasal route, and older children find it less intrusive than rectal administration. A recent report noted that midazolam can be given intranasally for anxiolysis for minor procedures in the ED, in a safe and effective manner, using an atomized delivery device. Since benzodiazepines have no analgesic properties, they are often used concomitantly with analgesics during painful procedures. This combination can lead to more side effects, particularly respiratory depression, than use of either drug alone. A reversal agent, flumazenil, can be used in case of severe adverse effects due to benzodiazepine administration. The initial dose of flumazenil is 0.01 mg per kg (maximum dose 0.2 mg) and may be repeated every 1 minute to total maximum dose of 1 mg. The duration of action is less than 60 minutes, so resedation may occur if medium- or long-acting benzodiazepines are used.

Chloral hydrate has no analgesic effects, but at recommended doses produces a light level of sleep and allows airway reflexes to be maintained. Its effects are more reliable in infants and children younger than 3 years old. Chloral hydrate is absorbed rapidly through the oral or rectal mucosa, and is then metabolized by the liver to trichloroethanol, the active ingredient. At doses of 50 to 100 mg per kg, the onset of action of chloral hydrate is between 10 and 15 minutes with the peak effect at about 60 minutes, and its effects last up to 4 to 8 hours. Although the transmucosal route of administration is advantageous, the onset and duration of action of chloral hydrate render it less useful in many emergency situations. Other clinically significant adverse effects seen in the ED are respiratory depression, hypotension, and gastrointestinal distress. Paradoxical excitability can be notable, particularly in children with developmental delay or preexisting emotional problems. The cardiorespiratory effects can be more pronounced in very young infants or those born prematurely, and the dosage, monitoring, and observation periods should be adjusted concomitantly. The recommended dose for neonates is 25 mg per kg per dose for sedation prior to procedures. Repeated doses should be used with great caution as drug metabolites accumulate with repeated use. At some centers, children younger than 1 month of age or premature infants younger than 60 weeks' postgestational age are monitored for 23 hours after chloral hydrate administration. Chloral hydrate should not be used in children with hepatic, renal, or cardiac disease.

The barbiturate medications, pentobarbital, thiopental, and methohexital, depress the reticular activating system via the GABA receptors. Barbiturates have no analgesic properties of their own and may actually increase pain perception, so they are not ideal for painful procedures. Pentobarbital is the most common barbiturate used in the ED. It has the greatest use for nonpainful procedures such as imaging studies. Sedation occurs rapidly after IV administration of 1 mg per kg (infants older than 6 months) to 2 mg per kg (children), and the effect dissipates in 15 to 20 minutes. Repeated doses of 1–2 mg/kg can be administered to a total of 3 mg/kg for infants and 6 mg/kg for children (maximum 100 mg/dose, total max 300 mg). Narcotics can also be combined with pentobarbital, but this may result in prolonged sedation, making the combination less convenient to use in a busy ED. Although used with relative success in adults, IV administration of thiopental or methohexital is not recommended when sedating children, given the severe complications resulting from intraarterial injection or local tissue infiltration. Rectal administration of methohexital offers some advantages, however, and has demonstrated shorter onset and recovery times than chloral hydrate. Rectal methohexital (20 to 30 mg per kg, maximum 500 mg) has a faster onset of action, with effects demonstrated in approximately 15 minutes. Thiopental is generally used rectally for procedural sedation in children. The rectal dose of thiopental is 5 to 10 mg per kg per dose for sedation. The barbiturates can cause respiratory depression and decrease the respiratory response to hypoxemia and can also cause decreased venous return and subsequent hypotension in hypovolemic patients. Thoipental decreases intracranial pressure and may be useful if increased intracranial pressure is a concern.

Propofol is an ultra-short-acting sedative-hypnotic with no analgesic properties. Propofol has gained favor in the ED because it has a rapid onset of action, a rapid offset, and some antiemetic and amnesic properties. However, this potent sedative has a relatively narrow therapeutic range, and the incidence of adverse events such as partial airway obstruction and apnea are slightly higher than other standard regimens. Some experts suggest using $EtCO_2$ monitoring for every propofol sedation; however, it is not yet clear that this alters outcomes in ED patients who are otherwise well monitored using standard clinical examination and monitoring procedures. Transient hypotension is expected with administration of this agent, albeit more common in patients with hypovolemia or fragile cardiovascular status. A number of studies using propofol in

pediatric ED patients have indicated excellent efficacy and safety, demonstrating short recovery times and shorter overall ED times. Some have begun using propofol in conjunction with an opiate medication such as fentanyl or alfentanyl; however, this increases the risk of adverse events. Notably, the procedures performed in these studies were limited to brief, intensely painful experiences, which seem to be best suited for this medication regimen. The volume of distribution and elimination of propofol is the same in children as it is in adults, making dosing recommendations similar as well. It is administered slowly as a bolus dose of 1 mg per kg (maximum 40 mg), supplemented by 0.5 mg per kg aliquots every 3 minutes to a maximum of 4.5 mg per kg. A continuous infusion rate of 67 to 100 μg per kg per minute is preferred for procedures of longer duration. Propofol can be mixed with 0.5 mg per kg lidocaine to decrease the pain of injection, or the 0.5 mg per kg of lidocaine can be given IV into a tourniqueted arm prior to propofol administration. If used with alfentanyl, this technique may not be needed, because that drug has also been noted to decrease the incidence of pain at the IV site. Patients who are allergic to eggs or soy should not receive propofol.

Etomidate is an imidazole hypnotic agent that has gained favor as an induction agent for endotracheal intubations. It has a rapid onset of action, short duration, and exhibits less hemodynamic and respiratory effects than other sedative/hypnotic agents. Whereas the dosage used for pediatric intubations is 0.3 mg per kg, the suggested dose for sedation is 0.15 mg per kg.

Etomidate may be useful in certain rapidly performed procedures such as anterior shoulder dislocations; however, a small number of patients experience clinically significant myoclonus. The adrenal suppression ascribed to the use of etomidate is rarely clinically apparent after one dose in the emergency setting.

N_2O is an odorless gas that can be an effective agent for painful procedures (Table 4.9). It has the distinct advantage that it can be delivered painlessly through inhalation. Onset and offset of effects are 4 to 5 minutes. If no effects are noted after 5 minutes of administration, then another agent should be selected. N_2O affects the cerebral cortex, not the brainstem, so circulatory and respiratory depression does not occur and there is little relaxation of skeletal muscle. N_2O provides mainly sedative, dissociative, and amnesic effects. Frequently, the patient remains awake and able to follow instructions during the procedure. Although N_2O exhibits some analgesic effects, not all patients report complete pain relief with N_2O. Studies have demonstrated marked pain relief in 29% of patients and partial pain relief in 61%. Because of the additional sedative effects of N_2O, it is not recommended for children who are already sedated, unconscious, or intoxicated. Patients who receive this gas describe feeling as if they are floating, drowsy, or euphoric, with some describing heaviness in their extremities. Some patients have experienced vomiting; however, this is less dangerous than other sedation regimens because patients maintain their cough and gag reflexes. Vomiting is more common in patients who report that they are susceptible to motion sickness. Prolonged intermittent dizziness has also been reported after N_2O–oxygen administration. Oversedation can occur, especially in patients who have received other sedating medications. Because N_2O rapidly diffuses into air-filled body cavities, its administration is contraindicated in patients with pneumothorax, bowel obstruction, or head injury. It is also contraindicated in pregnant patients, and pregnant staff members should not administer N_2O.

TABLE 4.9

NITROUS OXIDE–OXYGEN ANALGESIA

Advantages	Disadvantages
Has rapid onset, short duration of action	Fail-safe system required
Causes sedation, dissociation, and amnesia	Expensive equipment
Is useful when local anesthesia is impractical	Scavenger device needed
May be used for young children	Not all patients benefit
Is safe when mixed with oxygen	More personnel required

N_2O is useful for procedures that do not require systemic analgesia, either because the procedure is not very painful or the area cannot easily be anesthetized locally. This includes incision and drainage, paronychia, skin and vaginal foreign-body removal, laceration repair, burn dressing, and zipper entrapment.

Commercially available N_2O devices provide a 50-50 mixture of N_2O–oxygen, and contain a fail-safe system that shuts off the flow of N_2O when oxygen flow stops. Some delivery units require the patient to create a negative pressure of 3 to 5 cm H_2O to open the mask's "demand valve" that delivers the gas. This type of delivery system is best for children 8 years of age and older. A continuous-flow nasal mask can also be used to deliver N_2O and is more acceptable to younger children; some practitioners have developed a continuous-flow face mask that is potentially more reliable in children who typically breathe through their mouths. Each unit is fitted with a scavenger system that is connected to the vacuum system in the patient's room. The equipment is portable, but can cost several thousand dollars and must be inspected daily to ensure safety. In addition, the patient who receives N_2O requires the attention of a staff member who is skilled and experienced in the administration of the agent.

Ketamine

Ketamine hydrochloride is a dissociative anesthetic agent. It causes amnesia and a trancelike state in which the child cannot respond verbally. It also can provide some analgesia at subanesthetic doses. Ketamine is both water and lipid soluble, and therefore, can be used by IV (0.5 to 2 mg per kg) and IM routes (3 to 4 mg per kg) with equal success. The drug has a rapid onset of action (1 minute intravenously, 5 to 10 minutes intramuscularly). A single IV dose lasts about 15 minutes; however, with repeated doses or continuous infusion, its effect can last 1 to 2 hours. Ketamine can also be given orally (10 mg per kg), in which case sedation occurs within 30 to 45 minutes and lasts about 2 hours.

At the dosages used in ED procedures, ketamine does not characteristically depress spontaneous ventilation. It also allows a patient to maintain pharyngeal function and protective airway reflexes. Thus, the risk of airway compromise is less with ketamine than with some other agents. Laryngospasm may occur in less than 2% of patients; neonates and those with active respiratory infections are at higher risk for this compli-

cation. Importantly, the vast majority of patients who experience laryngospasm respond well to mask ventilation and do not require endotracheal intubation. The increased salivation caused by ketamine can also contribute to pharyngeal obstruction, but can be effectively prevented by prior administration of atropine (0.01 mg per kg) or glycopyrrolate (0.005 mg per kg). In summary, like any of the other PSA agents, ketamine should be used only by someone who is familiar with the uncommon complications and skilled in airway management.

In approximately 7% to 10% of pediatric patients, ketamine causes unusual, unpleasant sensations and dreams with subsequent flashbacks. Two recent prospective studies that administered midazolam *after* ketamine to pediatric patients found no effect of midazolam on recovery agitation or emergence phenomena. However, because preprocedure anxiety is strongly associated with recovery agitation, further research is needed to determine the effects of a benzodiazepine *before* the ketamine is administered. Regardless of the clinician's choice in this matter, all efforts should be made to control the environment to provide the child with a soothing, relaxing sedation induction. This includes dim lights and a prohibition on noisy movement, especially those that involve the child noticing the instruments to be used in the procedure. It is helpful to have the child choose a "dream" for himself, and ask the parent to help facilitate that dream through music, singing, or storytelling. Because of the potential agitation effects, ketamine is not recommended for use in psychotic or emotionally disturbed patients.

Vomiting can occur in up to 20% of patients who receive ketamine. However, this usually occurs in the recovery phase and may be less likely if midazolam is administered. Ketamine also can elevate blood pressure, intracranial pressure, and pulmonary artery pressure, so patients with head trauma, CNS malformations, and cardiovascular disease should not receive this drug. For many years, ketamine has been associated with increased ICP and avoided in head trauma and status epilepticus. Recent studies have cast doubt on this assumption and further research is needed.

SPECIAL SITUATIONS

The Emotionally Labile Child

There are a number of issues the clinician faces when caring for an injured child who is known to be emotionally labile. This includes children with autism, mental retardation, or an adjustment disorder. It is important to assess the child's expected emotional response in a foreign environment, use the social and emotional support available to the child at the time of the visit, and determine the need for and choice of medications for sedation and analgesia.

The parents' or caregiver's assessment of the child's anticipated emotional response is paramount in defining the best approach for the procedure. Despite an apparent lack of response to usual vocal or calming techniques, many of these children still do well if their caregivers stay near, and if it seems to them that there is less change occurring in their surroundings. These children may be taking medications already, and drug interactions must be considered when choosing a procedural sedative. However, if the child's initial medication has sedative properties (e.g., those found in phenobarbital or benzodiazepines), then simply adding or increasing a dose may be all that is needed. Studies have demonstrated that, despite the potential for paradoxical reactions in children with emotional disorders, benzodiazepines used in the correct dosage result in better cooperation through procedures. In fact, too little of the medication may simply reduce the patient's inhibitions and worsen the situation. Ketamine, in contrast, is more likely to cause a severe emotional response at any therapeutic dose in emotionally reactive children, and so it is usually avoided in these cases. The route of administration is also an important consideration, in that some children have a strong aversion to manipulation of certain body parts.

Abdominal Pain

Few, if any, over-the-counter medications are efficacious in relieving abdominal pain. Historically, there has been a conflict between the desire to alleviate pain and the concern that analgesics will obscure the ability to accurately diagnose the patient's condition. Recent studies suggest that this concern is unwarranted: Administration of morphine lowered the pain scores of children with abdominal pain but did not alter the location of tenderness, the confidence or diagnostic accuracy of the treating physicians, or the number of children who suffered perforation of the appendix. Dispelling the myth that analgesic medications are forbidden in patients with abdominal pain is an important advance in the consideration of the "ouchless" ED.

COMPLICATIONS AND ERRORS

Most children who receive sedation and analgesia in the ED have a good outcome and benefit from the efforts to reduce pain and anxiety during a procedure. However, administration of sedative and analgesic agents to children in the ED always carries some risk to the patient and potential liability for the provider. There is always a chance for error with such medications. Some errors are fatal; many are preventable. One study showed that up to 17% of pediatric procedural sedations have some type of complication. Most adverse events are respiratory and 1/200 require interventions to maintain a patent airway and to ventilate the patient. One in every 1,500 sedations results in an event that requires unanticipated admission to the hospital. Those providing care to sedated children must take steps in advance of a procedure, and vigilantly monitor the child during a procedure in order to minimize potential adverse outcomes. A recent study showed inadequate and inconsistent monitoring (particularly failure to use or appropriately respond to pulse oximetry) was a major factor contributing to poor outcome in sedated children.

The needs of the provider or the institution must not be placed ahead of the safety or comfort of the patient. A physician should always prepare, and ensure adequate staffing, for a deeper level of sedation than originally planned.

Medication Errors

All ED staff, including physicians, nurses, pharmacists, support staff, and others should take steps to prevent medication errors. Look-alike and sound-alike drugs, sometimes with similar packaging, are contributing factors in some errors. Caution should be used in stocking medications.

Allergic reactions are potential complications with any medications. Preventable errors related to medication allergies may occur when the health-care provider fails to obtain an adequate medical history, fails to read the record, or does not review previously documented allergies.

Some of the more serious medication errors involve a misplaced decimal point, which can result in a tenfold error. It is thus recommended when writing medication orders to place a zero before a decimal point to express a number less than one (e.g., 0.5 mL). However, one should never use a terminal zero (e.g., 5.0) because failure to see the decimal point may result in the patient getting ten times the dose desired. Also, write the word "units" rather than "u," which can be misinterpreted as an extra zero. Many other medication errors are due to incorrect computation. Some of these may be preventable by electronic order technology where only approved drug doses are accepted by the computer. Studies performed on inpatient units have shown that computerized physician order entry systems have reduced medication errors by 55%. More studies in the ED setting need to be conducted to determine if this reduction is comparable.

Institutions are required by the Joint Commission and the Center for Medicaid and Medicare Services (CMS) to establish a list of "high-alert" drugs that would require special or additional checks in their dosing, preparation, and administration. Double check medication dosages before any drugs are given. Research shows that 95% of all mistakes are found when someone checks the work of another. Double checks are more effective when performed independently. It is best to verify a colleague's result without visually examining the calculations that allowed them to arrive at that result. The checker might otherwise be drawn into the calculator's mistake, when he or she is only shown his or her calculations. Tenfold errors are easily missed this way.

Having a satellite pharmacy that serves the ED with unit dosing rather than having nurses prepare medications may be beneficial. It is interesting to note that, in the hospital setting, 39% of errors are detected before reaching the patient. In the ED setting, only 23% of errors are detected before reaching the patient. This may be related to the lack of a pharmacist's involvement in most ED decisions.

Take time to be sure all necessary equipment and medications are in place before giving sedative agents. The SOAPME checklist is familiar to many and reminds the clinician to plan in advance [Suction, Oxygen, Airway (appropriate-sized equipment), Pharmacy (drugs needed), Monitors, Equipment (perhaps a defibrillator)]. The Joint Commission advocates a "time-out" before any medication is given to verify the correct patient, site, and medications. Anticipate complications such as laryngospasm. Have a back-up plan for complications before they arise. The Joint Commission emphasizes the concept of "sedation rescue," which is essential to safe sedation. The ability to rescue a patient after an adverse event is also emphasized by AAP guidelines.

Documentation

Careful documentation of the use of sedatives and analgesics is extremely important. If an inpatient or outpatient record already exists, there is no need to repeat the information previously documented. However, a brief note is recommended to indicate that the chart was reviewed before giving sedative agents. A note indicating the child's pre-sedation status is helpful and there should be a notation that the patient's condition has not changed since arrival or since the last exam in the record.

When using sedatives and analgesics, a well-designed, time-based record is essential. The use of a separate form or checklist is particularly useful as a supplement to the ED note. The checklist may improve efficiency. It may serve to remind the caregiver to ask specific questions or perform a specific part of the physical examination. The record should indicate any history of allergies or adverse drug reactions, as well as medications used prior to sedation. It is wise to place this information near the section for writing the sedation orders so they can be reviewed when medications are ordered.

The physical examination should focus on the airway and cardiovascular system. The patient's weight must be carefully recorded in an obvious location in the record and it is best to record this consistently in kilograms. Dosing errors are the leading category of mishaps involving medications and about 10% of these are related to an incorrect weight (obtained or recorded incorrectly) for the child. It is also helpful to document the child's level of consciousness during the procedure (e.g., how he or she responds to verbal commands or tactile stimulation). Note the patient's level of consciousness again prior to discharge.

Discharge instructions must be reviewed with the child's guardian before the patient is allowed to go home. They may be preprinted and include a reminder to parents that the child should not be involved in activities that require coordination such as bicycle riding or skating for perhaps 24 hours. Adult supervision should be recommended for at least 8 hours. Unsupervised bathing and use of electrical devices or other possibly dangerous items should not be permitted for at least 8 hours.

SUMMARY

It is common to encounter children in pain in the pediatric ED. It is often difficult, but not impossible to avoid inflicting pain on some children in this setting. Management should be accomplished with nonpharmacologic techniques such as hypnosis and distraction, along with various narcotic and nonnarcotic analgesics, local and topical anesthetics, and sedative-hypnotics. Other agents, such as N_2O, ketamine, and propofol, play a more limited role in reducing pain and distress in the pediatric patient. Gentle restraint is needed occasionally and reassurance is of paramount importance.

CHAPTER 5 ■ EMERGENCY AIRWAY MANAGEMENT—RAPID SEQUENCE INTUBATION

LOREN G. YAMAMOTO, MD, MPH, MBA, FAAP, FACEP

Management of the airway is a critical initial step in the stabilization of patients who present to the emergency department (ED) with a life-threatening emergency. Endotracheal (ET) intubation is often the most reliable means of maintaining airway control. Indications for ET intubation include cardiopulmonary arrest, apnea, respiratory insufficiency, actual or potential airway obstruction, respiratory depression, severe burns, severe multiple trauma, severe head injury, increased intracranial pressure (ICP), a depressed sensorium, and a loss of the normal protective airway reflexes.

Airway management is most optimal when the ED staff is trained to recognize the need for intubation and to accomplish this while minimizing complications. The equipment necessary for ET intubation should be readily available at the bedside for immediate access and use during the management of any critically ill patient in the ED (Table 5.1).

ET intubation can be difficult when seizures, agitation, combativeness, and inadequate muscle relaxation, result in poor airway visualization. Laryngoscopy and intubation potentially result in ICP elevation, pain, bradycardia, and a higher risk of gastric regurgitation and hypoxemia. Patients who arrive in the ED often have not been fasted.

Although intubation can often be accomplished under these circumstances, the conditions are optimized and the adverse effects are minimized when a patient is intubated using rapid sequence intubation (RSI)—a rapid induction of general anesthesia that induces unconsciousness and muscle relaxation. The purpose of RSI is to rapidly render a patient unconscious and paralyzed so that intubation can be facilitated. Emergency intubations performed under a fully relaxed state are usually easier to perform and have fewer adverse effects, such as pain and ICP elevation.

While RSI and rapid sequence induction are both referred to as RSI, the former terminology is more commonly used in emergency medicine, while the latter is used more commonly in anesthesia. This difference is not absolute; however, the purpose of RSI in the ED is most often to emergently intubate a patient, while the purpose of RSI in the operating room is less emergent.

Pharmacologic paralysis makes it impossible to perform a neurologic examination on the patient and eliminates all respiratory effort by the patient. Would it be preferable to sedate a patient without paralysis for intubation because of these considerations? Although this was a common practice in the past, intubation using sedation alone has a higher complication rate than RSI does, making RSI the preferred technique.

RSI is not necessarily indicated in cardiac arrest. In cardiac arrest, for example, intubation without RSI would generally be preferable unless cardiopulmonary resuscitation, brain perfusion, muscle tone, and/or some degree of consciousness were maintained, in which case RSI may be of benefit. Understanding the principles of RSI is the best means of determining when it is indicated.

A typical RSI consists of premedications (most often lidocaine and/or atropine) to block vagal stimulation, a sedative to induce unconsciousness, and a muscle relaxant to induce paralysis. This typical sequence can become rather complicated when more considerations are added. It should be noted that the drugs for pediatric RSI have been recommended in their most basic forms as (i) premedications, (ii) sedative, and (iii) muscle relaxant. This chapter addresses the following controversies surrounding RSI: sedative selection, muscle relaxant selection, priming or defasciculation, and adjunctive medications such as lidocaine and fentanyl.

RAPID SEQUENCE INTUBATION SEDATIVES

The most common sedatives used in RSI include thiopental, ketamine, etomidate, propofol, midazolam (and other benzodiazepines). Narcotic analgesics such as fentanyl can also be used, but this is less common. Each drug has both beneficial and detrimental properties that must be understood to select the best sedative for RSI in the patient at hand. The advantages and disadvantages of each drug are summarized in Table 5.2. The most recent controversies in sedative selection include RSI indications for ketamine, etomidate and propofol.

Thiopental (an ultrashort-acting barbiturate) was initially one of the most commonly used sedatives for RSI. Its advantages are reliability and rapid onset (10 to 20 seconds), short duration, and a cerebral protective effect accomplished by reducing ICP, cerebral metabolism, and cerebral oxygen demand. Its main disadvantages are vasodilation and myocardial depression, which may result in profound hypotension. Thiopental should be avoided or used in lower dosages in hypotensive or hypovolemic patients. These effects can be also minimized by slowing the rate of injection. Thiopental causes respiratory depression and may result in coughing, laryngospasm, and bronchospasm. Thiopental is contraindicated in porphyria and status asthmaticus.

Ketamine produces rapid sedation, amnesia, and analgesia. It is described as a dissociative agent that induces a trancelike state in which the patient is unaware, but not necessarily asleep. In combination with a paralyzing agent as in RSI, this difference is not noticeable. Ketamine results in sympathetic stimulation and an increase in systemic blood pressure (BP); however, reduced doses or avoidance of a sedative are still recommended

TABLE 5.1

EQUIPMENT NEEDED FOR RAPID SEQUENCE INTUBATION

Pulse oximeter
End-tidal CO_2, monitor or detector
Electrocardiogram monitor
Uncuffed endotracheal tubes, sizes 2.5–6.0
Cuffed endotracheal tubes, sizes 6.0–8.5 (cuffed tubes smaller than 6.0 are available)
Endotracheal tube stylets
Laryngoscopes (straight blade sizes 0–3, curved blade sizes 2–4)
Oral airways
Oxygen masks, preferably a nonrebreather
Ventilation masks in all sizes for bag-valve-mask ventilation
Large and small self-inflating ventilation bag with oxygen reservoir tail and positive end-expiratory pressure valve attachment. Rusch type anesthesia bags can also be used but require a pressurized oxygen source and can be more difficult to ventilate large patients.
Laryngeal mask airways in all sizes
Oxygen source
Suctioning source
Large-bore stiff suction tips
Flexible suction catheters
Nasogastric tubes
Tracheostomy tubes
Tracheostomy surgical instrument set
12- and 14-gauge needle catheters for needle cricothyrotomy
Preassembled transtracheal ventilation setup

in potentially hypovolemic patients. Adverse effects, which include ICP elevation, intraocular pressure elevation, hallucinations, excessive airway secretions, and laryngospasm, limit its use to ED patients who have hypotension, hypovolemia, or status asthmaticus. Recent studies have been published addressing the use of ketamine in patients with elevated ICP, long thought to be a contraindication. More research is needed to substantiate these findings. Ketamine increases airway secretions, so routine atropine premedication is recommended. Ketamine has a bronchodilating effect, making it useful for RSI of patients with severe bronchospasm that requires intubation. Ketamine is contraindicated in patients with hypertension, head injury, psychiatric problems, glaucoma, or an open globe injury. In some older children the psychological reactions to ketamine have severely limited its use. However, this is rarely a problem when using ketamine for RSI as the effect of the medication will generally dissipate prior to extubation and awakening. These reactions usually disappear upon awakening but can be recurrent. The frequency of psychiatric disturbances with ketamine (sometimes reported to be 5% to 30%) are less common in children. Other reports have shown no significant adverse psychological effects compared with other sedatives. The use of benzodiazepines during ketamine anesthesia have been alleged to reduce the likelihood of adverse psychological effects; however recent studies do not clearly prove this. It is unclear whether benziodiazepine treatment is necessary, but its downside risk is minimal when using during RSI.

Etomidate has more recently been advocated as an RSI sedative. Although most RSI sedatives have advantages in certain clinical situations and disadvantages in others, etomidate has advantages in the broadest range of RSI patients. It shares some advantages of thiopental—rapid and reliable onset of unconsciousness, ICP reduction, and reduction of cerebral metabolic demand. Etomidate has minimal cardiovascular depression compared with thiopental. Etomidate at first glance appears to have superior cerebroprotective properties because it lowers ICP and cerebral metabolism with better preservation of cerebral perfusion pressure compared with thiopental. Etomidate is associated with myoclonus-resembling seizures. The frequency with which this occurs ranges from 10% to 80% in various reports. However, the etiology is not well-defined. Although etomidate has some anticonvulsant properties, it also appears to stimulate

TABLE 5.2

SIGNIFICANT PROPERTIES OF RAPID SEQUENCE INTUBATION SEDATIVES

Drug	Onset	Duration	Cerebroprotective effect	Cardiovascular effect	Bronchial effect	Other disadvantages
Thiopental	Rapid	Brief	Good	Significant depression	Bronchospasm	
Ketamine	Rapid	Brief	Adverse	Stimulatory	Bronchodilatory	Psychic reactions and excessive airway secretions
Etomidate	Rapid	Brief	Good	Neutral	Neutral	Myoclonus, cortisol suppression
Propofol	Rapid	Brief	Good	Significant depression	Neutral	Less experience with agent in emergency department rapid sequence intubation (RSI)
Midazolam	Less rapid	Brief	Modest	Neutral	Neutral	Titration recommended, is not feasible in RSI
Fentanyl	Less rapid	Brief	Modest	Neutral	Neutral	Seizure-like activity and chest wall rigidity

seizures in others. Etomidate suppresses glucocorticoid and mineralocorticoid levels. This effect is clearly clinically significant in long-term administration of etomidate. Single use as in ED RSI results in measurable decreases in corticosteroid levels, and more recent studies have concluded that this is likely to be clinically significant in shock states, especially in septic shock. It is unproven, but it makes logical sense to administer corticosteroids when etomidate is used to offset this problem. Although unproven, etomidate should not be used in patients with partial seizures and adrenal insufficiency. Because of its broad applicability for RSI, some experts have recommended that etomidate be the standard sedative used for RSI. Etomidate clearly has the broadest set of indications in RSI. Sedative selection is a difficult aspect of RSI, and etomidate potentially simplifies this decision. It is important for the clinician to remember that etomidate has no analgesic properties and is extremely short acting (~5 minutes), and plans must be in place for post-intubation sedation and analgesia.

Propofol use in the ED is increasing in frequency. It is largely used by anesthesiologists for short-term sedation and general anesthesia. It can be used as a sedative in RSI, but its degree of experience here is limited and it does not have substantial advantages over other sedatives. Propofol shares many features with thiopental. Propofol decreases ICP and cerebral metabolism. Propofol's onset is rapid and brief, but it can result in significant cardiovascular depression. Although propofol can be used in instances when thiopental could be used, there is more experience with thiopental.

Midazolam (and other benzodiazepines such as diazepam) has a slower onset than thiopental. It is more commonly used for mild or moderate sedation or as an adjunctive agent in general anesthesia. Midazolam is capable of anesthesia induction at higher dosages. Cardiovascular and respiratory depression occur less often than with barbiturates. Lack of recall or anterograde amnesia results from benzodiazepines used for anesthesia. Benzodiazepines should not be used in patients with glaucoma. Midazolam has many properties that suggest its use for RSI in the ED. Many reports in the literature have advocated its use despite the lack of data to document its deep sedation efficacy. The dosing range is suggested at 0.1 to 0.3 mg per kg. The lower dosage is clearly insufficient to reliably induce unconsciousness. Because these drugs also result in amnesia, studies may never be able to retrospectively assess the degree of unconsciousness attained during RSI.

Fentanyl is a short-acting narcotic analgesic that results in rapid analgesia and unconsciousness at higher dosages. Adverse effects associated with fentanyl are less than those of morphine. The doses of narcotics required to produce complete anesthesia are much higher than the doses required for analgesia alone and may vary extensively. Chest wall rigidity may occur with rapid injection of fentanyl, but this is preventable with slow administration and is sometimes reversible with naloxone, although a muscle relaxant may be required to adequately ventilate the patient. Fentanyl use has been associated with seizure-like activity. Fentanyl is used most often in cardiovascular surgery in combination with other anesthetics. Although it has some properties useful for RSI performed in the ED, literature sources to support fentanyl use for RSI in the ED are lacking. Fentanyl should not be used with monoamine oxidase inhibitors.

Although myocardial depression is most pronounced with thiopental, all sedatives cause some degree of cardiovascular depression, especially in hypotensive or hypovolemic patients. Because no sedative is entirely free of cardiovascular depression in the hypovolemic or hypotensive patient, such patients should receive reduced dosages or no sedative at all, depending on their cardiovascular status.

SEDATIVE SELECTION

Sedative selection remains one of the most controversial aspects of RSI. Etomidate appears to have the broadest applicability, but each agent should be well understood so individual practitioners can make the best decisions about which agent would be most optimal in each clinical situation. The clinical situation determines the optimal sedative selection. Table 5.3 summarizes sedative selections in different clinical categories.

The purpose of the sedative is to render the patient unconscious, while the paralyzing agent facilitates intubation. However, at least one study has demonstrated that thiopental and propofol facilitate intubation better than etomidate, ketamine, and benzodiazepines.

Although etomidate and propofol are said to be cerebroprotective, it is difficult to find the original data that compares the cerebroprotective properties of etomidate and propofol compared to thiopental and other barbiturates. Propofol has no significant advantages over thiopental and etomidate for RSI, making it difficult to justify its use here. It is generally agreed that barbiturate coma remains the standard means of cerebroprotection. Etomidate coma has not replaced barbiturate coma in this regard suggesting that etomidate's cerebroprotection has not been demonstrated to be superior to that of barbiturates. Additionally the risk of increased morbidity and mortality from adrenocortical suppression associated with continuous infusion or repeated doses of etomidate makes it unappealing for this use.

Etomidate can potentially be used in most clinical situations, but upon careful consideration, there may be superior alternatives in many situations. Thiopental can be used for all patients except those with hypotension, hypovolemia, status asthmaticus, or porphyria. In patients with suspected head injuries who have severe hypovolemia or hypotension, thiopental should be avoided. Any sedation agent may compromise cardiovascular function in such a state. There is not enough information in the literature to establish a clear consensus about which sedative would be the most optimal in this situation. Etomidate, a low-dose sedative or no sedative would be among the best options.

In potentially hypovolemic patients with suspected head injuries, etomidate, midazolam, or low-dose thiopental may be used in conjunction with volume resuscitation. Midazolam has the major disadvantage of ideally requiring titration, which is not feasible in RSI, making it difficult to justify its selection. Etomidate might be preferred over low-dose thiopental here.

In head injury patients without hypovolemia or hypotension, thiopental or etomidate both have cerebroprotective properties; however, if barbiturate cerebroprotection is superior to etomidate's cerebroprotection, then thiopental should be preferred. While propofol could be used here, it has no properties that make it superior to thiopental or etomidate for RSI. In a patient without head injuries who has hypotension/hypovolemia, ketamine or etomidate may produce the least

TABLE 5.3

RAPID SEQUENCE INTUBATION DRUGS AND DOSES (in mg)

Age	2 mo	6 mo	1 yr	3 yr	5 yr	7 yr	9 yr	11 yr	12 yr	14 yr	16 yr	Adult
Average weight (kg)	5	8	10	15	19	23	29	36	44	50	58	65
1. Preoxygenation: Positive-pressure ventilation with cricoid pressure only if hypoventilating or hypoxic												
2. Adjunctive agents												
Atropine (0.01–0.02 mg/kg): Optional in adults not requiring ketamine (1 mg maximum dose)												
	0.1	0.15	0.2	0.3	0.3	0.4	0.5	0.5	0.5–1	0.5–1	0.5–1	0.5–1
Lidocaine (1.5 mg/kg): Use when ICP elevation is suspected (otherwise, it is optional—see text)												
	8	12	15	22	28	35	44	54	66	75	90	100
3. Assess ability to establish ventilation if intubation fails; do not proceed if inability to mask ventilate is anticipated												
4. Sellick maneuver (cricoid pressure): Do not release until intubation is confirmed												
5. Paralyzing agent: Choose one—see text												
Rocuronium (0.6–1 mg/kg)	4	6	9	12	15	20	25	30	40	45	50	60
Succinylcholine (1–2 mg/kg)	8	12	15	25	30	40	50	55	60	65	70	80
Vecuronium (0.1–0.2 mg/kg)	0.5	1.5	2	3	4	5	6	7	8	10	11	13
6. Sedation agent: problem specific												
Head injury without hypotension: (i) thiopental, (ii) etomidate												
Head injury with mild hypotension: (i) etomidate, (ii) half dose thiopental												
Hypotension: (i) ketamine, (ii) etomidate. Consider reduced dose or no sedative at all since any sedative can worsen hypotension.												
Status asthmaticus: (i) ketamine, (ii) etomidate												
Status epilepticus: (i) thiopental, (ii) benzodiazepine												
Thiopental (3–5 mg/kg)	15–25	24–40	30–50	45–75	60–90	70–115	90–145	110–180	130–200	150–250	170–290	200–325
Etomidate (0.3 mg/kg)	1.5	2.5	3	4.5	6	7	9	10	13	15	17	20
Ketamine (1–2 mg/kg)	5–10	8–16	10–20	15–30	19–38	23–46	30–60	35–70	45–90	50–100	60–100	65–100
7. Intubate [endotracheal (ET) tube size]	3.5	3.5	4.0	4.5	5.0	5.5	6.0	6.5	7.0	7.0 female, 8.0 male		
ET tube depth at lip (cm)	11	12	13	14	15	16	18	19	20	22	22	22
Laryngoscope blade size	1	1	1	2	2	2	2	2	3	3	3	3–4
8. Optional NG/OG tube (F)	8	10	10	12	12	12	14	14	16	16	16	16
9. Longer-acting sedation and/or paralysis as needed												
10. If reversal of rocuronium is needed (see text)												

adverse effects. Atropine should be used with ketamine. No sedative or a low dosage of sedative (ketamine, etomidate, or thiopental) is recommended in severe hypotension/hypovolemia to reduce the likelihood of cardiovascular collapse in patients with maximal endogenous sympathetic stimulation while ensuring that the patient is not aware of being paralyzed. Etomidate's adverse effect of adrenal suppression becomes potentially more important in shock states.

Ketamine or benzodiazepines have been recommended for sedating patients with status asthmaticus who require intubation; however, ketamine is associated with a bronchodilatory effect, whereas benzodiazepines are not. Etomidate can be used here, but ketamine has superior characteristics for severe status asthmaticus.

Both thiopental and benzodiazepines have potent anticonvulsant effects, making these drugs useful for RSI in status epilepticus.

In patients with severe cardiovascular compromise or unconsciousness, a sedative may be considered optional to prevent further cardiovascular compromise.

MUSCLE RELAXANTS

Muscle relaxants result in total muscle paralysis, yet the patient may be fully conscious.

Succinylcholine is a depolarizing muscle relaxant with a rapid onset (30 to 60 seconds) and short duration (3 to 12

minutes). Even though it has been the most common muscle relaxant used in RSI, it has numerous disadvantages. Although not contraindicated in head injuries, it causes elevated ICP. Intraocular and intragastric pressure elevations may occur. Muscle fasciculations that might result in muscle pain, rhabdomyolysis, and myoglobinuria might also occur. These are more severe in muscular patients and can be prevented by a defasciculating dose of rocuronium before succinylcholine (this is not necessary in children younger than 5 years of age). Atropine premedication may prevent the bradycardia and excessive bronchial secretions associated with succinylcholine, although recent data has questioned this effect particularly in older children. Other less preventable adverse effects include negative inotropic and chronotropic effects, an association with malignant hyperthermia, hyperkalemia, hypertension, and arrhythmias. Another caution is the use of succinylcholine in a patient with neuromuscular disease. Succinylcholine is contraindicated in patients with glaucoma, penetrating eye injuries, significant neuromuscular disease, history or family history of malignant hyperthermia, and pseudocholinesterase deficiency. At 3 to 60 days after trauma or burns (in other words, day 3 or later following trauma or burns), succinylcholine results in an increased frequency of the risks described here and should not be used. Patients with severe burns or large crush injuries may already be acutely hyperkalemic; thus, the decision to use succinylcholine should consider this as well.

Of the nondepolarizing muscle relaxants, rocuronium currently has the fastest onset and shortest duration. Vecuronium was commonly used prior to rocuronium's introduction. Both agents have minimal cardiovascular effects. Onset times for rocuronium and high dose vecuronium are 30 to 90 seconds. Standard dose vecuronium (0.1 mg/kg) results in an onset time of 90–120 seconds. Duration for rocuronium is 25 to 60 minutes, wheras vecuronium can persist for up to 2 hours when true RSI doses of 0.3 mg/kg are used. Rocuronium is available in a premixed vial ready to use, and vecuronium comes in a powder that must be reconstituted. This factor gives rocuronium another advantage when the time to intubation may be prolonged because of medication preparation.

Other nondepolarizing muscle relaxants include pancuronium, atracurium, and mivacurium. Pancuronium has a slower onset and more cardiovascular side effects. Atracurium and mivacurium have rapid onset times but are associated with histamine release and cardiovascular side effects. Rocuronium is currently the nondepolarizing muscle relaxant of choice. A newer drug, rapacuronium has a rapid onset time and shorter duration than rocuronium, so its use could increase once experience with it is better described.

MUSCLE RELAXANT SELECTION

In comparing rocuronium and succinylcholine, rocuronium has fewer adverse effects, whereas succinylcholine has a shorter duration. The onset times are similar. Some view rocuronium as preferable because it is safer. The contrary view is that because of succinylcholine's shorter duration (which allows restoration of spontaneous ventilation within 3 to 12 minutes compared with 25 to 60 minutes for rocuronium), succinylcholine is better if intubation fails.

In most patients, neuromuscular blockade facilitates both intubation and bag-mask ventilation. For patients with risk factors that suggest a difficult intubation or will require frequent neurologic checks, succinylcholine may be preferable. For others, rocuronium may be preferable. Whether the shorter duration of succinylcholine justifies its greater risk of adverse effects is essentially a personal judgment that individual clinicians must make.

Rocuronium can be reversed pharmacologically. While edrophonium was commonly recommended, this drug is no longer available. Neostigmine (given with atropine or glycopyrrolate to block muscarinic bradycardia and excessive secretions) can be used; however, this is not clinically routinely useful because reversal cannot be achieved immediately. Reversal must wait for some degree of spontaneous recovery to occur, which occurs later than the duration of succinylcholine. Sugammadex is a new agent reported in trials to rapidly reverse rocuronium and vecuronium in the early stage (known as profound neuromuscular blockade). This might become a routinely available option in the future.

Defasciculation and Priming

Defasciculation refers only to the use of succinylcholine, which might cause fasciculations, muscle pain, rhabdomyolysis, and myoglobinuria. This effect is most pronounced in muscular individuals. Fasciculations might increase muscle tone and increase the risk of gastric regurgitation during RSI. To prevent fasciculations, "defasciculation" is recommended, where one-tenth the paralyzing dose of a nondepolarizing muscle relaxant (e.g., rocuronium 0.1 mg per kg) is administered 1 to 3 minutes before succinylcholine administration. This "defasciculating" dose of rocuronium will prevent fasciculations caused by succinylcholine. Defasciculation is most beneficial in muscular individuals. Defasciculation is not necessary in children 5 years of age or younger. Note that this defasciculating step delays the time to intubation and adds complexity to RSI.

Priming in RSI refers to nondepolarizing muscle relaxants only. Its purpose is to shorten the onset time of nondepolarizing muscle relaxants. A priming dose is one-tenth the paralyzing dose of a nondepolarizing muscle relaxant. Using vecuronium as an example, a priming dose of 0.01 mg per kg is administered. Five minutes should elapse for the "priming" to take effect. The paralyzing dose of 0.1 mg per kg is then administered. The full paralyzing onset time of vecuronium is about 100 seconds without priming, 50 seconds with priming. Unfortunately, priming adds an additional 5-minutes delay to intubation while saving 50 seconds in accelerating the onset of the full dose of vecuronium. Because the onset time of rocuronium is considerably faster, the advantage of priming is minimal. Although some experts still recommend priming, it appears to have little benefit in the ED when immediate intubation is required.

Defasciculation and priming are often confused because they both require one-tenth of the paralyzing dose of a nondepolarizing muscle relaxant. However, the two principles are different, even though they have similar characteristics in that they are optional, they delay the time to intubation, and they add complexity to the drug administrations in RSI. Most ED

RSI protocols have removed defasciculation and priming options from routine use.

ADJUNCTIVE AGENTS

The RSI sequence shown in Table 5.3 considers the use of atropine and lidocaine. Atropine use prior to intubation was considered routine in children to prevent bradycardia, although this has recently been challenged in the literature. Use of atropine is optional in adults, unless ketamine is used as a sedative, in which case, atropine is recommended in some protocols in adults as well. Lidocaine is more controversial. It has been shown to reduce ICP and airway reactivity under certain conditions when given 2 minutes before intubation. If ICP elevation is suspected, a cerebroprotective sedative (thiopental or etomidate) is generally preferred in RSI. Lidocaine is cerebroprotective in isolation, but it is unclear whether lidocaine results in additional benefit when added to a cerebroprotective RSI regimen that includes thiopental or etomidate. Despite this controversy, most practicing academic centers and consensus reports recommend the use of intravenous (IV) lidocaine prior to intubation if ICP elevation is suspected. In addition to IV lidocaine, topical lidocaine has been recommended to blunt the adverse reaction to ET intubation. This adds considerable complexity to the laryngoscopy procedure, especially in patients in whom neck immobilization is critical and/or airway visualization may be less than optimal. The recommendation that lidocaine be used in intubating asthmatics stems from its beneficial effect in attenuating bronchospasm. If one truly believes that lidocaine has such a benefit, then if possible, it should be administered long before the patient requires intubation (i.e., to prevent respiratory failure and the need for intubation), as opposed to administering it during RSI.

Opiate analgesics such as fentanyl and morphine have been advocated as adjunctive agents in RSI to further reduce the adverse effects of intubation. Ketamine has analgesic properties; thus, coadministration of analgesics is unnecessary with ketamine. Sedatives such as benzodiazepines, etomidate, and thiopental have little or no analgesic properties. The coadministration of analgesics has been recommended to address this. When considering that the patient is fully unconscious when reliable sedatives such as etomidate and thiopental are used, the additional benefit of analgesics to reduce the amount of "pain" felt by an unconscious patient becomes small. Narcotic analgesics have adverse reactions, and the additional risk that these pose may not justify their routine use. Benzodiazepines must ideally be titrated to assess the degree of sedation; thus, the degree of sedation with these agents is less reliable in RSI, in which case, coadministration of analgesics may be more beneficial.

If RSI is to accomplish its goal of rapid ET intubation, the addition of adjunctive agents should be critically considered because each additional agent adds time and complexity to RSI. This factor is often not considered when discussing the benefit of an individual adjunctive agent in isolation. Therefore, the RSI protocol described in Table 5.3 includes atropine for pediatric patients and IV lidocaine as an optional adjunctive agent for head trauma. Other adjunctive agents may be considered, but they have not been included in the table.

RAPID SEQUENCE INTUBATION PROTOCOL

After patient assessment, immediate stabilization, and IV/IO access, patients should be assessed for any contraindications to RSI or its agents. The major contraindication to RSI is the likelihood that intubation or ventilation might not be possible, as in cases of limited cervical mobility, a receding mandible, limited jaw opening, major facial or laryngeal trauma, upper airway obstruction, or distorted facial or airway anatomy.

To simplify RSI, a table such as Table 5.3 should be adapted. This table should be taped to the wall in the critical care area of your ED. This table is not a substitute for thoroughly understanding the characteristics of each agent and for the critical thinking necessary to select the agents. The following list explains the protocol shown in Table 5.3:

1. Preoxygenation (by spontaneously inspiring or mask-ventilating 100% oxygen for 2 to 5 minutes) results in an oxygen reserve. Positive-pressure mask ventilation may inflate the stomach and increase the likelihood of gastric regurgitation; thus, this procedure, in conjunction with cricoid pressure (see item 4), should be performed only if needed to oxygenate and ventilate the patient adequately. Hyperoxygenation is impossible in some patients. Pulse oximetry and an electrocardiogram monitor should be considered mandatory for patients undergoing RSI. If a self-inflating bag is used, oxygen is *not* delivered through the mask unless the bag is squeezed. Thus, if the patient is spontaneously breathing, a mask attached to a self-inflating bag should *not* be used; instead, a standard oxygen mask, such as a nonrebreather, should be used.
2. Atropine premedication is routinely administered in children. It prevents bradycardia and reduces oral secretions. This is considered optional for adults unless ketamine is used, in which case atropine is recommended. Lidocaine lowers ICP and suppresses the cough reflex. It may be beneficial to patients with ICP elevations. When used in conjunction with other ICP-lowering agents, however, its additional benefit is unclear. Lidocaine is generally recommended for patients with suspected ICP elevation.
3. Before proceeding, it should be ascertained that a good mask seal and an open airway can be maintained. In most instances, muscle relaxation facilitates mask ventilation and intubation. If an inability to intubate and/or mask ventilate is suspected, RSI should not proceed until additional assistance can be obtained.
4. The Sellick maneuver (application of pressure on the cricoid ring sufficient to occlude the esophageal lumen without compressing the airway lumen or moving the cervical spine) is alleged to reduce the likelihood of passive gastric regurgitation and aspiration and the likelihood of gastric distention resulting from mask ventilation. It should, therefore, be performed prior to positive-pressure mask ventilation, unless this results in gagging. It should be maintained until tracheal intubation is confirmed. Data

supporting the benefit of the Sellick maneuver are weak at best and at least one study has demonstrated that it is performed unreliably by ED staff.

5. After appropriate selection, a muscle relaxant followed by a sedative should be administered in rapid sequence. Administering the muscle relaxant first allows the sedative to be administered gradually while waiting for the full onset of the muscle relaxant. Some experts prefer the reverse sequence. For muscle relaxants, Table 5.3 lists rocuronium and succinylcholine. Optional priming (applies to nondepolarizing agents only) and defasciculation (applies to succinylcholine only) are not included in the sequence described in Table 5.3.
6. Intubation can take place when there is full relaxation of the airway muscles, usually 45 seconds after rocuronium or succinylcholine administration.
7. Once intubation is completed, proper ET tube placement should be confirmed by auscultation, end-tidal CO_2 ($ETCO_2$) detection, and the maintenance of oxygenation monitored by pulse oximetry. A confirmatory radiograph should be obtained.
8. Gastric evacuation can be performed with a nasogastric (NG) or orogastric (OG) tube at this time. Significant gastric distention noted prior to intubation can be deflated by an NG or OG tube prior to intubation if clinically tolerable by the patient.
9. Longer-acting sedatives and nondepolarizing muscle relaxants should be administered to maintain unconsciousness and paralysis as needed.
10. If reversal of rocuronium is necessary, neostigmine together with atropine can be administered to accelerate recovery; however, some degree of spontaneous recovery must be present for reversal to occur.

Nasal Intubation Compared with Oral Intubation in the Trauma Patient

Trauma victims who arrive in the ED have suspected cervical spine (C-spine) injuries in addition to other injuries. When it is not possible to rule out a C-spine injury before RSI, the head and neck should be immobilized during intubation.

Unless contraindicated, emergency intubation of pediatric patients should generally be performed orally. In spontaneously breathing patients, older literature sources have recommended blind nasal tracheal intubation, whereas newer recommendations prefer oral tracheal intubation using RSI. If the need for intubation is emergent, nasal tracheal intubation may not be as reliable as oral tracheal intubation. Nasal tracheal intubation is noxious, and it may cause the conscious patient to gag or become agitated, resulting in more neck movement, an increase in ICP, and possible vomiting. Nasal tracheal intubation is more difficult in children. Epistaxis, sinusitis, and cribriform fracture complications are other concerns with nasal tracheal intubation. Studies have not been able to show that nasal tracheal intubation results in less C-spine movement than oral tracheal intubation.

There is concern that laryngoscopy during oral tracheal intubation may displace a C-spine fracture. When using RSI, however, laryngoscopy manipulation and neck movement are minimized under these more ideal conditions. The concern that the loss of cervical muscle tone on an unstable C-spine will reduce its splinting effect and increase its instability has not been supported by evidence.

In a critical situation, intubation is best carried out by the means with which the clinician is most familiar for the given clinical condition. Oral tracheal intubation using RSI appears to be the best means of securing an airway for most clinicians.

Cervical Spine Immobilization During Endotracheal Intubation

The terms that describe C-spine immobilization are ambiguous. For example, traction has been used synonymously with immobilization, although "traction" generally indicates a pulling action with an undefined degree of force. Manual cervical immobilization implies that hands are somehow used to immobilize the neck. Cervical immobilization implies the use of a stiff collar and other devices to immobilize the neck. Philadelphia collars used with manual stabilization do not provide any additional C-spine stability compared with manual stabilization alone. Axial (inline) traction has been shown to worsen C-spine stability in patients. One preferred method is to remove the anterior portion of the cervical collar with an assistant immobilizing the head and neck after the patient is rendered unconscious and paralyzed. This enables the jaw to open wider, providing better visualization during laryngoscopy without sacrificing cervical immobilization.

Alternative Intubation and Airway Techniques

Because the experience level of most ED physicians is greatest with oral tracheal intubation, it is unwise to deviate from this in managing a critically ill child who requires intubation. Alternative procedures should be reserved for instances in which conventional airway techniques prove unsuccessful.

Flexible fiberoptic scopes, lighted stylets to guide nasal tracheal intubation, retrograde intubations, and surgical airways all require high skill and experience levels to be performed optimally. These procedures have less documented experience in children. Directly visualizing the airway through a fiberoptic scope is appealing; however, it requires extensive practice, and it may be especially difficult in critical intubations or in agitated patients. Intubation aided by bronchoscopy, lighted stylets, and the retrograde wire technique are not recommended in ED RSI because of the lack of spontaneous breathing during RSI and the time required for these procedures.

The Combitube™ (Sheridan Catheter Corporation, Argyle, NY) is a double-lumen airway that is blindly inserted through the mouth. One lumen exits through the distal end of the Combitube. The other lumen exits through multiple side holes proximal to the distal end. An inflatable (distal) balloon separates these two (the distal end hole and the more proximal side holes). Because the Combitube is inserted blindly, it will enter either the trachea or the esophagus. If it enters the trachea, the

distal balloon is inflated and the distal end-hole lumen is used to ventilate the patient just as if this were a conventional tracheal tube. If the Combitube enters the esophagus, the inflation of the distal balloon occludes the esophagus and the lumen ending in the more proximal side holes is used to ventilate the patient. The esophageal position of this tube is similar to an esophageal obturator airway. Use of the Combitube requires familiarity with its function and method of insertion. It has been demonstrated to be effective in providing an airway during resuscitation, but failures occur as well. Widespread experience with the Combitube in pediatric patients is lacking as there are no specific pediatric sizes.

The laryngeal mask airway (LMA) is another airway device. LMAs come in several different sizes, and their use in pediatric patients has been demonstrated. Experience with LMAs is growing. The correct insertion and placement position of the LMA is critical. The LMA is inserted blindly, taking about 15 to 20 seconds. LMA insertion methods are best taught using video or hands-on instruction. In-depth understanding of the LMA and previous hands-on experience are required to consider it as an airway management option. The LMA does not prevent aspiration but it may be useful when one is unable to successfully intubate.

Surgical airways, such as tracheostomy or cricothyrotomy, may be considered. Complications, including incorrect tube placement, subcutaneous emphysema, pneumomediastinum, pneumothorax, bleeding, tracheal stenosis, subglottic stenosis, arterial injury, blood aspiration, and persistent tracheocutaneous fistulae, are more common when the procedure is performed on an emergency basis in children. Cricothyrotomy is faster and easier to perform than tracheostomy and also has a lower complication rate. However, in small children, the cricothyroid membrane is not readily palpable and may be too small for an airway. It is not recommended in children younger than 10 years of age. Electrocautery devices should be avoided during these procedures because the presence of high-flow oxygen can result in spontaneous combustion.

Because surgical airways are difficult to perform in children, needle cricothyrotomy may be beneficial for children who cannot be ventilated by any other route, although the complications are similar to those of surgical airways and the experience level with this procedure in children is minimal as well. An over-the-needle 12- or 14-gauge IV catheter is directed inferiorly through the cricothyroid membrane, the needle is removed, and the catheter is left in place. It is vital to have a ventilation device preassembled and ready to use before such an emergency because ventilation through a transtracheal catheter requires a special setup. Many recommendations for transtracheal ventilation have appeared in the literature. Special transtracheal airway kits are available commercially that are generally superior to using an IV catheter. Two ventilation examples are shown in Figure 5.1. These use a wall outlet or tank oxygen pressure directly into the transtracheal catheter. It is the most optimal means to deliver

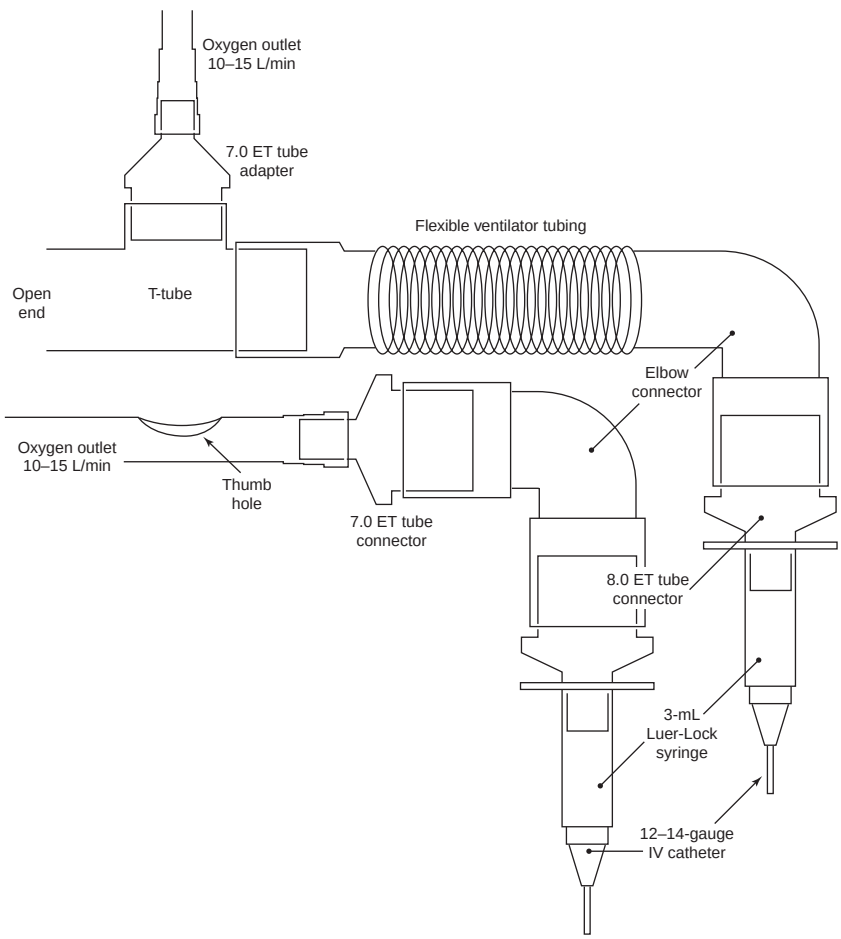

FIGURE 5.1 Transtracheal ventilation setup. (Adapted from Yamamoto LG. Rapid sequence anesthesia induction and advanced airway management in pediatric patients. *Emerg Med Clin North Am* 1991;9: 611–638, copyright by WB Saunders, with permission from author and publisher.)

an adequate tidal volume through the small catheter. By occluding the T tube or the side hole, oxygen is forced through the catheter at high pressure. Chest movement should be used as a visible indicator of adequate ventilation. Exhalation occurs passively through the larynx and not through the catheter. If exhalation is obstructed as well, transtracheal ventilation is contraindicated. The catheter must be held securely because a kink or movement of the catheter would compromise this fragile airway. Another common recommendation is to attach a ventilation bag to the transtracheal catheter through an ET tube connector (about size 3.0). Delivering an adequate tidal volume by aggressively squeezing the bag is possible, but such exaggerated motion may dislodge or kink the catheter.

Transtracheal ventilation is only a temporizing measure, and a more definitive airway should be established as soon as possible. It is important to have ED staff members familiarize themselves with the transtracheal ventilation setup. By attaching a balloon or glove to the transtracheal catheter, air flow can be visualized during practice sessions.

AVOIDING PROBLEMS

Being prepared by becoming aware of the following problems commonly encountered during RSI can greatly improve the success of the procedure.

1. Oxygen delivery devices must be well understood by the staff. New nurses and residents often do not know that oxygen is *not* delivered to the mask attached to a self-inflating bag unless the bag is squeezed. Thus, putting such a mask in front of a patient who is spontaneously breathing will deliver only 21% oxygen (room air), and the patient will fail to hyperoxygenate. For spontaneously breathing patients, oxygen should be delivered using a standard oxygen mask, such as a nonrebreather. A mask attached to a closed-circuit bag (anesthesia-type bag, Rusch bag) with 100% oxygen can also be used. For patients who require positive-pressure mask ventilation, a self-inflating bag with an oxygen reservoir tail is satisfactory.
2. Drug preparation is time consuming. Thiopental comes in kits that require reconstitution before use. Other drugs are less troublesome.
3. Sedatives and muscle relaxants may interact if administered together. The line between the two medications should be cleared. When RSI begins, it is better to have the IV running at a high rate to more effectively clear the line to prevent interaction. The IV rate should be turned back to baseline when RSI drug administration is completed. It may be more optimal to have two IVs running so the drugs can be administered in rapid sequence in two different lines.
4. Paralysis is not a substitute for sedation. Conscious patients remain conscious during paralysis (a frightening experience). It may be safer, however, to avoid sedatives in severely hemodynamically compromised or unconscious patients.
5. Intubation using a sedative without paralysis has a higher complication rate than RSI.
6. Incorrect weight estimates can result in underdosing or overdosing of drugs and can cause significant delays in the onset of RSI.
7. Avoiding unrecognized extubation and esophageal intubation is critical. Frequent clinical reevaluation, $ETCO_2$ monitoring, and pulse oximetry are highly recommended because they often can prevent this serious complication. $ETCO_2$ monitoring (capnometry) is preferable to $ETCO_2$ color detection because it permits quantitative P_{CO_2} monitoring, which is useful in patients who are difficult to ventilate or in those who require the P_{CO_2} to be maintained in a strict range. $ETCO_2$ color detectors work only for a short period. After 15 minutes or so, moisture renders them nonfunctional; thus, these should not be used for long transports unless they are frequently replaced.
8. Mainstem bronchial intubation can occur easily in small children who have a small degree of tracheal tube movement.
9. The duration of the sedative is frequently shorter than the duration of the muscle relaxant, potentially resulting in consciousness while paralyzed. Avoid this by maintaining sufficient sedation during the duration of paralysis.
10. RSI protocols should be reviewed with the ED staff at periodic in-services. A common problem occurs when the person who applies the Sellick maneuver releases it prematurely to tend to a seemingly more important task. This person should be dedicated to this maneuver alone and must not release it until intubation is confirmed.
11. Suction devices may malfunction; therefore, there always should be a backup available. Standard Yankauer tips may be clogged by food particles, so newer stiff suction tips with larger openings may be more useful.
12. Be prepared for transtracheal ventilation. This may be lifesaving in a patient who cannot be intubated or mask ventilated.

MULTIPLE TRAUMA

A disciplined airway, breathing, circulation (ABC) approach should take priority in the management of multiple trauma victims. Deformities and open wounds must not distract team members from these priorities. The ABC assessment should be made quickly, followed by a brief neurologic assessment (*D* for disability) that specifically checks for signs of ICP elevation.

Airway management must include precautions for a possible C-spine injury. (C-spine immobilization and nasal versus oral tracheal intubation are discussed earlier in this chapter.) Available information suggests that, in most instances, children with multiple trauma who require intubation are best intubated orally using RSI. Succinylcholine may worsen hyperkalemia in patients with severe crush injuries or severe burns. In children with severe craniofacial or airway injuries, oral tracheal intubation may prove to be difficult. In such cases, a surgical airway may be indicated. This can be done emergently in the ED, or it may be done as a standby procedure if oral tracheal intubation fails. (The complications of this procedure are discussed earlier in this chapter.) The child's airway status may worsen during the procedure because of bleeding, agitation, or additional airway trauma. Needle cricothyrotomy with transtracheal ventilation should be available as a standby procedure if further airway difficulties occur.

Oxygenation may be compromised by pulmonary injuries such as pneumothorax, hemothorax, chest wall injuries, pulmonary contusions, or aspiration. In addition to these, ventilation may be compromised by airway trauma and central nervous system depression. Oxygen administration should be considered routine for all multiple trauma victims. Intubation is indicated in patients who have ventilatory compromise, a potential for airway compromise, moderate or severe shock, and hypoxemia despite supplemental oxygen. Positive-pressure ventilation may worsen a pneumothorax if a chest tube is not in place.

Circulation should be assessed by using multiple clinical parameters. Early mild shock should be treated aggressively to reverse any progression toward late shock and hypotension, which is associated with a poorer outcome. Acute symptoms and signs of early shock are subtle and often underestimated. These signs and symptoms include agitation, restlessness, lethargy, pallor, delayed capillary refill, coolness of the feet, metabolic acidosis, a short perfusion bar/wave on the pulse oximeter, and difficulty in picking up a pulse oximetry signal. Tachycardia and hypotension are indicators of late, severe shock. Paradoxical bradycardia has been noted in shock with hypotension; therefore, the absence of tachycardia cannot be used to rule out shock. Dismissing a low BP as "normal for a child" because of the absence of tachycardia is not valid.

Sedatives and agents used for RSI may have significant adverse effects on BP because of myocardial depression or vasodilation. In hypovolemic or hypotensive children, sedative doses should be reduced or avoided, depending on the clinical situation.

The initial treatment of shock related to hypovolemia consists of frequent clinical reassessment and fluid restoration with volume-expanding crystalloids such as normal saline or lactated Ringer's solution. The usual initial bolus should be 20 mL per kg. This is followed by reassessment of clinical shock parameters. This process should be repeated if evidence of shock persists until fluid volume is restored. Red blood cells should be transfused if excessive hemorrhage is sustained. Large volume fluid resuscitation can result in complications because of hypothermia. When large fluid volumes are anticipated or the patient is very small, crystalloid solutions should be warmed gently and blood products should be infused through a blood warmer.

HEAD TRAUMA

The same priorities should be followed with head trauma as with multiple trauma. Children with head injuries who have depressed sensoriums may be hypoxic, hypovolemic, hypotensive, or acidotic. Although intracranial hemorrhage alone cannot account for significant hypovolemia that results in shock in an older child or adult, this is possible in an infant. Unconscious patients should be intubated using RSI. Patients responsive only to painful stimuli may also need to be intubated. Some patients with lesser degrees of sensorium depression may need intubation using RSI, depending on the degree of head injury and the rate of deterioration. Patients at risk of ICP elevation should be given thiopental or etomidate in addition to lidocaine pretreatment as part of RSI unless hypovolemia or hypotension exist, in which case the dose should be reduced or eliminated, depending on the clinical circumstances. Thiopental and etomidate lower ICP and cerebral metabolic oxygen demand.

Patients with head injuries may develop posttraumatic seizures related to cerebral contusions, cerebral edema, or intracranial hemorrhage. Under RSI, these seizures are not visible because of pharmacologic paralysis. It is prudent in most instances to give a loading dose of phenytoin (10 to 20 mg per kg) or fosphenytoin (10 to 20 mg PE/kg) after intubation is confirmed to treat prophylactically any undiagnosed posttraumatic seizure focus.

BURNS

Children with severe burns represent a special form of multiple trauma. Burn patients may also sustain blunt trauma, and ABCs are still the priority. Early intubation using RSI is advocated for patients at risk of airway injury because airway edema is expected to worsen rapidly. These cases include children with evidence of soot in sputum or vomitus, burns of the face, singed nasal hairs, lip burns, wheezing, stridor, or severe burns. The possibility of carbon monoxide poisoning should be considered. It may be preferable to avoid succinylcholine in patients with severe burns for fear of worsening hyperkalemia.

Pulmonary compromise may result from smoke inhalation, burn injury, bronchial edema, bronchospasm, blunt trauma, or adult respiratory distress syndrome. Initial chest radiographs may fail to show some of these injuries.

Children with severe burns have significant hypovolemia because of external fluid losses. Lactated Ringer's or normal saline boluses of 20 mL per kg should be used to immediately correct hypovolemia in conjunction with guidelines for fluid replacement based on body surface area (BSA) of the burns.

STATUS EPILEPTICUS

In patients presenting to the ED with prolonged seizures, the standard approach of ABC support and immediate administration of benzodiazepines is generally initiated. Loading with IV phenytoin/fosphenytoin and/or phenobarbital may also be considered if seizures continue. This process of administering anticonvulsants and waiting to assess its effect occurs in 3- to 5-minute cycles. If seizures fail to respond to several doses of anticonvulsants, the child could be continuously seizing for an additional 30 to 60 minutes.

Prolonged seizures result in hypoxia and respiratory acidosis due to poor ventilation. The brain is simultaneously hypermetabolic with greater oxygen demand. The agents used for RSI may effectively reverse this hypermetabolic process. Skeletal muscle activity stops. Oxygenation and ventilation are restored. The brain may still be hypermetabolic because it may still be epileptogenic, but at least hypoxia and acidosis are decreased. Thiopental is cerebroprotective, and both thiopental and benzodiazepines have potent anticonvulsant activity. Simultaneous IV administration of high dosages of benzodiazepines, phenytoin/fosphenytoin, phenobarbital, and/or other newer IV anticonvulsants (valproic acid, levetiracetam)

can potently reduce the seizure potential of the brain while maintaining oxygenation and ventilation. The major adverse effect of most anticonvulsants is respiratory depression. Following RSI, this is no longer a concern and maximum doses of anticonvulsants can be administered to provide maximum anticonvulsant activity.

In refractory status epilepticus, the duration of seizures, hypoxia, and acidosis is likely to contribute to cerebral injury. Refractory status epilepticus can be anticipated if the seizures fail to stop after initial IV benzodiazepine doses, at which point the failure of conventional anticonvulsants should be considered high risk and RSI followed by maximum anticonvulsant administration should be considered. Because potentially injurious seizure durations of 40 minutes or more can occur in the management of such patients, it may be prudent to initiate RSI earlier rather than later. The concern that seizures may be protracted yet can no longer be visibly appreciated after RSI should be tempered by the clinical benefits of RSI as described. Electroencephalogram (EEG) monitoring in the ED is often recommended, but it is not feasible in most hospitals, although portable bispectral index monitors (functionally, a portable EEG device) may have some potential to monitor this.

AGITATED PATIENTS WHO REQUIRE PROCEDURES OR TRANSPORT

Agitated or combative patients with head injuries or possible intracranial lesions that require computed tomography scanning cannot be scanned in such a condition. Sedation alone can be considered for such patients. In patients who fail to respond to standard sedation measures or in patients who may benefit from ET intubation, RSI provides an effective means of immediately securing airway control, breathing, and movement so imaging can be completed with minimal trauma to the patient. Patients who require transport to another facility, and who are agitated and difficult to control, may be unmanageable during transport. After the clinical situation has been assessed, RSI may be indicated if its benefits outweigh its risks. Patients are more difficult to monitor during procedures and transports. The immediate detection of unrecognized extubation or hypoxemia is crucial. Portable pulse oximeters and $ETCO_2$ monitors can monitor oxygenation and confirm intubation continuously.

CHAPTER 6 ■ EMERGENCY MEDICAL SERVICES AND TRANSPORT MEDICINE

GEORGE A. WOODWARD, MD, MBA, ANDREW L. GARRETT, MD, MPH, BRENT R. KING, MD, MMM, AND M. DOUGLAS BAKER, MD

OVERVIEW OF EMERGENCY MEDICAL SERVICES

Infants, children, and adolescents are commonly treated by emergency medical services (EMS) systems worldwide. This discipline of medicine is also termed *prehospital care*, and the terms are used interchangeably. In the United States, approximately 5% to 15% of calls for an ambulance will be for a patient younger than 18 years of age. This subgroup of the population usually enjoys relatively good health; however, accidental trauma is the leading cause of death. Similar to older patients, pediatric patients are also susceptible to acute medical illness and exacerbations of chronic conditions such as asthma and diabetes. Infants may also present with complications of congenital cardiac, respiratory, or oncologic disease, or with perinatal complications during and after delivery out of the hospital. Many of these sick or injured children will enter the EMS system for initial evaluation, treatment, and transport to the hospital. Pediatric patients consistently represent a challenge to most EMS systems and providers. They may be too small to fit most of the conventional EMS equipment. They may be one part of a large family unit needing care and they present an emotional challenge to the provider. Despite these difficulties, the goal is to seamlessly integrate the prehospital care of children in the prehospital environment into EMS systems that were originally designed to care for adults.

Summarized by Ludwig and Selbst, EMS for children (EMSC) is a concept for an all-encompassing, multidisciplinary care system that includes parents, primary care providers, prehospital care providers and transport systems, community hospital and tertiary care referral center emergency departments (EDs), and pediatric inpatient units, including critical care facilities. The elements of this system should be linked by effective communication and transportation systems and governed by well-established policies and procedures. The provision of pediatric EMS, although a single link in this chain, is a critical component. EMS providers are continually balancing the need for rapid transport to the hospital with the ability to stabilize the sick or injured child in the field. This must all be done with the patient's best interest in mind, being mindful that prehospital care is only one portion of the patient's medical management.

Until the 1970s, prehospital care was largely the part-time purview of taxi services and mortuary owners. There were no organized EMS systems to speak of, other than basic first aid providers. Changes began to occur when military patient movement systems successfully explored the lifesaving intervention of rapid transportation and surgery for injured soldiers. At that time, the success of physician-staffed civilian prehospital systems in Ireland led to the formation of experimental EMS systems in the United States, using specially trained "para-medics" instead of physicians. California, Florida, and Ohio had early EMS systems that proved successful in saving the lives of patients with cardiac emergencies. The *EMS Systems Act* of 1973 led to the establishment of several hundred new EMS regional systems across the United States, albeit without a clear mandate for physician oversight initially. The television show *Emergency!* (NBC 1972–1978) was pivotal in changing the public's perception and expectation of care outside of the hospital, and assisted in rapidly advancing the discipline from its infancy into adolescence.

In just over thirty years, EMS capabilities have grown to provide emergency prehospital access to nearly every American. There are more than 15,000 EMS systems in the United States utilizing approximately 800,000 EMS personnel who respond to an estimated 16 million requests a year. It can be estimated that approximately 800,000 to 1.5 million of these requests are for pediatric patients.

EMS systems exist across a broad range of environments beyond the use of ambulances to transport sick or injured patients to the hospital. In 2005, after Hurricane Katrina impacted the U.S. Gulf Coast, much attention was focused on the role of the EMS system and the challenges that were faced during the surge in demand for services that occurred. This incident in particular emphasized the role that EMS stakeholders must play in disaster preparedness and planning if they are to best serve the public during a crisis. Additionally, EMS professionals are becoming involved in providing care in nontraditional settings such as international humanitarian relief as well as with law enforcement tactical or SWAT teams. As these EMS disciplines continue to grow in complexity and capability, so will the need to oversee the care of children that occurs in these situations.

WHERE HAVE EMS SYSTEMS TRADITIONALLY FALLEN SHORT FOR CHILDREN?

The formalization of pediatric emergency medicine as a specialty helped enable an organized approach to investigating and developing EMS systems for children. The need to improve the capacity of EMS to manage sick and injured

pediatric patients initially came from the providers themselves as well as the physicians who received those patients. Shortfalls in provider training, pediatric-specific emergency equipment, established standards of care, and quality pediatric EMS research severely limited the advancement of the specialty.

Epidemiologic studies helped clarify the specific needs of children in the EMS system, and in doing so, identified many of its shortfalls. Tsai and Kallsen found those at the pediatric age extremes to be the principal users of prehospital services—teenagers for trauma and infants and preschoolers for illness (primarily seizures, ingestions, and respiratory diseases). Yamamoto et al. showed that persons with disabilities were also more likely to use an ambulance; however, ambulance personnel felt less prepared to handle those patients. This is an important consideration, as the prevalence of children with special health-care needs (CSHCN) is estimated at 13% to 18%. Baker and Ludwig found that infants with serious illness were more likely to be transported by EMS than were adolescents. The fact that most childhood cardiopulmonary arrests occur in children younger than 4 years of age emphasizes the need of EMS systems to provide age-appropriate equipment and personnel properly trained in pediatric resuscitative care, especially in the youngest age groups.

Institute of Medicine Report Findings and Significance

Recently, the Institute of Medicine (IOM) was commissioned to analyze and report on the capabilities of both prehospital- and hospital-based pediatric emergency care in the United States. They published two documents: *Emergency Care for Children: Growing Pains* and *Emergency Medical Services at the Crossroads* in 2007. While complimentary of the past accomplishments of the EMS system, their findings also highlighted many of the shortfalls that exist around the care of all patients, as well as children, in all of the components of the EMS system, and also suggested a system of interventions to address these issues. These reports highlighted the following:

- Insufficient coordination of EMS systems and hospitals
- Disparities in response times to emergency calls, with a focus on the flow of information from 911 operator to dispatcher to responder
- Uncertainties around the quality of EMS care, with an emphasis on a lack of a way to measure EMS quality overall
- A "divided" professional identity in EMS—meaning those who work in EMS often feel a lack of support from their partners in the field, typically fire and police services, as well as their hospital-based partners, physicians and nurses
- A general lack of disaster preparedness considering the role that EMS providers may play in a large incident or terrorist attack
- An overall lack of evidence exists to inform how EMS is evolving as a professional and medical specialty
- A significant percentage of EDs that lack all of the recommended equipment to care for a critically injured or sick child
- Pediatric training for EMSC is underemphasized and in many cases not required to be part of continuing education requirements for EMS personnel
- Pediatric treatment patterns vary widely between EMS and hospital-based care providers

While critical of the EMS system in many ways, the IOM reports do reflect the "still developing" nature of EMS as a discipline—one which is growing quickly since its birth in the 1970s, and still has a way to go to appreciate exactly what its role is. The onus is on EMS systems themselves to address these challenges as much as possible to ensure that they are providing excellent care to all of their patients, regardless of age.

It is difficult to perform quality clinical research in the EMS system. There are few large-scale, randomized clinical studies that have been undertaken in the pediatric EMS population. Even with well-designed research, it may be difficult to generalize the findings outside the study population and locale due to the high level of variability within EMS systems across the United States. No two systems are designed or operate in exactly the same way with regard to staffing, protocols, oversight, demographics, or training. The paucity of scientific scrutiny of EMS in general highlights the need for future research focusing on both EMS and EMSC. The emergence of EMS fellowships has given academic physicians an opportunity to specialize in EMS, and by doing so, to increase the likelihood of having future leaders in the field who are committed to quality research as an important component of medical oversight. The establishment of a federal EMSC program under the U.S. Department of Health and Human Services, as well as the federally funded EMSC National Resource Center, were important steps to assist EMS academicians in defining a research agenda around EMSC as well as providing avenues for funding these projects. As the discipline evolves, we must resist the temptation to quickly add new technologies, procedures, and protocols to prehospital care without ensuring that these modalities have proven efficacy. There is a real concern that in an effort to aid one patient, others will suffer from unnecessary intervention or inappropriate allocation or utilization of resources.

GOVERNANCE OF EMS SYSTEMS

As mentioned above, there is no nationally standardized definition of what constitutes an EMS system. In all 50 states, EMS legislation exists to provide a statutory basis for individual EMS to exist and operate. In addition to control at the state level, municipal, county, or regional local government may regulate the organization and authorization of services provided by EMS personnel. This patchwork of governance over EMS systems may make it very difficult to speak with a unified voice when it comes to patient care, training, and certification, and makes it difficult for EMS professionals to move between communities, much less across state lines. Although there is a National Registry of Emergency Medical Technicians (NREMTs) that serves as a centralized credentialing group, this organization does not authorize an EMT to practice in a state or region, and there is little consistency around the issue of states granting reciprocity for EMS providers.

After the *Emergency Medical Services Act* of 1973, all states identified lead agencies that coordinate EMS activities within the state. In most states, the lead agency is headed by an EMS director who reports to the state department of health. Often, state-level advisory councils exist to direct and assist in the development of protocols and minimum standards of operation.

States are frequently divided into EMS regions, at which level prehospital care becomes operational, and where local government, hospitals, and ambulance services interact with each other. Regional advisory councils may exist as well. Pediatric clinicians should be encouraged to become involved in these regional committees as advocates of the pediatric needs within their systems.

COMPONENTS OF PREHOSPITAL CARE SYSTEMS

The prehospital component of EMSC is an architecture that involves a variety of personnel and equipment, only some of which is standardized and regulated. To understand the extent of the services provided by prehospital care systems, it is important to understand the training, capabilities, and scope of practice of prehospital personnel and the equipment available to them.

Prehospital Personnel

In the past, prehospital personnel were not always trained to provide the specialty care that their patients required. It was not until 1964 that the first reports of attempts to train fire and police personnel in basic cardiopulmonary resuscitation (CPR) appeared in the literature. Since then, several classifications of prehospital care providers have emerged, each with different levels of training and varying degrees of capabilities. Several categories (and certification levels) of prehospital personnel exist (Table 6.1): first responders (FRs), basic life support (BLS) providers, intermediate life support providers (ILS), and advanced life support (ALS) providers. Some states and regions use their own notations for the skill levels of providers, but their personnel typically fit into one of the categories described here. Training standards and requirements for certification exist for all these groups, established by the U.S. Department of Transportation (DOT) and the National Highway Traffic Safety Administration (NHTSA). These agencies publish national standard curricula (NSC) for each level of provider, and they are periodically reviewed and updated. The NSC is a guideline only—the DOT does not conduct training or issue licenses or certifications to EMTs. There has been an extensive recent effort to create the language to standardize the training of personnel by proscribing a list of "competencies" for each level of provider. Nowhere is this more evident than in the recent publication The National EMS Scope of Practice Model, developed by NHTSA. This document can be accessed at http://www.nhtsa.dot.gov/staticfiles/DOT/NHTSA/Communication%20&%20Consumer%20Information/Articles/Associated%20Files/EMSScope.pdf.

First Responders

The layperson definition of a "first responder" to an emergency is the person who happens on the scene first to provide patient aid. In the context of classification of providers, however, a *first responder* refers to a person who is certified in limited but

Patient assessment
Basic wound care
Childbirth
Safe patient movement
Assisted ventilation (external)
Automated external defibrillator (AED) (elective)

EMT-Basic
All first responder scope, plus:
Vital signs assessment
Oxygen administration
AED
Assist patient with nitroglycerine, inhalation medications (e.g., albuterol)
Epinephrine autoinjector, oral glucose
On-scene triage
Splinting, spinal immobilization, helmet removal
Extrication and transport
Nasogastric tube (elective)
Orotracheal intubation (elective)

EMT-Intermediate
All EMT-Basic scope, plus some or all of the following:
Medical communications
Basic electrocardiogram (EKG)
Dual-lumen airway device or similar
Pulse oximetry
Orotracheal intubation (in some areas)
Naso- and orogastric tube
Basic determination of death
Manual defibrillation and pacing
Needle thoracotomy
Meconium aspiration
Administration of limited medications (in some areas)

EMT-Paramedic[a]
Scope of EMT-Intermediate, plus some or all of the following:
Termination of resuscitation/grief support
Needle or surgical cricothyrotomy (in some areas)
Digital or transilluminated intubation
Nasotracheal intubation
Peak expiratory flow rate (PEFR) testing
12-lead EKG
Rapid-sequence/medication-enhanced intubation (in some areas)
Use of intravenous, intramuscular, and oral medications

[a]The current paramedic National Standard Curricula does not make specific recommendations for an EMT-Paramedic pharmacopoeia.
From National Highway Traffic Safety Administration, U.S. Department of Transportation, National Standard Curricula. Adapted from http://www.nhtsa.dot.gov/.

significant lifesaving capabilities. A certified FR course with a standardized 40-hour curriculum has been developed, and providers can be registered by NREMT. The role of the FR is vital in rural and wilderness areas where extended response times are common, and skills such as hemorrhage control, airway positioning, and early defibrillation can be truly lifesaving. In suburban and urban EMS areas, this level of provider has been phased out in lieu of more highly trained volunteer and professional EMT-Basics (EMT-Bs), -Intermediates (EMT-Is), and -Paramedics (EMT-Ps), but is still prevalent in the police and non-EMS fire services, as well as in some rural areas.

Although the exact capabilities of FRs vary according to local standards, most are trained to help clear an obstructed airway, control blood loss, use an automated external defibrillator (AED), and to administer first aid or CPR while awaiting the arrival of more advanced personnel. Spinal immobilization, oxygen administration, and medication administration are skills typically beyond the capabilities of most FRs. Generally, FRs do not (and should not) provide patient transport in ambulances as the primary caregiver. In the new NHTSA model, this level provider is referred to as an Emergency Medical Responder (EMR).

Basic Life Support Providers—EMT-Basic

The proliferation of many certification levels of EMS providers has led to some confusion with regard to who can do what in the field. *EMT-Bs* are providers who have skills that exceed those of FRs. EMT-Bs are capable of patient assessment, spinal immobilization, noninvasive ventilatory assistance, and defibrillation with AEDs. In some areas, EMT-Bs who are certified in AED use may be classified as *EMT-D* (defibrillation). In the past, EMT-Bs were classified as EMT-A (ambulance) or EMT-NA (non-ambulance) based on their work environment, but this has been discontinued. EMT-Bs are trained to recognize and treat pulselessness, apnea, upper airway obstruction, and extremity deformity, as well as recognize respiratory distress, altered mental status, shock, mechanisms of injury, and obvious death.

EMT-B training typically requires 100 or more hours as well as observation time in an ED. This level is popular with volunteer fire department members and others who provide EMS on a volunteer basis. It is also the standard level of training for private industry EMTs who perform the interfacility and discharge transport of medically stable patients from a hospital, nursing home, or other medical facility. The EMT-B curriculum typically involves one educational module on infants and children, representing a relatively small percentage of the total training exposures. They learn basic resuscitation skills and external airway management as well as some of the nuances of injury that apply to children and infants. In the new NHTSA model, EMT-B's are referred to as simply Emergency Medical Technicians, or EMTs.

Midlevel Providers—EMT-Intermediate

Midlevel classifications developed in response to the specific perceived needs of local jurisdictions, regions, or states. The *EMT-I* provider possesses additional clinical skill beyond that of the EMT-B based on the region they practice, but less than those of a paramedic. This frequently includes the ability to acquire vascular access (including interosseous access) or to perform advanced airway management. Tracheal intubation typically remains an intervention for EMT-Ps, but in some cases EMT-Is are locally authorized to perform this skill. More typically, the mid-level provider's advanced airway management capabilities are limited to a dual-lumen airway device. Most systems will review pediatric skills during the approximately 175- to 225-hour training curriculum, and in the associated internship and clinical preceptorship. The EMT-I invasive airways are typically contraindicated in children and infants due to the size of the device.

The benefits of performing intermediate-level procedures in the field are and have been a topic of much debate. It is a concern that intermediate-level providers may focus their efforts on learning interventions that (independently) may be of diminished value or on skills that may easily deteriorate because of infrequent use. It is important that EMT-Is be expert providers of BLS skills and not overly reliant on rarely performed advanced interventions, especially in children. It is important to consider that, although this level of training may be ideal for someone who is paired with an EMT-P, it is rarely an acceptable alternative to paramedic-level services except when the EMS system would otherwise not be able to operate beyond the BLS level. The benefit of developing and initiating the use of skills that lengthen scene time but do not lead to immediate definitive treatment, such as intravenous (IV) access without the authorization to administer medications, and routine glucometer use without the approval to administer IV dextrose, must be evaluated carefully by each system and its medical director. Overall, the current trend is toward phasing out this level of EMT classification but EMT-Is still play an important role in providing EMS in rural and occasionally suburban settings when paired with an EMT-P. Under the new NHTSA model, this level of provider is classified as an Advanced EMT (AEMT).

Advanced Life Support Providers—EMT-Paramedic

ALS providers are EMT-Ps, or "paramedics." They have 1,000 hours to, in some cases, more than 3,000 hours of training, internship, and clinical hospital time, and they are capable of administering a high level of medical care in the field. Their capabilities include advanced diagnostic skills, recognition and treatment of arrhythmias, and advanced airway management, including endotracheal intubation and in some areas emergent surgical airways and medication-enhanced intubation using sedatives and paralytics. In addition, they can administer lifesaving medications and fluids in the field. Their ability to use diagnostic tools and diagnose suspected cardiac disease, stroke, and trauma in the field can lead to the diversion of eligible patients to medical centers that can provide the most appropriate care. This level of training has become the standard of prehospital care in the United States, but it can be prohibitively expensive for a volunteer service or smaller community to support. Paramedics have formal didactic training in the emergency care of children, which may include the AAP's (American Academy of Pediatrics) Pediatric Education for Prehospital Professionals (PEPP) or AHA's (American Heart Association) Pediatric Advanced Life Support (PALS) courses, but most will admit to being uncomfortable with younger patients due to the lower volume of and limited exposure to pediatric patients and the perceived (or actual) difficulty of performing advanced procedures and assessments in the prehospital environment. In the new NHTSA model, EMT-Paramedics are classified as Paramedics to simplify the concept.

EMS Physicians

In some cases a physician may serve in the role of a field responder. This may be a doctor who is serving as a service's medical director, or it may be as a specialized provider or as an EMS Fellow in a larger system. Physicians may also be a part of law enforcement tactical teams, to immediately provide the highest level of care in situations where there may be a risk of casualties. Although the field is not the typical practice environment for physicians in the United States (it is much more common in other countries), there are distinct advantages to having a physician responder. The first is that they may provide direct medical control to the intermediate and paramedic providers on a scene. Second, they may bring the ability to perform advanced interventions for patients with specialized needs, such as a field amputation of an entrapped extremity. Third, they may play an important role in the management of complex incidents, such as a mass casualty incident. EMS physicians should be specifically oriented and trained before working in this environment—this includes learning how to establish scene safety, proper lifting, emergency vehicle operation, and how to use the communications equipment properly.

Equipment and Modes of Transport

Until the 1970s, ambulances were little more than hearses, sometimes painted white, which were sparsely equipped and minimally attended. In 1969 and 1973, the National Academy of Science and the DOT published documents that generally defined the purpose of an ambulance and its contents. Since then, many states have established much more comprehensive ambulance licensing standards, some of which pertain specifically to pediatric equipment, and there is a list of both adult and pediatric equipment for ambulances published collectively by the American College of Surgeons (ACS), the American College of Emergency Physicians (ACEP), and the National Association of EMS Physicians (NAEMSP), with input from the AAP, which was revised in 2008. This list is commonly used to establish the minimum requirements for EMS programs.

There are typically two classes of ambulances now in service in the United States—each is primarily dedicated either to advanced (EMT-P) or basic (EMT-B) life support service. BLS units are equipped to conform to the previously mentioned list (Table 6.1). Included are ventilation and airway equipment, immobilization devices, bandages, two-way communication equipment, obstetric kits, extrication equipment, and other miscellaneous items.

In 1988, the ACEP published a position paper that detailed the staffing and equipment appropriate for ALS units. In addition to the equipment contained in the BLS list, these ALS units carry intubation and vascular access equipment, a portable monitor-defibrillator, and a variety of ALS medications. They must also carry at least one EMT-P. In some areas, the standard is two. Most states now require that the electrocardiogram (EKG) equipment be 12-lead capable in order to diagnose and potentially reroute a patient with suspected cardiac disease to a center with a cardiac catheterization facility.

AEDs have been approved for use in the pediatric population older than 1 year of age. Special pediatric step-down pads may be used that attenuate the delivered shock, but their use is not mandatory as per AHA recommendations. AEDs with adult and pediatric pads should be carried on all BLS ambulances, and should be optional for ALS ambulances that have other manual defibrillation capabilities. Some newer manual defibrillators have an AED option built in as an additional resource to the EMT.

Pediatric Equipment

Since the mid-1990s, great strides have been made in appropriately equipping BLS and ALS ambulances to safely manage pediatric patients. In 2009, a document outlining collaboratively developed standards regarding equipment needed in ambulances was developed and endorsed by the ACS Committee on Trauma, the AAP, the ACEP, NAEMSP, and the Pediatric Equipment Guidelines Committee–EMSC partnership for Children Stakeholder Group and published in the July 2009 Bulletin of the ACS (available at: www.facs.org/fellows_info/bulletin/2009/ambulance0709.pdf) and as a July 2009 AAP Policy Statement (available at: http://pediatrics.aappublications.org/cgi/reprint/124/1/e166) (Table 6.2). This list includes much of the specialized pediatric equipment that until 2009 had been recommended separately by the EMSC and other organizations. The new document details the minimum recommended equipment to be able to care for either an adult or pediatric patient.

Because of the limited space on an ambulance, most EMS crews will not have all the mechanical or pharmacologic options available in a hospital. Examples are a paramedic crew that carries morphine but not fentanyl for analgesia, or normal saline and not lactated Ringer's solution for fluid resuscitation. An example of a state-approved list of medications for ALS ambulances is provided in Table 6.3. More technically sophisticated equipment and medications can often be added if required, as long as its use is established and monitored by the medical director for the EMS service.

Interfacility Transport

An increasing trend is the use of ALS ambulances and paramedic crews for the interfacility transport of stabilized patients who require admission or treatment at another facility. This is typically done by private ambulance companies that are providing a service to the hospital industry, or by community EMS units in extraordinary circumstances or in remote rural areas. The transport by EMS of hospital-stabilized pediatric patients can be challenging for many reasons. For example, the EMT-P is not traditionally trained in the long-term monitoring of disease processes, continuation or titration of hospital-initiated therapies such as dopamine or insulin infusions, or the mechanics of using a hospital programmed IV pump or central line monitors. For this reason, prior to undertaking this type of transfer, the crew must have additional training that certifies their competency in using the required specialized equipment. There is a subspecialized level of training termed *critical care paramedic*, which emphasizes these issues.

Specialty Teams and Emergency Medical Services

In many geographic areas, the medical needs of the population served require specialty ALS or critical care transport services. Such services can be either air or ground equipment, and may be

TABLE 6.2

EQUIPMENT FOR AMBULANCES

REQUIRED EQUIPMENT: BASIC LIFE SUPPORT (BLS) AMBULANCES

A. Ventilation and Airway Equipment

1. Portable and fixed suction apparatus with a regulator (per federal specifications; see Federal Specification KKK-A-1822F reference)
   - Wide-bore tubing, rigid pharyngeal curved suction tip; tonsillar and flexible suction catheters, 6–16F, are commercially available (have 1 between 6F and 10F and 1 between 12F and 16F)
2. Portable oxygen apparatus capable of metered flow with adequate tubing
3. Portable and fixed oxygen-supply equipment
   - Variable flow regulator
4. Oxygen-administration equipment
   - Adequate length tubing; transparent mask (adult and child sizes), both nonrebreathing and valveless; nasal cannulas (adult, child)
5. Bag-valve mask (manual resuscitator)
   - Hand-operated, self-reexpanding bag; adult (>1000 mL) and child (450–750 mL) sizes, with oxygen reservoir/accumulator; valve (clear, disposable, operable in cold weather); and mask (adult, child, infant, and neonate sizes)
6. Airways
   - Nasopharyngeal (16–34F; adult and child sizes)
   - Oropharyngeal (sizes 0–5; adult, child, and infant sizes)
7. Pulse oximeter with pediatric and adult probes
8. Saline drops and bulb suction for infants

B. Monitoring and Defibrillation

All ambulances should be equipped with an automated external defibrillator (AED) unless staffed by ALS personnel who are carrying a monitor/defibrillator. The AED should have pediatric capabilities, including child-sized pads and cables.

C. Immobilization Devices

1. Cervical collars
   - Rigid for children aged 2 years or older; child and adult sizes (small, medium, large, and other available sizes)
2. Head immobilization device (not sandbags)
   - Firm padding or commercial device
3. Lower extremity (femur) traction devices
   - Lower extremity limb-support slings, padded ankle hitch, padded pelvic support, traction strap (adult and child sizes)
4. Upper and lower extremity immobilization devices
   - Joint-above and joint-below fracture (sizes appropriate for adults and children), rigid support constructed with appropriate material (cardboard, metal, pneumatic, vacuum, wood, or plastic)
5. Impervious backboards (long, short; radiolucent preferred) and extrication device
   - Short (extrication, head-to-pelvis length) and long (transport, head-to-feet length) with at least three appropriate restraint straps (chin strap alone should not be used for head immobilization) and with padding for children and handholds for moving patients

D. Bandages

1. Commercially packaged or sterile burn sheets
2. Triangular bandages
   - Minimum of two safety pins each
3. Dressings
   - Sterile multitrauma dressings (various large and small sizes)
   - ABDs, 10″ × 12″ or larger
   - 4″ × 4″ gauze sponges or suitable size
4. Gauze rolls
   - Various sizes
5. Occlusive dressing or equivalent
   - Sterile, 3″ × 8″ or larger
6. Adhesive tape
   - Various sizes (including 1″ and 2″), hypoallergenic
   - Various sizes (including 1″ and 2″), adhesive
7. Arterial tourniquet (commercial preferred)

E. Communication

Two-way communication device between EMS provider, dispatcher, and medical control

F. Obstetrical Kit (Commercial Package Is Available)

1. Kit (separate sterile kit)
   - Towels, 4″ × 4″ dressing, umbilical tape, sterile scissors or other cutting utensil, bulb suction, clamps for cord, sterile gloves, blanket
2. Thermal absorbent blanket and head cover, aluminum-foil roll, or appropriate heat-reflective material (enough to cover newborn)

G. Miscellaneous

1. Sphygmomanometer (pediatric and adult regular- and large-sized cuffs)
2. Adult stethoscope
3. Length/weight-based tape or appropriate reference material for pediatric equipment sizing and drug dosing based on estimated or known weight
4. Thermometer with low temperature capability
5. Heavy bandage or paramedic scissors for cutting clothing, belts, and boots
6. Cold packs
7. Sterile saline solution for irrigation (1-L bottles or bags)
8. Flashlights (two in number) with extra batteries and bulbs
9. Blankets
10. Sheets (minimum of four), linen or paper, and pillows
11. Towels
12. Triage tags
13. Disposable emesis bags or basins
14. Disposable bedpan
15. Disposable urinal
16. Wheeled cot (conforming to national standard at the time of manufacture)
17. Folding stretcher
18. Stair chair or carry chair
19. Patient care charts/forms
20. Lubricating jelly (water soluble)

H. Infection Control (*Latex-free equipment should be available*)

1. Eye protection (full peripheral glasses or goggles, face shield)
2. Face protection (e.g., surgical masks per applicable local or state guidance)

(continued)

TABLE 6.2

CONTINUED

3. Gloves, nonsterile (must meet 1999 National Fire Protection Association requirements, which can be found at http://www.nfpa.org/)
4. Coveralls or gowns
5. Shoe covers
6. Waterless hand cleanser, commercial antimicrobial (towelette, spray, liquid)
7. Disinfectant solution for cleaning equipment
8. Standard sharps containers, fixed and portable
9. Disposable trash bags for disposing of biohazardous waste
10. Respiratory protection (e.g., N95 or N100 mask—per applicable local or state guidance)

I. Injury-prevention Equipment

1. All individuals in an ambulance need to be restrained (there is currently no national standard for transport of uninjured children; see NHTSA Web site, http://www.nhtsa.gov/ for list of EMS-approved child occupant protection devices)
2. Protective helmet
3. Fire extinguisher
4. Hazardous material reference guide
5. Traffic-signaling devices (reflective material triangles or other reflective, nonigniting devices)
6. Reflective safety wear for each crew member (must meet or exceed American National Standards Institute/International Safety Equipment Association performance class II or III if working within the right of way of any federal-aid highway; visit http://www.reflectivevest.com/federalhighwayruling.html for more information)

REQUIRED EQUIPMENT: ADVANCED LIFE SUPPORT (ALS) AMBULANCES

For emergency medical technician-paramedic services, include all of the required equipment listed for the basic-level provider, plus the following additional equipment and supplies. For emergency medical technician–intermediate services (and other nonparamedic advanced levels), include all of the equipment for the basic-level provider and selected equipment and supplies from the following list, on the basis of local need and consideration of prehospital characteristics and budget.

A. Airway and Ventilation Equipment

1. Laryngoscope handle with extra batteries and bulbs
2. Laryngoscope blades, sizes 0–4, straight (Miller); sizes 2–4, curved, (MacIntosh)
3. Endotracheal tubes, sizes 2.5–5.5 mm uncuffed and 6–8 mm cuffed (two each), other sizes optional
4. Meconium aspirator adaptor
5. 10-mL non–Luer-Lock syringes
6. Stylettes for endotracheal tubes, adult and pediatric
7. Magill (Rovenstein) forceps, adult and pediatric
8. Lubricating jelly (water soluble)
9. End-tidal CO_2—detection capability
   - Colorimetric (adult and pediatric) or quantitative capnometry

B. Vascular Access

1. Crystalloid solutions, such as Ringer's lactate or normal saline solution (1000-mL bags × 4); fluid must be in bags, not bottles; type of fluid may vary depending on state and local requirements
2. Antiseptic solution (alcohol wipes and povidone-iodine wipes preferred)
3. Intravenous-fluid pole or roof hook
4. Intravenous catheters, 14–24 gauge
5. Intraosseous needles or devices appropriate for children and adults
6. Venous tourniquet, rubber bands
7. Syringes of various sizes, including tuberculin
8. Needles, various sizes (one at least 1½″ for intramuscular injections)
9. Intravenous administration sets (microdrip and macrodrip)
10. Intravenous arm boards, adult and pediatric

C. Cardiac

1. Portable, battery-operated monitor/defibrillator
   - With tape write-out/recorder, defibrillator pads, quick-look paddles or electrode, or hands-free patches, EKG leads, adult and pediatric chest attachment electrodes, adult and pediatric paddles
2. Transcutaneous cardiac pacemaker, including pediatric pads and cables
   - Either stand-alone unit or integrated into monitor/defibrillator

D. Other Advanced Equipment

1. Nebulizer
2. Glucometer or blood glucose measuring device
   - With reagent strips
3. Large-bore needle (should be at least 3.25″ in length for needle chest decompression in large adults)

E. Medications (Preloaded Syringes When Available)

Medications used on advanced-level ambulances should be compatible with current guidelines as published by the American Heart Association's Committee on Emergency Cardiovascular Care, as reflected in the advanced cardiac life support and pediatric advanced life support (PALS) courses, or other such organizations and publications (ACEP, ACS, NAEMSP, and so on). Medications may vary depending on state requirements. Drug dosing in children should use processes that minimize the need for calculations, preferably a length-based system. In general, medications may include:

- Cardiovascular medication such as 1:10000 epinephrine, atropine, antidysrhythmic agents (e.g., adenosine and amiodarone), calcium-channel blockers, β-blockers, nitroglycerin tablets, aspirin, vasopressor for infusion
- Cardiopulmonary/respiratory medications such as albuterol (or other inhaled β-agonist) and ipratropium bromide, 1:1000 epinephrine, furosemide
- 50% dextrose solution (and sterile diluent or 25% dextrose solution for pediatrics)
- Analgesics, narcotic, and nonnarcotic
- Antiepileptic medications such as diazepam or midazolam
- Sodium bicarbonate, magnesium sulfate, glucagon, naloxone hydrochloride, calcium chloride
- Bacteriostatic water and sodium chloride for injection
- Additional medications as per local medical director

OPTIONAL BASIC EQUIPMENT

This section is intended to assist EMS providers in choosing equipment that can be used to ensure delivery of quality prehospital care. Use should be based on local resources. The equipment in this section is not mandated or required.

(continued)

TABLE 6.2

EQUIPMENT FOR AMBULANCES (CONTINUED)

A. Optional Equipment

1. Glucometer (per state protocol)
2. Elastic bandages
   - Nonsterile (various sizes)
3. Cellular phone
4. Infant oxygen mask
5. Infant self-inflating resuscitation bag
6. Airways
   - Nasopharyngeal (12F, 14F)
   - Oropharyngeal (size 00)
7. Alternative airway devices [e.g., a rescue airway device such as the esophageal-tracheal double-lumen airway (ETDLA), laryngeal tube, or laryngeal mask airway (LMA)] as approved by local medical direction
8. Alternative airway devices for children (few alternative airway devices that have been approved by the Food and Drug Administration have been studied in children; those that have been studied, such as the LMA, have not been adequately evaluated in the prehospital setting)
9. Neonatal blood pressure cuff
10. Infant blood pressure cuff
11. Pediatric stethoscope
12. Infant cervical immobilization device
13. Pediatric backboard and extremity splints
14. Topical hemostatic agent
15. Appropriate chemical, biological, radiologic, nuclear, explosive personal protective equipment (CBRNE PPE), including respiratory and body protection
16. Applicable chemical antidote autoinjectors (at a minimum for crew members' protection; additional for victim treatment based on local or regional protocol; appropriate for adults and children)

B. Optional Advanced Equipment

1. Respirator
   - Volume-cycled, on/off operation, 100% oxygen, 40–50 psi pressure (child/infant capabilities)
2. Blood-sample tubes, adult and pediatric
3. Automatic blood pressure device
4. Nasogastric tubes, pediatric feeding tube sizes 5F and 8F, sump tube sizes 8F–16F
5. Pediatric laryngoscope handle
6. Size 1 curved (MacIntosh) laryngoscope blade
7. 3.5- to 5.5-mm cuffed endotracheal tubes
8. Needle cricothyrotomy capability and/or cricothyrotomy capability (surgical cricothyrotomy can be performed in older children in whom the cricothyroid membrane is easily palpable, usually by the age of 12 years)

OPTIONAL MEDICATIONS

A. Optional Basic Life Support Medications

1. Albuterol
2. EpiPens
3. Oral glucose
4. Nitroglycerin (sublingual tablet or paste)

B. Optional Advanced Life Support Medications

1. Anxiolytics
2. Intubation adjuncts including neuromuscular blockers

INTERFACILITY TRANSPORT

Additional equipment may be needed by ALS and BLS prehospital care providers who transport patients between facilities. Transfers may be done to a lower or higher level of care, depending on the specific need. Specialty transport teams, including pediatric and neonatal teams, may include other personnel such as respiratory therapists, nurses, and physicians. Training and equipment needs may be different depending on the skills needed during transport of these patients. There are excellent resources available that provide detailed lists of equipment needed for interfacility transfer such as the American Academy of Pediatrics Guidelines for Air and Ground Transport of Neonatal and Pediatric Patients.

APPENDIX: EXTRICATION EQUIPMENT

Adequate extrication equipment must be readily available to the EMS responders but is more often found on heavy rescue vehicles than on the primary responding ambulance. In general, the devices or tools used for extrication fall into several broad categories: disassembly, spreading, cutting, pulling, protective, and patient related. The following is necessary equipment that should be available either on the primary response vehicle or on a heavy rescue vehicle:

Disassembly tools

- Wrenches (adjustable)
- Screwdrivers (flat and Phillips head)
- Pliers
- Bolt cutter
- Tin snips
- Hammer
- Spring-loaded center punch
- Axes (pry, fire)
- Bars (wrecking, crow)
- Ram (4 ton)

Spreading tools

- Hydraulic jack/spreader/cutter combination

Cutting tools

- Saws (hacksaw, fire, windshield, pruning, reciprocating)
- Air-cutting gun kit

Pulling tools/devices

- Ropes/chains
- Come-along
- Hydraulic truck jack
- Air bags

Protective devices

- Reflectors/flares
- Hard hats
- Safety goggles
- Fireproof blanket
- Leather gloves
- Jackets/coats/boots

Patient-related devices

- Stokes basket

Miscellaneous

- Shovel
- Lubricating oil
- Wood/wedges
- Generator
- Floodlights

Local extrication needs may necessitate additional equipment for water, aerial, or mountain rescue.

TABLE 6.3

EXAMPLE OF REQUIRED MEDICATIONS FOR ADVANCED LIFE SUPPORT AMBULANCES

Activated charcoal
Adenosine
Albuterol
Aspirin
Atropine
Atrovent for nebulization
Calcium chloride
Cetacaine spray or 2% lidocaine jelly
Dextrose D10, D25, D50
Diazepam
Diltiazem HCl
Diphenhydramine
Dopamine
Epinephrine 1:1,000, 1:10,000
EpiPen
Furosemide
Glucagon
Oral glucose
Lidocaine
Magnesium sulfate
Midazolam
Morphine sulfate
Naloxone
Nitroglycerin
Nitropaste
Oxygen
Saline for flushes
Sodium bicarbonate
Terbutaline
Thiamine
Intravenous (IV) normal saline

Optional
Amiodarone
Cyanide antidote kit
Lorazepam
Metoprolol
Mark I kit autoinjectors
Nifedipine
Pralidoxime
Tetracaine
D5W or LR IV solutions

From Commonwealth of Massachusetts. *OEMS EMS pre-hospital treatment protocols.* 5th ed. Boston, MA: office of Health & Human Services, 2004, with permission.

EMS or hospital-based. Examples of specialty transport units are those assigned to neonatal or pediatric transport teams, high-risk obstetrics teams, and mobile intensive care units (MICUs). For each of these, specialized equipment and staffing are incorporated beyond the scope of EMS providers (typically for nurses, respiratory therapists, or physicians), although EMTs are frequently used as primary or secondary team members. For more information, see "Pediatric Interfacility Transport" section.

Air Transport

The gradual introduction of air medical transport into civilian prehospital care began in the 1960s. During that time, a National Academy of Sciences Research Council document recommended the initiation of pilot programs to evaluate ground and air ambulance services in sparsely populated areas. Since then, air medical transport has developed into a common part of some EMS systems.

Regardless of their degree of involvement, physicians should be aware of the air medical transport resources and capacities in their region. Two basic types of air transport exist: helicopter and fixed-wing (FW) aircraft. Helicopters [rotor-wing (RW) craft] are common in both rural and urban EMS systems, although they are typically hospital-based and usually carry a nurse, respiratory therapist, or physician as one (or more) of their crew members. The Association of Air Medical Services' Atlas and Database of Air Medical Services (ADAMS) notes that in the United States, as of September 2008, there are 310 Air Medical Services, 699 bases with helicopters (RW), 154 bases with FW aircrafts for a total of 840 RW aircrafts and 292 FW aircrafts. It is estimated that approximately 400,000 patients are transported by helicopter annually, with another 100,000 transported by FW aircraft.

ADAMS also estimate that 95% of those services provide emergency service to medical and trauma scenes. Many services have an EMT-P as a primary crew member. The unique capabilities of rapid, direct scene response give the RW craft a distinct advantage over FW aircraft and ground units in some cases. Helicopter EMS have allowed for the provision of ALS services to larger rural areas incapable of sustaining independent ALS units and have provided access to tertiary care centers for patients in regions without such centers. In both rural and crowded metro and suburban areas, RW aircraft offer the benefit of time saved in transit—a benefit in cases such as trauma and coronary syndromes. However, such a benefit comes at a high cost. One recent research project has suggested that direct air transport from an accident scene to a trauma center for pediatric patients may not improve survival when compared with local hospital stabilization prior to air transfer. Air medical transport is a specialized service and is typically an adjunct to, and not a substitute for, ground transport, with certain exceptions such as prolonged vehicle extrications or other situations where a patient is entrapped at an emergency scene. The proper provision of air medical services requires specialized equipment, staffing, and medical oversight, both on the ground and in the air. Additionally, the issue of medical helicopter safety was thrust to the forefront in 2008, with an unprecedented series of fatal medical helicopter incidents occurring in that year. The industry is aggressively exploring the issue of safety, and the National Transportation Safety Board (NTSB) has made the issue of medical helicopter safety one of its top ten priorities. It is likely that increased regulation of the industry will be the result along with elimination of some of the latitude that medical helicopters have had in the past with regards to freedom of operations.

MEDICAL OVERSIGHT OF EMERGENCY MEDICAL SERVICES

There are two types of medical oversight—direct (online) and indirect (offline). Both models require initial and ongoing input by physicians, and each model has its own risks and benefits. A physician "with experience and knowledge of EMS" (Emergency Medical Services Systems Act of 1973) is required to be involved in the operations of all ALS (and now most BLS) EMS systems.

Level I—Adult and Pediatric
❑ Adult: SBP < 90 any reading ❑ Pedi: SBP < 2 × age (yr) + 70 mm Hg
❑ Adult: GCS ≤ 10 ❑ Pedi: GCS ≤ 8
❑ Adult: all GSW neck/chest/abd/extrem above elbow or knee
❑ Pedi: all GSW
❑ Transfer receiving blood
❑ Penetrating injury with large blood loss at scene, exsanguinating hemorrhage, expanding hematoma
❑ Respiratory compromise
❑ Major impalement
❑ Complete or partial amputation above elbow/knee
❑ Other blunt or penetrating injury to neck, chest, or abdomen
❑ Any patient initially stable that then deteriorates
❑ Emergency department physician discretion: _____
❑ Other: _____

Level II—Adult and Pediatrics
Anatomic:
❑ head ❑ face ❑ neck ❑ chest ❑ abdomen ❑ extremities ❑ burns
Mechanism:
❑ high-speed MVA ❑ pedestrian ❑ bicycle ❑ falls
Other:
❑ multisystem trauma ❑ hypothermia ❑ drowning with trauma ❑ assault with LOC
❑ helicopter transport ❑ intentional injury ❑ comorbid factors
❑ initially stable/deterioration ❑ emergency department physician discretion
❑ pregnant ❑ age > 55 yr

Level III—Adult and Pediatrics
❑ all intoxicated (EtOH/drug) with evidence of traumatic injury
❑ traumatic event in past 24 hr requiring hospital admission (normal VS, GCS 15, with no other criteria noted)
❑ any pediatric burn >5% and <10% without other involvement of face, genitalia, and/or accompanied by inhalation or other injuries
❑ all falls in children >5 ft, <20 ft

FIGURE 6.1 Sample hospital-based protocol for trauma team activation by EMS report. SBP, systolic blood pressure; GCS, Glasgow Coma Score; GSW, gunshot wound; MVA, Motor vehicle accident; EtOH, ethyl alcohol; LOC, loss of consciousness; VS, vital signs. (From University of Massachusetts, Worcester, MA, with permission.)

Direct Medical Control

Direct medical oversight refers to the real-time provision of supervision or authorization of EMS activities by a physician using radio, phone, or on scene, sometimes referred to as "medical control" or "medical command." This model enables a clinician to direct care by EMS after an assessment is transmitted to them. This may include voice reports and electronic broadcast of data, such as a 12-lead EKG. The benefit of such an arrangement is true customized care, but the drawbacks include additional time spent reporting instead of treating, demand on the base station staff, the potential for technical problems with the communications gear, and the potential supervision of field EMS personnel by base station clinical staff who are not experienced in the EMS setting. Although once a common model, many EMS systems are trending toward using indirect oversight, such as the use of standing order protocols, to reduce some of the quality variability and time requirements associated with direct medical control.

Indirect Medical Control

Indirect medical control includes the medical management of an EMS system through the use of established care guidelines in place before the call for help arrives. The EMS medical director for a service, who is ultimately responsible for every aspect of patient care, authorizes the EMS personnel to utilize standard protocols for the care of patients in order to save time and reduce the variability of orders. In most systems, the option remains for EMS personnel to call in to speak with a clinician for direct medical control if they have questions or if the protocol does not clearly apply. This may also be necessary for certain procedures or medications considered to be higher risk to the patient. In many cases the protocols may be established by the regional or state EMS authority (Fig.6.1).

Figure 6.2 provides an example of a regional protocol for pediatric altered mental status. Note that there are a different set of actions for basic, intermediate, and paramedic providers. This protocol also clearly states when to contact online medical control for additional guidance. This enables the providers in the field to have a preestablished, physician-evaluated course of action for most patient care situations. This has the enormous benefit of saving time in critical situations as well as reducing interoperator variability in patient assessment in the field and medical decision-making at the hospital base station. The EMSC National Resource Center publishes model pediatric protocols that can be a very useful adjunct when designing or reviewing protocols.

THE TIMELINE OF EMS CARE

When an EMS system is activated, this places into motion a chain of events to efficiently deliver the most appropriate personnel to the patient for safe transport to the most appropriate

PARAMEDIC PROCEDURES

1. Ensure scene safety and maintain body substance isolation precautions as appropriate.
2. Maintain open airway and assist ventilations as needed. This may include repositioning of the airway, suctioning, and/or the use of airway adjuncts (NP airway/OP airway) as indicated. Assume spinal injury if associated with trauma and manage accordingly.
3. Administer oxygen using appropriate delivery device, as clinically indicated.
4. ALS STANDING ORDERS
   a. Advanced airway management if indicated
   b. Initiate IV normal saline KVO. If a hypovolemic etiology is suspected, administer fluid bolus at 20 mL/kg.
   c. Cardiac monitoring (12-lead EKG)/dysrhythmia recognition
   d. Treatment for specific etiologies
      i. Known Diabetic
         1. Dextrose 10% 0.5 g/kg IV bolus (neonates)
         2. Dextrose 25% 0.5 g/kg IV bolus (estimated body weight <50 kg)
         3. Dextrose 50% 0.5 g/kg IV bolus (estimated body weight >50 kg)
         4. Glucagon 0.1 mg/kg Push, IO, IM, or SC up to max. of 1 mg
      ii. Coma of Unknown Etiology
         1. Age less than 5 yr:
            a. Naloxone HCL: 0.1 mg/kg to max. dose of 2 mg, IV push, ET, IO, SC, IM
            b. Dextrose as listed previously
         2. Age greater than 5 yr:
            a. Naloxone HCL: 2 mg IV push, ET, IO, IM, SC
            b. Dextrose as listed previously
5. Initiate transport as soon as possible.
6. Contact MEDICAL CONTROL. The following may be ordered:
   a. Glucagon 0.1 mg/kg IV push, IO, IM, SC up to max. of 1 mg
   b. Normal saline fluid bolus 20 mL/kg
   c. Dextrose
      i. Dextrose 10% 0.5 g/kg IV bolus (neonates)
      ii. Dextrose 25% 0.5 g/kg IV bolus (estimated body weight <50 kg)
      iii. Dextrose 50% 0.5 g/kg IV bolus (estimated body weight >50 kg)
   d. Naloxone HCL
      i. If age <5 yr: 0.1 mg/kg to max. dose of 2 mg IV bolus, ET, IM, SC, IO
      ii. If age ≥ 5 yr: 2 mg IV bolus, ET, IM, SC, IO
   e. Additional fluid boluses of 20 mL/kg NS at intervals as needed
   f. If coma caused by specific drug overdose, physician may order:
      i. Atropine 0.02 mg/kg IV bolus or ET (min. dose of 0.1 mg), or IO
         1. NB: If given via ET route, follow with 2 mL sterile saline via ET
      ii. Sodium bicarbonate 1 to 2 mEq/kg as slow IV infusion. CAUTION: Pediatric patients must have adequate ventilatory function prior to the administration of sodium bicarbonate.
   g. Monitor and record vital signs every 5 min at a minimum if unstable, or every 15 min if stable.
   h. Notify receiving hospital.

FIGURE 6.2 Sample EMS protocol for pediatric altered mental status. (From Central Massachusetts EMS Regional Authority, with permission.)

receiving hospital. There are many steps to achieving this ideal goal; the major ones are presented in the following sections.

EMS Activation

It is typically the parent, caregiver, or bystander who recognizes that a child requires emergency medical help, and contacts EMS through the 911 emergency number. With widespread 911 education in place now, from time to time children make the call themselves. Nearly every community has 911 service, with many having Enhanced 911 (E-911) services that provide the dispatcher with the address of the caller. Using a cell phone to contact 911 is increasingly common, and improving technologies (wireless E-911 systems) can allow for the localization of the caller using the global positioning satellite (GPS) technology built into many wireless phones.

Receiving the Call and Dispatching Assistance

In most systems, a trained 911 operator will receive the emergency call and direct the request to the appropriate police, fire, or EMS agency. In many communities, the dispatchers are trained in emergency medical dispatch (EMD) to provide standardized medical advice to the 911 caller through the use of algorithms or protocols. Some dispatchers are trained as EMTs themselves and can assist the caller as needed until help arrives. It should be a goal in every community to have reliable medical advice available for the 911 caller while awaiting EMS response. The dispatchers are also responsible for simultaneously initiating the response of appropriate resources. In a *tiered system*, there is a set of criteria that determine whether an ALS or BLS response is indicated and dispatched, based on the caller's chief complaint.

For example, a call for an isolated minor foot injury would receive a unit with EMT-Bs. In contrast, a call for a seizure would receive a paramedic ambulance. In a *nontiered system*, the highest level of provider is dispatched to all calls for help, typically EMT-Ps. Based on local policies, other resources such as police and fire units may be dispatched along with EMS.

Field Treatment

When EMTs arrive, assessment and treatment is begun using established protocols or online medical control, the patient is rapidly stabilized, and transport to the receiving hospital is begun without delay. In many cases, transport will be initiated immediately and any assessment and procedures will be conducted while en route to the hospital to save time. Based on protocol and/or the online medical control, a decision is made regarding the receiving hospital, or point of entry (POE). The POE selection is based on various factors: patient condition, the capabilities of the receiving hospital, such as a cardiac catheterization team on-call or a pediatric trauma center, and the distance and time to a receiving facility. Many EMS systems are now specifying certain hospitals as approved POE for conditions such as stroke, acute coronary syndrome, or pediatric trauma. This assures that the patient is going to a facility that can best manage their condition.

A challenging situation for EMS providers is when a clinician unknown to the EMS service stops at an emergency scene and wishes to direct the medical care. This is a precarious situation for both the provider and the clinician, since there is no way to verify the qualifications of the bystander. Wherever possible, this situation should be guided by a protocol, and at no time should the clinician be allowed to endanger the patient or the providers. ACEP has produced a policy statement that outlines the issues involved in having a bystander clinician involved in the care of the EMS patient. Because of the liabilities involved in having an unknown bystander take a role in an established system of providing prehospital care, this is a circumstance where online medical control should be contacted to determine the ways in which the bystander may assist. Options may range from providing an extra set of hands to having the clinician assume control for the patient and accompanying them to the ED. It is strongly encouraged that EMS draft an information card or document to give to on-scene providers to explain how this will work for a specific service. This should be written in conjunction with the EMS service's medical director.

Transit to the Hospital

Once the child is en route to the receiving hospital, either medical control or the EMS unit itself should notify the receiving hospital of the transport. Based on the nature of the child's illness or injury, the facility then can begin to assemble personnel and equipment for prompt treatment. This is especially important for hospitals where some resources may not be immediately accessible and, in cases of trauma or serious illness, when a specific resuscitation team can be assembled to meet the EMTs in the treatment room. On arrival, essential information concerning the child's condition and the field treatment is transferred by verbal report to the accepting care team. It is important for ED staff to maintain a good working relationship with their community EMS providers. Taking the time to listen to and acknowledge their report and participation is both a professional courtesy and an important way to get another perspective on the patient's emergency that will be difficult to access once they depart the ED. Each encounter should be considered as a potential learning and teaching experience, and deficits noted as a stepping stone for future improvement. Providing patient follow-up, where allowable, is another way of including the EMTs in the care continuum.

ISSUES AND CONTROVERSIES IN EMS CARE

Lights and Siren Use

One of the most important aspects of the transit to the hospital is patient and provider safety. There are few times when a higher-speed drive with lights and siren (L&S) will be of benefit to a sick or injured child—in fact, this practice may be one of the most dangerous things EMS providers could do for the patient. Clawson published in 2002 that an estimated 15,000 to 25,000 ambulance or rescue vehicle accidents occur per year in the United States while the vehicles are using L&S, with over 100 fatalities. Sixty percent of these accidents are the fault of the emergency vehicle driver. Intersections are the most common site for accidents involving EMS vehicles operating L&S. Interventions in Salt Lake City that reduced the number of emergency vehicles responding to incidents using L&S (in units other than the first responding vehicle) resulted in a nearly 80% reduction in emergency vehicle-related collisions. Although in some communities it is legal for emergency vehicles to exceed the speed limit and pass through red lights, this does not mean that it is safe to do so. A NAEMSP position paper from 1994 recommends that an EMS service develops a policy on L&S use that should be reviewed by the medical director because accidents while running "hot" with L&S are a common cause of litigation. The same should be said for having multiple vehicles respond to an incident using L&S, something that is frequently done but is likely unnecessary. Emergency vehicle accidents are an area of high, and frequently unnecessary, liability in EMS that is borne more out of a tradition of L&S use than a medical necessity for the patient. This is a good example of a nonmedical aspect of an EMS system that does, in fact, directly affect patient care.

Transport Safety

Accidents involving ambulances are becoming tragically common, and when they do occur, the rear compartment of the vehicle is an extremely dangerous place to be. Every patient must be safety restrained in the vehicle with shoulder and body straps, in a position that minimizes further injury and protects the airway; however, this can pose a significant challenge with pediatric patients. Every ambulance should have the capacity to secure a child or infant safely. If the patient is an infant and his or her medical condition permits, the use of an approved child safety seat (CSS) should be encouraged in a forward facing seat without an airbag. Note that these are not available in most ambulances. For those pediatric patients that are to be secured on the ambulance cot, there are techniques that can be

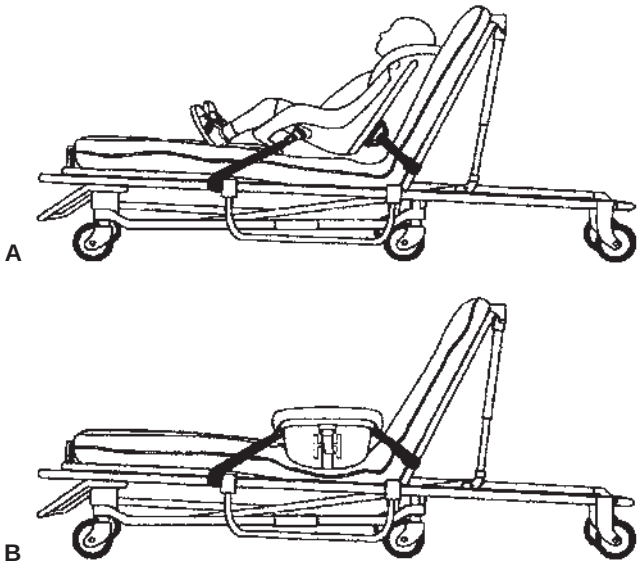

FIGURE 6.3 Diagram of a car seat attached to an ambulance cot. **A:** Recommended method for restraining children up to about 18 kg who can tolerate a semi-upright seated position, showing belt attachment to the cot and routing through the convertible child restraint. **B:** Recommended method for restraining infants who cannot tolerate a semi-upright seated position, showing belt attachment to the cot and routing through the car bed loops. (From Bull MJ, Talty J, et al. Crash protection for children in ambulances, recommendations and procedures. In: 45th annual proceedings of the Association for the Advancement of Automotive Medicine, 2001:353–367. Reprinted with permission from the Association for the Advancement of Automotive Medicine.)

used to make this practice as safe as possible to reduce the chance of another injury if the EMS vehicle is involved in an accident (Fig. 6.3). In many ambulances there is a seat in the rear of the vehicle that can be opened into a CSS that may be appropriate. New products are currently available that can secure a child to the ambulance cot and which have been crash-tested to establish their capabilities, such as a restraint developed by SafeGuard (Westfield, Indiana) (http://www.safeguardseat.com/ems); such a device can be used for children too large to fit in a CSS. Although specialized products do exist to secure a child to an ambulance cot, the EMS provider must take great care to ensure that it is properly attached to the cot, and that the child's head, torso, and pelvis are appropriately secured to prevent injury in an accident. It is important to keep in mind that many of these products may not have established crashworthiness, and the degree of protection they provide is unclear. The NHTSA, the federal entity that oversees EMS in the United States, has convened a work group in 2009 to establish the best practices for safety transporting pediatric patients in EMS and those results are pending. The family's own car seat secured properly in the ambulance may often be the best alternative providing it is medically safe and appropriate for the patient's condition. This also encourages a safe discharge home from the hospital by already have the child's safety seat available in the emergency department. EMS providers and parents must also be restrained in the ambulance whenever possible to prevent a secondary collision with the patient during an accident. Sixty percent of the fatalities in a study of ambulance crashes were EMTs who were unrestrained in the patient compartment. Any monitoring equipment must be secured to the frame of the ambulance because even a low-speed collision can turn loose objects into fatal missiles to a child or the provider. It is an additional recommendation that a child not be transported in an ambulance unless it is medically necessary. Other alternatives, such as a family member or a patrol car with a child seat, should be explored. With almost no exceptions, it is unacceptable to transport a child on the lap of a parent in an ambulance, regardless of how the child is secured to the parent or stretcher.

Medical-Legal Issues

Prehospital care providers and their medical overseers are legally responsible for their actions or lack thereof. *Good Samaritan* laws are variable by state and may not provide any coverage if a provider, from an EMT to a physician, is being paid to be present at the scene of the emergency. It is vital to understand what type of professional liability coverage exists for both EMS providers as well as medical control clinicians.

Prehospital care providers practice in a precarious setting. They commonly attend to children in cramped, poorly lit conditions; encounter crowded, emotional, or even hostile environments; and may lack the appropriate equipment for pediatric patients. Despite these and other obstacles, prehospital care providers often must make important decisions about the management and transport of critically ill children with rapidly changing conditions. Because of inadequate pediatric training or experience, some prehospital care providers might not feel prepared well enough to provide such management. Many lawsuits that involve EMS result from the transport of patients to inappropriate facilities, deviation from standardized protocols, perceived or actual slow response time, or the failure to transport patients when indicated (a "no load"). When in doubt, it is usually safest to transport the patient. Language barriers can be an important factor in accurately assessing a patient and situation, and it is important to address how to approach language incompatibilities ahead of time. There are numerous resources for telephone-based interpreters available (at a cost), but these are difficult to access unless the EMS service already has an existing account with a translation service (such as Language Line®). Using telephone interpreters is cumbersome in the EMS setting due to the need for privacy and mobility, but at times it is the only option. It may also be useful to have printed medical translation cards specific to the demographics of the EMS service area.

EMTs can minimize their risks by attending to the three Ds: details, duties and documentation. When a situation is unclear, prehospital care providers should consult with the online medical control physician.

Details of Standards of Care

All prehospital providers and medical control personnel should provide care that mirrors the standards of practice that apply to their profession. As previously discussed, some areas rely heavily on the use of protocols to standardize prehospital care activities, where others require real-time discussions with an online medical control base station. Whichever model is followed, the onus is on the provider to ensure that the care they are giving is not operator dependent but dictated by the scenario being faced. Standards of care and medical control are established to protect the EMS provider professionally as

well as serve the patient. Deviating from one's level of training or from an established and reviewed protocol with or without the involvement of medical control can expose the EMT to unfortunate legal scrutiny in the event of a poor patient outcome.

Attention to the routine details of emergency care and transport is vital, as many complaints and lawsuits are based on minor deviations from the standards of care, which may seem insignificant at the time of an emergency. It is important to look at each EMS run as a part of a whole. There are many routine details of care that are vital but are frequently overlooked on a case by case basis. This mentality should be avoided, as it will likely lead to a problem. Examples include

- improperly restraining adult and pediatric patients
- using excessive speed or failing to yield
- the inappropriate use of lights and siren
- having patients with painful or cardiac complaints ambulate to the ambulance
- improperly extricating patients from motor vehicle accidents
- incomplete spinal immobilization onto a backboard when it is indicated

Duties to Provide Care

All health-care providers must understand their duties to provide care. Questions often arise concerning issues of consent, especially when children are involved. The *doctrine of implied consent* permits the treatment of minors without parental consent when a medical emergency exists. In general, any minor with a condition that threatens "life and limb" is considered an emergency and should be treated and transported. This is typically true even in the difficult situation when a parent refuses EMS for a patient who appears to be emergent. Minor patients cannot refuse treatment and transport in an emergency situation. The same is true when parents are incapable of understanding the risks of refusing care because of cognitive impairment from intoxication or injury. The use of online medical command can help evaluate and resolve a situation where there may be disagreement at the scene regarding the need for transport.

If parents are present and refuse care for their injured or ill child, they should be asked to sign a standard form releasing the EMS system from responsibility. If at all possible, an assessment should be done to determine if there is a medical emergency, and online medical control should be sought if the EMTs are unclear about whether a threat to life or limb exists. The parents must be informed of the risk of not transporting a sick or injured pediatric patient, which typically may include death or permanent disability. Regardless of religious beliefs or parental desires, a child must be treated and transported if there is a life-threatening emergency or if providers suspect child abuse, even if parents refuse. Involve medical control early in these situations, and utilize law enforcement resources as necessary to ensure that the patient receives the necessary emergency stabilization and transport. Remember that all EMTs, regardless of certification level, have a *duty to report* suspected child abuse at all times and in all patients. Even if the ED says that they will report a suspected case later on, it is important to still immediately file a report with the authorities to protect the EMS provider.

Many states have an EMS *do not resuscitate* (DNR) protocol to limit resuscitative efforts for those who have made that decision with their physician. Remember that these are under the authority of the parent, not the physician, and they can be revoked at any time if the parent changes his or her mind, something common in pediatric medical emergencies. Providers and medical oversight physicians must be familiar with the specific documents required for an EMS DNR to be in effect, commonly a patient wristband as well as accompanying paperwork. When in doubt, EMS providers must resuscitate a patient and transport them to the ED.

Documentation

An accurate medical assessment and record of any and all interventions in the field during an EMS encounter are vital for the receiving ED staff. Any accompanying paperwork, such as a 12-lead EKG tracing, or paperwork given to the EMTs should be attached to the documentation that is left at the hospital. EMS run sheets become an important part of the patient's permanent medical record and may play an important role in determining the patient's hospital care. Especially important aspects of documentation are vital signs, medical allergies, initial evaluation and responses to interventions, and any changes en route as well as a record of the mechanism of injury and details that helps put the incident in perspective.

In addition, in our increasingly litigious society, proper documentation of EMS activities is the best defense against potential legal action. Special attention should be given to accurately documenting the patient's condition on arrival, including vital signs, position and restraint during transport, medication and fluid administration, airway status, and other interventions. Of special importance is the documentation of a properly placed, secured, and patent airway if intubation is performed by EMTs. Some departments use a separate intubation checklist with multiple redundant confirmations for this important but inherently risky procedure. It is important to realize that no EMS will have a 100% intubation success rate, but they must have a 100% success rate at airway management including detecting misplaced or displaced tubes.

All EMS documentation should be completed legibly, with errors noted by a single line cross out, initial, and date. The provider's signature must be legible and include a printed name and credentials. The EMS chart is a medical-legal document as well as a simple record of what transpired in the field. The chart must tell the story and relay all the important assessment and treatment data. It should reflect the medical decision-making thought process as well as document any online medical control orders that were acquired. For paramedics, it is essential to have times associated with any medications that were given.

Increasingly, EMS services are utilizing electronic medical records (EMR) or other electronic charting, typically done with tablet-style laptop computers connected wirelessly to the patient-monitoring equipment and to the hospital's centralized information system. This has the potential to improve the accuracy of collecting data associated with patient care, although this information is typically unfiltered and may not accurately reflect the real-time condition of the patient because of problems with the equipment, motion artifact, or other variables in the EMS setting.

EMERGENCY MEDICAL SERVICES FOR CHILDREN—RESOURCES AND LINKS

We recommend that physicians and other advanced health-care providers become involved in the EMSC system in their community, especially those who work in emergency medicine, critical care, pediatrics, surgery, and family medicine. On a local, regional, or state level, physicians can contact the EMSC organization for ways to advocate for pediatric EMS issues. The state Office of EMS or its equivalent can be contacted for a schedule of local community medical services meetings. This is a good way for an interested physician to learn more about the issues facing their EMS providers. There are standardized educational opportunities that can afford the teacher and provider more experience with pediatric EMS, such as the PEPP curriculum through the AAP. More and more EMTs are undertaking the PALS course (AHA) to supplement their pediatric training, and physician educators play an important role in the success of this course.

Many other organizations exist to serve as educational resources and as forums for discussing, teaching, and implementing policies used to promote the specific needs of pediatric EMS. National organizations and their web sites are listed in Table 6.4. EMSC is an example of a national initiative designed to reduce child and youth disability and death due to severe illness and injury. Medical personnel, parents, volunteers, community groups, businesses, national organizations, and foundations contribute to the effort. Examples include the many projects on childhood injury prevention and the previously referred to list of essential pediatric EMS equipment for ambulances.

PEDIATRIC INTERFACILITY TRANSPORT

Pediatric interfacility transport involves patient transfer from one medical location to another. Patient status can vary from relatively stable to critically ill. The disease processes involved are detailed throughout this text and include inpatients with progressive or unresolved problems and the entire spectrum of neonatal illness. Although the ABC (airway, breathing, circulation) approach to care remains the integral focus during interfacility transport, it is essential to understand the disease process and expected progression of the disease during the transport period.

Interfacility transport can originate from or be directed to hospitals, emergency care centers, physician offices, clinics, or other medical care facilities. There may not be a clear distinction between interfacility and prehospital transport in terms of equipment, process, and in some instances, personnel. Many interfacility transport teams routinely transport patients from the prehospital care environment, and EMS may be involved in interfacility transport. The differences between prehospital and interfacility transport teams often revolve around extrication issues, personnel education, and experience.

Although transport teams care for patients with disease processes similar to those seen in ED and critical care units, the delivery of care can differ. The transport environment offers many opportunities for problems if care is not managed appropriately. Although issues of transport team organization can be found in other texts, we briefly review important concepts of interfacility transport here.

Interfacility transport begins with the recognition of a need or a desire for medical care not available at the patient's current location. Reasons for transport can include a requirement for advanced or specialized levels of care or services, a patient's preference for a particular caregiver, the desire to obtain a second opinion, insurance issues, and parent or provider frustrations. However, as outlined in the Consolidated Omnibus Budget Reconciliation Act of 1985 and the federal Emergency Medical Treatment and Active Labor Act (EMTALA) regulations, interfacility transport cannot be used as a method to avoid initial assessment, stabilization, or intervention, especially with regard to a patient's ability to pay.

To prepare for interfacility transport, a transport system must have access to specialized equipment, trained personnel, and appropriate licenses (Tables 6.5A to 6.5D). The transport system

TABLE 6.5A

AN EXAMPLE OF EQUIPMENT AND PHARMACEUTICAL SUPPLIES USEFUL FOR PEDIATRIC CRITICAL CARE TRANSPORT: CONTENTS OF A "UNIVERSAL" PEDIATRIC CRITICAL CARE TRANSPORT EQUIPMENT BAG[a]

Center Lid Zippered Panel
Heimlich valve (2)
Chest tubes (1 each)
  10F, 12F, 16F
  Stylette (1 each)
    Neonatal and adult
  Ventilator circuit
  Cricothyroid kits
    3 or 3.5 mm (1)
    4 mm (1)
  Pneumothorax kit

Center Panel—Pouch
AAA batteries (2)
AA batteries (4)
C batteries (2)
9-Volt batteries (1)
Electrocardiogram electrodes
  Infant and pediatric
pH paper
Nonsterile gauze
Lancets
Thermometer

Center Panel
Infant/pediatric self-inflating bag
Adult self-inflating bag
Buretrol and secondary medication set
Folder with extra paperwork
  Flowsheets
  Consent forms
  Progress note paper
  IV solution recipe list
  STATMed card
  Parent handbook
  i-STAT reference
Salem sump (1 each)
  Sizes: 6, 8, 10, 12, 14, 16, 18
Replogle tube
Infant Oxyhood
Nasal cannula (1 each)
  Infant and pediatric
Assorted respiratory masks
Venturi tube
Green bubble tubing
Face masks (1 each)
  Preemie, infant, toddler
  Child and adult
Suction catheters (3 each)
  6F, 8F, 10F, 12F, 14F
Intraflow transducer

Center Panel—Airway Pouch
Green O_2 suction catheters (2 each)
  10F, 14F
Extra laryngoscope bulbs (large and small)
Saline vials for suctioning
Laryngoscope handles (2)
Laryngoscope blades
  Miller: 0, 1, 2, 3
  Wis-Hipple: 1.5
  MacIntosh: 2, 3, 4
Oral airways (1 each)
  Sizes: 4, 5, 6, 7, 8, 9
Magill forceps
Tygon
Benzoin
Yankauer
K-Y Jelly
Humidivent
Tongue blades
5-cc Syringe
Nipples

Center Panel—IV Kit
NSS flushes (3)
3-cc syringes (3)
5-cc syringes (3)
Saline vials (2)
Heparin flush (3)
Stopcocks (3)
T-connectors (3)
Clear tape
Tourniquet or rubber bands
Blood culture bottle
Bullets (1 each)
  Clear, red, green, purple
Uterine artery/uterine vein (UA/UV) catheter (2 each)
  3.5F, 5.0F, 8.0F
Jelco and Flash catheters (3 each)
  18, 20, 22, 24 gauge
Butterflies (2 each)
  19, 23, 25, 27 gauge
Alcohol swabs
Betadine swabs
PRN adapters (3)
Band-Aids
Interosseous needles (1 each)
  16 and 18 gauge
  Arm boards (1 each size)

Right-side Pocket
Goggles
Hot packs (3)
Neonatal pulse oximetry probes (2)
Easy Cap O_2 Sensor

Back Pocket
Mapelson circuit with metal valve
Mapelson circuit with disposable valve
Endotracheal tube (2 each)
  2.5, 3.0, 3.5, 4.0, 4.5, 5.0, 5.5, 6.0, 6.5, 7.0
Cuffed endotracheal tube (2 each)
  5.0, 6.0, 7.0, 8.0, 9.0
Manometer
Extra bags (0.5 L, 1 L, 2 L)

Left Front Pocket
Nebulizer pouch
  Nebulizer
  Adapter for Mapelson
  Albuterol 5 mg/mL 20-mL bottle
  Albuterol Jets 2.5 mg/5 mL
  Saline vials
  Racemic epinephrine
Lacri-Lube
Penlight
5-in-1 Connector (1)
6-in-1 Connector (1)
O_2 tank key
Nasopharyngeal airways (1 each)
  12, 14, 16, 18, 20, 22, 24, 26, 28, 30
Arterial pressure tubing (3)
Arterial set (1)
Microtubing (3)
Extension tubing (4)
Bifurcated connector (1)
Trifurcated connector (1)

Right Front Pocket
Syringes
  1, 3, 5, 10 cc (5 each)
  20, 30 cc (3 each)
  60 cc (4), 60 cath tip (1)
Assorted needles
Pressure bag

Left-side Pocket
Formulary
DINAMAP cuffs (1 each)
  1, 2, 3, 4, 5
Safe cuffs (1 each)
  Infant, child, small and large adult

[a]Transport teams must be self-sufficient during the transfer process; therefore, care should be taken to ensure adequate and appropriate supplies. Specifics may vary as per team function and intended patient population.

is responsible for ensuring the safety of the patient, team, and family members during the transport as well as guaranteeing that the patient is cared for in the medically appropriate environment. The transport system should have an identifiable medical director who is responsible for ensuring adequate training and education as well as continuing assessment of the transport personnel and process. The medical director is the person ultimately responsible for ensuring a safe, reliable transport system.

Significant preparation is required to be an efficient user of transport services. The users of a transport system (the referral hospitals and physicians) must ensure the transport services meet the standards required for the transfer of their patients.

TABLE 6.5B

ADDITIONAL TRANSPORT EQUIPMENT TO BE CONSIDERED WHEN EQUIPPING A PEDIATRIC CRITICAL CARE TRANSPORT TEAM

- Cardiorespiratory monitors
  - Noninvasive
  - Invasive
- Ventilators
  - Pressure
  - Volume
- Capnography
- Pulse oximeter
- Defibrillator with pacing capability
- Infusion pumps
  - Single and/or multichannel
- Blood sample measuring devices
  - Point of care testing
  - Glucometer
- Portable suction
- Portable oxygen
- Cellular phone(s)

The referral providers must avoid the mind-set of getting the patient out of the initial care environment as quickly as possible without first ensuring transport safety and medical stability.

Transport medicine is an established section within the AAP. Many other groups, such as the Air Medical Physicians Association, are dedicated to ensuring optimal care for transported patients. These organizations offer continuing education and are conduits for information regarding transport medicine. The AAP published the third edition of its "Guidelines for Air and Ground Transport of Neonatal and Pediatric Patients" in 2007. There are several listservs dedicated to pediatric transport. These include the pediatric interhospital transport discussion list (PEDTPT-L@listserv.brown.edu) and the AAP transport section listserv (transmedaap@listserv.aap.org). Subscribe to these lists by contacting listserv@listserv.brown.edu and www.aap.org/sections/transmed/.

Transport Considerations

Familiarity and the ability to understand the transport environment and troubleshoot as necessary is critical for the successful transport of a patient. Therefore, emergently configuring a transport team in response to an acute request for patient transport, unless there has been adequate preparation and training, should be avoided. Logistic issues to consider include ensuring proper equipment and medication supplies; intervening in a potentially cramped, moving environment; safely securing the patient to the stretcher and the stretcher to the transport vehicle; and recognizing and managing the loss of inverter power. In addition, oxygen delivery and suction—as well as the issue of motion sickness—can be difficult for the non–transport-oriented participant. Noise, vibration, and temperature can also be formidable problems for the patient and provider if not anticipated and planned for.

In the transport process, one must be prepared for all types of patients and complications. When the transport team arrives, the patient's status may be significantly different than

TABLE 6.5C

A STANDARD PEDIATRIC/NEONATAL CRITICAL CARE TRANSPORT MEDICATION SUPPLY[a]

Medication	Number	Medication	Number
Albumin 5% 250 mL	1	Procainamide 100 mg/mL 10 mL	1
Albumin 25% 50 mL	1	Propanolol 1 mg/mL 1 mL	2
Ampicillin 1 g	2	Sodium chloride 0.9% 10 mL	4
Amiodarone 50 mg/mL 3 mL	5	Sterile water injection 10 mL	4
Benzocaine spray 20%	1	Terbutaline 1 mg/1 cc 1 mL	10
Cefazolin 1 g	1	Tolazoline 25 mg/mL 4 mL	2
Cefotaxime 2 g	1	Vancomycin 500 mg	2
Dexamethasone 4 mg/mL 30 mL	1	Vasopressin 20 U/mL	5
Digoxin 100 μg/mL 1 mL	4	Verapamil 2.5 mg/mL 2 mL	3
Diphenhydramine 50 mg/mL 1 mL	1	**IV Solutions**	
Furosemide 10 mg/mL 2 mL	4	Dextrose 5% 0.2 NS 1,000 mL	1
Gentamicin 10 mg/mL 2 mL	4	Dextrose 10% 1,000 mL	1
Glucagon 1 mg	2	Sodium chloride 0.9% 1,000 mL	1
Heparin 1,000 U/mL 10 mL	1	Theophylline 4 mg/cc 50 cc	1
Hydrocortisone 100 mg/2 mL	2	**Additional Medications to Consider**	
Lidocaine spray 10% 33 g	1	Albuterol-metered inhaler	
Magnesium sulfate 4 mEq/mL 2 mL	2	Albuterol 5 mg/mL 20 mL	
Mannitol 25% 50 mL	2	Albuterol jet 2.5 mg/3 mL	
Methylprednisolone 125 mg/2 mL	2	Insulin 100 U/mL	
Methylprednisolone 1,000 mg	1	Lorazepam 2 mg/mL	
Neostigmine 0.5 mg/mL 1 mL	2	Prostaglandin E 0.5 mg/mL	
Nifedipine capsule 10 mg	3	Racemic epinephrine 2.25%, 15 mL	
Oxymetazoline nasal spray 15 mL	1	Survanta 8 mL	
Phenylephrine 10 mg/mL	1	Topical thrombin 1,000 U	
Phenytoin 50 mg/mL 5 mL	2	Tromethamine 500 mL	
Potassium chloride 2 mEq/mL 10 mL	2		

[a]Care should be taken to ensure all medications are current (not expired).

TABLE 6.5D

A RAPIDLY ACCESSIBLE "STAT" MEDICATION SUPPLY SHOULD BE INCLUDED

Medication	Number
Adenosine 3 mg/mL 2 mL	5
Albumin 5% 50 mL	2
Amiodarone 50 mg/mL 3 mL	5
Atropine 0.4 mg/mL 1 mL	4
Calcium gluconate 100 mg/mL 10 mL	3
Dextrose 50% 50 mL	1
Dobutamine 12.5 mg/mL 20 mL	1
Dopamine 40 mg/mL 5 mL	3
Epinephrine 1 mg/mL 1 mL	3
Epinephrine 1 mg/mL 30 mL	1
Isoproterenol 0.2 mg/mL 5 mL	2
Lidocaine 20 mg/mL 5 mL	2
Naloxone 1 mg/mL 1 mL	4
Nitroprusside 60 mg/mL	1
Pancuronium 1 mg/mL 10 mL	1
Sodium bicarbonate 44.6 mEq/mL 50 mL	3
Sodium chloride 0.9% 10 mL	2
Sterile water injection 10 mL	3
Succinylcholine 20 mg/mL 10 mL	1
Thiopental syringe 250 mg/10 mL	1
Vecuronium 10 mg	2
Controlled Substances	
Diazepam 5 mg/mL 2 mL	3
Fentanyl 50 μg/mL 5 mL	1
Ketamine 10 mg/mL 20 mL	1
Midazolam 5 mg/mL 2 mL	2
Morphine Tubex 2 mg/mL	5
Phenobarbital 65 mg/mL	3

that initially described. This can be the result of a change in the patient's condition, incomplete assessment by the referring physician or transport team, or inadequate information flow. The ability to correctly assess severity of illness or injury before transport, from both the referring physician and the receiving physician perspectives, helps facilitate appropriate triage, advice and pretransport care of the patient, mode of transport, and personnel configuration decisions. Orr et al. have done considerable work in studying predictive models to help appropriately triage for and critically assess the use of pediatric transport systems. This research suggests several factors are useful in predicting in-hospital mortality. These include blood pressure, respiratory rate, oxygen requirement, and altered mental status. They also found that risk of mortality increased with performance of major interventions, as did the occurrence of unplanned events. Orr et al's 2009 paper "Pediatric specialized transport teams are associated with improved outcomes" clearly demonstrates the positive patient impact of specialty pediatric transport teams. Others have looked at the Shock Index (SI) in an attempt to determine stability and level of illness, while other systems use specific triage tools to determine optimal response required (ALS, level of critical care transport) for each particular patient. Kanter et al. evaluated use of the PRISM score in the pre-ICU populations. Use of electronic adjuncts to care is also increasing. Telemedicine interactions prior to and during transport can potentially improve information flow and accessibility, ultimately improving patient care and safety. The transport team may also be asked to transfer a different patient if a more critical patient has presented to the same referring institution. Inadequate numbers or types of personnel, equipment, or medications can render the transport team less effective in these situations.

The medical capabilities of the transport systems are important to assess. All transport teams do not have equivalent levels of pediatric skills. Transport services can vary from specialized pediatric teams, such as those supplied by tertiary care pediatric hospitals, to generalized transport services. In addition, some teams have additional capabilities (in addition to specialized personnel support), such as those who perform or transport patients requiring (or receiving) extracorporeal membrane oxygenation (ECMO), inhaled nitric oxide, and high-frequency ventilation or oscillation. Foley et al. presented a review of 100 patients, including 32 children, transported while on ECMO. A generalized transport service accepts all ages and types of patients; unfortunately, there are no universal standards or regulations regarding the level of experience or expertise in pediatrics required to transport pediatric patients. There are, however, accrediting agencies and standards that can be reviewed. The most specific accreditation process for transport systems is through the Commission on Accreditation of Medical Transport Systems (CAMTS). Although this is often a voluntary appraisal of a system, certification has been used as a mandatory review for licensing of some services in specific states. All hospital-based teams must, however, comply with Joint Commission on Accreditation of Healthcare Organizations requirements for patient care and safety. The 2003 National Patient Safety Goals mandate to improve safety of high-alert medications does not exempt transport teams from compliance. The mandate to remove concentrated electrolytes (including, but not limited to, potassium chloride, potassium phosphate, and sodium chloride greater than 0.9%) from patient care units, moving from use of the rule of 6s and standardizing and limiting the number of drug concentrations available in the transport organization, has been a challenge for some systems, but must be accomplished for optimal patient safety. Transport personnel need to potentially predict certain electrolyte needs prior to transport, or ensure availability at the referring facility, if they do not have the availability to carry or prepare specific fluids during the process because of this restriction.

Although pediatric patients can be efficiently and safely transported by different types of transport systems, the referring physician is responsible for assessing each program for medical sophistication and safety. Pediatric diseases and processes are different from those in adults, and one should not assume a general transport service has adequate experience in pediatrics to offer the appropriate or optimal level of care. Although patient transport by a general team may be quickly accomplished, the process may be classified as getting the patient to pediatric care quickly as opposed to rapidly bringing pediatric care to the patient. For many patients, this is an academic distinction. For example, the stable trauma patient, the child with a clearly defined medical process, or the patient needing referral for a nonprogressive, non–life-threatening issue may be adequately transported by a transport team without extensive pediatric experience. It is imperative, however, that general ALS and/or critical care skills be available for most of these transports. Consultation with a pediatric expert should also be included. When the differential diagnosis needs to be explored during the transport process or when the patient's

condition is rapidly changing, an experienced pediatric team is usually preferred. In geographic locations where specialized pediatric transport is unavailable, involvement of an appropriately skilled acute care/critical care pediatrician on the referring and/or receiving end is important. When possible, an unstable patient should not be referred from a nonpediatric provider to a pediatric institution via a transport team inexperienced in pediatric disease process and management. Ideally, advanced pediatric care should begin the moment the transport team is contacted. Pediatric medical or surgical advice, as well as adequate instruction before arrival of the transport team, can be stabilizing and potentially lifesaving for that particular patient.

Technical skill capability in general transport teams does not necessarily translate into technical skill competence in the treatment of children. This is perhaps most evident in children needing advanced airway intervention. A child's anterior larynx and the recommendation to avoid nasal intubation in children can preclude successful airway intervention by personnel who are not sufficiently educated or experienced in managing the pediatric airway. This discussion is not meant to cause one to avoid nonpediatric transport services, but only to ensure that the technical skill and competency necessary for adequate assessment and care of the patient during the transport process are optimal and that the cognitive components, if necessary, are augmented by an outside pediatric specialist.

When a decision is made to transport a pediatric patient, there is often a discussion of the appropriate mode of transport. Nonmedical transports include a parent's automobile or a taxicab. Problems with these choices include lack of assurance of direct transport to the receiving facility, inability to ensure patient safety, and the lack of available medical care during the transfer. Even the accompaniment of a physician or nurse does not markedly improve the ability for medical intervention in these nonmedical vehicles. A BLS ambulance offers direct transportation to the receiving institution, but does not offer much in the way of pediatric expertise or intervention capability. Physician or nurse accompaniment in a BLS ambulance increases potential level of medical care; however, the BLS environment is limited with regard to basic personnel, pediatric equipment, and medications. ALS transport offers more sophisticated resuscitation abilities but may provide variable and inconsistent levels of pediatric experience and/or expertise. Physician accompaniment may increase the level of available medical care within the ALS environment, but that impact may be decreased by the particular service's use of protocols and offline medical direction. Critical care transport services can increase the medical sophistication of ALS providers by ensuring the presence of a critical care transport nurse, but these providers may be lacking significant pediatric training, experience, expertise and/or skills. Pediatric critical care transport systems include critical care participants (nurses and physicians) with significant pediatric experience and expertise.

When transport services are needed, the modes to be considered include ground ambulance, RW aircraft (helicopter), and FW aircraft (jet or prop plane) (Figs. 6.4 to 6.6). Often, the decision is straightforward. For example, the available transport system may be ground only, or inclement weather may prevent air transport. Alternatively, the distance may be so great or traffic issues significant enough that ground ambulance transport is impractical. Several important issues should be considered when mode of transport is discussed. The first is personnel availability. If the transport modes require or offer different personnel configurations, the mode with the most appropriate personnel should be strongly considered. Ideally, a pediatric transport service with the capability for air and ground transport is available so comparative personnel issues are not the major deciding factors. A choice between speed of transport and appropriate medical personnel can be difficult, although they

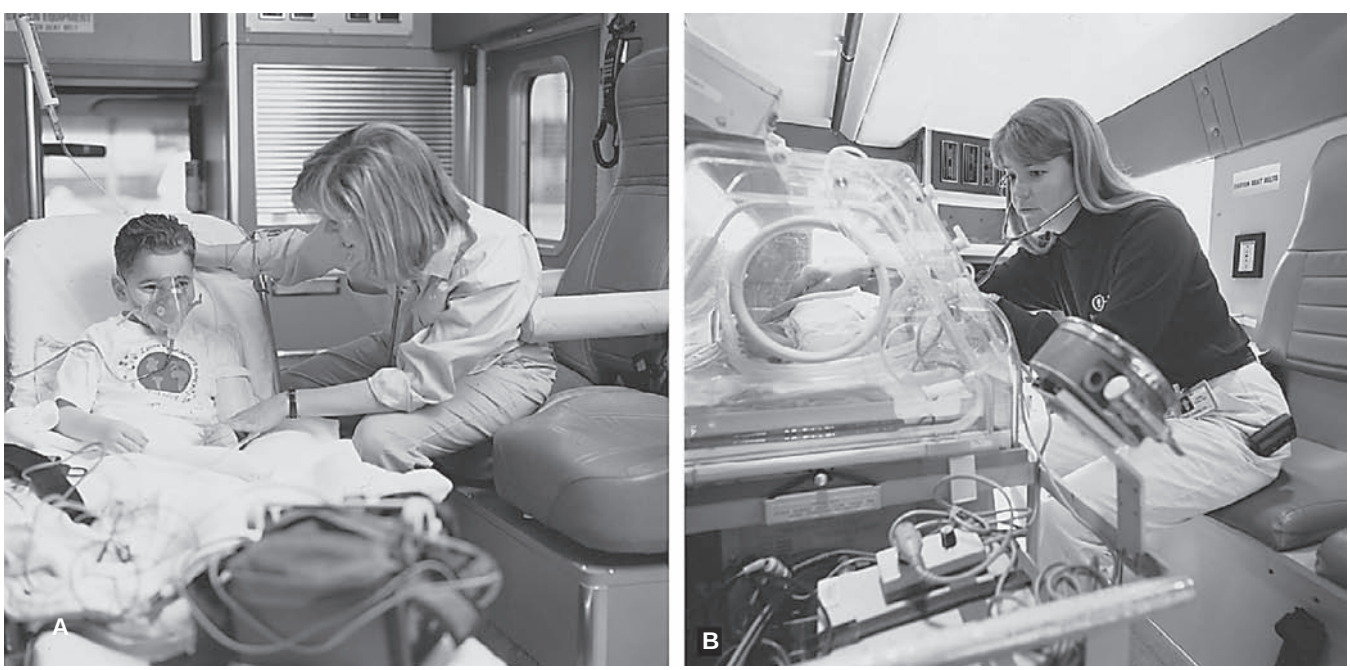

FIGURE 6.4 **A, B:** Pediatric interfacility ambulance environment. Examples of patients being transported within the ambulance environment. Note relative limitations of space and patient access. (Used with permission, © The Children's Hospital of Philadelphia, Philadelphia, PA.)

FIGURE 6.5 **A–D:** Air medical transport environment. Examples of design of a medical helicopter ("rotor-wing"). Note relative space and patient access limitations. (**A–C:** From Hahnemann University Hospital, University MedEvac, Philadelphia, PA, with permission; **D:** Used with permission, © The Children's Hospital of Philadelphia, Philadelphia, PA.)

are not necessarily mutually exclusive. Often, the referral hospitals or physicians want to have a patient taken to the receiving hospital as quickly as possible. They are sometimes willing to accept a transport team with little pediatric sophistication based solely on speed. Occasionally this may be appropriate, but caution needs to be exercised to ensure the transport system is capable of handling issues that can occur during the transport process. The referral physicians must be proactive in the mode of transport decision. This includes being aware of the transport systems that are available and evaluating those systems before using them. In areas without tertiary care pediatric transport options, local pediatric providers and the receiving pediatric physicians should be available to provide expertise to the general transport services to help bridge the gap between the general (primarily adult) and pediatric providers.

FIGURE 6.6 Fixed-wing transport. Both jet and piston (propeller) aircraft are used. Picture used with permission, Airlift Northwest, Seattle Washington.

Transport across international borders may also be required. This mode of transport requires significant preplanning. Specific issues to be considered for these patients include, but are not limited to, language issues of providers (and patients), compatibility and redundancy of medical equipment, power sources, medication issues with customs, communications during process, visas, passports, other documentation, and logistics of transport durations. For many international, long-distance transports, air crews are required to "time out," necessitating transport times that may go into days or use of additional personnel for the process. The same concerns, although not as rigid in established requirements, must be afforded to the health-care personnel as well. Options and solutions to some of these issues are available, but must be anticipated prior to need. Several services specialize in international transport and should be consulted for one trying to

determine or arrange optimal international transport options. During international operations, if both custodial parents are not accompanying the patient, it may be necessary to have a certified letter from the parent(s) not present giving the team permission to leave the country.

The disease process must also be considered in mode of transport decisions. The patient with developing petechiae, fever, and hypotension should not be transported several hours by ground if a quicker method of transport is available. Thomas et al. reported an association between helicopter transport and increased survival in blunt trauma patients (adult and pediatric). However, a short air transport for a relatively stable patient may not be an appropriate use of resources or be in the patient's or team's best interest. Eckstein et al. and Arfken et al. suggested that helicopter services may be overused and may not influence outcomes when compared with alternative modes of transport. One must be cognizant of the many issues surrounding the mode of transport choices. These choices should be individualized for each patient. Although appropriate medical care should not be withheld for financial reasons, a cost comparison of air and ground transports is often useful, especially if done before the acute transport. This may be an important factor in the decision process; however, if the referral or receiving physician or hospital is responsible for guaranteeing the cost of the transport. In general, RW (helicopter) transport costs two to three times as much as a ground transport for local transfers. However, the cost may potentially be offset by the savings in time. A helicopter, which can travel directly to and land at the patient's location, is much quicker than an ambulance, which must take a more circuitous route. If the helicopter cannot land directly at the referring or receiving center, however, the time savings by air transport may be less significant. In that situation, in addition to the decreased time savings, the patient may be placed at greater risk with the multiple transfers from referral center to ambulance to helicopter to ambulance to receiving hospital. The riskiest time for the patient is often during transfer from stretcher to stretcher or vehicle to vehicle (Fig. 6.7). These transfers increase the opportunities for dislodgement of endotracheal tubes, central venous catheters, chest tubes, and other lifesaving equipment. Communication center personnel, transport team, members and medical command physicians should all be aware of times, distances, and particular medical and logistical nuances of each referring institution and location.

Personnel Issues

Many types of providers can function effectively as part of a pediatric transport team. Nurses, ARNPs, respiratory therapists, EMTs, paramedics, and physicians serve on various transport teams. The choice of personnel depends on several factors, but the most important are the team's primary mission and the resources available for training and skill maintenance. In general, the personnel chosen for the transport team should have experience in the care of critically ill infants and/or children, and they must be competent in the transport environment. The best bedside clinician may be ineffective if he or she does not know where to find resources in the ambulance or helicopter, or how to turn on the oxygen or suction. The team may also be functionally limited if one of the providers is limited in knowledge or ability to perform specific patient care tasks, such as medication administration and delivery. The

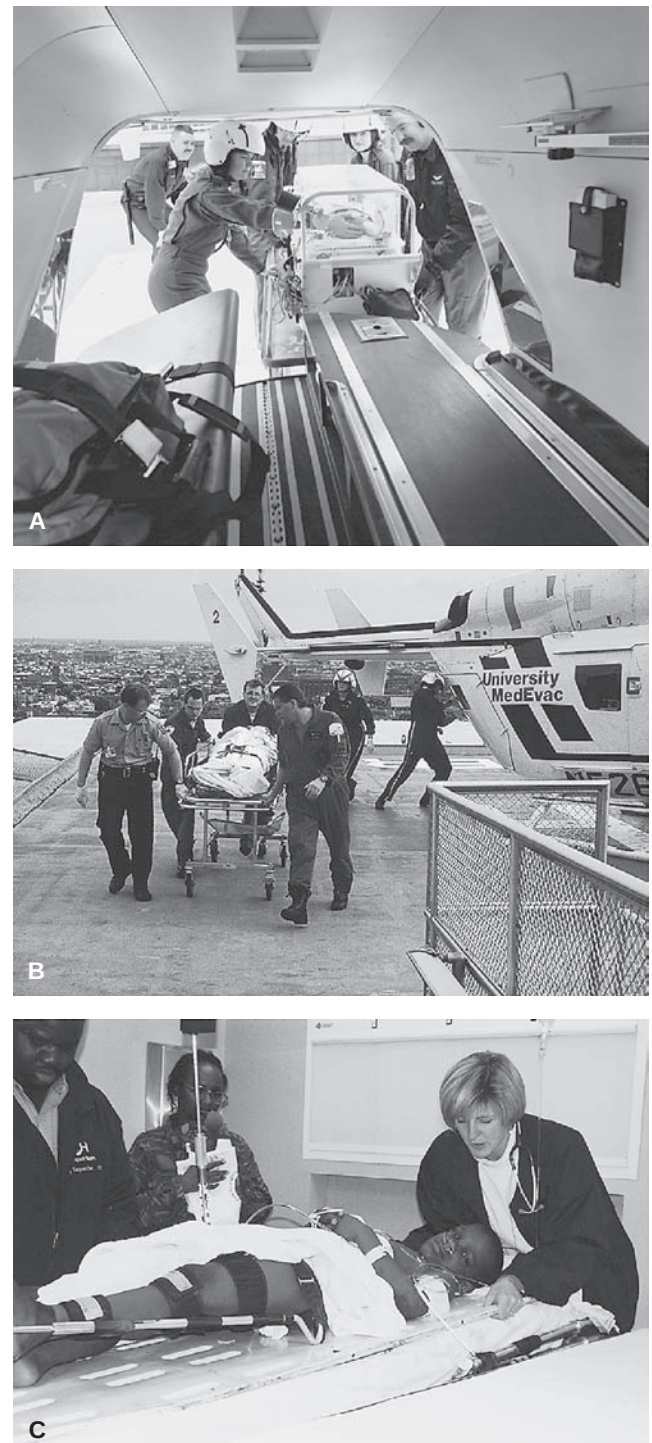

FIGURE 6.7 **A–C:** Transfer of patient during transport process. Patient transfer between vehicles or stretchers can be risky to the patient. Tube, line, oxygen, or medication disconnection or disruption, as well as shifts in immobilization, must be avoided. (**A, C:** Used with permission, © The Children's Hospital of Philadelphia, Philadelphia, PA; **B:** From Hahnemann University Hospital, University MedEvac, Philadelphia, PA, with permission.)

transport environment is not the appropriate place to learn basic pediatric critical care skills.

The primary mission of the team must be kept in mind when selecting personnel and planning training. For example, a team devoted to neonatal transport should consider team members with experience in the care of critically ill neonates, whereas teams that perform transports from nonhospital locations may want to employ personnel with prehospital care experience. Teams that have multiple missions, such as those that transport both neonates and older children, should attempt to recruit team members from varied backgrounds. By necessity, such teams have to devote considerable time to the medical cross-training of staff members. However, having team members from varied backgrounds offers the potential for those members to assist in the training and care delivery processes. Regardless of the medical background of the transport participants, education and experience in the transport environment is imperative.

Transport team capabilities and types of personnel vary significantly, depending on the transport system. However, pediatric critical care transport teams, the ideal interfacility transport configuration for children, often have several specific types of providers. At the heart of most pediatric critical care transport teams are highly trained pediatric critical care transport nurses. These nurses usually have significant critical care or emergency medicine experience before becoming members of the transport service. They have often had their technical and cognitive skills enhanced by formal or informal specialized training, as described here. Such training may allow them to be classified as practitioners with advanced skill certification in certain jurisdictions. Depending on the sophistication of the transport system, training opportunities, skills and assessment, and medical licensure issues, transport nurses often provide advanced management for these children. This can include diagnosis and assessment skills as well as interventions (e.g., advanced airway management, central venous access, resuscitation). In addition to their cognitive and technical skills, transport nurses have become experts in the environment in which they practice. The transport nurse should be intimately aware of all operating systems within the transport environment as well as safety procedures for the patient and the transport team. The medical skills of pediatric transport nurses can often be complemented by the addition of an attending, fellow, or resident physician; ARNP; respiratory therapist; nonpediatric transport nurse; or paramedic. Team compositions vary greatly in different systems, and no single team configuration is preferred. The ideal team composition is one that addresses the acute, projected, and potential needs of a particular patient and that has the flexibility to be amended when necessary.

One also needs to recognize the potential educational value (as compared with service use) of resident trainees during the transport environment. Many pediatric programs include residents and fellows as part of the patient care team, while in some cases, they participate as additional members in primarily an educational role. Durbin et al., as well as Fazio et al., reviewed the use and educational value associated with residents on transport. If residents or fellows are used in more than an educational role, they must bring a skill set to the transport environment that is additive and complementary to the other team members and equals or exceeds that of those who could take their place. If the resident cannot function as a full member of the team, and has replaced someone who could, reassessment of personnel configurations is indicated.

In addition to the personnel already described, transport teams usually include drivers or pilots who may have no role in patient care or who may assist the other personnel. Communications specialists may be employed as part of the team's call receipt and dispatch process. Finally, all transport teams should have a clearly identified supervisory medical director(s) and appropriate medical command physicians who are involved with every transport.

Other important educational considerations are the resources of both time and money available to devote to training and maintaining competencies for team members. If training time is limited, the transport team must consider hiring staff that is already well trained. For instance, a neonatal team could hire neonatal nurse practitioners. However, such well-trained staff usually demand higher wages, making them potentially more expensive than instituting an ongoing training program. Many teams do not have the opportunity to hire nurse practitioners or other previously trained and highly skilled personnel; therefore, those teams especially need to devote significant time and resources to training team members. The amount of time necessary varies with the team's mission and its customary personnel composition. A team with a well-defined scope of practice, such as neonatal transport, should employ experienced neonatal nurses. In this circumstance, only those additional skills that are new to the team members need to be added, although competency in all expected cognitive and technical skills need to be assured. Likewise, if a team usually includes a physician, the other team members may not need to learn advanced skills such as tracheal intubation. Teams must ensure their members, regardless of background and previous education/experience are competent in all procedural and management skills that may be required during transport. Such extensive training usually includes a didactic component, a skills segment, and rotations through various clinical care areas. If the group is large enough, the didactic component may be a series of lectures. However, this type of experience is difficult to arrange for one or two new team members. Alternatives to formal lectures include video- or audiotaped lectures or a modular self-study curriculum.

Unfortunately, skill acquisition is only the beginning. Rarely used skills are quickly forgotten, so a process for skill maintenance must be established. Furthermore, as in all areas of medical practice, the knowledge base in transport medicine is constantly changing, making continuing education vital. Skill retention and continuing education are best accomplished using a three-part process. The first component is renewal of basic procedural and cognitive skills. Such retraining may include rotations through the operating room to practice airway techniques; dry or animal laboratory experiences for interosseous infusion, cricothyroidotomy, thoracostomy tube placement, and other important but rarely needed procedures; and simulated codes to practice resuscitation.

The second component is formal continuing education through regularly scheduled programs, including lectures, journal clubs, and presentations of particularly unusual or difficult patients. In addition, such forums may be used to learn about new medical equipment, communication devices, and vehicle issues.

The final component of an effective education program is quality improvement. Routine, periodic case reviews should take place by the transport service in conjunction with other medical

experts. A formal morbidity and mortality conference may be included as a part of such a program. In addition, topics such as response times and parent satisfaction may be discussed. The focus of these sessions should be on the process of patient transport. Determining and assigning blame for less-than-optimal outcomes is important only when the staff member involved was clearly negligent. It is far more important to focus on ways in which the team's practices may be changed to improve performance and minimize risk of similar events in the future.

Although the team's mission dictates most of the cognitive and technical aspects of training, all teams will need to work together in a cohesive fashion. This might be particularly challenging for transport teams as they practice in a unique and somewhat isolated environment and in a fashion that might be quite different from the traditional medical hierarchy. The interactions and relationships necessary for success in this type of practice may have more in common with other high-performance teams, such as military special forces units and aircraft crews, than with those found in many other health-care situations. A growing body of evidence from the airline industry, and now from health care, suggests that these team skills can be learned and that, when fully integrated into the culture of the program, serve to improve team performance and decrease medical errors.

Communication

A key component of any transport team is effective communication. Referring physicians must be able to contact the transport service, including the appropriate medical command physicians, quickly and easily, and teams in the field must be able to communicate with the receiving facility and providers. The ability to communicate with a command physician is particularly important for teams using resident physicians or nonphysician practitioners because they may need online medical direction. Ideally, a single point of contact (e.g., a dispatch/communication center) should be established to help ensure centralized access, to help ensure that no calls are missed, and that all communications are properly documented (Fig. 6.8).

FIGURE 6.8 Transport communication center. A dedicated transport communication center and personnel are invaluable in coordinating all aspects of pediatric transport. The system need not be as elaborate as demonstrated, but should include dedicated phone lines, radio access, personnel notification capability systems, and personnel. (From Hahnemann University Hospital, University MedEvac, Philadelphia, PA, with permission.)

Communication with the transport team begins with an initial call from the referring provider. This initial contact is best managed by the use of a protocol or template, which helps ensure that the necessary patient and logistical information is properly received by the transport team (Fig. 6.9). During the initial call or soon thereafter, the referring provider may request advice regarding the medical management of the patient. Alternatively, such advice may be offered by the receiving physician. For critically ill infants and children, medical advice via telephone may be needed intermittently from the time of initial contact through arrival, evaluation, and departure from the referring facility until arrival at definitive location in the receiving facility. For these reasons, it is preferable to have transport requests initiated and received by senior physicians who can ask for and offer appropriate advice directly. The more people between the source of the information and the final recipient, the greater the potential for significant changes or omissions that may be vital to the patient. We also recommend that transport nurse–to–referral bedside nurse conversation to evaluate the patient from the nursing perspective be an expected part of the transport process. Together, these two avenues of information flow offer the greatest potential for complete awareness of all aspects of the patient's disease process and current medical condition.

After the transport team has arrived at the referring facility and performed a preliminary evaluation of the patient, they often need to communicate with one or more people at the receiving hospital. These calls can involve patient review and logistical issues such as patient disposition, scheduling of studies, and need for consultants. The ability to conference in various participants, such as specialty physicians, charge nurses, and bedside nurses, can greatly impact the information flow, logistics, and potential delivered care of the patient. Such calls are best facilitated by a communication center.

En route to the receiving hospital, it may be necessary for the transport team to contact the medical command physician either for advice or because the patient's medical condition has changed. Reliable communications are especially important at this point in the transport. The team should be equipped with redundant systems to ensure a reliable means of communication is always available. These should include cellular technology, long-range alpha beepers, land radio communications systems and satellite phone where necessary. Newer technologies, including telemedicine and global positioning systems, may improve communication and logistics capabilities. The transport command physician should be immediately accessible to the transport team by telephone or designated beeper.

After arrival at the receiving hospital, the transport team is responsible for ensuring an efficient, informative, and seamless transition of care to the inpatient physician and nursing team. Adequate communication and information flow must take place to fully inform the inpatient team of the patient's disease process and care to date. Complete documentation, written in a clear, concise fashion, is mandatory (Fig. 6.10). Anything less than a complete transfer of information and a seamless transition from referral physician to transport team to receiving physicians is a disservice to the patient and a source of potential liability.

It is important to remember that transport communications have other medical-legal ramifications. The most important of these involves the giving of medical advice and the assumption of legal responsibility for patient management. When giving or

FIGURE 6.9 Transport referral form. A standardized form for recording transport referral information is important. This form should be readily accessible to those who receive the referral. Copies can also be distributed to referral centers to help streamline the process. The forms should, at least, be in duplicate to allow for an official medical record copy (which stays with the command physician during the transport process to document transport progress) and one to accompany the transport team, which eventually resides in the patient's transport record. Calculation of Continuous Drug Infusions
Ordered in Base Concentration (based on weight)

Drug _____

Patient Weight (kg) _____

PATIENT PLATE IMPRINT

Fill in the appropriate horizontal row for the base concentration ordered. Complete correlating solution preparation boxes using the calculation examples on the back of this form. Verify that the continuous infusion drug label matches the calculated information below. Solution preparation boxes should be verified by each new nurse caring for the patient.

___ u/kg/hr to run at 10 mL/hr (Insulin)		A. ___ u/hr	B. ___ u/10ml	C. ___ u/ml	D. ___ u/ ___ ml
___ u/kg/hr to run at 1 mL/hr		E. ___ u/hr		F. ___ u/ml	G. ___ u/ ___ ml
___ u/ kg/min to run at 1 mL/hr	H. ___ u/min	I. ___ u/hr		J. ___ u/ml	K. ___ u/ ___ ml
___ mcg/kg/min to run at 1 mL/hr	L. ___ mcg/min	M. ___ mcg/hr	N. ___ mg/hr	O. ___ mg/ml	P. ___ mg/___ ml
___ mcg/kg/hr to run at 1 mL/hr		Q. ___ mcg/hr	R. ___ mg/hr	S. ___ mg/ml	T. ___ mg/___ ml
___ mg/kg/hr to run at 1 mL/hr			U. ___ mg/hr	V. ___ mg/ml	W. ___ mg/___ ml

Document most recent MD order in the Ordered Dose box. Calculate Rate (ml/hr) using example on the back of this form. This section must be completed at the initiation of the infusion, at the beginning of each shift, with dose change, and when changing the bottle/bag/syringe.

Date/Time Reason	Ordered Dose	X. Rate (ml/hr)	Syringe Exp. date/time	RN Signature

units/kg/hr to run @ 10 ml/hr (INSULIN ONLY)

Box A Calculate **units/hr:** ____ Base concentration X _____ pt wt = _____ units/hr to run @ 10 ml/hr
e.g.: 0.1 units/kg/hr to run @ 10 ml/hr X 6 kg = 0.6 units/hr to run @ 10 ml/hr

Box B When run at 10 ml/hr, units/hr is the same as **units/10 ml**
Therefore: 0.6 units/hr @ 10 ml/hr is the same as 0.6 units/10 ml

Box C Calculate **units/ml:** ____ units/10 ml ÷ 10 = _____ units/ml
e.g.: 0.6 units/10 ml ÷ 10 = 0.06 units/ml

Box D Calculate **total units in container:** _____ units/ml X _____ container size = _____ total units /_____ container
e.g.: 0.06 units/ml X 100 ml bottle = 6 units/100 ml bottle

units/kg/hr to run @ 1 ml/hr

Box E Calculate **units/hr:** ____ Base concentration X _____ pt wt = _____ units/hr to run @ 1 ml/hr
e.g.: 15 units/kg/hr to run @ 1 ml/hr X 8 kg = 120 units/hr to run @ 1 ml/hr

Box F When run at 1 ml/hr, units/hr is the same as **units/ml**
Therefore: 120 units/hr to run @ 1 ml.hr is the same as 120 units/ml

Box G Calculate total units in container: _____ **units/ml** X _____ container size = _____ total units/ _____container
e.g.: 120 units/ml X 250 ml bottle = 30,000 units/ 250 ml bottle

units/kg/min to run @ 1 ml/hr

Box H Calculate **units/min:** _____ Base concentration X _____ pt wt = _____ units/min to run @ 1 ml/hr
e.g.: 0.01 units/kg/min to run @ 1 ml/hr X 7 kg = 0.07 units/min to run 1ml/hr

Box I Calculate **units/hr:** _____ units/min X 60 min/hr = _____ units/hr
e.g.: 0.07 units/min X 60 min/hr = 4.2 units/hr

Box J When run at 1 ml/hr, units/hr is the same as **units/ml**
Therefore: 4.2 units/hr to run @ 1 ml/hr is the same as 4.2 units/ml

Box K Calculate **total units in container:** _____ units/ml X _____ container size = _____ total units/ _____ container
e.g.: 4.2 units/ml X 50 ml syringe = 210 units/ 50 ml syringe

mcg/kg/min to run @ 1ml/hr

Box L Calculate **mcg/min:** _____ Base concentration X _____ pt wt = _____ mcg/min to run @ 1 ml/hr
e.g.: 10 mcg/kg/min to run @ 1 ml/hr X 9 kg = 90 mcg/min to run 1 ml/hr

Box M Calculate **mcg/hr:** _____ mcg/min X 60 min/hr = _____ mcg/hr
e.g.: 90 mcg/min X 60 min/hr = 5400 mcg/hr

Box N Calculate **mg/hr:** _____ mcg/hr ÷ 1000 mcg/mg = _____ mg/hr
e.g.: 5400 mcg/hr ÷ 1000 mcg/mg = 5.4 mg/hr

Box O When run at 1ml/hr, mg/hr is the same as **mg/ml**
Therefore: 5.4 mg/hr run @ 1 ml/hr is the same as 5.4 mg/ml

Box P Calculate **total mg in container:** ____ mg/ml X _____ container size = _____ total/ _____ container
e.g.: 5.4 mg/ml X 50 mL syringe = 270 mg/50 ml syringe

mcg/kg/hr to run @ 1 ml/hr

Box Q Calculate **mcg/hr:** _____ Base concentration X _____ pt wt = _____ mcg/hr to run @ 1 ml/hr
e.g.: 5 mcg/kg/hr to run@1 ml/hr X 12 kg = 60 mcg/hr to run 1 ml/hr

Box R Calculate **mg/hr:** _____ mcg/hr ÷ 1000 mcg/mg = _____ mg/hr
e.g.: 60 mcg/hr ÷ 1000 mcg/mg = 0.06 mg/hr

Box S When run at 1 ml/hr, mg/hr is the same as **mg/ml**
Therefore: 0.06 mg/hr run @ 1 ml/hr is the same as 0.06 mg/ 1 ml

Box T Calculate **total mgs in container:** _____ mg/ml X _____ container size = ____ total mg/ _____ container
e.g.: 0.06 mg/ml X 50 ml syringe = **3 mg/50 ml syringe**

mg/kg/hr to run @ 1 ml/hr

Box U Calculate **mg/hr:** _____ Base concentration X _____ pt wt = _____ mg/hr to run @ 1 ml/hr
e.g.: 2 mg/kg/hr to run @ 1 ml/hr X 18 kg = 36 mg/hr to run@1ml/hr

Box V When run at 1 ml/hr, mg/hr is the same as **mg/ml**
Therefore: 36 mg/hr to run @ 1 ml/hr is the same as 36 mg/ml

Box W Calculate **total mg in container:** _____ mg/ml X _____ container size = ____ total mg/ _____ container
e.g.: 36 mg/ml X 50 ml syringe = 1800 mg/50 ml syringe

Box X Rate Calculations/Changes:

"Desired Have Method"

Ordered Dose (units/kg/hr) / Base Concentration (units/kg/hr) X Base Conc Rate (ml/hr) = Ordered Dose Rate

Example 1: Physician order reads: Insulin.... Base concentration 0.1 units/kg/hr equal to 10 ml/hr; Dose: 0.07 units/kg/hr.

0.07 units/kg/hr / 0.1 units/kg/hr x 10 ml/hr =

0.7 x 10 ml/hr = 7 ml/hr

"Ratio Method"

Base Concentration (units/kg/hr) / Base Concentration Rate (ml/hr) = Ordered Dose (units/kg/hr) / Ordered Dose Rate (X ml/hr)

Example 1: Physician order reads: Insulin....Base concentration 0.1 units/kg/hr equal to 10 ml/hr; Dose: 0.07 units/kg/hr.

0.1 units/kg/hr / 10 ml/hr = 0.07 units/kg/hr / X ml/hr

(0.1 units/kg/hr)(X) = (0.07 units/kg/hr)(10 ml/hr)

0.1 units/kg/hr (X) = 0.7 units/kg/hr

0.1 units/kg/hr (X) / 0.1 units/kg/hr = 0.7 units/kg/hr / 0.1 units/kg/hr

X = 7 ml/hr

AUTHORITY FOR TRANSFER, TREATMENT AND TRANSPORTATION BY THE EMERGENCY TRANSPORT TEAM OF THE CHILDREN'S HOSPITAL OF PHILADELPHIA

(PATIENT PLATE IMPRINT)

I hereby consent to the transfer and transport of _____ (Patient's name)

from _____ (Referring medical facility) to _____ (Accepting medical facility or home)

I consent to the transfer and transport of the patient to any other hospital or medical facility enroute to the location mentioned above should it become indicated by the Emergency Transport Team of The Children's Hospital of Philadelphia for the patient's safety or well being.

I understand that the condition of the above patient is such that the referring physician recommends transfer of the patient by the Emergency Transport Team of The Children's Hospital of Philadelphia.

I acknowledge there are potential unanticipated risks to the transportation such as possible traffic hazards, adverse weather conditions, vehicle operator errors, failure of medical equipment and the vehicle, and consequences of actions of persons outside of the control of transport personnel, all of which could have an impact on the patient.

I understand that this transport may be accomplished with or without a physician in attendance but under the direction of protocols or telephone triage orders from the Medical Command Physician from The Children's Hospital of Philadelphia.

I also consent to the treatment and care that may be provided to the patient during the transportation. I acknowledge that there may be a delay or interruption of the patient's previous medical treatment during the period of transport. I understand that not all the resources required to fully diagnose and treat the patient are available during transport. These delays, interruptions or lack of resources may increase the severity of the patient's condition and may in rare cases, result in the death of the patient.

I have considered the above risks, and other risks not mentioned by the transport team and the alternatives and benefits of the transfer and transportation, and consent to the transfer and transportation provided by The Children's Hospital of Philadelphia.

I authorize The Children's Hospital of Philadelphia to provide medical information to the patient's family physician(s).
☐ yes ☐ no

I authorize The Children's Hospital of Philadelphia to provide medical information to the patient's referring physician(s).
☐ yes ☐ no

I acknowledge that I have read the above authorizations and that no guarantee or assurance has been made to me as to the results that may be obtained. I have read this form and completely understand it.

_____ Printed name of consenting party _____ relationship to patient

_____ Signature of consenting party _____ date and time

_____ Signature of The Children's Hospital of Philadelphia employee acting as witness _____ date and time

receiving management advice by telephone, both parties should remember that the transport command physician is usually unable to see and are always unable to examine the child in question. Therefore, his or her advice will often be somewhat general. The receiving physician must do his or her best to offer clear and complete information, especially when specific information is requested. Suggestions for care must be clearly and completely communicated. For example, if the transport command physician believes that a fluid bolus is needed, that advice should include type and amount of fluid and speed of infusion to avoid any misinterpretation of advice or an inadvertent mistake in one of those parameters. All advice should be documented in writing and/or by audio recording. The referring physician is under no obligation to accept the advice of the receiving physician, but he or she would be prudent to give it serious consideration. If the referring physician is unable or unwilling to perform suggested interventions because of disagreement, personnel issues, equipment limitations, or other reasons, this should be discussed with the receiving physician. Likewise, results from interventions or marked changes in the patient's condition during the referral process should be communicated to the receiving physician and transport service. Clear, precise, efficient, and honest communication is imperative for the patient to receive the most appropriate care.

Communication with the patient and family is also important during the transport process. Straightforward communications about disease process and expectations can help prepare a family to accept the consequence of the illness or injury. Lack of communication or reluctance to give bad news can cause a family to expect different outcomes than they should and may pave the way for anger and resentment.

Written communication of all data regarding the patient's care is imperative. Patient summaries, copies of all medical paperwork, laboratory values, and radiographs should be

- o Laboratory data copied
- o X-rays and radiology reports copied

FIGURE 6.10E A standardized form can be distributed to referral centers to allow demographic information to be collected prior to the arrival of the transport team. Identification of all principals involved in the patient's care can help future flow of information regarding the patient's diagnosis and outcome. (Used with permission, © The Children's Hospital of Philadelphia, Philadelphia, PA.)

available for the transport team on their arrival at the referring location. A transport referral checklist may be useful to help streamline the process (Fig. 6.11). Adequate preparation of these documents before arrival of the transport team can greatly improve the efficiency of the transport process and the transition of care. Availability of the referring personnel at the time of transport can also make the process more efficient for all concerned. Telephone and fax numbers and the addresses of the referring and primary physicians should be available to the transport team so follow-up information may be easily conveyed. Likewise, the referring and primary physicians should be given contact numbers for the transport team and its medical and administrative directors.

Finally, the family should receive preprinted directions to the receiving facility. Information about the facility, parking, city, local transit, and the visiting policies of the receiving unit should also be provided. Enabling a family member to accompany the transport team has been shown to be important to both the patient and family, while not diminishing the delivered quality of care. Recognition of the family's role in the overall care of the child will pay dividends to the team, patient, and family.

Patient and Team Safety

Safety is a key consideration for the transport team. The team should do everything possible to provide for the safety of all involved in the transport process. This includes more than providing pediatric medical expertise for the patient during the transport. It starts with vehicle selection, driver or pilot capabilities, and ongoing licensure requirements. The transport medical director is responsible for continually assessing the capabilities of the particular modes of transport and the personnel involved with those functions. This goes beyond licensure issues. Active inspections and evaluations, as well as continuous quality improvement (CQI) issues, are important. Unsafe vehicles or personnel must be attended to or removed from service. Safety of the transport personnel must also be a priority. Avoiding the use of RW transport in bad weather is a good example of a safety decision in the transport environment. Improvement in helicopter EMS (HEMS) safety profiles were recognized when pilots were isolated from patient care information. Instead of being informed that a critical child might die without their intervention, pilots now often make "go" or "no go" decisions based solely on weather and equipment issues. If an appropriate "no go" decision is made, this should not be questioned or countermanded by medical or administrative personnel. If a "no go" decision is made based on weather considerations, another mode of transport or other patient care options must be considered. Competition between transport programs or aeromedical providers can be a safety hazard. In their desire to gain a competitive advantage, one or all the programs (or specific personnel) may be willing to bend weather and safety rules. It is the policy of our systems that if one air service has denied a transport for weather-related issues, another air service is not contacted unless it is located in a separate environment that may change the weather issues. There is no excuse for risking or losing the lives of several caregivers for any one particular transport. Unfortunately, the HEMS industry has seen an unprecedented accident and fatality rate over the past several years. In 2006, the National Transportation Safety Board (NTSB) critical reviewed 55 EMS accidents from January 2002 to January 2005. These included 54 fatalities and 19 serious injuries. They determined that 29 of the 55 fatalities could have been prevented with systematic corrective actions. This review resulted in safety initiative recommendations, which are outlined in the NTSB publication, *Special Investigative Report on Emergency Medical Services Operations*, available at www.ntsb.gov. As per that report and the Blumen's referenced 2002 safety review, the number of HEMS flight hours increased approximately 85% from about 162,000 to 300,000 (1991–2005) and the average accident rate increased during the last 5 years of the report from 3.53 (1992–2001) to 4.56 (1997–2001) per 100,000 flight hours. The following recurring safety issues were noted: (i) less stringent requirements for EMS operations conducted without patients on board; (ii) lack of aviation flight risk-evaluation programs for EMS operations; (iii) lack of consistent, comprehensive flight dispatch procedures for EMS operations; and (iv) no requirements to use technologies such as terrain awareness and warning systems (TAWS) to enhance EMS flight safety. There were two accidents with four fatalitiesin 2006 and two accidents with seven fatalities in 2007. From December 2007 to October 2008, there were nine fatal HEMS accidents with 35 fatalities. The Federal Aviation Administration (FAA) reported that there were 33 EMS helicopters involved in 32 fatal accidents, with 83 related fatalities from 2002 through September 2008, resulting in an annual average of 4.5 fatal accidents and 12 deaths per year. It was noted that 23 of these accidents, and 65 of the fatalities occurred at night. Compared to ground ambulance transport (15 million annual patient exposures), the fatal accident rate is greater for helicopter transport by approximately 13.5 times, and the helicopter fatality rate exceeds that seen with ground ambulances by 34 times. Interventions by the FAA have resulted in safety improvements, including certification of night vision goggles (NVG) for helicopter use. Other recommendations included TAWS, more stringent flight operation requirements, improved preflight risk management and hazard identification, and mitigation programs and formalized dispatch procedures to include up-to-date weather information and assistance in flight risk-assessment decisions.

Although there is not a singular intervention or assessment tool that will guarantee risk-free air transport, accreditation by the CAMTS demonstrates adherence to the safety standards proposed for the air medical transport industry.

STABILIZATION FOR TRANSPORT

The patient care paradigm of most interfacility transport teams stands somewhat in contrast to that of prehospital care systems. EMS providers are usually bringing a patient from an environment without medical care (e.g., home or accident scene) to a hospital. In many of these cases, the patient is better served to have the minimum stabilization necessary at the scene followed by rapid transport to an appropriate hospital, with further intervention being performed en route or on arrival. In contrast, the interfacility transport team is most often taking a patient from a hospital, usually an ED or another monitored setting, to a monitored bed within a higher level or specialty

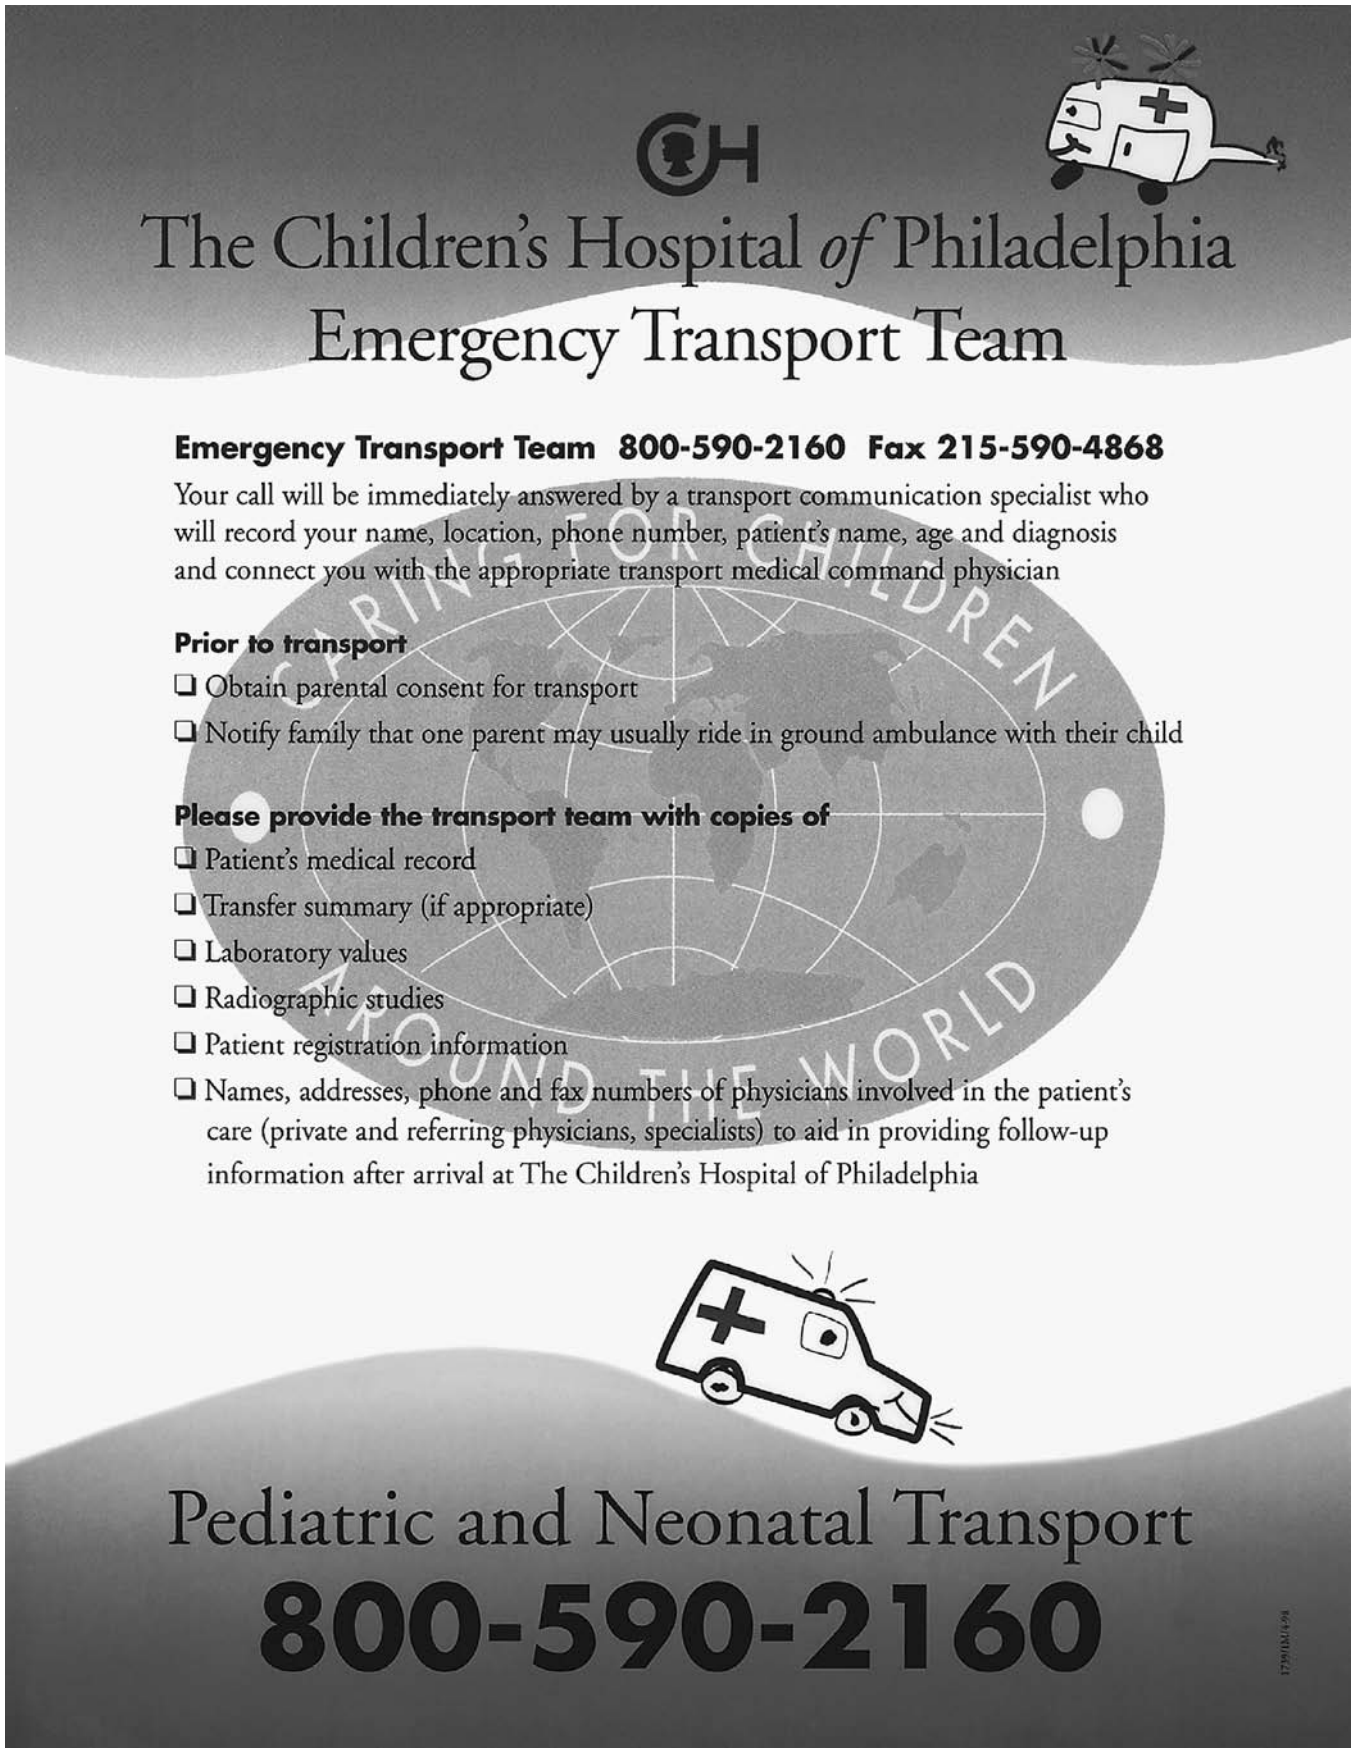

FIGURE 6.11 Referral checklist. Transport referral checklists can decrease the transition time at the referring hospital by allowing the referral team to anticipate the logistics of the pretransport process and accomplish many tasks prior to the arrival of the transport team. (Used with permission, © The Children's Hospital of Philadelphia, Philadelphia, PA.)

care center. The transport team, therefore, is responsible for maintaining an appropriate advanced level of care between the two centers. Ideally, the transport team should provide the level of care that the patient will have at the receiving facility. At a minimum, the transport team must maintain the patient's present level of care under difficult circumstances. Stabilization before transport is the key to this process.

Initial preparation for transport often begins when the referral caregivers recognize that the patient requires care beyond the capabilities of their center. Appropriate advice and suggestions from transport personnel or the receiving physician may allow much of the necessary stabilization, interventions, and preparation for transport to be accomplished before the team arrives. Telemedicine promises to improve the pretransport assessment opportunities in the future. Availability of visual and other data to be reviewed by local experts should offer a more individualized, higher level of initial assessment and suggested advice.

When the transport team arrives, they should review the medical history, including all therapeutic maneuvers and interventions performed at the referring hospital. An immediate and thorough physical examination is mandatory. During this pretransport review process, endotracheal tubes, chest tubes, IV and intraarterial catheters, and other indwelling devices should be checked for proper placement and stabilization. When doubt exists, devices should be replaced or better secured.

After this initial assessment, the transport team, in concert with the medical command physician, should decide which, if any, further medical interventions are required to be initiated and/or continued before leaving the referring center. Such interventions are most appropriate when they may have a direct impact on patient outcome. For example, the child who may have meningitis should definitely receive antibiotics before or during the transport process, but a lumbar puncture may be deferred until he or she arrives at the receiving hospital. The appropriateness of interventions will, to some degree, be dictated by the distance to the receiving hospital. For example, a child with a circumferential burn of an extremity may require a fasciotomy to prevent vascular compromise. If the receiving hospital is 5 minutes away, this might be appropriately deferred. However, if the receiving hospital is 2 hours away, it may be prudent to have the procedure performed before departing from the referring center. Again, transmission of images or materials to the receiving center or medical command physicians can help in the patient management. This could include images of computed tomography scans or x-rays as well as copies of EKGs or other assessments. The availability of point-of-care testing is helpful during prolonged transport processes to assess metabolic or other laboratory markers.

After the patient is optimally prepared for transport, he or she must then be moved from the referral facility's bed to the transport stretcher and then to the vehicle. Such movements represent great risk to the patient. If an IV catheter or an endotracheal tube is going to be displaced, it will likely occur while the patient is being moved. This fact has several implications. First, patients should be subjected to the fewest transfers necessary to get them from the referring hospital to the definitive bed/location they will occupy at the receiving hospital. Movement from the transport stretcher to a holding bed in the ED is often unnecessary and can be avoided with advanced planning. Second, extra vigilance should be used during patient transfer. Personnel should be assigned to secure lines and tubes, and the movement should be coordinated by a team leader. Precautions such as planned, temporary disconnection of the ventilator from the endotracheal tube may need to be considered during these moves. Finally, the patient must be reassessed immediately after each movement. The team must be assured that the airway is stable, immobilization is secure (if appropriate), and that potentially lifesaving tubes, lines, and medications have not become dislodged or disrupted.

Monitoring is imperative during the transport process. Observation and palpation may be hindered by patient position relative to the caregiver within the vehicle. This may be especially evident in a small transport helicopter. Auscultation may also be impaired in a noisy transport environment. The air transport environment, especially in a RW or turbo prop aircraft, may be 50% louder than a comparable ground transport. Therefore, more reliance is placed on sophisticated monitoring tools, including cardiorespiratory, pulse oximetry, capnography, and gas delivery monitors with audible and visual alarms as well as point-of-care laboratory testing.

ALTITUDE PHYSIOLOGY AND THE AIR MEDICAL ENVIRONMENT

When pediatric patients are transported by helicopter or FW aircraft, one must be cognitive of issues regarding altitude physiology. An increase in altitude brings with it a decrease in ambient oxygen as well as the potential for an increase in the size of air spaces. For most patients, however, these should not be major issues. For patients with severe hypoxia at sea level, diving injuries, or large, enclosed pockets of air, however, air transport can be dangerous.

Two gas laws are most important in the transport process. Boyle's law states that with a constant temperature, the volume of a gas varies inversely with the pressure ($P_1V_1 = P_2V_2$) (Fig. 6.12). As altitude increases, barometric pressure decreases; therefore, the volume of the gas increases. Dalton's law (the law of partial pressure) says that the partial pressure of a gas mixture is the sum of all the partial pressures of the gas within the mixture ($PT = P_1 + P_2 + P_3 \ldots$) (Fig. 6.13). For example, the total pressure of air is 1. The partial pressure of nitrogen is 0.78, oxygen is 0.21, and other gases are 0.01. The partial pressure of oxygen will always be 21%. At higher altitudes, air becomes less dense and the partial pressure of oxygen, while still 21%, offers diminished oxygen availability.

These issues can be important during the air medical transport. Entrapped air, if not vented, can be painful (middle ear sinus, teeth, bowel), annoying (flatus, belching), and dangerous (pneumothorax). Use of tight-fitting earplugs in flight can cause an artificial air pocket that may trigger the same problems. More significant air space issues include simple pneumothorax and pneumocephalus, which can become symptomatic at high altitudes. Patients with bowel obstructions may have increased gas volume, leading to vomiting and potential aspiration. Air in military antishock trousers may vary with altitude as will the air in pressure splints and blood pressure cuffs. Air in endotracheal tube cuffs and Foley catheters may also be affected and might need to be adjusted during flight. Patients with an air embolism from a diving injury or other cause are especially prone to gas volume–related issues during air transport.

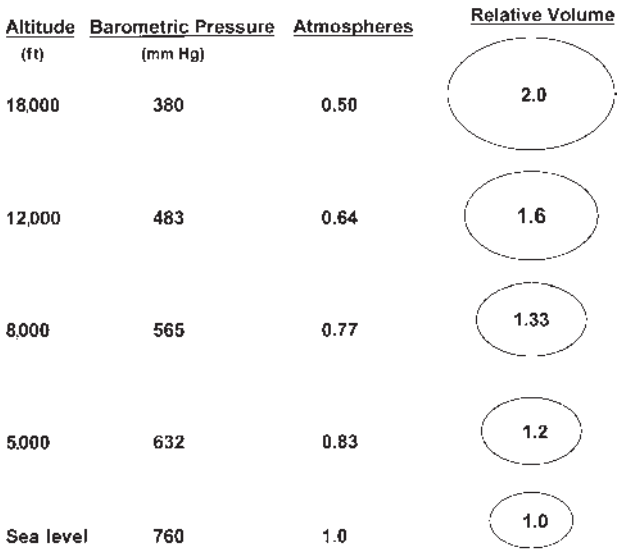

FIGURE 6.12 Boyle's law ($P_1V_1 = P_2V_2$ or $P_1/P_2 = V_1V_2$). As altitude increases, barometric pressure decreases and volume of gas increases. The diagram illustrates enclosed gas expansion at specific altitudes. "Atmospheres" is compared with the amount of pressure exerted by an overlying 1 square inch air column. At sea level, this equals 14.7 pounds per square inch (psi) and one-half that amount (7.35 psi) at 18,000 ft. (From Woodward GA, Vernon DD. Aviation physiology in pediatric transport. In: Jaimovich DG, Vidyasagar D, eds. *Pediatric and neonatal transport medicine*. Philadelphia: Hanley and Belfus, Inc., 1995:40, with permission.)

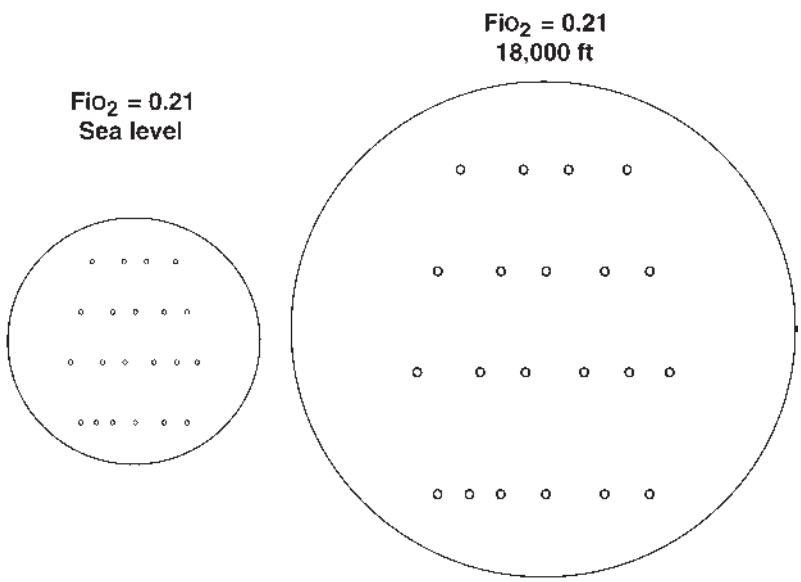
Hypoxia can also be a major issue. This can usually be overcome with addition of 100% FiO_2—unless the patient is already hypoxic at lower altitudes on 100% oxygen. Positive end-expiratory pressure is usually not effective in augmenting the hypoxemia that occurs secondary to an increase in altitude.

Most air transports, however, do not reach an altitude that will greatly influence the patient's care. Helicopter transport routinely occurs at 1,000 feet or less above ground level, although this can be greatly altered in mountainous regions where traversing high-altitude peaks may be necessary. FW transport aircraft are usually pressurized, meaning that they can simulate the atmospheric pressure of a lower environment. Air pressure in these aircraft is often set at a level of 5,000 to 8,000 feet, which can, however, still lead to a significant increase in gas volume. Opportunities for achieving higher ambient pressure (lower altitude pressure) may be available, depending on the limitations of the particular aircraft. If an aircraft cannot be pressurized to a higher pressure, one can consider flying at a lower altitude. Trade-offs include increased turbulence, speed restrictions, and fuel issues.

Other issues to be considered in air transport include vibration, turbulence, noise, humidity, temperature, air sickness, exhaust fumes, specific aircraft dangers, and gravitational forces. Helipad availability, landing zones, and other issues of aircraft accessibility must also be determined. Although these logistical issues are ultimately the responsibility of the air transport service and are usually predetermined for the interfacility



A

Altitude (1000 feet)

	0	10	20	30
Barometric pressure	760	523	349	225

B

FIGURE 6.13 **A:** Dalton's law (law of partial pressure): ($P_T = P_1 + P_2 + P_3 \ldots$). The total pressure of a gas is the sum of its component gases. The diagram illustrates that the percentages of air components (oxygen illustrated and represents 21% of air) at different altitudes does not change, although air is less dense at a higher altitude. **B:** The effects of altitude and decreased barometric pressure on oxygen availability. (From Woodward GA, Vernon DD. Aviation physiology in pediatric transport. In: Jaimovich DG, Vidyasagar D, eds. *Pediatric and neonatal transport medicine*. Philadelphia: Hanley and Belfus, Inc., 1995:41, with permission.)

transport, any additional information should be offered by the referral center personnel. One must be especially careful around running (hot) aircraft. The helicopter's tail rotor and plane's propellers are often invisible when turning but capable of inflicting severe damage upon those who venture too close. Loose clothing, medical equipment, and stretcher pads can become entangled in a helicopter's rotors, causing severe damage to the vehicle and to the passengers of the transport. In general, no one should approach an aircraft other than crew and specifically trained personnel. Approach to the aircraft should be done under the direction of the flight crew or designated flight safety personnel.

MEDICAL–LEGAL ISSUES

Patient transport is governed by a variety of federal, state, and local statutes. Transport teams and their members may be sued for malpractice under traditional tort law. Therefore, it is important that all members of the transport team understand applicable regulations and avoid unnecessary medical-legal risk. Timely, legible, and complete documentation is imperative. This includes not only the team members on site, but also the communications personnel and the medical team receiving information or giving advice. This documentation should address any decision points and inconsistencies in standard of delivery of care, including responsiveness, mode of transport, personnel notification, preparation for patient's needs, and any delays that may be anticipated or encountered.

Of all regulations, the EMTALA has the greatest impact on the management of patient transport. Woodward's review of legal issues in transport discusses the impact of EMTALA on the interfacility transport populations. Frew and Williams also offer excellent in-depth publications describing EMTALA. This act places clear duties on both the referring and receiving hospitals. The referring clinicians must do everything possible to stabilize the patient's medical condition before transport and may not transfer a patient against his or her will unless the facility cannot provide the appropriate level of care. Furthermore, the referring physician must obtain informed consent for transfer and, as part of this process, must advise the patient or the parents of a minor about the risks and benefits associated with transfer. Under EMTALA rules, these discussions should not include the financial ramifications of the decision. This aspect of the law is particularly important when the patient is being transferred solely because of a managed care contract. It seems only fair that parents know that a refusal of transfer may leave them responsible for a hospital bill. However, under EMTALA rules, such information, however, well-intentioned, may be construed as financial coercion to enable the transfer. Instead, the patient should be told to contact the representatives of his or her insurer or the hospital financial personnel to discuss these issues. The referring team is also responsible for selecting an appropriate means of transport. Obviously, the more critical the need for medical care and expertise, the more sophisticated the transport capabilities need to be. This is an important point for the referral physician to remember. The desire to transfer a child to a more appropriate medical facility as soon as possible is understandable, but if the method chosen places the child in a medical environment that does not offer at least the level of care at the referral center, that center and physician will be liable for any untoward effects that can be construed as having occurred because of the choice of transport. Finally, EMTALA requires the receiving hospital to accept the patient in transfer if the appropriate type and level of care are available. The ability of the patient to pay for medical care cannot be considered by either the referring or the receiving facility. In addition to the EMTALA, there are often local regulations that direct transport services. For example, some cities have laws designating certain agencies as official providers of prehospital services. Such laws must be considered when offering transport services. It is important to note, however, that guidelines, such as trauma center transfer protocols, do not negate or supersede EMTALA guidelines. Any law that contradicts or conflicts with EMTALA is considered preempted by EMTALA.

The Health Insurance Portability and Accountability Act (HIPAA) of 1996 also impacts the traditional transport system. Limitations are placed on information dispersion that could be potentially linked to a specific patient. Although this should not impact patient information flow between primary providers or the assessment of services by an established CQI system, the generic follow-up letters that many systems used for feedback and as a marketing tool are no longer permitted. Legal advice should be sought on how to replace this time-honored, but now outdated, method of generic communications.

Traditional tort law also applies to the transport team. Most of these issues are no different than those encountered in other health-care venues. However, one potential source of medical-legal risk is unique to the transport team. As stated earlier, the transport team gradually becomes more and more involved in the care of the patient. At first, this involvement is limited to giving advice and management suggestions. It is the referring physician's responsibility to carry out these suggestions as he or she deems appropriate. At this stage in the transport process, transport personnel should try to gain the clearest possible picture of the patient's condition so the most appropriate suggestions may be given. Furthermore, advice may be best prefaced with general phrases such as "Most patients with this condition" or "We often manage this problem by doing." Finally, the transport team should clearly document any advice given, in writing or by audio recording, in case disagreements regarding what advice was given arise later.

The next stage of involvement occurs when the transport team arrives at the referral facility and begins to care for the patient, often along with one or more members of the referring hospital's staff. At this point, the greatest medical-legal risks are conflicts over management and difficulties in determining who gave or carried out medical orders. When management conflicts arise, the medical command physician should be contacted, and he or she should resolve these conflicts by speaking directly with the referring physician. The medical record should clearly reflect who gave and who carried out each order.

Finally, the transport team assumes total responsibility for the care of the patient when they leave the referral center. The team should be assured that the patient is as stable as possible before leaving. If an unstable patient is transported, the team must document why it was in the patient's best interest to undertake transport at that time.

In some cases, transfer agreements exist between hospitals. Typically, such agreements stipulate that the receiving hospital will accept all transfers from the referring hospital. In the past,

transfer agreements served to decrease the time needed to accept the patient by eliminating or shortening the approval process. More recently, transfer agreements have become less important for two reasons. First, the EMTALA places a duty on the receiving hospital to accept the patient as long as there is an appropriate bed location available. Second, for patients who are not critically ill, managed care organizations often stipulate certain facilities. In such cases, the transfer agreement exists between the managed care organization and the receiving hospital. However, the referring hospital must still meet obligations to the patient under the EMTALA.

Finally, if the transport team operates under specific guidelines or protocols, these may become the focus of legal action. Therefore, it is imperative that all guidelines represent the current standard of care. Furthermore, guidelines should be designed to ensure providers do not exceed their scope of practice as defined by state and local regulations. Periodic review of existing protocols and guidelines is warranted. New guidelines should be developed in conjunction with recognized authorities and should be reviewed by risk-management specialists before implementation.

REIMBURSEMENT FOR TRANSPORT SERVICES

As the costs of health care continue to increase, reimbursements to providers and hospitals have largely remained level or decreased. Hospital operating margins have become increasingly narrow, forcing administrators to make difficult programmatic decisions. This situation may increase the need for transport teams to recoup as much of their costs as possible. Unfortunately, in most cases, only services provided by a licensed provider can be billed to third-party payers. In practical terms, this places the burden of documentation and billing upon the shoulders of physicians and licensed nurse practitioners. Teams that do not include these individuals as members will be unable to bill some payers.

There are, in essence, three types of current procedural terminology (CPT) codes that may be used for transport billing:

1. Codes for giving direction or advice to other providers by telephone (e.g., 99373). These codes were originally intended to allow physicians to receive reimbursement for the time spent advising patients by telephone. However, they may also be used when the transport physician is advising personnel at the referring hospital on the management of a patient prior to the arrival of the transport team. The interaction must be documented and, even with documentation, many payers will not reimburse for this service.
2. Codes for directing the transport team by phone or radio (e.g., 99288). This code was originally intended to reimburse physicians for time spent directing the actions of prehospital providers. To be reimbursed, the physician must be in direct communication with the team and must be making the medical decisions. These interactions must also be documented.
3. Codes for the provision of transport services (e.g., 99289, 99291). These codes designate transport services provided by the physician. Currently, codes 99289 and 99290 are intended, respectively, for the initial and subsequent care of patients younger than 2 years of age, whereas 99291 and 99292 are used for children older than 2 years. Critical care physicians will recognize that codes 99291 and 99292 are the same codes that are used for the critical care services. For billing purposes, transport is considered to be critical care and the same rules apply. First, the billing provider must be physically present during the transport. Second, the patient must meet the definition for critical illness. Third, just as in critical care situations, the provider can only bill for procedures that he or she performs personally or that a resident physician performs under his or her direct supervision. To be billed separately from critical care time, the time spent performing the procedure must be deducted from the overall critical care time. For example, a transport physician attending to a neonate spends a total of 80 minutes directly attending to the patient and reviewing records, but 10 minutes of that time was spent placing a thoracostomy tube. Then the physician is able to bill for 70 minutes of critical care time and for the procedure.

In most cases, services and procedures that are "bundled" under traditional critical care codes are also "bundled" under transport codes.

CHAPTER 7 ■ EMERGENCY DEPARTMENT RECOGNITION AND MANAGEMENT OF VICTIMS OF BIOLOGICAL AND CHEMICAL TERRORISM

RICHARD J. SCARFONE, MD, FRED M. HENRETIG, MD, THEODORE J. CIESLAK, MD, JAMES M. MADSEN, MD, MPH FCAP, FACOEM, COL, MC-FS, AND EDWARD M. EITZEN JR., MD, MPH

BACKGROUND—THE THREAT OF BIOLOGICAL AND CHEMICAL TERRORISM

In the aftermath of the release of the nerve agent sarin in the Tokyo subway system in 1995, another 1995 plot to release chlorine gas in California's Disneyland theme park, the events of September 11, 2001, and the intentional spread of anthrax through the U.S. mail, the potential for emergency care providers being confronted with children who are victims of terrorism is greater than ever. Biological and chemical terrorism, in particular, involve the use of highly virulent or toxic agents with the intent to cause mass casualties, an outcome that could overwhelm regional emergency medical services (EMS) capacity and pose unique medical management challenges. Only through comprehensive community planning, research and development, and medical education can this potential catastrophe be mitigated. This chapter discusses the use of biological and chemical weapons as agents of terror, indicates specific pediatric vulnerabilities, offers initial approaches to syndrome recognition for potential victims of such attacks, and highlights the major biological and chemical agents of concern and their management.

BIOLOGICAL AND CHEMICAL WEAPONS

Microbial pathogens, biologic toxins, and highly toxic chemicals have long been considered for use as military weapons. Currently, considerable concern surrounds their possible use on civilian populations, including children, by terrorist groups. These agents are often included in the category "weapons of mass destruction" but are more properly termed *mass-casualty weapons*, because they do not necessarily destroy infrastructure and because of their potential to cause hundreds to thousands of casualties, especially in scenarios involving a large-scale attack via an aerosol release. However, even smaller-scale, technologically primitive incidents can cause considerable morbidity and wreak havoc on regional medical care systems thereby successfully terrorizing a population. Modern examples of the latter include the intentional spread of salmonella on restaurant salad bars in Oregon in 1984; the Tokyo subway sarin attack in 1995 in which perpetrators punctured plastic garbage bags, allowing sarin vapor to escape; and the mail-borne anthrax attacks in the fall of 2001.

The medical consequences and epidemiology of a large-scale attack with these agents would mimic more traditional disasters, but with some distinct differences (Table 7.1). A chemical attack may combine elements of traditional mass disasters of high acuity (e.g., earthquake, bomb explosion, airplane crashes) and hazardous materials incidents (e.g., chemical tank car crash, factory explosion). Casualties in these disasters would occur almost immediately and first responders such as paramedics, police, and fire personnel as well as "first receivers" such as emergency department (ED) physicians and nurses may be disproportionately affected.

The details of the Tokyo sarin attack illustrate many of these features. At about 8:00 a.m., five subway cars were attacked simultaneously. By 8:28 a.m., an ambulatory victim arrived to one area ED a short distance from the affected subway stations. At 8:43 a.m., the first ambulance arrived, and the next hour brought an additional 500 patients, including three in cardiopulmonary arrest. Citywide, 5,510 persons sought emergency medical treatment at more than 200 facilities within a few hours of the attack; about 25% required hospitalization. Of note, most of the victims went to hospitals by taxi, bus, or private vehicles, rather than by formal EMS transport, further compounding the initial chaos. Until the identity of the agent was known, significant efforts at patient decontamination were lacking, resulting in several cases (most mild) of secondary exposure to hospital workers from "off-gassing" from casualties.

A covert (unannounced) biological attack, in contrast, would more likely simulate a natural infectious disease outbreak and present as a public health crisis evolving over a longer period of time. Illness onset would be delayed by variable incubation periods with victims typically presenting some time and distance from the point of exposures. The "first responders" for most exposed children would actually be first receivers such as pediatricians and ED physicians. Of note, the mail-borne anthrax cases in the fall of 2001 had elements of both overt (e.g., the letters opened by Senate office workers) and covert (e.g., postal workers unknowingly exposed and then becoming infected) attacks.

In this context, pediatric ED providers should have a grasp of the fundamental principles of epidemiology and be able to apply these principles in working up an unexpected outbreak

TABLE 7.1

CHARACTERISTICS OF CHEMICAL AND BIOLOGICAL ATTACKS

Chemical weapons attack (differences in comparison to "routine" hazardous materials incidents)	Biological weapons attack (differences in comparison to natural infectious disease epidemics)
Intent to cause mass casualties	Intent to cause mass casualties
More toxic substances	More virulent agents
Initial substance identification delayed	Rare, nonendemic diseases, delayed diagnosis
Greater risk to EMS first responders	Greater risk to physicians and other first receivers
Overwhelming numbers of patients	Overwhelming numbers of patients
Many "worried well"	Many "worried well"
Mass hysteria, panic	Mass hysteria, panic
Discovery of chemical dispersal device	Discovery of biological agent dispersal device
	More compressed time frame of outbreak
	Very high infection rates, morbidity, mortality
	More respiratory forms of disease than in natural forms
	Multiple epidemics at once
	Reduced rate of infection in sheltered persons
	Infected, dying animals

EMS, emergency medical services.
Adapted from Henretig FM, Cieslak TJ, Eitzen EM Jr. Biological and chemical terrorism. *J Pediatr* 2002;141: 311–326.

of unusual illness. Attempts should be made to (i) identify who is affected, (ii) determine possible routes of exposure, (iii) describe clinical findings of the disease, (iv) formulate a case definition, (v) quantify the number of cases, and (vi) calculate the attack rate in an attempt to identify the causative organism. The epidemic can then be described in terms of timing, place, routes of exposure, and other clinical characteristics of ill patients. Thus, pediatric ED providers can play a pivotal role on the "front lines" of our nation's public health infrastructure in our defense against both terrorism-induced and naturally occurring diseases. In some systems, real time ED visit data is captured by syndromic surveillance engines, alerting monitoring organizations (i.e. CDC) and thus potentially identifying an epidemic early in the course.

SPECIFIC PEDIATRIC CONCERNS

Several physiologic, developmental, and psychological considerations are unique to the pediatric population in the context of planning for biological and chemical terrorism. In addition, there are specific vulnerabilities within our EMS system as it responds to critically ill children that might well be exacerbated by such an incident. These challenges and some potential remedies are highlighted in Table 7.2.

Pediatricians may experience unique problems in managing childhood victims of biological or chemical terrorism. For example, many of the drugs useful in treating such casualties are unfamiliar to pediatricians or have relative contraindications in childhood. To date, there have been no formal consensus guidelines authored or endorsed by authoritative pediatric societies that specifically address the treatment of pediatric victims. The recommendations offered herein, therefore, represent the authors' best interpretation of current pediatric infectious disease and toxicology experience as extrapolated to this context.

BIOLOGICAL AGENTS

A working group convened by the Centers for Disease Control and Prevention (CDC) has identified anthrax, smallpox, plague, botulinum toxin, tularemia, and the viral hemorrhagic fevers as the biological diseases that would constitute the gravest threats to public health and security; the causative microorganisms are termed Category A agents. We thus limit our focus here to these six agents (Table 7.3). In addition, we add a brief discussion of the phytotoxin (plant toxin) ricin because of its ready availability and ease of production. Treatment protocols for these uncommon conditions are likely to evolve continuously, particularly if future incidents occur, as was the case when the mail-borne anthrax outbreak unfolded. The CDC offers a telephone hotline and a website for up-to-date management advice (Table 7.3).

Of note, the fluoroquinolones and/or tetracyclines are currently considered drugs of choice in the treatment and prophylaxis of anthrax, plague, and tularemia. Although these have been little used by pediatricians in the past, there is now considerable recent experience with the use of these antibiotics for selected serious pediatric infections. Furthermore, the risk of morbidity and mortality from these biological agent-induced diseases far outweighs the putative minor risks (arthropathy with fluoroquinolones, dental staining with tetracyclines) associated with short-term pediatric use of these medications. In fact, ciprofloxacin and doxycycline appear to be relatively free of these adverse effects, and more recently became U.S. Food and Drug Administration approved medications specifically for use in children for the prophylaxis and treatment of anthrax following inhalational exposure (i.e., in the context of terrorism).

Specialized laboratory services would likely be required to rapidly identify these agents or confirm a diagnosis of disease

TABLE 7.2

PEDIATRIC VULNERABILITIES TO BIOLOGICAL AND CHEMICAL TERRORISM

Realm	Potential vulnerability	Potential response
Physiologic	Increased respiratory exposure (higher minute ventilation, live "closer to the ground")	Early warning, sheltering[a] (gas masks for the general population are not advised at present due to risk of poor fit, suffocation)
	Increased dermal exposure (thinner, more permeable skin; larger body surface area/mass ratio)	Protective clothing, earlier decontamination[a]
	Increased risk of dehydration, shock with toxin-induced vomiting, diarrhea (decreased fluid reserves, larger body surface area/mass ratio)	Recognition, aggressive fluid therapy
	Increased risk of hypothermia during decontamination (larger body surface area/mass ratio)	Warm-water decontamination
	More fulminant disease (possible), immunologic immaturity, more permeable blood–brain barrier	Pediatric-specific research for early diagnosis and treatment of biological- and chemical-weapons victims[a]
	Differing disease manifestations	Education
	Relative antibiotic contraindications	Research trials in children
Developmental	Less capacity to escape attack site, take appropriate evasive actions (developmental immaturity, normal dependence on adult caregivers who might be injured or dead) or be reunited with families	Increased public education, especially of parents, teachers, and caregivers
Psychological	Less effective coping skill of children who suffer injury or witness parental, sibling death (psychological immaturity)	Child psychiatry involvement, cognitive therapy, research for preventing pediatric posttraumatic stress disorder[a]
	Greater anxiety over reported incidents, hoaxes, media coverage, etc.	Pediatric counseling of parents and children[b]
EMS	Less capacity to cope with influx of critical pediatric patients, loss of routine hospital transfer protocols, limited ability to expand pediatric hospital bed capacity through NDMS	Community and regional planning with significant pediatric input

EMS, emergency medical services; NDMS, national disaster medical system.
[a]Plausible, but unproven or unstudied, and/or not intuitively obvious.
[b]See Chapters 20, 129, and 131.

caused by them. Further, work with most of these agents is very hazardous. As such, a national Laboratory Response Network (LRN) has been established to facilitate the timely detection of bioterrorism-related diseases. This network involves laboratories at local, state, and federal levels. The latter include the CDC in Atlanta, Georgia, and the U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID) at Fort Detrick in Frederick, Maryland. If pediatric emergency care providers suspect such an illness, they should immediately inform their hospital microbiology laboratory and infection control office, as well as the local public health departments, to effect prompt notification and transport of specimens to the appropriate laboratory. In addition, the CDC and USAMRIID may be contacted directly (Table 7.3).

Early Recognition of a Covert Biological Attack

Pediatricians and ED physicians face seriously ill and injured children in their practices every day, but rarely encounter children who are victims of biological agent exposure. Considering three critical epidemiological characteristics of such an attack might enhance early recognition: an *epidemic* number of patients, a common *exposure* history, and *exotic* disease presentations. A large number of patients, out of proportion to time of year and expected clinical syndromes, might trigger suspicion. Although some variations in the incubation period may occur after a biological agent attack, most persons would initially be exposed at the same time, and thus become ill and present in a relatively compressed time frame. In contrast, most natural epidemics evolve with a gradual rise in disease incidence because persons are progressively exposed to increased numbers of infectious patients, fomites, or vectors that spread the organism.

A history of geographic connection among patients, or some observation of an unusual source of exposure, such as a powder in an envelope, might also sound the alarm. By exotic diseases, it is suggested that many infections caused by biological weapons, particularly with advanced disease, are relatively unusual and unique. Diseases that are rare, not endemic in the area of exposure, or that are normally spread by vectors that are not indigenous to the relevant geographic area would also be suspect, especially if numerous cases developed simultaneously.

Additional clues to a biological agent attack might include especially high infection rates among exposed persons, high rates of patients with atypical pneumonia, particularly high

TABLE 7.3

PRIMARY THREAT BIOLOGICAL AGENTS OF TERRORISM

Syndrome	Clinical presentation	Incubation period	Transmission and precautions	Diagnosis	Treatment	Prophylaxis
Acute respiratory distress with fever	*Inhalational Anthrax*—Abrupt onset of fever, chest pain, respiratory distress; mediastinitis; progression to shock and death within 24–36 h	1–5 days (may be weeks)	Person-to-person transmission: None Standard Precautions	Chest x-ray: widened mediastinum, hemorrhagic pleural effusion Isolation of *B. anthracis* from affected tissue (usually blood, nasal secretions, or pleural fluid)	Ciprofloxacin [a,b] 15 mg/kg q 12 h, or Doxycycline[c] ■ **If >8 yr and >45 kg:** give 200 mg loading dose, then 100 mg q 12 h; ■ **If >8 yr and ≤45 kg:** give 4.4 mg/kg loading dose then 2.2–4.4 mg/kg/day in 2 divided doses; ■ **If ≤8 yr:** same as >8 yr and ≤45 kg, **Therapy if strain is susceptible:** Penicillin G[d] 400,000 units/kg/day in divided doses (if susceptible) Treat for 60 days	Ciprofloxacin 15–20 mg/kg PO q 12 h (not to exceed 1 gm/day), or doxycycline ■ **>8 yr and >45 kg:** give 200 mg loading dose, the 100 mg q 12 h; ■ **>8 yr and ≤45 kg:** give 4.4 mg/kg loading dose then 2.2–4.4 mg/kg/day in 2 divided doses; ■ **≤8 yr:** same as >8 yr and ≤45 kg, **Therapy if strain is susceptible:** Amoxicillin ■ If ≥20 kg: give 500 mg PO q 8 h; or If <20 kg: give 40 mg/kg divided into 3 doses to be taken q 8 h Prophylaxis for 60 days
	Pneumonic Plague—Apparent severe community-acquired pneumonia; hemoptysis, cyanosis, gastrointestinal symptoms, septic shock	2–3 days	Person-to-person transmission: YES Droplet precautions	Gram-negative bacilli/coccobacilli in sputum, blood or lymph node; safety-pin appearance with Wright or Giemsa stain. Confirmation with isolation of *Y. pestis* from blood or sputum	<u>Preferred Therapy</u> Gentamicin 2.5 mg/kg IM or IV 3 times daily[e] <u>Alternative Choices</u> Doxycycline ≥45 kg give adult dose <45 kg give 2.2 mg/kg IV 2 times daily (Maximum 200 mg daily) Ciprofloxacin 15 mg/kg 2 times daily[f] Chloramphenicol 15 mg/kg IV 4 times daily[g]	Doxycycline[b] If ≥45 kg give adult oral dose If <45 kg give 2.2 mg/kg orally 2 times daily or Ciprofloxacin 20 mg/kg orally 2 times daily[d] Prophylaxis for 10 days
	Ricin (aerosolized)—Acute onset of fever, chest pain, and cough, progressing to respiratory distress and hypoxemia; not improved with antibiotics; death in 36–72 h	Symptomatic within hours	Person-to-person transmission: None Standard precautions	Isolation of toxin from respiratory secretions or serum	Supportive therapy	Supportive therapy

	Tularemia (pneumonic)—Abrupt onset fever, fulminant pneumonia	2–10 days	Person to person transmission: None Standard precautions	Chest x-ray: infiltrate, hilar adenopathy, effusion. Small, faintly staining, slow-growing, gram-negative coccobacillus in sputum or blood.	**Preferred Therapy** Gentamicin 2.5 mg/kg IM or IV 3 times daily[e] **Alternative Choices** Doxycycline = 45 kg give adult dose <45 kg give 2.2 mg/kg IV 2 times daily (Maximum 200 mg daily) Ciprofloxacin 15 mg/kg 2 times daily[f] Chloramphenicol 15 mg/kg IV 4 times daily[g]	**Preferred Choices** Doxycycline[b] If ≥45 kg give adult oral dose If <45 kg give 2.2 mg/kg orally 2 times daily or Ciprofloxacin 20 mg/kg orally 2 times daily[d]
Acute rash with fever	*Cutaneous anthrax*—Papule progressing to vesicle, to ulcer, then to depressed black eschar, with marked edema. May not be associated with fever.	1–10 days	Person to person transmission: YES Contact precautions	Isolation of *B. anthracis* from affected tissue	As with inhalation anthrax	Not recommended
	Plague (bubonic)—Tender, enlarged, fluctuant lymph node in the distribution of the infected flea bite; fever and malaise; progresses to DIC, sepsis	4–7 days	Person to person transmission: None Standard Precautions	Confirmation with isolation of *Y. pestis* from blood or bubo aspirate	If signs/symptoms of sepsis, treat as with pneumonic plague	Not recommended
	Smallpox—Macules and papular evolve to pustules and scabs; fever; headache; delirium; rash is synchronous and is more prominent on the extremities	7–17 days	Person to person transmission: YES Airborne precautions	Clinical diagnosis with laboratory confirmation	Supportive therapy	Smallpox vaccine within 96 h of exposure

(continued)

TABLE 7.3

PRIMARY THREAT BIOLOGICAL AGENTS OF TERRORISM (CONTINUED)

Syndrome	Clinical presentation	Incubation period	Transmission and precautions	Diagnosis	Treatment	Prophylaxis
	Viral hemorrhagic fever (e.g. Ebola)—Fever with mucous membrane bleeding, petechiae, thrombocytopenia, hypotension	7–42 days (virus-specific)	Person to person transmission: YES Airborne precautions	Clinical diagnosis with laboratory confirmation	Supportive therapy	Supportive therapy
Neurologic syndromes	*Botulism*—Acute bilateral descending flaccid paralysis beginning with cranial nerve palsies	1–3 days	Person to person transmission: None Standard precautions	Clinical diagnosis with confirmation after toxin isolation	Supportive therapy; an antitoxin may prevent disease progression	Supportive therapy

[a]Therapy with ciprofloxacin may be initiated either as IV (preferred method) or oral dosage. The pharmacokinetics are such that oral ciprofloxacin is rapidly absorbed in the GI tract with no substantial loss by first-pass metabolism. Maximum serum concentrations are attained 1–2 h after oral dosing.
[b]Ciprofloxacin dose should not exceed 1 g/day in children.
[c]In 1991 the American Academy of Pediatrics amended their recommendation to allow treatment of young children with tetracyclines for serious infections such as Rocky Mountain spotted fever for which doxycycline may be indicated. Doxycycline is preferred for its twice-a-day dosing and low incidence of GI side effects.
[d]If laboratory testing reveals isolate is penicillin-susceptible, therapy should be changed to IV penicillin.
[e]Other fluoroquinolones can be substituted at doses appropriate for age. Ciprofloxacin dosage should not exceed 1 g daily in children.
[f]Concentration should be maintained between 5 and 20 μg/mL. Concentrations greater than 25 μg/mL can cause reversible bone marrow suppression. Children younger than 2 yr should not receive chloramphenicol.
[g]In children, ciprofloxacin does should not exceed 1 g daily, chloramphenicol should not exceed 4 g daily. Children younger than 2 yr should not receive chloramphenicol. In neonates, gentamicin-loading dose of 4 mg/kg should be given initially.
[h]Tetracycline may be substituted for doxycycline.

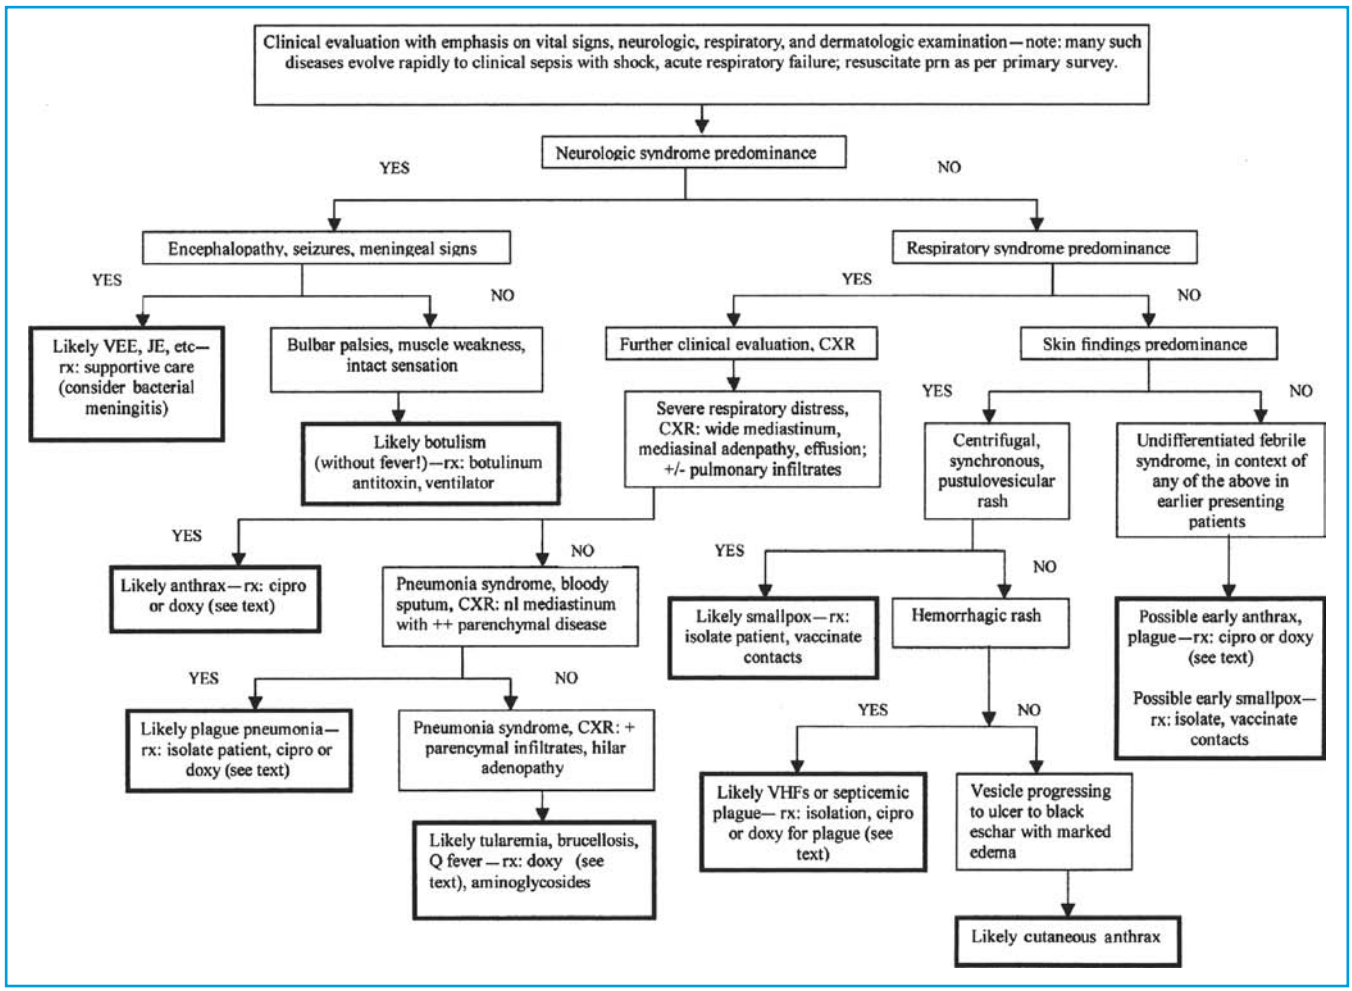

FIGURE 7.1 Approach to the early recognition and diagnosis of an attack with an unknown biological agent. VEE, venezuelan equine encephalitis; JE, Japanese encephalitis; rx, treatment; CXR, chest x-ray; VHF, viral hemorrhagic fever. (From Henretig FM, Cieslak TJ, Kortepeter MG, et al. Medical management of the suspected victim of bioterrorism: an algorithmic approach to the undifferentiated patient. *Emerg Med Clin North Am* 2002;20:351–364, with permission from Elsevier.)

morbidity or mortality, several epidemics at once, attack rates lower in persons sheltered from the suspected route of exposure, presence of infected or dying animals, and the discovery of suspicious actions or potential delivery systems.

Most of the primary biological threat agents can be categorized as causing the subacute onset of effects (e.g., days after exposure) and further divided into predominantly respiratory, neurologic, or dermatologic syndromes. Thus, with a careful medical and epidemiological history, physical examination, and limited, routine laboratory evaluation, an early suspicion of a biological attack might be raised, and initial diagnostic impression considered, as outlined in Figure 7.1. This in turn could trigger appropriate requests for infectious disease consultation and more definitive laboratory testing, as well as early empiric therapy. A similar approach, applied universally with unusual increases in patient volume or illness presentations, might also help practitioners to participate in the early recognition of a new or reemerging natural infectious disease (e.g., West Nile disease or severe acute respiratory syndrome, to name more recent examples). If a pediatrician recognizes, or even suspects, any such natural or intentional outbreak, immediate reporting to local and regional public health authorities is appropriate, even before a specific diagnosis can be confirmed.

Minimizing Spread of Infection

As soon as ED staff suspect that a patient may be the victim of biological terrorism, appropriate steps must take place to prevent or minimize exposure to limit the spread of disease. The level of ED mitigation and preparedness activities will largely depend on the level of awareness of the disease outbreak. For example, if society were faced with a known release of smallpox by terrorists, EDs would need to take dramatic steps to protect staff and patients. Such steps might include setting up screening stations outside of the hospital, staffed by clinicians wearing gowns, gloves, N-95 respirators, and eye protection. If a child suspected to have smallpox were encountered at the screening station, he or she would need to be covered with a sheet, provided a mask, and escorted directly to a negative-

pressure room for further evaluation and treatment. Infection Prevention and Control specialists would need to provide guidance on specimen collection, handling, and testing. Patients suspected to have smallpox would need to be cohorted into specific units of the hospital, or in dedicated facilities.

At the opposite end of the spectrum, would be the inadvertent discovery of a patient suspected to have an infectious disease. Perhaps an ED triage nurse discovers that within a short period of time two separate children arrive with complaints of floppiness and weakness, raising the concern for botulism. Perhaps a pediatric resident becomes concerned about a viral hemorrhagic fever after encountering a highly febrile and ill-appearing child with a purpuric rash who recently traveled to Africa. Although not all of the Category A biological agents are spread from person to person (see Table 7.3), in these cases it would be prudent to assume this mode of spread. The staff member, after washing his hands, should put on a gown, gloves, an N-95 respirator, and eye protection. The child should be covered with a sheet, provided a mask, and escorted directly to a negative-pressure room for further evaluation and treatment.

THE SPECIFIC AGENTS

Anthrax

Background

Anthrax is caused by infection with *Bacillus anthracis*, a gram-positive spore-forming rod capable of surviving long periods in its spore form without nutrients or moisture. Natural disease caused by *B. anthracis* exhibits cutaneous, gastrointestinal (GI), and inhalational forms. Anthrax spores can be formulated in a manner to enhance aerosolization. The resulting small particles may drift long distances with air currents, produce lethal infection when inhaled, and resist environmental degradation, making them a formidable terrorist weapon.

The anthrax attack of 2001 was characterized by 22 confirmed or suspect cases (11 inhalational, 11 cutaneous), with five deaths, resulting from presumed or known exposure to anthrax-contaminated mail. The attack resulted in enormous public anxiety, as well as major demands for medical care and public health resources. Antibiotic prophylaxis was prescribed for more than 30,000 persons, and decontamination of the Hart Senate Office Building alone took months and cost an estimated $23 million. Many bioterrorism defense experts, however, fear an even more widespread aerosol release (e.g., from a small cropduster-type airplane) that could potentially sicken hundreds of thousands.

Inhalational anthrax is the disease form that poses the greatest threat. Following the accidental release of anthrax spores from a Soviet military facility at Sverdlovsk in 1979, 66 of 77 known victims of inhalational anthrax died. In the recent U.S. attack, all five deaths were among the 11 patients with this form of disease.

Pathophysiology/Common Manifestations

Inhalational anthrax results from spore uptake in the alveoli by pulmonary macrophages, followed by bacterial germination and toxin production in the mediastinal lymph nodes, leading to hemorrhagic lymphadenitis, mediastinitis, and sepsis. Symptoms typically begin 1 to 5 days after exposure, although incubation periods up to several weeks in length have been reported. The disease begins as a nonspecific febrile illness, characterized by fever, headache, myalgia, and cough. The relative lack of eye, nose, and throat findings such as red, watery eyes, rhinorrhea, or sore throat with pharyngeal injection or exudate helps to distinguish this phase from common viral infections, such as those due to rhinovirus. A brief intervening period of improvement sometimes follows, but rapid deterioration then ensues with high fever, dyspnea, cyanosis, and shock marking this second phase. Hemorrhagic meningitis occurs in up to 50% of cases. Chest radiographs or computed tomography scans may reveal a widened mediastinum or prominent mediastinal lymphadenopathy; infiltrates and pleural effusions may also be seen. Gram stains of peripheral blood smears may demonstrate the bacterium at this stage. Prompt treatment is imperative because historically death occurred in as many as 95% of inhalational anthrax cases if such treatment began more than 48 hours after symptom onset. Even with modern intensive care, in the 2001 anthrax attack, all four patients with inhalational anthrax who exhibited signs of fulminant disease prior to antibiotic administration died. Thus, in the context of a known bioterrorism incident, a potential dilemma facing emergency care providers is deciding which patients who may have been exposed to anthrax and are now presenting with nonspecific flulike, febrile illness are optimal candidates for empiric antibiotic therapy.

Cutaneous anthrax occurs when organisms gain entry into skin, particularly through abrasions or cuts. It is characterized by the appearance of a papule at the inoculum site, which then progresses over days to a vesicle, then to an ulcer, and finally to a depressed, black eschar. The surrounding tissue becomes markedly edematous, but not particularly tender, distinguishing this infection from typical cellulitis. It is, however, quite amenable to therapy with a variety of antibiotics, and, with timely institution of treatment, is rarely fatal. In the 2001 outbreak, all 11 patients with cutaneous anthrax survived. The one pediatric victim of the 2001 attack was a 7-month-old boy with cutaneous anthrax on his arm, presumably contracted after a brief visit to a New York City television news studio that had received contaminated mail (a similar lesion is pictured on the face of a child in Fig. 7.2 [see also color plate]). He was suspected initially of having a brown recluse spider bite, and the correct diagnosis was only confirmed after the discovery of anthrax contamination at another television studio. Of note, he also developed evidence of hemolysis, thrombocytopenia, and renal insufficiency, features not usually observed in otherwise uncomplicated cases of cutaneous disease, thus raising the possibility of a particular vulnerability in infancy.

The finding of gram-positive rods in skin biopsy material (in the case of cutaneous disease) or in blood smears, pleural fluid, or spinal fluid should suggest anthrax. Chest radiographs demonstrating a widened mediastinum in the context of fever and constitutional signs should also lead one to consider the diagnosis. Confirmation may be obtained by blood culture. State health laboratories, USAMRIID, and the CDC can also confirm a diagnosis of anthrax by polymerase chain reaction and immunohistochemical assay.

FIGURE 7.2 Cutaneous anthrax on the eyelids of a young child. (Courtesy of Dr. Larry Schwab. From Ostler HB, Maibach HI, Hoke AW, et al. *Diseases of the eye and skin: a color atlas*. Philadelphia: Lippincott Williams Wilkins, 2004, with permission.)

Management

As anthrax has little potential for person-to-person transmission, standard precautions (Table 7.3) are adequate for healthcare workers caring for anthrax victims. Given the usual 1- to 5-day incubation period, decontamination of victims presenting days after exposure is unwarranted. Reaerosolization of organisms from skin or clothing likewise poses little threat under typical circumstances, but bathing and laundry with soap and water would seem prudent soon after direct physical contact with a suspect substance.

Although naturally occurring strains of *B. anthracis* are usually quite sensitive to penicillin G, penicillin-resistant strains of *B. anthracis* are known; thus, many experts consider ciprofloxacin [10 to 15 mg per kg, max 400 mg, IV (intravenous) q12h] or doxycycline (2.2 mg per kg, max 100 mg, IV q12h) as essential components of first-line treatment for victims of intentional anthrax. Infectious Disease and Emergency Preparedness experts can provide advice regarding postexposure prophylaxis. See Table 7.3 for detailed treatment recommendations for children. Newer treatments under development include the use of monoclonal antibodies and anthrax immune globulin; these are not currently available nor have they been tested for use in children.

Plague

Background

Plague, caused by infection with the gram-negative bipolar-staining rod *Yersinia pestis*, is usually transmitted in nature via the bite of fleas. Endemic disease is still seen in areas of the southwestern U.S., South and Southeast Asia, as well as in South America and Africa. Plague has long appeared attractive as an agent of bioterrorism. Testimony to its extreme lethality and infectivity can be obtained by considering that the "Black Death" eliminated one-third of the population of Europe during the Middle Ages.

Pathophysiology

Y. pestis is a facultative intracellular pathogen that is able to survive temporarily within macrophages, thus aiding its dissemination to distant sites following inoculation or inhalation. It is lymphotropic, and significantly tender regional lymphadenopathy (e.g., in the distribution of a flea bite) is often a prominent feature of bubonic plague. Pneumonic plague (along with smallpox) is one of the few bioterrorist threats readily transmissible from person to person via the respiratory route, and coughing patients are often highly contagious. However, because plague, unlike smallpox, is spread by large respiratory droplets, close contact is needed for transmission.

Clinical Manifestations

Bubonic plague is characterized by the classic bubo, a tender, enlarged, fluctuant lymph node in the distribution of the infected flea bite. Fever and malaise are usually present. Bubonic plague may progress to septicemia as bacteria gain access to the circulation; 80% of bubonic plague victims have positive blood cultures. Petechiae, purpura, and overwhelming disseminated intravascular coagulation (DIC) may develop.

Pneumonic plague may arise secondarily after blood-borne seeding of the lungs or may be seen primarily after aerosol exposure. Symptoms include high fever, chills, malaise, fatigue, headache, and cough. Chest radiographs may reveal a patchy or consolidated broncho-pneumonia, and the classic clinical finding is one of blood-streaked sputum; DIC and an overwhelming sepsis may develop as the disease progresses. Meningitis develops in 6% of cases. Untreated pneumonic plague has a mortality rate approaching 100%.

A presumptive diagnosis of plague can be made by observing the classic bipolar-staining "safety pin"–like rods in Gram or Wayson stains of sputum, aspirated lymph node material, or cerebrospinal fluid. Confirmation is obtained via blood, sputum, or aspirate culture. The organism grows on standard blood or MacConkey's agars but is often misidentified by automated systems.

Management

Droplet precautions should be employed in cases of suspected pneumonic plague. Such precautions should be continued in confirmed cases until sputum cultures are negative. Standard precautions are adequate in managing bubonic plague victims. Given the incubation period, decontamination would not be necessary in a clinical setting. A previously licensed plague vaccine is currently out of production. This vaccine was developed to prevent bubonic plague in endemic regions, and animal data suggest that it is unlikely to protect against the pneumonic form of the disease. See Table 7.3 for detailed treatment recommendations for children.

Smallpox

Background

The global eradication of smallpox represents one of the great success stories of public health, with the last endemic case occurring in Somalia in 1977. Since then, research stockpiles of variola virus have been consolidated into two World Health Organization (WHO)—approved stores—at the CDC in Atlanta

and at a Russian institute in Koltsovo, near Novosibirsk. This achievement would seem to make terrorist use of this virus impossible; however, several factors give cause for concern. First is the fear that other stockpiles already exist in the hands of belligerent nations unbeknownst to WHO. Second, the entire viral genomic sequence is known and published; therefore, it is likely only a matter of time before technology permits reconstruction of the virus. Finally, although the virulence factors of variola virus are poorly understood, it may be possible for someone to manipulate related orthopoxviruses such as monkeypox to enhance their virulence in humans and create a disease similar to smallpox. In light of these considerations, the CDC in 2003 recommended a strategy of reintroducing vaccination in the United States after a nearly 30-year hiatus, with the initial goal of vaccinating up to 10,000,000 front-line EMS and health-care providers. This program has subsequently proven controversial and has been suspended in light of cardiac toxicities not described previously; probably fewer than 50,000 civilians were vaccinated. The U.S. military, however, has vaccinated several hundred thousand personnel in recent years very successfully and serious adverse events have been rare.

Several factors might make smallpox an attractive weapon to potential belligerents. First, the duration of immunity after vaccination is a matter of some controversy, with some studies suggesting a duration of only 3 to 5 years while other studies suggest the possibility of lifelong immunity. Second, until the recent licensing of a new product (ACAM2000, Acambis Corporation), vaccine had long been out of production, and stockpiles of vaccinia vaccine were dwindling and losing potency; susceptibility to the disease has thus become nearly universal. Also, effective therapy is lacking and health-care providers are unfamiliar with the disease. Finally, the potential for rapid spread potentially permits a terrorist to cause widespread disease and panic with a minimum of infectious material.

Pathophysiology

Although infectivity is highest when the smallpox rash first appears, the disease may be spread by exposed persons about 24 hours before the exanthem appears. During the 7- to 17-day-long incubation period, the virus replicates in upper respiratory tract mucosa, giving rise to a primary viremia. The liver and spleen are then seeded, further amplification of the virus occurs, and a secondary viremia ultimately develops. The skin is seeded with this secondary viremia, and the classic exanthem of smallpox develops.

Clinical Manifestations

Clinical illness begins rather abruptly during the phase of secondary viremia and is characterized by fever, malaise, rigors, vomiting, headache, and backache. The classic exanthem typically begins 2 to 4 days later as macules on the face and extremities. These lesions progress in synchronous fashion to papules, then to pustules, and finally form scabs. As scabs separate, survivors are left with disfiguring depigmented scars. The rash spreads centrally to the trunk but remains more abundant at the periphery. This centrifugal distribution and synchrony distinguish smallpox from the principal differential diagnostic consideration, chickenpox, which has a centripetal distribution of lesions in varying stages of development (Fig. 7.3). An enanthem usually accompanies the characteristic exanthem, and internal organs become viral targets as well.

FIGURE 7.3 A child with smallpox. (From Henretig FM, McKee MR. Preparedness for acts of nuclear, biological and chemical terrorism. In: Gausche-Hill M, Fuchs S, Yamamoto L, eds. *APLS: the pediatric emergency medicine resource*. American Academy of Pediatrics and American College of Emergency Physicians. Sudbury, MA: Jones and Bartlett, 2004:568–591, with permission.)

Death occurs in 30% of variola major (the predominant form of smallpox in the past) patients and typically results from hypotension and immune complex–associated toxemia, as well as visceral organ involvement. Eye involvement leads to blindness in a small number of victims. Uncommon variants with lesser (variola minor) or greater (hemorrhagic and flat-type variants) mortality also existed.

Management

The diagnosis of smallpox should be suspected on clinical grounds. Laboratory confirmation (e.g., cultures, electron microscopy, polymerase chain reaction) is probably best effected by emergent notification and specimen of pustule fluid transported to the CDC or local health department.

Based on past experience, vaccination (with vaccinia, an orthopoxvirus closely related to variola) of smallpox-exposed persons within the first 4 days after exposure may prevent the development of overt disease. Although the vaccine has been used safely and successfully in even young infants, it has a relatively high rate of serious complications in certain patients. Notably, fetal vaccinia and resultant fetal demise can occur when pregnant women are vaccinated. Vaccinia gangrenosa, a frequently fatal complication, occurred when immunocompromised persons were inadvertently vaccinated. Eczema vaccinatum may occur in those with preexisting skin conditions and can be serious. Myocarditis and pericarditis may occur. A severe postvaccinial encephalitis was well-known albeit relatively rare during the era of widespread vaccination; because this complication occurs only in primary vaccines, it would disproportionately affect pediatric patients. Autoinoculation can occur when virus from the primary lesion arising at the site of vaccination is transferred by scratching to eye or other areas of the skin. Young children would likely be at greater risk for such inadvertent transmission, although this might be mitigated by the use of folded gauze and a semipermeable adhesive membrane (not a water-tight dressing) to cover vaccination sites. To manage these complications, vaccinia immune globulin (VIG)

should be available when undertaking a vaccination campaign. VIG [0.6 mg per kg intramuscularly (IM)] may be given to vaccine recipients who experience severe complications or to significantly immunocompromised individuals exposed to smallpox in whom vaccination would be unsafe. Today, stocks of vaccine and VIG are controlled by the CDC. Even a single case of smallpox occurring anywhere in the world today would represent a grave public health emergency. A suspected case should thus prompt immediate notification and consultation with health authorities. Strict airborne, droplet, and contact precautions should be instituted immediately for victims and should continue until all scabs have separated. Decontamination of symptomatic patients is unnecessary. Contacts must be observed closely for 17 days following their last potential exposure. The development of fever during this period would be cause for isolation. Multiple victims would ideally be managed as a cohort at dedicated sites removed from conventional hospital facilities.

Botulism

Background

Botulism occurs as a result of exposure to one of seven botulinum neurotoxins (A through G). Only types A, B, E, and rarely, F appear to cause human botulism in nature. Botulinum toxin was included in the U.S. biological arsenal in the 1950s and 1960s, and was weaponized by Iraq in the 1980s. The Aum Shinrikyo cult in Japan tried unsuccessfully to disseminate botulinum toxin before deciding to release sarin in the Tokyo subway system.

Pathophysiology

Botulinum toxins are produced by certain strains of *Clostridium botulinum*, a strictly anaerobic spore-forming gram-positive rod commonly found in soil. In addition, a few cases of type F neonatal botulism have been described; in these cases, *Clostridium baratii* was believed to be the source of toxin. Most cases of natural botulism result from ingestion of preformed toxin (food poisoning) or intestinal toxin formation (infant form). Infant botulism has additional unique epidemiologic considerations; more extensive discussion of this form, and of botulism in general, may be found elsewhere in this text (see Chapters 92 and 96). The botulinum neurotoxins are the most toxic substances known to man, with an LD_{50} (for type A toxin) of 0.001 mcg per kg. These toxins function at the peripheral cholinergic presynaptic nerve terminals, principally the neuromuscular junction, by preventing the release of acetylcholine and thereby leading to a generalized flaccid paralysis and autonomic symptoms. In keeping with the fact that toxins are chemical poisons produced by biological organisms, it is important to keep in mind that most cases of terrorist-caused botulism will represent chemical intoxication rather than a disease caused by colonization and infection of tissues by replicating *C. botulinum* organisms.

Clinical Manifestations

Following a latent period ranging from 24 hours to several days, victims begin to experience cranial nerve dysfunction, manifesting as bulbar palsy, ptosis, photophobia, and blurred vision owing to difficulty in accommodation. Symptoms progress to include dysarthria, dysphonia, and dysphagia. Ultimately, a descending, symmetric, flaccid paralysis ensues, although sensorium and sensation are not affected primarily. The mucous membranes are dry; this fact, along with mydriasis, the nature of the paralysis (lack of initial fasciculations), and the latent period, all differentiate botulism from nerve agent intoxication. A solitary case of botulism must also be differentiated from myasthenia gravis, Guillain-Barré syndrome, tick paralysis, and a few other uncommon neurologic disorders. The presence of multiple casualties with similar symptoms should raise the concern for botulism.

Management

Supportive care, with meticulous attention to ventilatory support, remains the mainstay of botulism management. Patients may require such support for several months, making the management of a large-scale botulism outbreak especially problematic in terms of medical resources. Diagnosis of botulism is made through identifying toxin in serum, stool, gastric aspirate, or contaminated food. Infant botulism is best detected through stool culture. These methods may be time consuming. Use of nerve conduction studies may lend support to the clinical diagnosis and antitoxin administration should not wait for final culture results.

A bivalent (types A and B) botulinum antitoxin is licensed and available through the CDC. A separate investigational anti-E preparation is similarly available after consultation with CDC experts. Although administration of antitoxin is unlikely to reverse disease (the antitoxin is most effective when given during the clinically asymptomatic, or latent, period following inhalation of the toxin), it may be useful in preventing progression when administered to exposed persons. The antitoxin is prepared from horse serum and requires that a test dose be administered before therapy; patients reacting to this test dose require desensitization prior to treatment.

In addition, an investigational heptavalent despeciated (Fab2) antitoxin, also produced in horses, is now available in the Strategic National Stockpile through the CDC. Finally, a licensed human botulinum immunoglobulin is available to treat infant botulism (see also Chapters 96 and 102). While the product (BabyBIG) contains antibody against botulinum toxin types A–E, it has only been studied, and is thus only licensed, to treat type A and B intoxication. Botulism is not contagious, and standard precautions are adequate for patient care.

Tularemia

Tularemia is a highly infectious plaguelike disease caused by the gram-negative coccobacillus *Francisella tularensis*. Several clinical forms of naturally occurring tularemia are known, but pneumonic tularemia would presumably be the most likely clinical presentation in the event of an intentional bioaerosol release of *F. tularensis*. The onset of symptoms may be abrupt and include fever, nonproductive cough, substernal tightness, pleuritic chest pain, occasional hemoptysis, chills, headache, malaise, anorexia, and fatigue. Chest radiographs may show infiltrates, hilar adenopathy, pleural effusion, or miliary infiltrates (may mimic tuberculosis).

Tularemia is not contagious, and standard precautions are adequate in patient care. However, processing cultures is a very significant risk to laboratory staff, who thus must be notified of a suspected case. See Table 7.3 for detailed treatment recommendations for children.

Viral Hemorrhagic Fevers

The viral hemorrhagic fevers are a heterogeneous group of illnesses caused by infection with lipid-enveloped RNA viruses belonging to the families *Arenaviridae*, *Bunyaviridae*, *Filoviridae*, and *Flaviviridae*. These viruses may cause fulminant illnesses with fever, hypotension, and bleeding diathesis. The capacity for human-to-human transmission and high lethality makes the filoviruses (e.g., Ebola and Marburg viruses) and arenaviruses (e.g., Lassa Fever virus) particularly concerning. Supportive care remains the cornerstone of therapy for most of the viral hemorrhagic fevers. IV ribavirin appears somewhat efficacious in treating disease due to the *Arenaviridae*.

Ricin

The distinction between biological agents, which are living organisms capable of causing infections, and chemical agents, which are nonliving poisons, is obvious. Toxins, such as ricin, however, are chemical poisons produced by biological organisms and are increasingly seen as "midspectrum agents." Although discussed with biological agents, it should be kept in mind that they cause chemical intoxication (poisoning) rather than infections, do not replicate in hosts, and do not produce communicable, or contagious, conditions.

Ricin is a toxin derived from the castor bean, and its production is not technologically challenging. It is quite toxic if ingested, and far more so if injected or inhaled. It is infamous as a homicidal weapon of espionage used by the Bulgarian secret service during the Cold War against defector Georgi Markov. More recently, in February 2004, it was discovered in a U.S. Senate office building, apparently having been delivered through the mail. At least 16 persons required decontamination, although no one became ill. Ricin is an inhibitor of cellular protein synthesis via enzymatic attack on the 28S ribosomal subunit.

The clinical presentation of ricin intoxication depends on the route of exposure. Exposures due to aerosols are dose dependent. Four to 8 hours after inhalation, fever, chest tightness, cough, dyspnea, nausea, and arthralgias can be expected followed within 36 hours by progressive cough, dyspnea, cyanosis, and pulmonary edema resulting in respiratory failure. If ingested, necrosis of the GI epithelium, local hemorrhage, and hepatic, splenic, and renal necrosis can be expected followed by vascular collapse and death. If injected, severe local necrosis of muscle and regional lymph nodes with moderate visceral organ involvement will be seen.

Ricin poisoning is not contagious. Establishing a diagnosis may be challenging. Early post exposure (zero to 24 hours) nasal or throat swabs and respiratory secretions may be submitted for toxin assay for epidemiological purposes, although positive nasal swabs do not prove penetration of toxin to the lungs and negative swabs do not exclude exposure in any given patient. In addition, toxin assays and measurement of antibody response can be performed on serum. Management is primarily supportive, although the U.S. military has found that postexposure prophylaxis with an investigational toxoid is efficacious in animal trials.

Other Agents

Numerous other agents may present bioterrorist threats of varying degrees. In addition to previously discussed incidents, terrorists and belligerents have attempted to use *Salmonella*, *Shigella*, glanders, cholera, typhus, and probably many other organisms or toxins to induce disease. Many of these agents are discussed adequately elsewhere in this and other texts; a few warrant additional comment here.

Venezuelan equine encephalitis makes an attractive weapon because of its high infectivity; virtually all nonimmunes contracting the virus become symptomatic. In adults, this disease is usually self-limiting, with few patients developing encephalitis. In infants and young children, however, the disease can be severe, with as many as 4% developing overt encephalitis, often leading to permanent sequelae and death. In nature, the disease is transmitted via the bite of Culex mosquitoes. When delivered intentionally via aerosol, access to the olfactory bulbs may produce more rapid and/or more severe neurologic disease. Treatment is supportive.

Staphylococcal enterotoxin B (SEB) is a bacterial toxin that has been weaponized in the past. Although familiar to many clinicians as a common cause of food poisoning, SEB would also be a potent incapacitating toxin if delivered by aerosol. Symptoms produced in this manner would begin 3 to 12 hours after exposure and consist of fever, headache, chills, myalgias, and nonproductive cough. Dyspnea and chest pain accompanies high dosages of inhaled toxin. Nausea, vomiting, and diarrhea may occur as a result of inadvertently swallowed toxin. Treatment is supportive; meticulous attention should be paid to fluid management. Patients may be ill for as long as 2 weeks with aerosol exposure.

Various fungal toxins, such as the trichothecene mycotoxins, have been mentioned in a biowarfare or bioterrorism context. After the Vietnam War, the U.S. government accused the Soviets of using a trichothecene toxin, T-2 (otherwise known as "yellow rain"), against Hmong tribesmen. The Iraqis are known to have weaponized another fungal toxin, aflatoxin, which in addition to acute clinical effects, is a potent hepatic carcinogen. Symptoms produced by various mycotoxins are variable and depend on the route of exposure. The trichothecene mycotoxins are different from virtually all other bioterrorist agents in that they are dermally active. Treatment is supportive.

CHEMICAL AGENTS

Background

Chemical warfare dates back to antiquity, when the Chinese used arsenical smokes in about 1000 BC and Spartan allies used burning sulfur and coal smoke during the Peloponnesian

War. World War I became the venue for the first large-scale use of such agents, particularly the gases chlorine and phosgene and the vesicating agent sulfur mustard, resulting in thousands of casualties. During the Holocaust, the Nazis infamously used the commercially available fumigant Zyklon B to release cyanide, as the genocidal agent in their concentration camps. Furthermore, both Allied and Axis powers also produced and stored enormous amounts of both vesicants and (after the war) nerve agents, leaving a heritage of chemical-weapon stockpiles throughout the world today. Iraq is known to have used chemical agents against Iran and also its own Kurdish population during the Iraq–Iran war in the 1980s. During the 1991 Gulf War, the existence of the Iraqi chemical agent armamentarium was well-known and led to an increased determination to prepare and defend American military forces against such an attack. Finally, religious terrorists used sarin against civilians in a residential neighborhood of Matsumoto, Japan, in June 1994, and again, as previously noted, in the more infamous attack on the Tokyo subways in March 1995.

Most chemical warfare agents are liquids at room temperature, but may exist as aerosols (visible mists or fogs composed of tiny droplets suspended in the atmosphere, or invisible aerosols composed of even smaller particles) after dispersal by munitions. Liquids are also volatile to varying degrees, and thus, may vaporize into a typically invisible gaseous phase, particularly in conditions of high temperature, strong wind, and deposition onto relatively nonporous surfaces. A few agents—for example, chlorine, phosgene, and hydrogen cyanide—exist primarily as gases in typical summertime conditions. Chemical agents may also be characterized by their environmental persistence, which is inversely related to volatility. Persistent agents, such as mustard and the nerve agent VX, pose a greater secondary contamination hazard from exposed terrain or material, or via contact by rescue or health-care workers with a victim's clothing or skin, than do the nonpersistent agents chlorine, phosgene, hydrogen cyanide, and the G nerve agents.

Toxic effects from chemical agents usually follow dermal or inhalational exposure and may present as (i) topical effects to the skin, the eyes, and the respiratory epithelium of the respiratory tract following contact and superficial absorption, (ii) effects on the body as a whole following systemic distribution, and (iii) both local and systemic effects. Although certain chemical agents under the appropriate conditions may be volatile, dermally active, or both, biological agents in general possess neither of these properties. Most of the modern medical literature on the clinical effects of chemical warfare agents focuses on the nerve agents, which are emphasized in this chapter. Clinical syndromes related to vesicants, pulmonary agents, cyanide, and riot-control agents are also briefly summarized (Table 7.4). General principles of supportive care for poisoned patients are detailed in Chapter 102; these principles also apply largely to the general support of chemical warfare agent victims.

Early Recognition of a Covert Chemical Attack with an Unknown Agent

By analogy with the previous parallel discussion regarding early recognition of a biological attack, alert pediatric emergency care providers will again be cognizant of three critical epidemiologic features: an epidemic number of patients, a common exposure history, and exotic disease presentations. In the context of chemical attack, this will manifest as an acute illness onset (within seconds to minutes, or hours in the case of some of the vesicants and pulmonary agents). In the more severe chemical incident scenarios, the recognition that such an attack has occurred will not be subtle; there might be numbers of persons collapsing, or dying, within minutes of exposure. As for the biological agents, it is convenient to categorize chemical weapons as causing predominantly neurologic, respiratory, or dermatologic syndromes that can help the practitioner in distinguishing attacks with nerve agents or cyanide, chlorine or phosgene, or vesicants, respectively (Fig. 7.4). Further input into more definitive diagnosis and management advice may be available from public health authorities or the regional poison control center (1-800-222-1222).

The most critical emergent decision will likely be the distinction of cyanide from nerve agent attack because the immediate antidotal therapies are quite different. As noted previously, in both cases, there may be numbers of victims with sudden collapse, coma, and seizures, with many deaths occurring rapidly. Nerve agent casualties will be more likely to be cyanotic, have miotic pupils with altered vision, have copious oral and nasal secretions, and have findings of acute bronchospasm and bronchorrhea, but clinical differentiation may be difficult in an individual case.

General Management, Decontamination, and Personal Protection Strategies

The general treatment of chemically contaminated victims begins with extrication, triage, emergent resuscitation as needed, and decontamination performed by rescue workers or health-care providers garbed in appropriate personal protective equipment (PPE). Patient decontamination has two important purposes: (i) prevention of secondary exposure of health-care workers and facilities and (ii) prevention or minimization of continuing absorption of agent into the patient. *This latter point is typically underemphasized, but by preventing absorption of a lethal dose of agent, immediate decontamination can be the most important life-saving action available for a chemical casualty.* This process would ideally occur at the scene, and thus ED staff would be spared the considerable challenges posed by the arrival of contaminated patients to their facility. However, as noted previously, in a large-scale terrorist incident, it is far more likely that some victims will self-transport to the ED. In this context, decontamination must take place prior to significantly contaminated patients being allowed into the ED. In brief, airway and cardiopulmonary support, including bag-valve-mask ventilation, possibly endotracheal intubation, and emergent antidotal therapy are provided as necessary, while contaminated clothing is removed as soon as possible. Simple disrobing may remove as much as 90% of the contamination hazard to health-care personnel. This is accompanied or followed immediately by more definitive decontamination as detailed in the following section. ED staff in bulky protective gear may find it difficult to provide significant advanced life support to small children prior to decontamination. In many cases, such support may be limited to manual airway maneuvers, provision of oxygen, bag-valve-mask ventilation, and the

TABLE 7.4A

PRIMARY THREAT CHEMICAL AGENTS OF TERRORISM

Agent	Toxicity	Clinical findings	Onset	Decontamination[a]	Management
Nerve agents: Tabun, sarin, soman, VX	Anticholinesterase: muscarinic, nicotinic, and CNS effects	Vapor: miosis, rhinorrhea, dyspnea Liquid: diaphoresis, vomiting Both: coma, paralysis, seizures, apnea	Seconds: vapor Minutes–hours: liquid	Vapor: fresh air, remove clothes, wash hair Liquid: remove clothes, copious washing skin, hair with soap and water, ocular irrigation, *decontaminate as soon as possible!*	ABCs Optimal therapy for individual, critical patients includes parenteral atropine and pralidoxime as follows: Atropine: 0.05 mg/kg IV[b], IM[c] (min 0.1 mg, max 5 mg), repeat q2–5 min pm for marked secretions, bronchospasm Pralidoxime: 25 mg/kg IV, IM[d] (max 1 g IV, 2 g IM), may repeat within 30–60 min pm, then again q1 h for 1 or 2 doses pm for persistent weakness, high atropine requirement Treatment of mass casualties in the ED or the prehospital setting may be better effected by use of autoinjectors of atropine and pralidoxime (see Table 7.4.b) Diazepam: 0.3 mg/kg (max 10 mg) IV; Lorazepam: 0.1 mg/kg IV, IM (max 4 mg); Midazolam: 0.2 mg/kg (max 10 mg) IM pm seizures, or severe exposure
Vesicants:					
Mustard Lewisite	Alkylation and inflammation Arsenic toxicity, including increased vascular permeability	Skin: erythema, vesicles Eye: inflammation Respiratory tract: inflammation	Hours (immediate pain with Lewisite)	Skin: soap and water Eyes: water (both: major impact only if done within minutes of exposure)	Symptomatic care (possibly BAL 3 mg/kg IM q4–6 h for systemic effects of Lewisite in severe cases)

Pulmonary agents: Chlorine Phosgene	Liberation of HCl; alkylation Alkylation (primary effect), liberation of HCl (at higher doses)	Eyes, nose, throat irritation (especially chlorine) Respiratory: bronchospasm, pulmonary edema (especially phosgene)	Minutes: eyes, nose, throat irritation, bronchospasm; Hours: pulmonary edema	Fresh air and water to skin	Symptomatic care
Cyanide	Cytochrome oxidase inhibition: cellular anoxia, lactic acidosis	Tachypnea, coma, seizures, apnea	Seconds	Fresh air Skin: soap and water	ABCs, 100% oxygen Na bicarbonate prn metabolic acidosis Choose antidote: Nitrite/Thiosulfate or Hydroxocobalamin (both IV) Na Nitrite Dose (mL/kg) Estimated Hgb (g/dL) 0.27 10 0.33 12 (est. for average child) 0.39 14 (max 10 mL) Na thiosulfate (25%): 1.65 mL/kg (max 50 mL) Hydoxocobalamin 70 mg/kg (adult dose 5 g) May repeat 35–70 mg/kg (2.5–5 g adults) pm severe toxicity
Riot Control agents: CS CN (Mace®) Capsaicin (pepper spray)	Nonspecific irritation (most agents); stimulation of release of substance P (pepper spray)	Eye: tearing, pain, blepharospasm Nose and throat irritation Pulmonary failure (rare)	Seconds	Fresh air Eyes: lavage	Ophthalmics topically, symptomatic care

CNS, central nervous system; ABCs, airway, breathing and circulatory support; min, minimum; max, maximum; pm,, as needed; BAL, British Anti-Lewisite; HCl, hydrogen chloride; Hgb, hemoglobin concentration; est, estimated hemoglobin concentration.

[a]Decontamination, especially for patients with significant nerve agent or vesicant exposure, should be performed by health-care providers garbed in adequate personal protective equipment. For ED staff, this consists of nonencapsulated, chemically resistant body suit, boots, and gloves with a full–face air–purifier mask/hood.

[b]Intraosseous route is likely equivalent to intravenous.

[c]Atropine might have some benefit via endotracheal tube inhalation, as might aerosolized ipatropium.

[d]Pralidoxime is reconstituted to 50 mg/mL (1 g in 20 mL water) for IV administration, and the total dose infused over 30 min, or may be given by continuous infusion (loading dose 25 mg/kg over 30 min, then 10 mg/kg/h). For IM use, a higher concentration of 300 mg/mL (1 g added to 3 mL water—by analogy to the U.S. Army's Mark 1 autoinjector concentration) might be utilized to effect a reasonable volume for injection; the contents of an autoinjecter can also be obtained by injection into an empty sterile vial (see text).

TABLE 7.4B

AUTOINJECTOR ADMINISTRATION OF ATROPINE AND PRALIDOXIME FOR MASS CASUALTIES AND/OR PREHOSPITAL SETTINGS

Atropine autoinjector therapy		
Approximate age	**Approximate weight (kg)**	**Autoinjector size (mg)[a]**
<6 mo	<7.5	0.25
6 mo–4 yr	7.5–18	0.5
5–10 yr	18–30	1
>10 yr	>30	2 (adult size)

Pralidoxime autoinjector therapy[b]			
Approximate age (yr)	**Approximate weight (kg)**	**Number of autoinjectors**	**Pralidoxime dose range (mg/kg)**
3–7	13–25	1	24–46
8–14	26–50	2	24–46
>14	>51	3	35 or less

[a]Administer one autoinjector.
[b]Pediatric autoinjectors of pralidoxime are not FDA approved or available at this time. Adult-intended autoinjectors (600-mg pralidoxime in 2 mL), while not approved for pediatric use, might be considered as initial treatment in dire (especially prehospital) circumstances, for children with severe, life-threatening nerve agent toxicity who lack intravenous access, and for whom more precise, mg/kg IM dosing (as per Table 7.4A) would be logistically impossible. Suggested dosing guidelines are offered: note potential excess of initial pralidoxime dose for age/weight, although within general guidelines for recommended total over first 60–90 min of therapy of severe exposures.
Adapted from Henretig FM, Cieslak TJ, Eitzen EM Jr. Biological and chemical terrorism. *J Pediatr* 2002;141:311–326.

use of autoinjector-delivered IM antidotes in severe cases of nerve agent toxicity. A partial solution resides in the recent recommendations of the Occupational Safety and Health Administration (OSHA) to establish a hospital decontamination corridor ("warm zone") in which more maneuverable PPE can be used than at the site of exposure (the "hot zone"). Following decontamination in the hospital decontamination corridor, only standard precautions then need to be used in the decontamination zone ("cold zone"), which would begin at or before the entrance to the emergency room unless the emergency room itself becomes contaminated.

Decontamination

Decontamination of casualties contaminated with chemical agents is usually of far greater immediacy than is decontamination of biological agents. The reason is that most biological agents will not penetrate intact skin, whereas chemical agents, particularly liquid nerve agents and vesicants as either liquids or vapors, can be absorbed within only a few minutes. Although the effects of percutaneously absorbed chemical agents may not appear for minutes to hours, tissue damage from vesicants occurs within a few minutes and agent that penetrates the skin is far less amenable to decontamination than is agent that has not yet been absorbed.

Until very recently, providing decontamination to critically ill children in the hospital setting would have constituted a significant challenge for most emergency care providers. Traditionally, hospital EDs had one designated area for a (single!) contaminated patient; often, this facility would go unused for years at a time and ED staff was not frequently drilled in its proper utilization. It is now recognized, however, that a special decontamination treatment area in proximity to the ED (in the OSHA-designated hospital decontamination corridor, or warm zone) would markedly facilitate this process and accreditation agencies have mandated that all hospitals provide such decontamination capacity; thus most hospitals have taken steps to create such areas in recent years.

Decontamination capability must be available on a short setup time basis. Many models have been proposed, but most authorities recommend an outdoor facility with multiple patient stations, arranged so that parallel lines of ambulatory and nonambulatory patients may be processed simultaneously (Fig. 7.5). An outdoor facility is more capable of handling multiple patients and may make the use of copious water irrigation easier; however, it may be challenging to protect victims from inclement weather in temperate climate zones, an issue especially important in the management of young children. An alternative might be the use of a facility that is enclosed, and adjacent but separate structurally from the main ED, with a separate and high-volume ventilation system vented directly outdoors (Fig. 7.6).

Optimally, the surface would allow drainage, minimizing risk of patients slipping and falling and risk of further exposure to contaminated rinse water. Medical personnel in warm-zone-appropriate PPE (OSHA provides suggested lists) should staff an initial triage station at the entrance to the decontamination structure. Triage at this point facilitates rapid identification of patients requiring immediate antidotal or other life-saving intervention, as well as diversion of nonambulatory patients to the appropriate area with medical assistance. Ideally triage is done by EMT or paramedic level practitioners who are used to rapid field triage. Ambulatory patients are instructed in self-decontamination. Obviously, young children require assistance or may be accompanied by parents if present. An outdoor facility must provide adequate water, some temperature control during environmental extremes, and measures to maintain personal modesty, such as curtains or other barriers separating shower lines for males from lines for females.

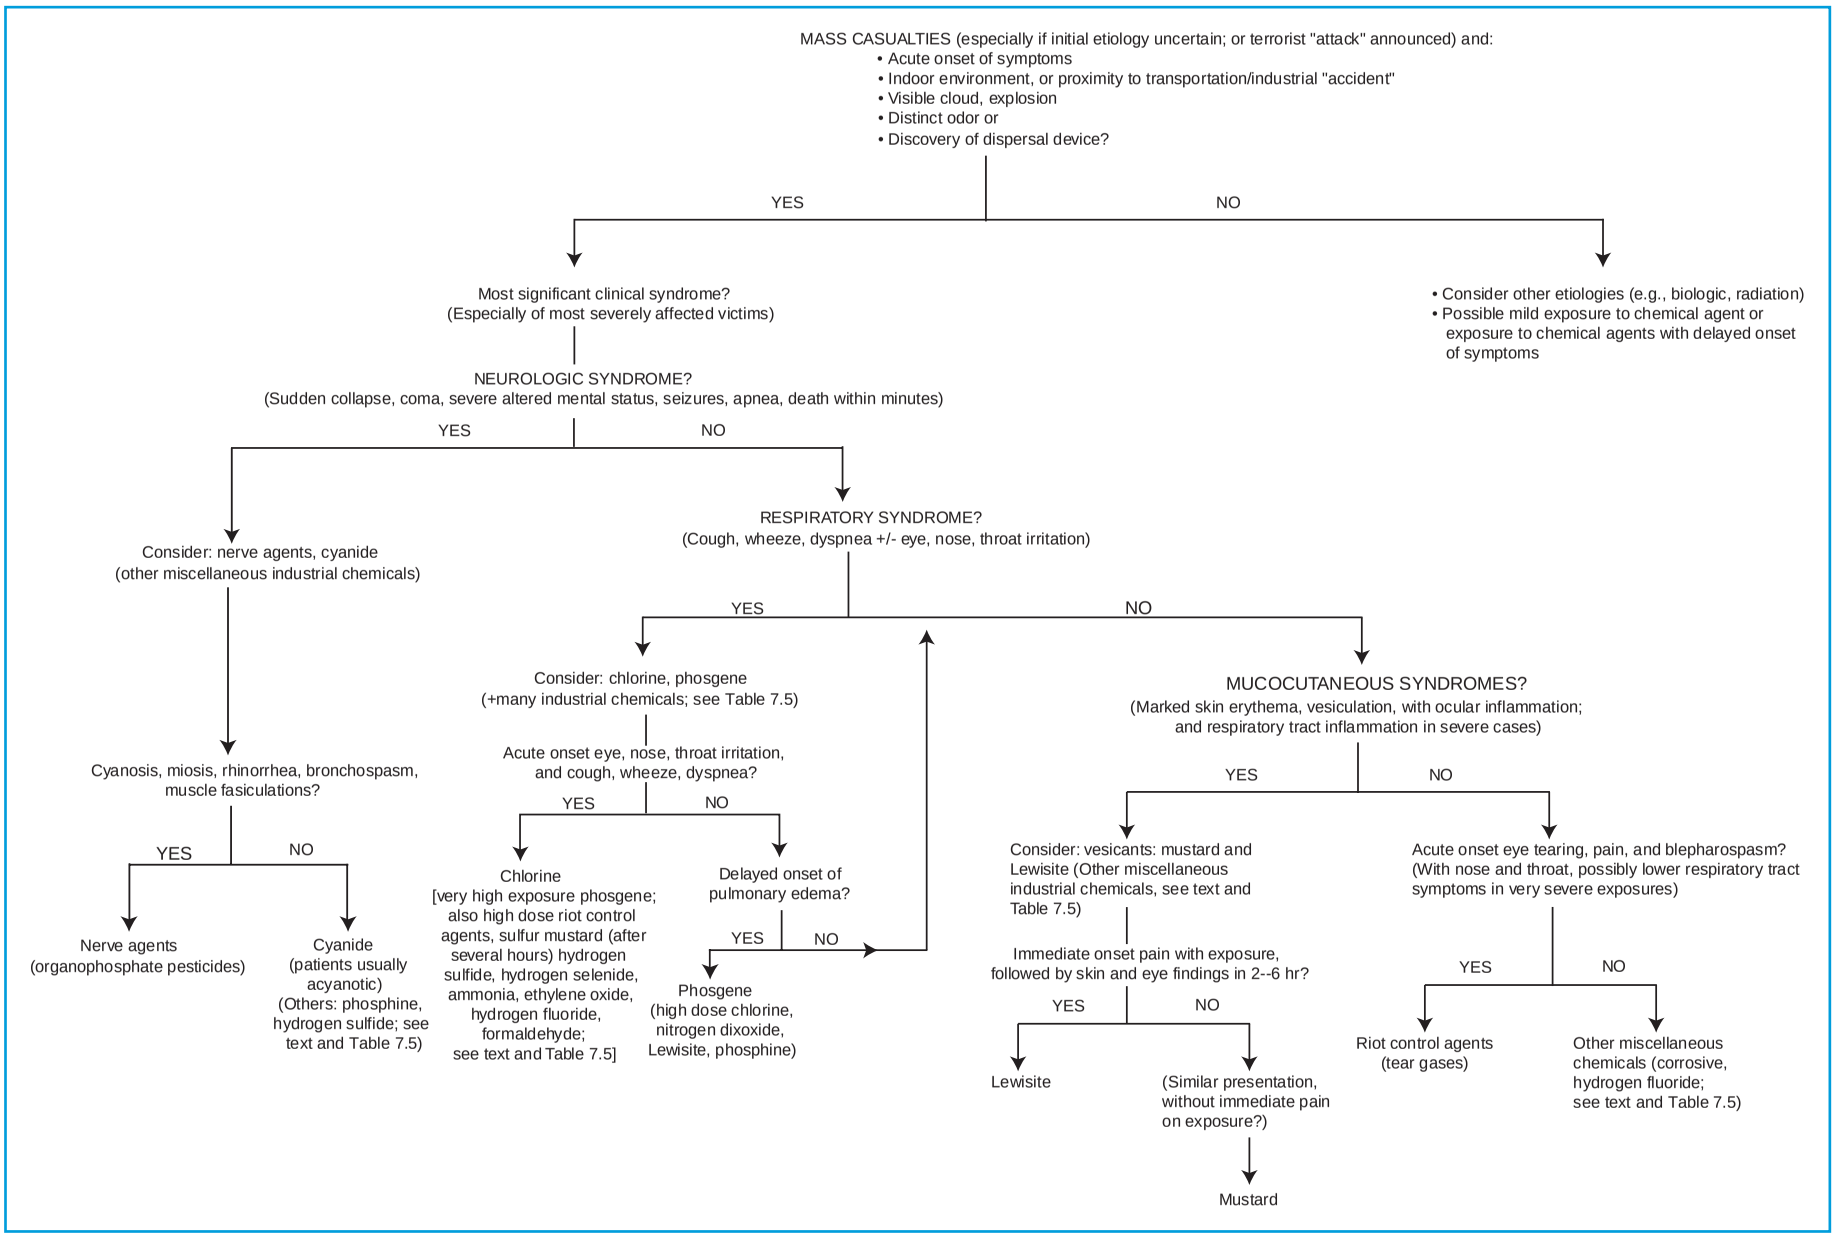

FIGURE 7.4 Approach to the recognition and diagnosis of an attack with an unknown chemical agent.

FIGURE 7.5 **A:** A rapidly deployable outdoor decontamination facility. **B:** The pediatric emergency care provider is garbed in appropriate level C personal protective equipment.

Decontamination efforts should stress physical and mechanical removal over chemical decontamination. For vapor-exposed patients, decontamination is effected primarily by clothing removal and hair washing with soap and water. In contrast, patients with liquid dermal exposure require disrobing and thorough skin decontamination. Agent present on their skin or in their clothing poses a serious threat to ED personnel. Clothing must be carefully removed double-bagged, and labeled, not only for prevention of further exposure to the agent but also for evidence collection when the event is criminal in nature, such as terrorism. Patients with ocular exposure require copious eye irrigation with saline or water. Skin and hair should be washed thoroughly with soap and tepid water. Previously, some authorities have recommended 0.5% sodium hypochlorite (dilute bleach) for skin decontamination of nerve agents and vesicants. However, even dilute bleach may be a skin irritant, thus increasing permeability to agent, its use is time consuming and not proven superior to copious soap and water washing, and in particular, there is little experience with this approach in infants and young children. Another approach that has been developed for military field use is that of a decontamination lotion, reactive skin decontamination lotion, which is packaged as a lotion-impregnated sponge and functions both by physical removal and neutralization of chemical agents. However, hospital-based, and particularly, pediatric experience with this product is currently limited.

Although not anticipated as high-priority terrorist threats, it should be noted that a few hazardous materials, such as reactive metals (sodium, potassium, lithium) and strong corrosives in powder or particulate form, are rare exceptions to the "universal" approach described above in that with these substances application of water is best avoided until all visible particles are removed with forceps, gentle brushing, or vacuuming.

The matter of wash/rinse water runoff, and its containment, has been the subject of some controversy. Current guidelines from the Environmental Protection Agency (EPA) and from The Joint Commission stress that a plan for disposal of

FIGURE 7.6 A fixed, indoor decontamination facility, contiguous with, but structurally separate from the main ED. **A:** The external entrance from the ambulance bay. **B:** Three parallel lanes to provide capacity for both ambulatory and nonambulatory victims. (Courtesy of Tony Van Dyke and Michael Goldberg, Department of Environmental Health and Safety, Children's Hospital of Philadelphia, Philadelphia, PA.)

contaminated waste needs to be put into place by hospitals as part of their preparation for an event. Appropriate PPE for ED staff is an important consideration. The amount of chemical agent believed to contaminate patients who would arrive alive at the ED after a WMD (weapon of mass destruction) attack would consist essentially of that on their skin and clothing, and would thus be of far lower concentration than rescue workers would face at the scene of exposure. Most authorities thus believe that adequate protection in the hospital decontamination corridor (warm zone) would be afforded to ED staff garbed in level C PPE, which consists of a nonencapsulated chemically resistant body suit, gloves, and boots, with a full-face air purifier mask containing a cartridge with both an organic-vapor filter for chemical gases and vapors and a HEPA filter to trap aerosols of biological and chemical agents (Fig. 7.5). Such PPE is much less cumbersome to work in than level A or B outfits (which use self-contained breathing apparatus) and is much less expensive.

Choices regarding specific materials used in level C PPE options are difficult because few such barrier materials have been tested against WMD agents. At least one such material, DuPont's Tyvek F, has been found effective against mustard and organophosphate agents, but given the predicted low concentration and short contact times relevant to the ED decontamination process, less expensive fabrics may be adequate. Again, OSHA provides a list of suggested PPE for use in the warm zone. Biological agents require a considerable degree of energy to reaerosolize from contaminated skin or clothing, and they are not (in contrast to chemical agents) either volatile or (with the exception of trichothecene mycotoxins) dermally active (i.e., they neither cause skin lesions nor penetrate intact skin to cause disease). Thus, surface decontamination of biological agents, although still necessary after gross contamination, is nevertheless considered less critical than decontamination of chemical agents.

Nerve Agents

Nerve agents are organophosphorus esters, and, like the less potent "organophosphate" (OP) insecticides, are potent and essentially irreversible inhibitors of acetylcholinesterase (see Chapter 102). Certain oximes can dissociate bound nerve agents from acetylcholinesterase but only initially; after a variable period (depending on the structure of the nerve agent), a portion of the organophosphate is cleaved (in a process called *aging*) and the resulting nerve agent—cholinesterase complex becomes refractory to oxime action. The "G" (for "German") nerve agents, developed in Germany just before and during World War II, include GA, or tabun; GB, or sarin; and GD, or soman. VX (reportedly "Venom" X) was developed by Great Britain and the United States in the late 1940s and early 1950s. All four nerve agents are liquids at temperate conditions but may be aerosolized by spraying or during an explosive detonation.

The G agents are moderately volatile and relatively nonpersistent; the most volatile, sarin, evaporates at almost exactly the same rate as does water. Although VX is minimally volatile, potentially lasting weeks or longer on contaminated surfaces, at temperatures above 100°F (37.8°C) it can cause significant inhalational toxicity. The time required for these agents to undergo aging varies from a few minutes for soman to 48 hours for VX. The nerve agent vapors are all heavier than air and would thus affect persons closer to the ground (e.g., those in trenches and basements, and perhaps young children) disproportionately. Although all these agents are hazardous by ingestion, inhalation, and cutaneous absorption, the primary danger from the G agents is inhalation of vapor, whereas VX is primarily a skin contact hazard, except in hot environments or when it is explosively aerosolized.

Toxicology

Nerve agent–induced inhibition of acetylcholinesterase causes the neurotransmitter acetylcholine to accumulate in cholinergic synapses and in neuromuscular and neuroglandular junctions; this excess of acetylcholine initially causes end-organ stimulation that may then lead to end-organ failure. Cholinergic sites are found in the central nervous system (CNS), in the neuromuscular junctions of somatic nerves, and in several autonomic nervous system sites, including parasympathetic nerve endings, some sympathetic nerve endings (e.g., sweat glands), and both parasympathetic and sympathetic ganglia.

The cholinergic syndrome thus produced is classically divided into CNS, nicotinic (neuromuscular junction and sympathetic ganglia), and muscarinic (smooth muscle and exocrine gland) effects.

CNS effects include altered mental status progressing through lethargy to coma, ataxia, convulsions, and respiratory depression (central apnea). Although seizure initiation is initially largely a result of excess cholinergic stimulation of excitatory glutamate receptors, antagonism of inhibitory gamma-aminobutyric acid receptors may also play important roles in seizure propagation. Neuropathological changes observed in animal studies also suggest that prolonged seizure activity further disturbs excitatory amino acid and *N*-methyl-D-aspartate receptor function, ultimately leading to neuronal calcium influx and neuronal injury.

Nicotinic effects include muscle fasciculations and twitching, and then weakness progressing to flaccid paralysis. Nicotinic effects on sympathetic activity may also result in tachycardia, hypertension, and metabolic aberrations (e.g., hyperglycemia, hypokalemia, metabolic acidosis).

Muscarinic toxicity is manifested by (i) ocular findings (miosis, visual blurring, eye pain, lacrimation); (ii) respiratory findings (watery rhinorrhea, bronchospasm, increased bronchial secretions causing cough, wheezing, dyspnea); (iii) dermal findings (flushing, sweating, cyanosis); (iv) GI findings (salivation, nausea, vomiting, diarrhea progressing to fecal incontinence and abdominal cramps); (v) genitourinary findings (frequency, urgency, incontinence); and (vi) cardiovascular findings (bradycardia, hypotension, atrioventricular block). Because muscarinic effects on the heart are opposed by the cardiovascular effects of nicotinic hyperstimulation at autonomic ganglia, heart rate and blood pressure in nerve agent victims may be either elevated or depressed and are not reliable indicators of the severity of nerve agent intoxication.

Clinical Presentation

The clinical presentation in a given patient depends on dose and route of exposure. For vapor exposures, mild toxicity would be suggested by miosis, rhinorrhea, mild dyspnea, and wheezing—all local effects caused by contact of vapor with epithelial surfaces. As the dose increases, and systemic distribution of the

agent occurs, the victim might experience increased respiratory secretions and dyspnea, nausea, vomiting, and muscle weakness. In the Tokyo experience with sarin vapor exposure, miosis (99%), dyspnea (63%), nausea (60%), and headache (74%) were particularly common among moderately symptomatic patients at hospital admission. In severe cases with exposure to high vapor concentrations, rapid onset of paralysis and seizures leading to death from respiratory arrest may occur within minutes. In the Tokyo sarin incident, 3 of 640 patients presented to one ED in cardiopulmonary arrest. One patient was unresponsive to resuscitation, 1 patient experienced severe hypoxic damage and died on hospital day 28, and 1 patient recovered fully.

With vapor inhalation, affected patients do not typically deteriorate once they are removed from the exposure. In contrast, with dermal exposure, symptoms may progress even after the agent is removed from the skin surface. Initial findings after a small dose might include localized sweating, followed by localized fasciculations of underlying muscle. Systemic effects from larger doses of liquid usually begin with GI signs and symptoms, and then progress to generalized fasciculations, muscle weakness, paralysis, convulsions, and death resulting from respiratory failure from CNS depression and respiratory muscle paralysis. Eye findings and obstructive respiratory effects tend to be less prominent in these patients, at least early in the course and with low doses. Because of the time (up to 18 hours for a small drop of VX) needed for liquid nerve agent to penetrate the skin, dermal exposures have a longer latency, and patients may not become symptomatic for several hours after exposure, even after decontamination. However, a pin head–size droplet (10 mg) of VX may cause sudden collapse with paralysis, apnea, and death after a latent interval of only 10 to 30 minutes.

Management

The diagnosis of nerve agent poisoning is primarily by clinical recognition and response to antidotal therapy. Routine toxicological studies do not identify organophosphorous compounds or their metabolites in blood or urine. Measurements of acetylcholinesterase in plasma or in erythrocytes have traditionally been used to confirm OP insecticide poisoning, and the activity of these enzymes is decreased after significant nerve agent toxicity as well. Erythrocyte acetylcholinesterase activity is a more accurate guide to acute toxicity, whereas measurements of plasma cholinesterase (pseudocholinesterase or butylcholinesterase) are more useful for monitoring patient recovery during the weeks after exposure. However, correlation between cholinesterase levels and clinical effects is poor in mild to moderate exposures, and the test is not widely available. Treatment for symptomatic patients is indicated without awaiting cholinesterase levels, but antidotal therapy is not needed for exposed asymptomatic patients, even if cholinesterase levels are depressed. These patients, however, should be carefully observed if there is any possibility of concomitant exposure to liquid nerve agent. The overall treatment approach for these agents focuses on airway and ventilatory support, aggressive use of antidotes, particularly atropine and pralidoxime chloride, prompt control of seizures, and the provision of decontamination as necessary (Table 7.4). Atropine is used for its antimuscarinic effects and pralidoxime serves to reactivate acetylcholinesterase. Atropine treats bronchospasm and increased bronchial secretions, bradycardia, GI effects of nausea, vomiting, diarrhea, and cramps, and may lessen seizure activity. However, atropine will not improve skeletal muscle paralysis. Pralidoxime (2-PAM) cleaves organophosphate away from the cholinesterase and regenerates the intact enzyme if aging has not yet occurred. This effect is observed most at neuromuscular junctions, with improved muscle strength.

Both atropine and pralidoxime are administered IV in severe cases, although intraosseous access is likely equivalent to IV. However, animal data suggest that hypoxia should be corrected, if possible, prior to IV atropine use, to prevent arrhythmias; otherwise, IM use might be safer initially. Atropine is dosed initially at 0.05 mg per kg, with minimum dose 0.1 mg and maximum 5 mg; pralidoxime is dosed at 25 mg per kg, with maximum doses of 1 g IV or 2 g IM (Table 7.4). Atropine has also been administered by the endotracheal or inhalational route in some contexts, and such use (or that of ipratropium as an aerosol) might also have salutory effects.

Pediatric experience with OP pesticide poisoning suggests that the continuous infusion of pralidoxime may be optimal. However, the IM route is acceptable if IV access is not readily available. This might be quite relevant in a pediatric mass-casualty incident. In fact, most U.S. EMS systems now stock military IM autoinjector kits of 2-mg atropine and 600-mg 2-PAM. Pediatric-size autoinjectors of atropine are now available in 0.25-, 0.5- and 1-mg doses. Of note, during the Gulf War, 240 Israeli children, none of whom were exposed to nerve agent, were evaluated for accidental autoinjection of atropine, as reported by Amatai et al. Systemic anticholinergic effects occurred in many of these patients, but seizures, severe dysrhythmias, and deaths were not observed.

Pediatric-size 2-PAM autoinjectors are not currently available in the United States. However, in dire circumstances, even the adult autoinjectors with 0.8-inch needle insertion lengths and 600-mg pralidoxime might find utility in children older than ages 2 to 3 years or who weigh more than 13 kg (suggested guidelines and weight-based dosing for children of all sizes are detailed in Table 7.4A and 7.4B). For infants, one might consider using the adult pralidoxime autoinjector as a convenient source of concentrated (300 mg per mL) pralidoxime solution suitable for IM injection. This can be effected by the discharge of one or several autoinjector's contents into an emptied 10-mL sterile saline vial (Fig. 7.7). The solution may then be withdrawn through a filter needle into one or several syringes suitable for small-volume IM injections, each of which are then capped with new needles appropriate for IM use. Finally, the routine administration of anticonvulsant doses of benzodiazepines is recommended in significant cases, even without observed convulsive activity, because animal studies have indicated some amelioration of subsequent seizures and morphologic brain damage with such use. Potential future advances in nerve agent treatment currently under investigation include the use of more effective bis-quaternary oximes, such as HI-6, fetal bovine serum acetylcholinesterase, scopolamine for anticholinergic effects (potentially better CNS penetration than atropine), and the use of ketamine as an adjunct to treat prolonged nerve agent–induced seizures.

Specific Pediatric Considerations

Little experience is available to comment on differences between pediatric and adult patients in the dose–response

FIGURE 7.7 Autoinjector-packaged proalidoxime can be injected into an empty vial for subsequent reuse in small pediatric patients. (From Henretig FM, Mechem C, Jew R. Potential use of autoinjector-packaged antidotes for treatment of pediatric nerve agent toxicity. *Ann Emerg Med* 2002;40:405–408, with permission.)

curve or the toxic-effect spectrum with exposure to nerve agents, or in response to therapy. The thinner skin of children and greater surface area to mass ratio might make them more susceptible to dermal absorption on a mg per kg basis in comparison to adults. Likewise, the immature blood–brain barrier in infants might increase the relative risk of CNS toxicity. One case series of anticholinesterase pesticide poisoning in children found that depressed sensorium and muscle weakness/flaccidity were more prominent than muscarinic findings. Nevertheless, more than half of these patients did demonstrate miosis (80%), tearing and excess salivation (60%), and GI findings (52%). Also, severe OP pesticide poisoning in children may certainly manifest by dramatic muscarinic findings, including respiratory compromise, in many cases (see Chapter 102). It seems doubtful that the nerve agent toxidrome, and hence the appropriate management approach, would differ significantly in children from that in adults. Nevertheless, the clinician should be prepared for subtle and sometimes significant differences in children from the classic cholinergic toxidrome seen in adults.

Disposition and Prognosis

The disposition of exposed patients depends on severity of symptoms and route of exposure. Most patients presenting after vapor exposure manifest peak toxicity by the time of hospital arrival, and when their symptoms have either resolved or abated to only mild eye findings (miosis from exposure to nerve agent vapor may persist for up to 6 weeks), they may be discharged. After dermal exposure, symptom onset may lag up to 18 hours, even after thorough skin decontamination, and most experts recommend a 24-hour observation period even in initially asymptomatic victims.

The prognosis for apparently full recovery from even severe nerve agent poisoning appears to be good with timely life support interventions and adequate antidotal therapy. Apneic patients have recovered ventilatory function within 3 hours, and once consciousness was regained, muscle weakness and obtundation have resolved over a few days, whereas miosis and subtle mental status effects have persisted for several weeks. Nerve agents, unlike some pesticides, have not been implicated in delayed peripheral neuropathy, although some follow-up studies on survivors of the Tokyo sarin attack suggest a considerable incidence of neurocognitive and affective sequelae.

Vesicants

The major vesicants, or blistering agents, are cellular poisons and include the mustards (sulfur mustard and nitrogen mustards) and Lewisite. The mustards are believed to act primarily as alkylating agents, whereas Lewisite is an organic arsenical believed to affect the thiol groups in critical cellular enzymes. However, because little clinical experience with Lewisite exposure exists, this discussion focuses on mustard.

Mustard exists as an oily, yellow to dark brown liquid with a garlic or mustard odor. It has relatively low volatility and is considered persistent, although at high temperatures its vapor hazard is considerable. Mustard vapor, unlike most other chemical vapors, can penetrate skin and lead to early tissue damage and eventual blistering. This fact is the warrant for the exception of vesicants to the general rule that skin decontamination is not an immediate priority for vapor-exposed chemical casualties. An estimated 80% of mustard casualties during World War I were caused by mustard vapor exposure (although 80% of *fatalities* from chemical warfare agents were caused by pulmonary agents). The lethality of mustard to well-protected troops on the battlefield in World War I was less than 5%, but this agent would be far more deadly against unsuspecting and unprotected civilians; an amount as little as 1 teaspoon may kill a 70-kg adult.

Mustard forms a cyclic ethylsulfonium ion that is a potent alkylating agent causing injury to rapidly reproducing cells (its systemic effects are often described as radiomimetic), and its local effects are most evident on the skin, in the eyes, and in the respiratory tract. With severe exposures, the bone marrow, GI mucosa, and the CNS may also be damaged. Although mustard-induced cell injury begins within the first few minutes after exposure, clinical effects of mustard usually follow a latent period that is inversely related to dose but that is often 4 to 6 hours. Skin lesions after liquid contact begin with erythema, followed by blister formation, or if the dose is large enough, skin sloughing without blister formation (Fig. 7.8). The burns are usually partial thickness (second degree). Blister fluid does not contain active mustard and is not hazardous. Vapor exposure results in later, and usually milder, skin injury.

Ocular lesions from vapor include conjunctival inflammation, corneal damage, and often severe lid edema. Permanent blindness is a rare complication, but many patients presenting for treatment may be functionally blind because the pain and blepharospasm induced by mustard renders them unwilling to open their eyes. Vapor-induced pulmonary effects begin with upper respiratory tract irritation, and may progress through dyspnea and a productive cough to a severe necrotizing tracheobronchitis with pseudomembrane formation. Patients may succumb to secondary bacterial bronchopneumonia. Bone marrow damage may occur in severe cases on about the third to fifth days after exposure, and manifest as progressive pancytopenia. Low leukocyte counts (less than 500 per mm^3), or a precipitous decreases in the leukocyte count, portend a

FIGURE 7.8 A patient with mustard-induced skin blisters. (From Greenberg MI. Greenberg's Text-Atlas of Emergency Medicine. Philadelphia: Lippincott Williams & Wilkins, 2005:968.)

serious risk of sepsis and death. An accident involving the explosion of a mustard-containing shell caused a heavy exposure to three children. These patients presented acutely with altered mental status and muscle activity, and two of them died 3 to 4 hours after exposure. A case series of Iranian children and adolescents exposed to mustard during the Iraq–Iran War found that compared with adults, the younger victims exhibited a shorter onset and more severe dermal lesions, attributable to the more delicate skin in this age group.

Because mustard penetrates tissue rapidly and binds to cellular components within the first two to five minutes, the most important early intervention is immediate (i.e., at the scene) decontamination as soon as possible after exposure. Skin and eye decontamination are accomplished similarly as discussed for nerve agents. Additional, or delayed, decontamination at the time of ED arrival may still be of value in preventing continuing absorption and thus systemic distribution in patients and secondary contamination of the patient and health-care workers, although it must again be pointed out that blister fluid from mustard casualties does not pose a contamination threat. No specific antidotes to mustard poisoning are available. Supportive care for skin lesions is analogous to that provided for burn injury, although fluid requirements are usually far less than with comparable body-surface-area thermal burns. Additional treatment of respiratory tract inflammation, ocular injury, and immunosuppression associated with leucopenia may be required (see Chapters 108, 98, 117, and 91, respectively). Research directions in management include the potential salutary effect of granulocyte colony-stimulating factor in the further treatment of mustard-induced leucopenia, and the use of oral *N*-acetylcysteine both as a potential prophylactic agent and for mitigating chronic pulmonary effects.

Pulmonary Agents

Toxic inhalant agents, including chlorine and phosgene, may cause injury in several ways, including simple asphyxia by displacing oxygen, topical damage to airways or alveoli, systemic absorption through the pulmonary capillary bed, and allergic hypersensitivity reactions. Both chlorine and phosgene were used in battle in World War I, are commonly used for industrial purposes today, and are reviewed briefly in this section.

Chlorine is considered a gas with relatively low to intermediate water solubility and chemical reactivity, whereas phosgene is considered to have low solubility and reactivity. Because the initial irritant symptoms of gas exposure tend to correlate directly with water solubility and chemical reactivity, low-dose exposures to chlorine, and even moderate exposures to phosgene, might cause either no symptoms at all or only mild irritation of eyes, nose, and upper airways during exposure. Victims could easily dismiss these effects, thus prolonging exposure and the severity of the ultimate lung injury. Chlorine lung injury is probably mediated by both hydrochloric acid generation in the upper airway and by free oxygen radical cascade at the alveolocapillary membranes in the lower airway.

Phosgene (carbonyl chloride) is also believed to generate hydrochloric acid, contributing particularly to upper airway, nasal, and conjunctival irritation at higher doses (as mentioned, lower but still potentially lethal doses may not give rise to any irritation at all) as well as a carbonyl group that participates in acylation reactions at the pulmonary alveolocapillary membranes; the resulting leaking of fluid across damaged membranes eventually leads, after an asymptomatic period, to pulmonary edema and acute lung injury. Phosgene lung injury may also be mediated in part by an inflammatory reaction associated with leukotriene production.

Chlorine is a dense, acrid yellow-green gas of intermediate solubility and intermediate chemical reactivity that tends to settle close to the ground. Initial effects after mild to moderate exposure include ocular and nasal irritation, followed by cough, and progressing to a choking sensation and substernal chest tightness. Bronchospasm often occurs, especially in patients with a history of reactive airway disease. Pulmonary edema may follow significant exposures within 2 to 4 hours. Severe exposures result in the rapid onset (within 30 to 60 minutes) of pulmonary edema, in addition to the initial irritation.

Mild to moderate exposures to phosgene may be initially asymptomatic, with only the perception of a pleasant odor of newly mown hay. Thus, lung exposure time may be significant before the victim removes himself from the affected area. Pulmonary edema occurs after a considerable delay, typically 4 to 6 hours, but with lower exposures as late as 24 hours after exposure. In these cases, dyspnea precedes objective clinical or radiologic findings. With higher exposures, early lacrimation may be followed by cough and dyspnea, and pulmonary edema, although still delayed, supervenes earlier than with a low-dose exposure. The pulmonary edema may be so severe as to result in hypotension from hypovolemia. The onset of dyspnea within the first 4 hours after exposure to phosgene portends the eventual development of massive pulmonary edema and a grave prognosis.

Management of exposure to pulmonary agents is primarily supportive (see Chapter 98). Decontamination is primarily removal to fresh air. Careful attention to control of pulmonary secretions, bronchospasm, and pulmonary edema, as well as to

aggressive treatment of secondary bacterial infection (often occurring 3 to 5 days after exposure) is required. Animal studies suggest a modest benefit of steroid therapy in mitigating lung injury after chlorine inhalation, and thus steroids may be considered for patients with chlorine exposure, especially as an adjunct to bronchodilators in those manifesting bronchospasm and/or a history of asthma. In addition, some symptomatic relief has also been reported for chlorine exposure with nebulized 3.75% sodium bicarbonate therapy, but the impact of this regimen on pulmonary damage is unknown. Animal models have suggested a benefit of antiinflammatory agents, including ibuprofen and *N*-acetylcysteine, to ameliorate phosgene-induced pulmonary edema, as well as the utilization of low tidal volume ventilation (protective ventilation), but these interventions have not yet been reported in clinical trials.

Cyanide

Compounds containing the cyanide ion (CN^-) have a long history as favored agents for homicide and suicide, but their efficacy as chemical warfare agents is somewhat limited by their volatility in open air and, on the battlefield, by their flammability. However, if released nonexplosively in a crowded, closed room, they could have devastating effects. Chemical agents containing cyanide include the liquids hydrocyanic acid (hydrogen cyanide, HCN) and cyanogen chloride (ClCN), both of which rapidly vaporize after release.

ClCN may cause some initial eye, nose, and airway irritation from its chlorine moiety, but its systemic effects are the same as those of HCN and result from toxicity of its cyanide anion. Hydrogen cyanide dissociates only minimally to hydrogen ions and cyanide, but the intact molecule (HCN) appears to act by the same mechanism as the cyanide anion itself.

Toxicology

Some cyanide is normally present in human tissues and several pathways exist for its metabolism. Cyanide reacts reversibly with metals such as ferric ion (Fe^{3+}) and cobalt; in the body, the reaction of hydroxocobalamin with cyanide yields cyanocobalamin, or vitamin B_{12}. Cyanide also reacts with sulfur-containing compounds. Recent evidence also supports a significant interaction of cyanide with endogenous nitric oxide (NO). The enzyme rhodanese detoxifies cyanide by catalyzing its reaction with a sulfur donor to form the relatively nontoxic thiocyanate and sulfite ions, which are then renally excreted. The ability of the body to metabolize small quantities of cyanide, given sufficient time, accounts for the dependence of cyanide toxicity on conditions of concentration and exposure time. The same amount of cyanide that will kill when given over a few minutes may be successfully metabolized by the body if administered over several hours.

Doses of cyanide large enough to overwhelm normal metabolism inhibit electron transport at the cytochrome-aa_3 complex (cytochrome oxidase) of the mitochondrial cytochrome chain. The inactivation of this enzyme site, critical to aerobic adenosine triphosphate production, results in cellular anoxia and a decreased arteriovenous oxygen difference (from inability of cells to use delivered oxygen), metabolic acidosis (from accumulation of hydrogen ions not incorporated with oxygen) and increased lactic acid (from the failure to generate energy aerobically).

Clinical Manifestations

Clinical manifestations of cyanide poisoning relate to cellular anoxia; thus, those organs that are metabolically most active, particularly the brain and heart, are most severely affected. The carotid body chemoreceptors, which receive the highest relative blood flow and oxygen delivery of any tissue in the body, are rapidly stimulated by the presence of high concentrations of cyanide, and mediate a pronounced gasping reflex, which increases rate and depth of respiration. They also indirectly stimulate the adrenal medulla to release epinephrine, with resulting initial tachycardia and hypertension. Thus, high concentrations of cyanide vapor initially produce tachypnea, hyperpnea, and hypertension within 10 to 15 seconds. Anoxic injury to the CNS and myocardium soon follow, with unconsciousness and seizures (30 seconds after exposure), opisthotonus, trismus, decerebrate posturing, bradycardia, arrhythmias, hypotension, and eventually cardiac arrest (as soon as 4 to 8 minutes after exposure).

Exposure to low concentrations of vapor produces nonspecific effects such as headache, light-headedness, nausea, and ataxia. "Classic" signs of cyanide poisoning are said to include severe dyspnea without cyanosis, or even cherry-red skin (because of lack of peripheral oxygen use), and a bitter almond odor to breath and body fluids. However, some cyanide-poisoned patients develop cyanosis, and only about half the population is genetically capable of detecting the cyanide odor. Noteworthy laboratory abnormalities in cyanide poisoning include an abnormally high mixed venous oxygen saturation with resultant decreased arteriovenous oxygen content difference (one of the most useful laboratory indicators of cyanide poisoning), high-anion-gap metabolic acidosis, and increased blood lactate.

Sidell has emphasized that in a chemical attack the observation that people are convulsing or dying within minutes of exposure implies that the weapon is either cyanide or a nerve agent. With high concentrations of cyanide, seizures begin within seconds and death ensues within minutes, often with little cyanosis or other findings. Exposure to lethal concentrations of a nerve-agent liquid or vapor may also lead to sudden collapse with preterminal apnea and convulsions. Cyanosis in such cases tends to be more common than in cyanide casualties. Miosis and increased nasoocular secretions indicate exposure to nerve agent vapor rather than to cyanide but could be absent in a victim exposed only to lower doses of nerve-agent liquid.

Management

Management of cyanide poisoning begins with removal to fresh air. Dermal decontamination is unnecessary if exposure has been only to vapor, but wet clothing should be removed and the underlying skin should be washed with soap and water, or with water alone if liquid on the skin is a possibility. Attention to the basics of intensive supportive care is critical and includes (i) provision of 100% oxygen to all significantly symptomatic patients (regardless of arterial Po_2), (ii) mechanical ventilation as needed, (iii) circulatory support with crystalloid and vasopressors, (iv) correction of metabolic acidosis with IV sodium bicarbonate, and (v) seizure control with

benzodiazepine administration. The cyanide-induced inhibition of cellular oxygen use might lead to the expectation that supplemental oxygen would not be of use in cyanide poisoning, but in fact, administration of 100% oxygen has been found to empirically exert a beneficial effect, possibly by directly displacing cyanide from cytochrome oxidase-binding sites.

Symptomatic patients, especially those with severe manifestations, may further benefit from specific antidotal therapy. Currently, two regimens are available in the United States, and many hospitals are now considering the stocking of one system or the other; thus, both are described here in some detail.

The older cyanide antidote approach utilized a two-step process. First, a methemoglobin-forming agent such as amyl nitrite or sodium nitrite is administered. The ferric ion (Fe^{3+}) in methemoglobin has an even higher affinity for cyanide than does cytochrome aa_3. The equilibrium of this reaction causes dissociation of bound cyanide from the cytochrome oxidase and restores aerobic energy production. Nitrites may also have therapeutic efficacy independent of methemoglobin formation, possibly via conversion to NO with subsequent beneficial vasodilatory effects. However, nitrite administration is potentially hazardous because too rapid IV infusion may cause or exacerbate hypotension, and overproduction of methemoglobin may compromise oxygen-carrying capacity. Thus, nitrite is probably not indicated for conscious patients with minimal symptoms and is relatively contraindicated in patients whose cyanide toxicity is complicated by existing impaired oxygen delivery (e.g., smoke inhalation victims from a house fire, with likely concomitant lung injury and carbon monoxide poisoning).

These potential adverse effects of nitrites would obviously be less compelling in the context of a severely intoxicated, prostrate casualty of a terrorist cyanide vapor attack, and careful attention to proper dosing and rate of administration should allow safe use of this antidote. Pediatric nitrite dosing depends on body weight and hemoglobin concentration. The recommended initial pediatric dosage, assuming hemoglobin concentration of 12 g per dL, is 0.33 mL per kg of the standard 3% sodium nitrite solution, given slowly IV over 5 to 10 minutes; the initial adult dosage is 10 mL. Dosing may be adjusted for patients with significant anemia, although this knowledge would rarely be available in the context of emergent treatment of a critically poisoned child. The second step is provision of a sulfur donor, typically sodium thiosulfate, which is used as a substrate by rhodanese for its conversion of cyanide to thiocyanate. Thiosulfate itself is efficacious, relatively benign, and also synergistic with oxygen administration, and thus may be used without nitrites in situations such as smoke inhalation. The initial thiosulfate dose for children is 1.65 mL per kg of the standard 25% solution IV, and the initial adult dose is 50 mL. Second treatments with one half the initial dose of nitrite and thiosulfate may be given 30 minutes after the original dose if needed in severe cases.

The newer antidote available in the United States is hydroxocobalamin. This compound is the hydroxy form of cobalamin, and in the presence of cyanide exchanges its hydroxy group for cyanide, forming cyanocobalamin (vitamin B_{12}), which is subsequently excreted by the kidneys. Its use is not complicated by the potential for nitrite-induced hypotension or methemoglobinemia, and has a low order of toxicity. Thus, hydroxocobalamin may be especially suited for use in the prehospital and ED management of a mass-casualty incident with cyanide. The recommended initial dose is 5 g in adults or 70 mg per kg in children, administered IV over 15 minutes. A second dose (2.5 to 5 g in adults, 35 to 70 mg per kg in children) may be repeated in severely affected patients, with the second infusion rate ranging from 15 minutes to 2 hours based on patient condition. Hypertension is a predictable side effect of hydroxocobalamin administration. The medication is dark red in color, and treatment does result in reddening of skin and mucous membranes and red-colored urine that may last several days. This phenomenon may also skew some common laboratory results that are based on colorimetric tests, such as creatinine, bilirubin, and hepatic transaminases, as well as cooximetry results. Although no human controlled trials are available to compare hydroxocobalamin to nitrite/thiosulfate-based therapies, many authorities currently feel that hydroxocobalamin's efficacy and safety profile favor it as the cyanide antidote of choice, especially for children in the mass-casualty context.

The combined use of hydroxocobalamin and thiosulfate in severe cases might provide synergistic effects and still avoid the potential hazards of nitrite therapy. Lastly, newer compounds with oral availability are under investigation, and include cobinamide, a cobalamin precursor with high cyanide affinity, and analogs of 3-methylpyruvate, which like thiosulfate enhance conversion of cyanide to thiocyanate.

Because clinical distinction between cyanide and nerve-agent casualties may be difficult, any patient thought to have been exposed either to cyanide or to a nerve agent but who does not respond to antidotal therapy specific for the suspected agent should be given a trial of the antidotes for the other agent.

Riot Control Agents

Riot control agents, also called lacrimators ("tear gas," although they are actually aersosols rather than gases), include several compounds, the most important of which are CS (*o*-chlorobenzylidene malononitrile), CN [1-chloroacetophenone, "Mace" (although Mace is also often used to refer to pepper spray)], and pepper spray (containing capsaicin). CS and CN are solids and are typically dispersed as an aerosol of fine particles. Although the United States does not consider riot control agents to be official chemical warfare weapons, these agents are widely available, cause significant incapacitating effects in closed spaces, and could conceivably be used in a terrorist attack; therefore, they are outlined briefly in this section.

Their mechanism of action after low-level exposure is unclear but, in the case of pepper spray, appears to be related to the release of the pain-modulating neurotransmitter substance P. All these agents can cause (i) transient ocular effects, including burning sensation, tearing, blepharospasm, and photophobia; (ii) irritation of the nose, throat, and upper airway; and (iii) skin burning, erythema, and (at high concentrations and high ambient temperatures and humidity) vesication. A few riot control agents, such as Adamsite (DM), cause pronounced vomiting in addition to delayed-onset irritation of the eyes and the upper airway, and are referred to as vomiting

agents. Most victims under usual circumstances of exposure become symptomatic within seconds from the traditional lacrimating agents (irritation after exposure to DM may take up to 20 minutes to develop) but remain so for only 20 to 60 minutes.

However, high concentrations in closed spaces or discharge of agent close to the victim's face have been associated with serious medical complications, including severe ocular toxicity, dermal burns, and pulmonary failure. A few lethal cases have been described in which death was caused by severe tracheobronchitis with pseudomembrane formation and pulmonary edema.

Management includes careful ocular and dermal decontamination. The skin should be washed with soap and water, although this may cause transient increased pain. Hypochlorite solution should not be used because it may exacerbate dermal burns via the creation of toxic by-products. The eyes should be thoroughly lavaged after a single dose of topical anesthetic if necessary. Respiratory complications must be managed supportively, as previously described for mustard and pulmonary agent toxicity. Severe respiratory effects may not manifest for 12 to 24 hours; therefore, patients with dyspnea or any objective findings should probably be observed in the hospital. Severe respiratory complications from exposure to riot control agents have been described in at least two young infants, one of whom was in a house into which CS was sprayed. A canister of pepper spray was accidentally discharged directly into the face of the other infant. Both survived with prolonged care, the latter requiring ventilatory support, including five days of extracorporeal membrane oxygenation. A few cases of children ingesting CS powder are known, which resulted only in transient diarrhea and abdominal cramping.

Miscellaneous Chemicals

The potential of a terrorist attack on industrial sources of dangerous chemicals such as factories, railroad and vehicular tank cars, or storage depots expands the list of potential "chemical weapons" considerably. In addition, the development of potent incapacitating agents, such as fentanyl derivatives, by law enforcement or military agencies for use in combating terrorist incidents, might unfortunately lead to mass casualties requiring medical treatment, as occurred in the October 2002 theater hostage incident in Moscow. Further, the advent of such agents may allow them to fall into terrorist hands for use as an offensive weapon. A full discussion of all such possible chemical injuries and their management is obviously beyond the scope of this discussion. In general, many of the relevant industrial chemicals (e.g., methyl isocyanate, ammonia, nitrogen dioxide, sulfur oxides) might be expected to induce respiratory effects analogous to those of chlorine or phosgene discussed previously; others (e.g., strong acids or alkalies, hydrogen fluoride, formaldehyde, acrolein) could cause dermatologic injury from irritant or caustic properties, as well as more systemic effects in severe exposures (Table 7.5). Fentanyl derivatives can be lethal from suppression of the respiratory center in the medulla of the brain. Some of the principles in managing such toxic injuries are discussed in Chapter 102, and further information is available from standard reference toxicology texts and by consultation with the regional poison control center (1-800-222-1222).

EMERGENCY DEPARTMENT PREPAREDNESS

The ED response to WMD incidents will need to be integrated into the hospital's standing disaster plan. Appropriate protocols for notifying additional personnel, using hospital security for patient direction and diversion at the ED entrance and around the decontamination site, and handling the dissemination of information to the public and news media should be anticipated. Hospital spaces that are not routinely used for patient care, such as cafeterias, may be used as holding areas for large numbers of exposed but minimally symptomatic patients. Routine hospital supplies such as gowns and towels may be depleted rapidly in the face of mass casualties. Demands for hospital beds, and particularly intensive care unit beds, are likely to be overwhelming. Alternative care facilities staffed by outside help may be needed in mass-casualty situations (e.g., warehouses or other such buildings might need to be converted to temporary care sites). Predisaster planning for both "natural" disasters and WMD incidents must take into account such factors. A framework exists for activating medical assistance plans at the federal level through the National Response Framework and the National Disaster Medical System, augmented if necessary by military medical assets from the Department of Defense.

The issue of stocking-specific antidotes, medications, and vaccines in the context of planning for a WMD event involving the potential for mass casualties poses additional challenges. Many hospitals do not routinely stock adequate amounts of such pharmaceuticals for even one critical patient. WMD incident planning should establish some mechanism for local or regional stockpiling of these critical medications and/or a means to rapidly acquire them. Table 7.6 offers an attempt to quantify the amount of antidotal medications that might be needed in one ED for the management of a nerve agent or cyanide attack involving both pediatric and adult victims on a scale of the Tokyo sarin attack. A biological agent attack would place similar enormous demands on the hospital pharmacy for antibiotics, vaccines, antitoxins, and so on. A federal system for stockpiling pharmaceuticals and emergency medical supplies, managed through the CDC, has been created to augment local resources in this critical logistical arena. The first large-scale deployment of this Strategic National Stockpile occurred in the hours following the September 11, 2001 attacks on New York and Washington, DC. However, because prompt treatment is crucial in chemical emergencies, national stockpiles should be viewed as a resupply source and do not obviate the need for each hospital to develop its own stockpile of antidotes that might be needed during the first few hours after such a mass-casualty incident.

Obviously, many unanswered questions remain regarding ED preparedness for a biological- or chemical-agent attack, including (i) optimal decontamination techniques, especially for young children; (ii) optimal PPE for ED staff; (iii) logistics of patient and hospital staff flow, and isolation, in the context of a potentially lethal, contagious disease (e.g., smallpox,

TABLE 7.5

REPRESENTATIVE CLASSES OF INDUSTRIAL CHEMICALS—SUMMARY OF PEDIATRIC MANAGEMENT CONSIDERATIONS

Agent	Clinical findings	Onset	Decontamination	Management
Strong acids/ bases	Eye—caustic injury Skin—chemical burns GI—chemical burns of mouth, larynx, esophagus, stomach	Rapid	GI: defer, immediate ED referral Ocular, skin: immediate copious water irrigation	Supportive care, early endoscopy for significant ingestion; antibiotics and steroids controversial, should be individualized, consult PCC
Respiratory tract irritants (e.g., ammonia, HCl and HF gases)	ENT and respiratory tract irritation with cough, chest pain, dyspnea, wheeze (possible pulmonary edema in severe cases)	Rapid	Move to fresh air	Supportive respiratory care (consider nebulized calcium gluconate solution for HF, consult PCC)
Fentanyl and other opioids	CNS and respiratory depression, miosis	Rapid	Move to fresh air (for aerosol exposure): consider AC for ingestion, consult PCC	Supportive care, naloxone 0.01–0.1 mg/kg
Cellular asphyxiants: Phosphine, sodium azide	Cough, dyspnea, headache, dizziness, vomiting, tachycardia, hypotension, severe metabolic acidosis, may progress to coma, seizures, death; may have delayed onset pulmonary edema with phosphine	Rapid (except pulmonary edema with phosphine)	Move to fresh air (consider AC for ingested sodium azide—caution with vomitus, which may emit toxic hydrazoic acid fumes: consult PCC)	ABCs, 100% oxygen
Arsine	Severe hemolysis	2–4 h	Move to fresh air	Supportive care, enhance urine flow, consider alkalinization, consult PCC

GI, gastrointestinal; ED, emergency department; PCC, poison control center (1-800-222-1222); HCl, hydrogen chloride; HF, hydrogen fluoride; EENT, eye, ear, nose, and throat; CNS, central nervous system; AC, activated charcoal 1 g/kg p.o. or n.g.; ABCs, airway, breathing and circulatory support.

TABLE 7.6

PHARMACEUTICAL STOCKING ESTIMATES FOR ONE EMERGENCY DEPARTMENT IN A HYPOTHETICAL CHEMICAL AGENT ATTACK[a]

Agent/antidote	Pediatric dose	Adult dose	Total requirement (for 500 patients)
Nerve Agents			
Atropine	0.02–0.05 mg/kg (minimum dose, 0.1 mg)	2–5 mg	6,875 mg = 17,188 amps (1 mL of 0.4 mg/mL); 859 vials (20 mL of 0.4 mg/mL)
Pralidoxime	25–50 mg/kg	1–2 g	1,875 g = 1,875 vials (1 g each)
Cyanide			
Na nitrite (3%)	0.33 mL/kg (for Hgb 12 g/dL)	10 mL	4575 mL
Na thiosulfate (25%)	1.65 mL/kg	50 mL	25,000 mL = 500 vials (50 mL each)
Hydoxocobalamin	70 mg/kg	5 g	2138 g

Note: Cyanide treatment would require either 375 nitrite/thiosulfate-based or 428 hydroxcobalamin-based cyanide antidote kits.
Na, sodium; Hgb, hemoglobin.
[a]Assumptions: 500 patients to one emergency department (as per one hospital's experience in the Tokyo sarin attack); one-half the patients are children with average weight of 10 kg; if nerve agent attack, severe exposure necessitating maximal doses of atropine and pralidoxime; five atropine doses over 12 h; three pralidoxime doses over 12 h; if cyanide attack, severe exposure necessitating initial full dose of Na nitrite/Na thiosulfate, or hydoxocobalamin, followed by 50% of initial dose × 1.

plague, viral hemorrhagic fevers); (iv) safety of decontamination water runoff into public drainage systems; (v) the communitywide needs for education and training; and (vi) financial considerations for individual hospital and regional planners. Continued activity on an expert consensus basis, as well as new research, should help to address many of these issues.

CONCLUSION

The prospect of a mass-casualty incident from the terrorist use of biological or chemical agents is unfortunately more likely now than ever before. Although the impact of such an event is almost unimaginable, at the same time, efforts must be made to prepare for the "unthinkable." Such preparedness requires highly coordinated responses involving local and regional EMS systems, HAZMAT (hazardous materials) teams, police and fire departments, hospital EDs, local and federal public health agencies, and military medical specialists. In particular, EDs must consider important issues, including (i) the early recognition, triage, decontamination, treatment, and disposition of multiple casualties of such an attack; (ii) protection of health-care workers and existing patients; and (iii) the integrity of the ED itself to provide ongoing care to later-arriving casualties and to continue to meet normal patient demands. Fortunately, in 2009, our pediatric emergency care providers, academic medical centers, regional health departments, and several federal agencies, including the U.S. Departments of Health and Human Services, Homeland Security, and Defense, are actively engaged in confronting these vital public health and national security challenges.

CHAPTER 8 ■ ABDOMINAL DISTENSION

JEFFREY R. AVNER, MD, FAAP

Abdominal distension is generally defined as an increase in the breadth of the abdominal cavity. Often, the distention is large and thus easily noticeable to the child or parent. However, subtle increases in abdominal girth may be first appreciated by the child's sensation of abdominal pressure, fullness, or bloating. In general, abdominal distention is often due to an increase in intraabdominal volume by air, fluid, stool, mass, or organomegaly. Nevertheless, care should be taken not to confuse true abdominal distention with certain conditions that cause an *apparent* increase in abdominal girth such as poor posture, the natural exaggerated lordosis of childhood, abdominal wall weakness, obesity, and pulmonary hyperinflation. Examination of the patient in both the supine and upright positions assists the clinician in recognizing these factors before considering diagnoses that truly increase the volume of the abdominal cavity.

Abdominal distension is a nonspecific sign. That is, the causes of abdominal distension are numerous (Table 8.1). Even when the discussion is limited to the more common causes (Table 8.2) or emergent and urgent causes of abdominal distension (Table 8.3), the list is long. When confronted with a patient with abdominal distension, one approach is to divide the causes into the following generic categories: distended bowel, extraluminal gas (e.g., free air), extraluminal fluid, massive hepatomegaly, massive splenomegaly, and other causes. This categorization is more easily described on paper than discerned at the bedside. A large cystic mass can be easily mistaken for ascitic fluid. A Wilms' tumor may feel much like splenomegaly. Another difficulty in the clinical application of this categorization is that many pathologic processes that lead to abdominal distension do so through several of the previously mentioned categories. For example, kwashiorkor causes abdominal distension secondary to hepatosplenomegaly and ascites. For these reasons, the reader is urged to regard this initial categorization, when used at the bedside, as tentative, pending confirmation from plain radiograph, ultrasound, computed tomography (CT), or other imaging studies.

DIFFERENTIAL DIAGNOSIS

Bowel distension occurs secondary to mechanical or functional intestinal obstruction, aerophagia, malabsorption, or obstipation. Mechanical obstruction most commonly occurs in infants secondary to congenital malformations (atresia, volvulus, Hirschsprung's disease), incarcerated hernia, duplication cysts, or intussusception. At any age, a history of previous abdominal surgery usually suggests intraabdominal adhesions as the cause of intestinal obstruction. The amount of bowel distention is often related to the level of obstruction. The more distal the obstruction, the more proximal is the bowel distention to the obstruction. After many hours, most of the gas distal to the obstruction is passed, leaving an airless segment distally. Therefore, the lack of air in the rectum and sigmoid colon on a prone cross-table lateral radiograph of the abdomen supports the diagnosis of mechanical obstruction. Functional obstruction, or paralytic ileus, is suggested by tympanitic abdominal distension with the absence of bowel sounds. In general, all parts of the gastrointestinal (GI) tract are dilated, but the colon is usually more distended than the small intestine. Paralytic ileus may occur secondary to numerous causes. Signs such as involuntary guarding and pain with movement suggest peritoneal irritation secondary to infection, pancreatic enzymes, bile, or blood. Fever without peritoneal signs suggests intestinal inflammation, gastroenteritis, systemic infection, or anticholinergic poisoning (see Chapters 92 and 102). Various poisonings (atropinics), toxins (botulism), antimotility drugs (loperamide), and metabolic abnormalities (hypokalemia, hypercalcemia, uremia, acidosis) may also result in an ileus. These will most likely occur in the patient who has no abdominal findings other than tympanitic abdominal distension. In these cases, the abdomen is usually nontender. Toxic megacolon, an extensive dilatation of the colon, is a potentially fatal complication of severe colitis. This condition is usually seen with ulcerative colitis but may accompany Crohn's disease or antibiotic-related pseudomembranous colitis. Children with toxic megacolon have abdominal distention along with diarrhea, pain, fever, dehydration, and possibly sepsis. It is important to note that some conditions such as sepsis and peritonitis may cause a combination of functional and mechanical obstruction. Finally, gastric dilatation may result from several causes, including localized paralytic ileus (due to gastroenteritis or a pulmonic process), aerophagia, and iatrogenic reasons (bag-valve-mask respirations or esophageal intubation). The resulting gastric distension is an extremely important entity that may result in significant respiratory embarrassment secondary to upward pressure on the diaphragm unless decompressed through a nasogastric tube or other means.

Bulky, foul-smelling, or diarrheal stools suggest malabsorption secondary to many causes, which may include formula enteropathies, bacterial overgrowth, parasites, and cystic fibrosis (see Chapters 89 and 92). In lactose intolerance, bacterial metabolism of unabsorbed lactose produces intestinal gas causing abdominal distention, cramping, flatulence, and diarrhea. The severity of the symptoms is related primarily to

the quantity of lactose ingested. Celiac disease may present with prominent abdominal distention, especially in children younger than 2 years, along with nonspecific GI symptoms and poor weight gain. Obstipation is a common cause of abdominal distension. The patient usually has a history of irregular stooling or chronic constipation. This is often due to a severe functional disturbance, but pathologic processes, including Hirschsprung's disease and other defects in bowel enervation, and hypothyroidism should be excluded.

Toxic megacolon

Extraluminal gas usually causes abdominal distention only when present as free peritoneal air. This may result from intestinal perforation (due to trauma, inflammation, ulcer, foreign-body ingestion, or other causes) or secondary to a pneumomediastinum. It is demonstrated with an upright or cross-table lateral radiograph of the abdomen or on an upright chest radiograph. An ileus generally contributes to the abdominal distension.

Extraluminal fluid in the abdomen may be an effusion, blood, chyle, bile, urine, or pus. The most common reason in pediatrics for the accumulation of fluid in the abdominal cavity is secondary to a low serum albumin. This may be the result of protein loss due to nephrotic syndrome or protein-losing enteropathy, or due to decreased protein synthesis such as that which occurs in cirrhosis and malnutrition. There is usually associated peripheral edema and pleural effusion. Increased venous and lymphatic resistance through the portal and hepatic veins may also cause accumulation of abdominal fluid. Obstruction of blood flow through the liver is suggested by distended abdominal wall veins, a history of hemoptysis, and an enlarged spleen. The obstruction may occur at the prehepatic level (portal venous thrombosis), within the liver parenchyma (end-stage cirrhosis), at the hepatic veins (Budd-Chiari syndrome), or at the intrathoracic level [congestive heart failure (CHF), pericarditis]. Obstruction at the porta hepatis is usually idiopathic, although a history of umbilical venous catheterization or omphalitis in the newborn period should suggest this possibility. Obstruction at this level generally does not cause marked ascites. Although cirrhosis evolves gradually, its clinical presentation may be abrupt. It results from Wilson's disease, α_1-antitrypsin disease, biliary atresia, and other congenital problems, or occasionally, from chronic active hepatitis. Decreased clotting factors would be among the many laboratory findings of cirrhosis. Obstruction of flow at the hepatic veins or above occurs as a result of Budd-Chiari syndrome, CHF, or constrictive pericarditis (see Chapter 82). The liver is engorged, resulting in hepatomegaly and right upper quadrant tenderness in each of these entities. Finally, a diseased peritoneum from infectious, inflammatory, or malignant causes can also cause an intraabdominal effusion.

A history of recent trauma and signs of shock point to intraperitoneal bleeding, usually due to a splenic or hepatic laceration. An ileus secondary to both peritoneal inflammation and shock likely contributes to the abdominal distension. Trauma in the recent past suggests chylous ascites. Finally, a diffusely tender abdomen suggests infectious peritonitis, pancreatitis, or bile peritonitis.

Extreme hepatomegaly that develops acutely occurs secondary to inflammation, congestion due to increased central venous pressure or vascular obstruction, or trauma (see Chapter 89). There will be marked right upper quadrant tenderness and general systemic toxicity. Causes include hepatitis, CHF, constrictive pericarditis, and congenital enzyme deficiencies. Neoplastic disease, especially the proliferative blood cell disorders (leukemia, lymphoma), commonly cause significant hepatomegaly and splenomegaly. Other causes of extreme hepatomegaly include storage diseases and congenital hemolytic

anemias. However, the hepatomegaly in these conditions usually develops gradually and is accompanied by many other signs of chronic illness.

Extreme splenomegaly without marked hepatomegaly in the toxic-appearing child suggests intraparenchymal bleeding with an intact capsule, sickle cell sequestration crisis, or malaria (see Chapters 91, 92, and 103). In the nontoxic child, portal hypertension, neoplastic disease, and chronic hemolysis should be suspected. Neoplastic disease often results in a spleen with an irregular surface. Chronic hemolysis secondary to sickle cell disease, β-thalassemia, and hereditary spherocytosis may also result in a very large spleen. In the case of hemoglobin "SS" disease, but not hemoglobin "SC" disease or sickle-thalassemia, splenic enlargement is followed by splenic atrophy beyond 5 years of age. A peripheral blood smear generally identifies this group of causes of massive splenomegaly (see Chapter 91).

Other causes of abdominal distension include cysts, masses, tumors, uterine enlargement, obstructive uropathy, bowel duplication, and inflammation. Cystic lesions include ovarian cysts; mesenteric, omental, or peritoneal cysts; choledochal cysts; and polycystic kidneys. These conditions generally present with a subacute history and physical examination. The exception is torsion of the large ovarian cyst, which produces vomiting and marked abdominal pain. Abdominal ultrasound generally identifies intraabdominal cysts readily. Of course, an abdominal CT scan is also diagnostic but is associated with significant radiation exposure. Renal masses are probably the most common cause of abdominal distension in early infancy. Renal cystic disease is the most common cause of flank mass in the neonate. Hydronephrophesis due to ureteral-pelvic junction obstruction or posterior urethral valves may also cause abdominal distention in the neonate. Over time, bilateral renal obstruction may cause dehydration, renal failure, and shock. Although the diagnosis of obstructive uropathy is supported by an abnormal urinalysis or blood urea nitrogen (BUN):creatinine ratio, these results may be normal. Confirmation of renal anomalies is made by ultrasound. Tumors such as neuroblastoma, Wilms' tumor, an ovarian tumor, and a teratoma generally can be palpated easily as firm, discrete abdominal masses by the time they are causing frank abdominal distension (see Chapter 97). Bowel duplication can be a subtle diagnosis until a complication such as mechanical bowel obstruction or hematochezia develops. A contrast CT scan of the abdomen, however, generally confirms this diagnosis once suspected. Regional enteritis with sufficient inflammatory mass to cause abdominal distension is preceded by a long history of obstructive and malabsorptive symptoms. Acute-phase reactants such as the sedimentation rate are likely to be abnormal in regional enteritis. Finally, a midline pelvic mass should suggest pregnancy or hematocolpos.

EVALUATION AND DECISION

History

The history should attempt first to differentiate acute from chronic symptomatology by focusing on the rate of progression, recent trauma, weight loss, or weight gain. Parents may note early, subtle changes in these symptoms before they become apparent to the clinician. Next, systemic signs such as fever, anorexia, edema, and lethargy further define the acuteness of the problem and, to some degree, narrow the diagnostic possibilities. One must always be on the alert, however, for an acute complication superimposed on a more subtle chronic condition. Next, symptoms relative to specific organs, including the GI, renal, cardiac, and gynecologic systems, should be pursued. These include questions about nausea, vomiting (bilious or nonbilious), abdominal pain, change in bowel habits, stool history (color, consistency), shortness of breath, cough, hemoptysis, urine output (including strength of stream and any abnormality of urinary color or foamy urine), menstrual history, and sexual activity (asked in a confidential manner). Other important historical information includes stress or anxiety (associated with aerophagia), previous abdominal surgery, and recent medication use (including laxatives and antidiarrheal agents). Finally, a family history of anemia, early infant death among relatives or metabolic disease, a travel history, and a careful newborn history may be revealing.

Physical Examination

After ruling out life-threatening respiratory embarrassment and shock, the physical examination should focus on determining whether the cause of the abdominal distension is related to bowel (air or stool) (Fig. 8.1), free fluid (Fig. 8.2), massive hepatomegaly (Fig. 8.3), massive splenomegaly (Fig. 8.4), inspissated stool, or a discrete mass (Fig. 8.5). A tympanitic abdomen suggests bowel distension (either by a mechanical obstruction or an ileus) or, especially in a toxic-appearing child, free air. A fluid wave or shifting dullness (more reliable in younger children) suggests ascites. Palpable loops of bowel or a palpable descending colon suggests stool. Massive hepatomegaly and splenomegaly generally are defined easily by palpation. However, care should be taken to begin palpation in the pelvic area and advance superiorly so as not to overlook the liver edge. Furthermore, the examiner must be cautious since other masses may mimic hepatomegaly and, in particular, splenomegaly. Thus, it is important to note not only the location of the mass, but also whether it is firm, fixed (suggesting retroperitoneal origin), cystic, smooth, or nodular. Other key physical findings include signs of CHF, abdominal tenderness, peripheral edema, signs of trauma or easy bruising, lymphadenopathy, pallor, and jaundice. A rectal examination for a mass, tenderness, gross (frank blood, currant jelly stool) or occult blood, and the presence or absence of stool is also helpful. More specific findings may be pursued once an initial hypothesis is made based on the algorithms in this chapter.

Laboratory

The initial laboratory evaluation of abdominal distension is determined by the clinical findings and may include complete blood count with smear, erythrocyte sedimentation rate, C-reactive protein, and reticulocyte count; liver function tests, including serum albumin and clotting studies; electrolytes with BUN, creatinine, lipase, and amylase; a urinalysis with reducing substances; and a chest radiograph and a two-view abdomen plain radiograph. The radiographs are helpful in

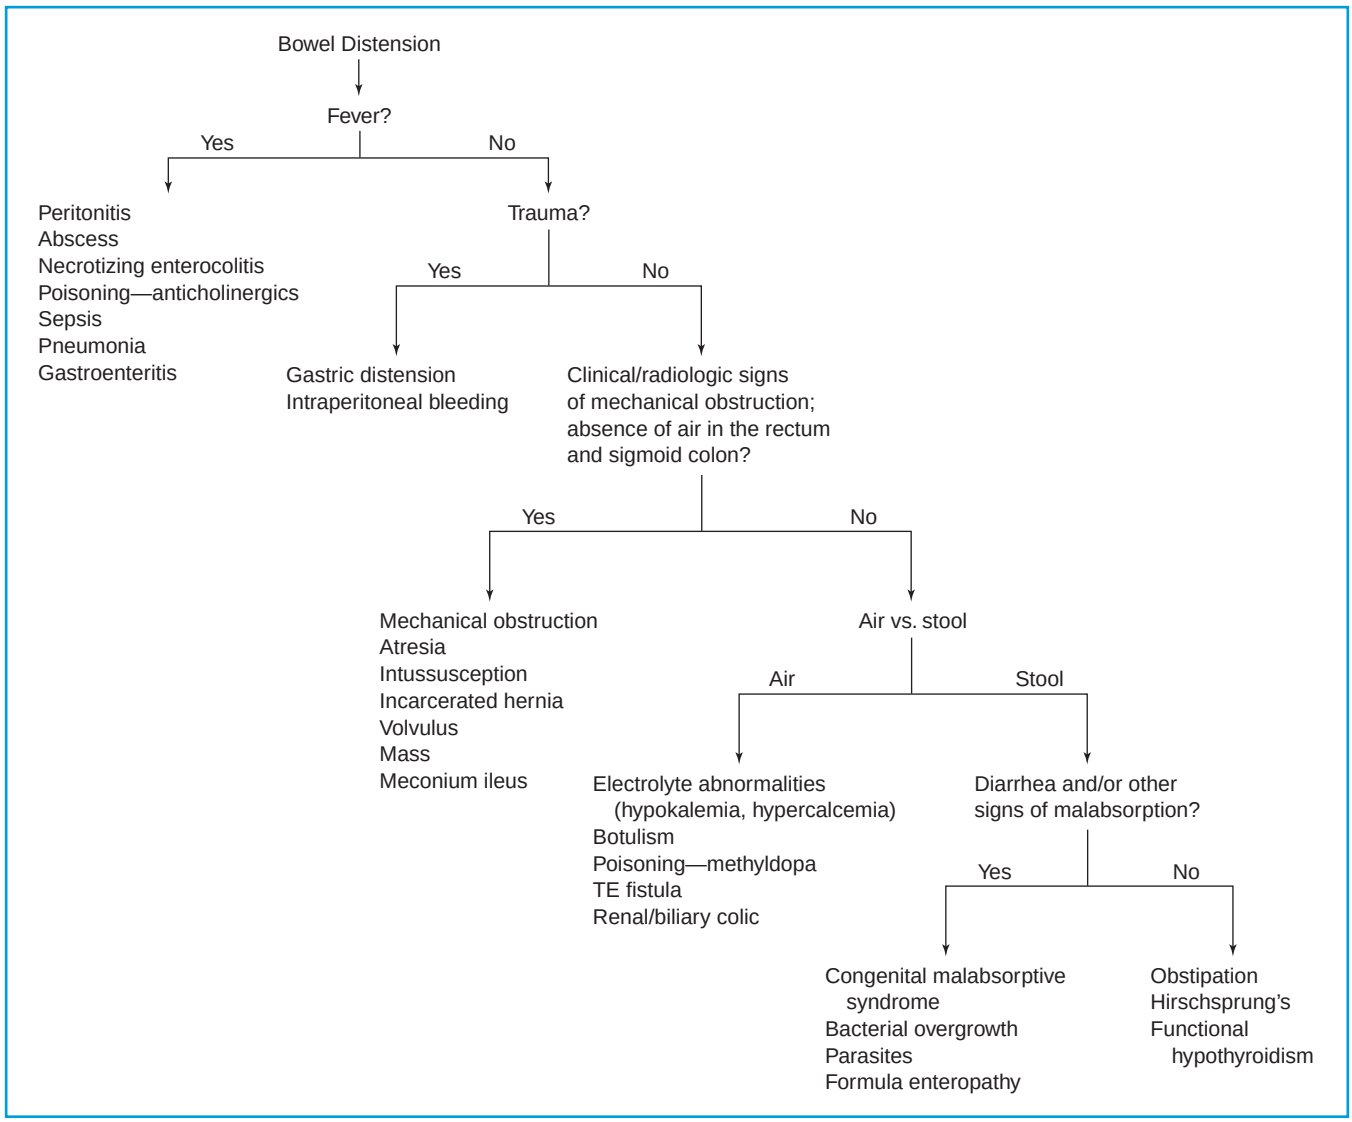

FIGURE 8.1 Bowel distension (TE, tracheoesophageal).

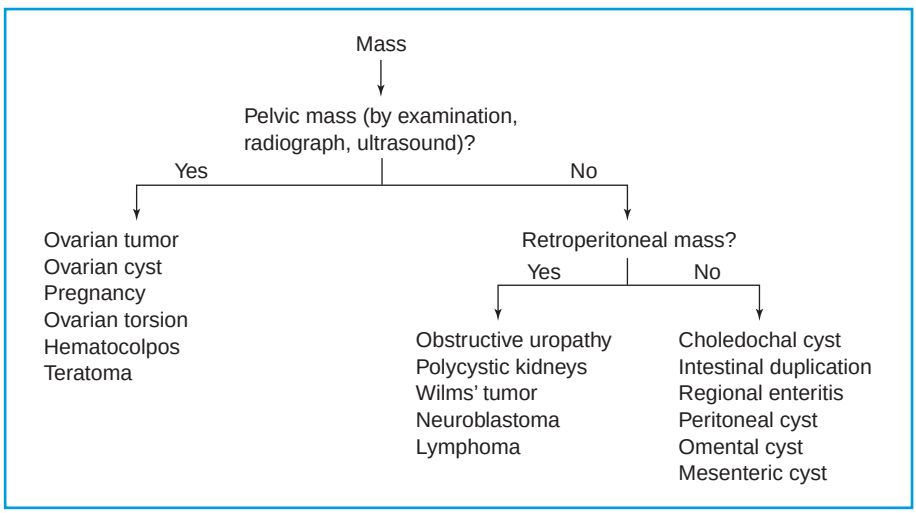

FIGURE 8.5 Mass.

determining the intestinal gas pattern, presence of free intraabdominal air, and presence of intraabdominal calcifications. If intestinal obstruction is suspected, one of the plain radiographs should be a prone cross-table lateral view to determine the presence or absence of air in the rectum and sigmoid colon. The addition of a left lateral decubitus view to the supine radiograph of the abdomen adds to the diagnostic utility if an intussusception is suspected.

Often, after the initial history, physical examination, and laboratory evaluation, further imaging studies will be necessary. Ultrasound is an excellent first step since it is becoming widely available and is portable, has no ionizing radiation, is inexpensive, and can usually determine the presence and characteristics of a mass, organomegaly, and ascites (see Chapter 134). It is also fairly accurate in the diagnosis of GI obstruction, malrotation, and intussusception. Furthermore, physical exam findings (site of maximal tenderness and/or distention) can be correlated with ultrasound findings. An abdominal CT scan is the preferred study in the evaluation of abdominal distention if an ultrasound is inconclusive or unable to be obtained (i.e., obesity). Focused abdominal sonography for trauma (FAST) is a useful screening tool in the initial evaluation of abdominal trauma in pediatrics (see Chapter 107). However, the FAST exam should not be used as the sole diagnostic test to exclude suspected intraabdominal injury; CT scanning has higher sensitivity and specificity in this setting.

Management

Abdominal distension by itself may represent a medical emergency. First, this occurs when the distension is so severe that diaphragmatic excursion is compromised. For example, gastric and bowel distension secondary to aerophagia and ileus posttrauma may significantly impair a child's respiratory status. Massive ascites and free peritoneal air may also compromise respiration. Therefore, the first step in management is to assess and stabilize the child's respiratory status, including the use of positive-pressure ventilation and/or emergent relief of distension, if needed. Passage of a nasogastric or orogastric tube may also result in dramatic improvement in the child's respiratory status.

The second, far less common situation in which abdominal distension may represent an emergent situation in itself is compression of the inferior vena cava (IVC), resulting in a compromised cardiovascular status. For example, occasionally, a child with severe obstipation may present with weak pulses and cool extremities. In this situation, rapid infusion of intravenous fluids, as well as disimpaction, will improve the patient's perfusion status rapidly. Managing the child in the lateral decubitus position may relieve pressure on the IVC. When the airway, breathing, and circulation have been stabilized, the diagnostic evaluation can proceed with laboratory and imaging studies as discussed previously.

CHAPTER 9 ■ APNEA

SUSAN B. TORREY, MD

Neonates and infants can experience apneic episodes in response to a variety of physiologic and pathophysiologic processes not seen in later life. Differences in maturity of the central nervous system (CNS), respiratory reserve, and susceptibility to infectious agents are among the factors that interact to make the very young patient unique. The causes of apnea in older children are similar to those in adults, although the susceptibility and reserve of the child, again, are different. In this chapter, the neonate and the young infant are emphasized, but for completeness, the older child also is considered.

Apnea is defined as a respiratory pause of greater than 20 seconds, or of any duration if there is associated pallor or cyanosis and/or bradycardia. Apnea must be distinguished from periodic breathing, which is a common respiratory pattern in young infants and is characterized by cycles of short respiratory pause followed by an increase in respiratory rate. Normal newborn infants display respiratory patterns that vary by gender and by conceptual age, as well as by sleep state. Research studies have demonstrated that premature infants typically have more apneic episodes than do term infants. Normal-term infants experience significantly more episodes of nonperiodic apnea during rapid eye movement (REM) sleep than during non-REM sleep, although respiratory failure occurs more often during non-REM sleep. Severe apnea may be accompanied by change in color, muscle tone, or mental status, or by choking. Such an episode is described as an acute life-threatening event (ALTE).

PATHOPHYSIOLOGY

Control of respiration by respiratory centers in the pons and medulla through output to the upper airway and bellows apparatus is modulated by peripheral factors such as hypoxia, hypercarbia, and laryngochemical stimulation. The immature response of the neonate and the young infant to these influences, in comparison to that of the older child, accounts for some of the vulnerability of these small patients. The adult response to hypoxemia is to increase respiratory rate in proportion to the decrease in oxygen partial pressure (Po_2). Tachypnea is maintained for the duration of the hypoxic stimulus. In contrast, the neonate demonstrates a brief increase in respiratory rate followed by depression of respiratory drive and, often, apnea. As an example, during sleep, infants who are mildly hypoxic tend to breathe periodically or develop apneic spells. Furthermore, hypoxemia during sleep may not cause arousal. Hypoxemia also results in less of a response to rising arterial carbon dioxide tension ($Paco_2$) with further depression of respiratory drive.

Feeding affects ventilation in young infants. Poor coordination of sucking and breathing can result in apnea. Furthermore, infants can develop apnea with hypoxia and bradycardia as the result of exaggerated laryngeal chemical reflexes in response to regurgitation. Mild hypoxia, as can occur in association with feeding or sleep, exacerbates this response.

A number of exogenous factors, including toxins and metabolic derangements, affect respiratory control by causing medullary depression. Clinical experience demonstrates that newborn and very young infants are particularly sensitive to these factors; for example, hypoglycemia can be manifested as apnea in young infants, and anemia is often related to apnea in premature babies. The young infant is susceptible to bellows failure on a purely mechanical basis. The infant's thoracic cage is extremely pliable, which can cause the chest wall to collapse during inspiration. More muscular effort is then required to produce an adequate tidal volume, resulting in increased work of breathing. In addition, the diaphragmatic muscles have limited glycogen stores and tire easily, resulting in greater vulnerability to respiratory failure as a result of respiratory distress.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of apnea is extensive (Table 9.1). Gastroesophageal reflux is frequently diagnosed in infants with an ALTE, with or without a history of vomiting. Several infectious processes can cause apnea. Meningitis, even in the absence of fever, must be included in the differential diagnosis. Respiratory syncytial virus, the predominant cause of bronchiolitis, may cause apnea in infants who were premature or have preexisting lung disease or congenital heart disease. Pertussis can cause apnea in small infants. Infant botulism is a diagnosis that will hopefully be made before apnea occurs. It must be suspected on the basis of age, symptoms, and clinical findings. Apnea may be the only clinical manifestation of seizure activity. This may be particularly difficult for emergency physicians to identify if they did not witness the episode and neurologic examination may be normal in the postictal period. Apnea may be a symptom of several systemic disease processes, including metabolic abnormalities that result in hypoglycemia, and sepsis. Congenital abnormalities must always be considered in newborns and in young infants. Prolongation of the QT interval can cause a dysrhythmia that is manifested as an ALTE. Finally, there have been well-substantiated reports of ALTE as the result of life-threatening child abuse such as Munchhausen's by proxy or inflicted head injury. Frequently, no cause for the ALTE is identified.

Of great concern to both parents and physician is the risk of sudden infant death syndrome (SIDS) for an infant who has an

TABLE 9.1

DIFFERENTIAL DIAGNOSIS OF APNEA

	Neonate, infant	Older child
Central nervous system	Infection (meningitis, encephalitis) Seizure Prematurity Inflicted head injury Increased intracranial pressure (ICP) Congenital anomaly (e.g., Arnold-Chiari) Breath-holding spell	Infection Toxin Tumor Seizure Increased ICP (trauma, hydrocephalus) Idiopathic hypoventilation ("Ondine's curse")
Upper airway	Laryngospasm (e.g., gastroesophageal reflux) Infection (e.g., croup, pertussis) Congenital anomaly (e.g., Down syndrome)	Obstructive sleep apnea Infection (epiglottitis, croup) Foreign body
Lower airway	Infection (pneumonia, bronchiolitis) Congenital anomaly	Infection Asthma
Other	Infant botulism Hypocalcemia, hypoglycemia Anemia Sepsis Dysrrhythmia	Guillain-Barré syndrome Spinal cord injury Flail chest Dysrrhythmia Ingestion

unexplained ALTE. Multiple studies have identified no causal relationship between ALTE and SIDS. Furthermore, although the rate of SIDS in the United States has dropped dramatically since 1992 when the American Academy of Pediatrics recommended that infants be placed supine or on the side during sleep, there has been no change in the incidence of ALTEs. In addition, the vast majority of SIDS events occur at night, whereas infants typically experience ALTEs during the day.

EVALUATION AND DECISION

Initial Stabilization

The first priority of the emergency physician, after immediate resuscitation of the patient, is to identify life-threatening conditions (Fig. 9.1) such as persistent or recurrent apnea, hypoxia, septic shock, or hypoglycemia. In addition to assessment of the vital signs, including a rectal temperature and blood pressure, the general appearance and mental status should be noted. Regardless of the cause, apnea is life threatening; therefore, a diagnostic investigation, guided by history and physical findings, should be performed to evaluate the child for several common etiologies (Table 9.2). The next phase of evaluation addresses two key questions: (i) Is this episode of clinical significance? (ii) What is the risk of recurrence? Factors to consider include signs of another acute illness, the age of the child, and other possible risk factors for clinically significant or recurrent apnea (Table 9.3).

Has a Significant Apneic Episode Occurred?

The key to answering the two questions is invariably in the history (Table 9.3). A clear initial history from a firsthand observer without the predictable influence of repeated questions is vital. This may not be a simple task, considering the observer's recent stressful experience. The following details should be included: (i) where the event took place; (ii) how long the event lasted; (iii) whether the infant was awake or asleep; (iv) whether there was an associated color change and, if so, to what colors and in what order; (v) description of associated movements, posture, or changes in tone; (vi) what resuscitative efforts were made and the infant's response to them; and (vii) when the infant was last fed. The response to these questions may provide the physician with clues to the diagnosis. As an example, an 8-month-old infant who was interrupted in a favorite activity, began to cry, turned red and blue, and finally had several seconds of tonic-clonic motor activity likely had a breath-holding spell. In contrast, a history of 40 minutes of cyanosis and apnea in a now well-appearing child may be unreliable. Other recent events that should be documented are symptoms of other illnesses, including changes in behavior, activity, and appetite, as well as recent trauma and immunizations.

In many cases, the description of the event may be concerning, although the child appears well. In this situation, hospitalization for further workup, as outlined next, is warranted. A typical case might be the previously well 5-week-old child who was noted by the parents to be apneic during a nap. The infant was described as limp and blue and "looked like he was dead." There was no response to tactile or verbal stimulation

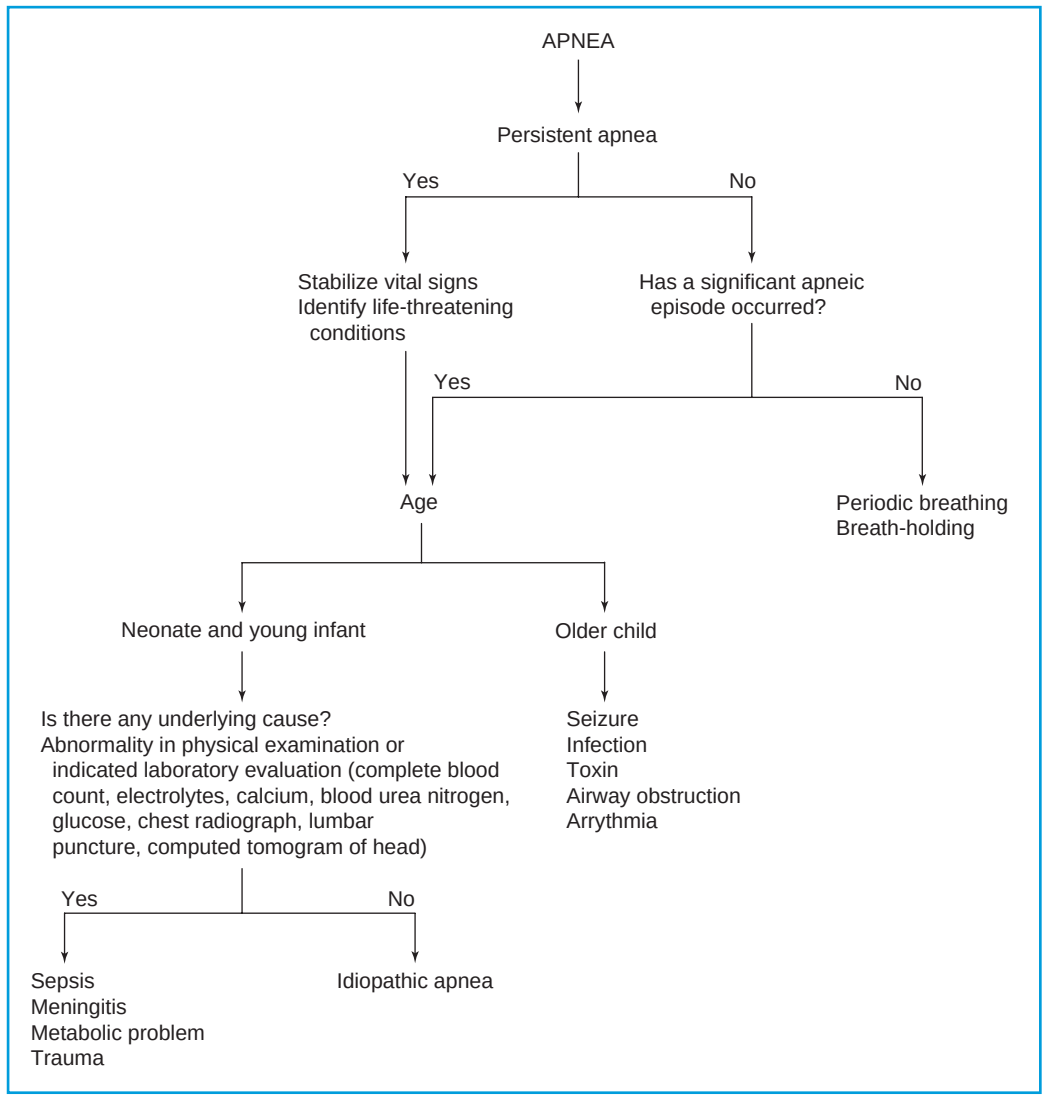

FIGURE 9.1 Approach to the diagnosis and management of apnea.

for 5 to 10 seconds, but after 15 to 20 seconds of mouth-to-mouth breathing, the child coughed, gagged, and began to breathe. His color improved over the next 30 seconds, and the parents rushed him to the emergency department (ED). Although the baby now looks entirely normal, he may be at grave risk for experiencing another ALTE.

The medical history also may provide important information regarding infants at risk for significant or recurrent apnea. The physician should ask specifically about previous similar episodes. Information about perinatal events, including gestational age (birth weight), labor and delivery, maternal health, and nursery course, is helpful. A family history with specific reference to seizures, infant deaths, and serious illnesses in young family members also should be included. Finally, information regarding poisons available in the household may be important in treating an older child.

TABLE 9.2

COMMON LIFE-THREATENING CONDITIONS THAT CAUSE APNEA

Pneumonia
Sepsis/meningitis
Hypoglycemia
Seizures
Intracranial hypertension
Shock
Ingestion (e.g., analgesics, sedatives, muscle relaxants)

Is There an Underlying Cause?

A careful physical examination identifies many treatable acute illnesses that can cause apnea. One clue to serious systemic disease is fever or hypothermia. Tachypnea suggests either a respiratory problem or a metabolic problem. Shock may be secondary to sepsis or hypovolemia from occult trauma. Evaluation of the nervous system should include notation of mental status, palpation of the fontanelles, and funduscopic examination. Dysmorphic features might suggest an underlying congenital abnormality; however, an entirely normal physical

TABLE 9.3

HISTORICAL FEATURES OF APNEA

History	Significant apnea
Duration of event	Greater than 20 s or of any duration associated with pallor, cyanosis, and/or bradycardia
Was child asleep or awake?	Either, but apnea during sleep is more worrisome
Color change	Pallor or cyanosis
Associated movements, posture, or change in tone	Seizure activity Hypotonia "He/she looked dead"
Resuscitative efforts and response	Color change or hypotonia requiring cardiopulmonary resuscitation to improve
Interval since last feeding	If shortly after feeding, consider gastroesophageal reflux
Where event occurred	Association with sleep, trauma

examination provides no reassurance that the described event was clinically insignificant and will not recur.

Laboratory evaluation should be guided by the history and physical examination. Tests to consider in the ED include a measurement of blood glucose and serum electrolytes. Any indication that the infant could have a serious infection should be pursued with cultures of blood and urine and by examination of cerebrospinal fluid. Urine and blood for toxicologic analysis should be obtained from patients who may have been exposed to toxic substances or medications. Noninvasive pulse oximetry is adequate to identify hypoxemia, and significant metabolic acidosis will be apparent on determination of serum electrolytes. The arterial or venous blood gas examination does not serve as a screening test for a serious event and should be obtained on the basis of specific indications. Radiologic studies, (such as of the lateral neck, chest, abdomen, or computed tomography of the head) should be performed as indicated by the history and physical examination.

The tasks of the emergency physician faced with a young patient who has had an apneic episode are to identify whether he or she should be hospitalized and to treat underlying conditions. If a careful history and physical examination suggest that a significant apneic episode has not occurred, the diagnosis of periodic breathing or breath-holding can be made, and the patient can be discharged after appropriate counseling of the parents and arrangements for follow-up. The evaluation of a young child with apnea, however, rarely will be so straightforward. If historical information indicates that significant apnea has occurred, the infant is at risk for a recurrence of this life-threatening event. An aggressive search for an underlying cause is necessary and often includes laboratory studies, lumbar puncture, chest radiograph, and electrocardiogram (EKG). Hospital admission should be arranged for observation and further diagnostic evaluation.

A significant apneic episode in the absence of systemic disease leaves the emergency physician in a quandary. There may not be an explanation for the event that satisfies the physician or the anxious parents. Thus, it is judicious to refer the family to an available specialist or center. There is considerable practice variation in the inpatient evaluation and management of an ALTE. The approach that is usually pursued is designed to identify known causes of primary apnea. It generally includes in-hospital observation with monitoring and an evaluation of the CNS with an electroencephalogram, some type of sleep study, a chest radiograph, and an EKG. Respiratory function is evaluated with a pneumogram, and a barium swallow and esophageal pH study might identify gastroesophageal reflux. An ultrasound or CT of the head would be indicated if a central (CNS) cause for apnea, such as inflicted head injury, is suspected. The decision to recommend home cardiorespiratory monitoring is beyond the scope of emergency practice.

In many instances, a thorough history and careful physical examination with appropriate laboratory studies will suggest that a significant apneic event has not occurred and that there is no serious underlying illness. In this situation, the emergency physician should reassure and educate the family before discharging the patient. Good medical practice dictates that the parents also should be given specific instructions regarding indications for another ED visit and a follow-up visit to a primary care provider.

CHAPTER 10 ■ ATAXIA

JANET H. FRIDAY, MD

Acute childhood ataxia is an uncommon presenting complaint in the emergency department. *Ataxia* is defined as a disturbance in coordination of movements and may be manifest as an unsteady gait. When it occurs, it is a distressing problem to both parent and clinician. It is important to establish the sign because true ataxia may be difficult to differentiate from clumsiness in toddlers. Parents are generally more sensitive to gait abnormalities in this age group. In older children, ataxia may be confused with weakness or vertigo. Life-threatening causes of pure ataxia are rare in children. After consideration of these, the problem may be approached in a cautious, stepwise fashion.

PATHOPHYSIOLOGY

The cerebellum coordinates complex activities such as walking, talking, and eye movements. Ataxia may be caused by a pathologic condition at either a focal or global level within the cerebellum or by disruptions in the afferent or efferent pathways. Anatomically, the cerebellum is located in the posterior cranial fossa, separated from the cerebrum by the tentorium. The ventral borders of the cerebellum form the roof of the fourth ventricle. Space-occupying lesions such as posterior fossa tumors and cerebellar hemorrhage may impede cerebrospinal fluid (CSF) flow, leading to hydrocephalus and increased intracranial pressure (ICP). Conversely, direct pressure on the cerebellar peduncles may cause ataxia to present.

The cerebellum links with other portions of the central nervous system through the superior, middle, and inferior peduncles via the midbrain, pons, and medulla. Proprioceptive and sensory afferent impulses from muscles, joints, and tendons are carried via inferior peduncles to the cerebellar cortex. Labyrinthine afferent input is also conducted through the inferior peduncles. Connections from frontal motor cortex travel through the middle cerebellar peduncles. The superior peduncles carry efferent output to musculoskeletal tracts from the nuclei of the cerebellum.

The cerebellum is composed of two hemispheres. Because of the decussation patterns, a lesion that affects only one side of the cerebellum will result in movement abnormalities of the ipsilateral side, with distal movements more affected than proximal ones. Midline lesions lead to truncal ataxia, with swaying during standing, sitting, and walking, and/or with titubations (small rhythmic movements) of the head and neck. Finally, the intrinsic function of the cerebellum may be disrupted by toxins and autoimmune and metabolic disorders.

DIFFERENTIAL DIAGNOSIS

Ataxia as a presenting sign invokes a broad differential diagnosis (Table 10.1). Distinguishing among acute, intermittent, and chronic progressive and chronic nonprogressive ataxia may be helpful, although some diagnoses have overlap in their time course at presentation. Fortunately, common causes of pure ataxia (Table 10.2) are not rapidly progressive. Acute cerebellar ataxia or postinfectious cerebellitis is truncal in nature and occurs 8 days to 3 weeks after an infectious illness (see Chapter 92). Children ages 1 to 3 years are most commonly affected. Varicella is the classically identified culprit. Other prodromal infections include mumps, Epstein Barr virus, and mycoplasma. Nystagmus is the most common accompanying symptom. The ataxia is most severe at its onset. Complete recovery usually is noted after several weeks, but has been described as several months. CSF may show mild lymphocytosis and increased protein. Imaging studies are normal. A small percentage of patients may show long-term sequelae such as learning disabilities or coordination problems.

Ingestions of anticonvulsants, alcohol, or sedative-hypnotics generally cause depressed mental status (see Chapter 102) and may have associated ataxia. However, for certain substances (phenytoin, carbamazepine, primidone), ataxia may be the most remarkable feature of intoxication.

When an ataxic patient presents with weakness and areflexia, Guillain-Barré syndrome may be present. If ophthalmoplegia and areflexia are prominent, the Miller-Fisher variant can be suspected. Neuroimaging is normal, and the CSF may show a mild leukocytosis and elevated protein. Tick paralysis may present similarly, with the discovery of an engorged tick (which may be hidden by long hair), as the diagnostic finding.

Ataxia may be an early prominent sign of posterior fossa tumors (especially medulloblastoma) and other conditions associated with increased ICP, including hydrocephalus and supratentorial tumors (see Chapter 97). Labyrinthitis and benign paroxysmal vertigo are rarely seen in young children but are occasionally encountered in adolescents. The sensation of loss of balance classically produces a wide-based gait. Conversion disorder should be suspected in a patient who walks with a narrow gait and has elaborate "near falls."

Life-threatening causes of ataxia (Table 10.3) rarely present as ataxia alone. In a few cases, bacterial meningitis has been reported with ataxia as the first symptom. Viral cerebellitis may occur as a result of enteroviral disease. Neuroblastoma

LIFE-THREATENING CAUSES OF ATAXIA

Meningitis
Drug intoxication
Brain tumor
Neuroblastoma
Cerebral vascular accident (stroke)
Intracranial hemorrhage

Migraine, seizure, transient ischemic attack, and metabolic disease are the most common causes for intermittent ataxia. Chronic progressive ataxias may have a basis in metabolic defects, some of which are treatable. When a progressive ataxia acutely worsens, this may signify severe hydrocephalus or hemorrhage into a posterior fossa tumor. A variety of familial, metabolic, and congenital causes exist for chronic nonprogressive ataxias.

EVALUATION AND DECISION

The approach to the problem should begin with a thorough history and physical examination. The duration and progression of the illness can be established and will help define the ataxia as acute, intermittent, or chronic. Chronic ataxia should be further divided into progressive or nonprogressive. Key historical points to cover include recent illnesses such as varicella or other infectious diseases and access to medications or alcohol (Table 10.4). Family history may be helpful in recurrent or genetic causes.

Physical examination should focus on signs of increased ICP (bulging fontanel, papilledema, bradycardia, hypertension, abnormal respirations), meningeal irritation (nuchal rigidity, Kernig's or Brudzinski's sign), fever, rash, attached tick, and evidence of middle ear disease. A detailed neurologic

examination should document general level of consciousness, cranial nerve function, strength, tone, reflexes, sensation, and proprioception. Romberg's test will demonstrate a sensory deficit. Observation of the actual movements will help sharpen the diagnosis because particular syndromes have more truncal versus distal involvement, or unilateral versus bilateral involvement. Specific testing of cerebellar function is impossible in young children. However, a cooperative older child can be asked to perform a finger–nose–finger test, heel–shin test, and rapid alternating movements to further delineate neurologic dysfunction.

The decision to pursue specific laboratory testing is outlined in the algorithm shown in Figure 10.1. Patients with an acute presentation, focal neurologic deficits, recent head trauma, or signs of increased ICP warrant urgent evaluation via cranial computed tomography scan. Evidence of intracranial hemorrhage, hydrocephalus, or posterior fossa tumor provides an etiology for the ataxia. Neurosurgical involvement should be sought. If the imaging study is normal, the diagnosis may be postconcussion syndrome for patients with head trauma. Consultation with a neurologist may be indicated if physical examination findings other than ataxia persist.

If the patient appears "toxic" with fever or nuchal rigidity, an emergent imaging of the head is indicated because cerebellar tonsil herniation may cause neck stiffness. If imaging results are negative, a lumbar puncture can be performed safely. When bacterial meningitis is strongly suspected, appropriate antibiotics may be administered before the testing is done.

When other causes have been eliminated, it is prudent to suspect drug or alcohol ingestion (Table 10.4). With the exception of benzodiazepines, the routine toxicologic screen of urine

will not detect many of these drugs. Thus, specific blood levels are indicated when intoxication is suspected.

Management of ataxia in children is directed at the underlying cause. Fortunately, the most common cause, acute cerebellar ataxia, is a self-limiting illness that resolves completely in most cases. During periods of significant ataxia, head protection may be warranted because of the risk of falling. Also, special caution with sedatives is necessary because their effect may be greatly heightened.

CHAPTER 11 ■ BREAST LESION

RAKESH D. MISTRY, MD, MS

Complaints related to the breast usually involve pain, discharge, and either discrete or diffuse enlargement. Presentation of a breast lesion in a pediatric patient in the emergency setting is uncommon; however, pediatric emergency physicians must be able to distinguish etiologies that require immediate intervention from those that are more appropriately handled by referral to a specialist or close follow-up with a general pediatrician. Fortunately, most breast lesions in children and adolescents are benign and self-limited. However, many patients and their families will benefit from reassurance that neoplastic diseases of the breast are extremely rare in all pediatric age groups. This chapter covers the spectrum of disorders that pediatric emergency physicians are likely to encounter, focuses on the diagnostic approach to breast lesions, and discusses the management of common etiologies.

DIFFERENTIAL DIAGNOSIS

Breast lesions in children can be easily divided into the following categories: infections, benign cysts or masses, malignant masses, abnormal nipple secretions, lesions associated with pregnancy and lactation, and miscellaneous causes, including both anatomic and physiologic entities (Table 11.1). A complete history and physical examination are essential to narrow the differential diagnosis and usually provides sufficient information to guide management. With few exceptions, most breast lesions require little diagnostic testing in the emergency department (ED) and typically can be evaluated using outpatient referral to an appropriate specialist. The commonly encountered disorders (Table 11.2) are almost always benign, but consideration must be given to potentially life-threatening processes (Table 11.3).

Breast Infections

Infection in the breast may take the form of a generalized cellulitis (mastitis) or an abscess. The incidence to breast infection occurs bimodally, with the early peak in the neonatal age group and the later, more common, peak in postpubertal females. Neonatal breast infection (mastitis neonatorum) most frequently presents in the first few weeks of life, commonly resulting from infection of the already enlarged breast bud produced by intrauterine maternal estrogen stimulation. As a result, mastitis neonatorum is more likely to occur in full-term, as opposed to premature infants. In some cases, excessive handling of the hypertrophied tissue by concerned caregivers may facilitate introduction of bacteria. The most common infecting organism is *Staphylococcus aureus*; however, gram-negative enterics and group B streptococci are frequently isolated. More recent studies have demonstrated an increased incidence of community-associated methicillin-resistant *S. aureus* (CA-MRSA), and the presence of anaerobic bacteria in neonatal, adolescent, and adult breast infections.

The clinical presentation of neonatal breast infection is characterized by local signs of inflammation, such as edema, erythema, and warmth. Fever may be present in just 22% to 38% of cases and, although systemic symptoms are uncommon, the potential exists for seeding and associated invasive infections, including bacteremia, osteomyelitis, and pneumonia. For this reason, a complete evaluation for sepsis should be strongly considered in the presence of neonatal breast mastitis or abscess under the age of 2 months, especially in the setting of ill or toxic appearance. For older, well-appearing neonates, the emergency physician may elect to perform only a blood culture, and culture of purulent discharge, if present. Initial ED therapy consists of empiric broad-spectrum intravenous antibiotic for *S. aureus* (CA-MRSA if indicated by local resistance rates), group B streptococcus, and gram-negative enterics; appropriate choices may include vancomycin (no gram-negative coverage), third-generation cephalosporins, or combination therapy with a beta-lactamase–resistant penicillin and an aminoglycoside. Subsequent antibiotic therapy can be guided by the results of a Gram stain and lesion culture. For cases where a breast abscess has developed, removal of purulent material is indicated. However, great care must be taken to avoid damaging the breast bud; therefore, specialty consultation is recommended, and needle aspiration is preferred to incision and drainage of the abscess.

Breast infection in postpubertal females can be further classified as lactational or nonlactational. Lactational mastitis is discussed later in this chapter. Nonlactational mastitis and, less commonly, breast abscess can develop in the central or peripheral regions of the breast and is usually the result of the introduction of bacteria from the skin into the ductal system. These infections are more likely to occur in women who are overweight, have large breasts, have nipple piercings, or practice poor hygiene. Peripheral mastitis can be associated with diabetes, rheumatoid arthritis, steroid treatment, granulomatous disease, and trauma. Other predisposing factors for mastitis include previous radiation therapy, foreign body, sebaceous cysts, hidradenitis suppurativa, and trauma to the periareolar area. Signs and symptoms of infection include local erythema, warmth, pain, and tenderness, and may also include dimpling of the overlying skin and

purulent nipple discharge. Systemic signs, including fever, are less commonly present. Organisms commonly implicated in this age group include both methicillin-sensitive and resistant *S. aureus*, streptococcal species, *Enterococcus*, *Pseudomonas* species, and anaerobic organism such as *Bacteroides* species.

Recommended treatment for mastitis in the postpubertal female includes initiation of antistaphylococcal oral antibiotic therapy and warm compresses. Patients should be instructed to keep the area as clean and dry as possible, to wear a clean cotton bra to help prevent excessive sweating, and to avoid

skin creams or talcum powders. The majority of patients may be managed as outpatients, but require a follow-up appointment in 24 to 48 hours to ensure the infection is improving. For patients with systemic symptoms, those who appear toxic, or demonstrate a lack of response to outpatient antibiotics, hospital admission for intravenous antibiotics is indicated. If a breast abscess is suspected, confirmation via ultrasonography is preferred. Breast abscesses should be drained via needed aspiration by a surgical specialist; incision and drainage are only occasionally necessary.

Benign Cysts and Masses

Enlargement of breast tissue may occur at any age, even in the neonatal period. As previously discussed, the male and female neonatal breast bud is hypertrophied in the first few weeks of life secondary to in utero maternal estrogen stimulation. This is a normal physiologic response and will abate over time; therefore, treatment is not required and caregivers should be instructed to avoid manual stimulation. In preschool age girls, a temporary unilateral or bilateral enlargement of the breast bud may occur. This is typically consistent with isolated premature thelarche in the absence of other manifestations or development of secondary sexual characteristics. If premature thelarche is suspected, reassurance should be provided; the enlargement will most likely spontaneously resolve and can be followed up with the primary care physician. The presence of breast enlargement in young girls in the setting of secondary sexual characteristics (precocious puberty), or in young boys (prepubertal gynecomastia), is atypical, and a specific cause should be aggressively pursued. Careful history and examination focused on the presence of adrenal, ovarian, or hypothalamic pathology, including hormone-secreting tumors and intracranial tumors, are indicated in these cases. Recent medication usage should be reviewed as several medications can cause gynecomastia. Unless an intracranial mass is suspected, most young children can be referred for outpatient workup with an experienced physician or endocrinologist.

Fibroadenomas are the most common benign breast lesion in the pediatric and adolescent age groups, accounting for approximately 75% of breast masses. When present in adolescent girls, these lesions are sometimes called juvenile fibroadenomas.

Fibroadenomas are usually discovered by self-examination and present as solitary, mobile, rubbery, occasionally tender masses with normal overlying skin. Fibroadenomas are more common in African Americans and are more likely to occur in the upper outer quadrants of the breast. These lesions are benign and do not require extensive evaluation. If the emergency physician feels imaging is required, breast ultrasound is most helpful to confirm the diagnosis and exclude more severe pathologies. Of note, mammography is usually not helpful, owing to the increased fibroglandular tissue present in children and adolescents. Fibroadenomas can be observed over time, and reassurance that the malignant potential of a fibroadenoma is very low should be provided. If treatment is required, for example, with giant fibroadenomas (>5 cm), referral to a pediatric surgeon or breast surgeon for excisional biopsy is preferred.

Fibrocystic disease is a benign, progressive process that is generally seen in women during adolescence and young adulthood that may be encountered by emergency physicians. Fibrocystic masses may be solitary or multiple, unilateral or bilateral, feel nodular within the breast tissue, and are most prominent in the upper outer quadrants of the breast. Frequently, presentation is that of cyclically painful masses, with changes in size or nodularity during the course of the menstrual cycle, with the worst degree of pain during the premenstrual phase. Nipple discharge may also be present and is typically nonbloody, green, or brown. Importantly, in the pediatric and adolescent population, these lesions are not considered precancerous. Breast ultrasonography can be used to confirm the diagnosis and surgical intervention is rarely required. Treatment is largely symptomatic with breast support, nonsteroidal analgesics, and avoidance of caffeine. Oral contraceptive agents can reduce symptoms in severe cases for adults, but are not typically prescribed for fibrocystic disease in childhood and adolescent. Follow-up and subsequent evaluation by a primary care physician is recommended; referral to a surgeon for needle aspiration or excisional biopsy is indicated for painful, large, solitary lesions.

Nipple masses represent another group of generally benign breast masses. Benign intraductal papillomatosis is the most common etiology and can be seen in prepubertal or pubertal boys and girls, often coming to attention because of bleeding from the nipple. Occasionally, the lesion may obstruct the nipple and become more painful and possibly infected. In extremely rare instances, a nipple mass can represent an intraductal carcinoma. In these cases, cytologic examination of the bloody nipple discharge can be of diagnostic value. Therefore, expedient referral to a breast surgeon or pediatric surgeon is indicated after detection. In cases of benign nipple masses, careful observation for several weeks by an experienced primary care physician or surgical specialist is indicated. If the nipple mass or bleeding persists, excision is the treatment of choice.

Trauma to the breast can commonly result in the formation of hematomas and fat necrosis, both of which can be palpated as firm, well-circumscribed breast masses. Initially, these lesions may be tender. If left untreated, they may develop into areas of scar tissue that are affixed to the skin. Breast trauma and fat necrosis are relatively common, but the differentiation from other more serious lesions may be difficult, requiring consultation with a surgeon in cases of uncertainty.

Malignant Masses

Cancers of the breast have been reported in young children, but are exceedingly rare, accounting for less than 1% of all breast tumors in adolescence. In both children and adolescents, metastatic disease secondary to rhabdomyosarcoma, Hodgkin's and non-Hodgkin's lymphoma, neuroblastoma, and leukemia are far more common than primary breast malignancies. Adolescent or childhood breast tumors are often classified as secretory carcinomas that behave more benignly than breast cancers in adults. Other histologic classifications of breast malignancies reported in children and adolescents include carcinomas, sarcomas, and cystosarcoma phylloides, which can have both benign and malignant features. Physical examination characteristics suggestive of malignancy include a hard, nontender, solitary mass with ambiguous margins. The mass may be fixed to surrounding tissues, and overlying skin changes such as edema, warmth, skin dimpling, and/or nipple retraction may be present. Other signs include bleeding from the nipple and local lymphadenopathy. The appropriate treatment for suspected malignant lesions is the same as that for a benign mass–prompt referral to a pediatric surgeon or breast surgeon for definitive workup, usually consisting of excisional biopsy. Risk factors for malignant breast masses in the pediatric population include chest irradiation, such as for Hodgkin's disease or radioiodine treatment for thyroid cancer, and a strong familial history of breast malignances, such as patients who are offspring of women with inherited cancer syndromes. Important for detection of potential malignant breast masses is self-examination of the breast; adolescents should be encouraged to routinely perform self-examinations, especially if they are at increased risk of developing breast cancer.

Abnormal Secretions (Nipple Discharge)

There are multiple etiologies of abnormal nipple secretions in children and adolescents. These can be divided according to their potential for surgical management. Nonsurgical causes typically present as nonspontaneous discharges. The most common example is discharge fluid expressed during breast self-examination. The fluid may be milky, multicolored, and sticky and is a normal, physiologic discharge of little concern. When breast infection (mastitis or abscess) is present, a purulent discharge may be expressed or occur spontaneously.

Galactorrhea is the most common spontaneous nipple discharge and usually occurs bilaterally. Pregnancy and lactation are typical causes of galactorrhea; however, in the absence of these conditions, increased prolactin states should be suspected. Structural lesions of the hypothalamus and pituitary (e.g., adenomas) and exogenous medications can cause increased prolactin levels. Drugs implicated in increased prolactin secretion include oral contraceptives, tricyclic antidepressants, phenothiazines, metoclopramide, reserpine, α-methyldopa, and anabolic steroids. As mentioned earlier, in utero estrogen exposure can lead to breast bud hypertrophy in neonates; additionally, this hypertrophy can be accompanied by a colostrum-like

material that has been referred to as "witch's milk." This discharge occurs temporarily, until maternal estrogen levels decline, and is not considered pathologic.

Other nonsurgical spontaneous nipple discharges have been described as multicolored, grossly bloody, serous, or clear and watery. Nonbloody discharges are rarely indicative of malignancy. Mammary duct ectasia, traumatic nipple erosions (e.g., "jogger's nipple"), and eczema are among the more common causes of nonbloody discharges. These disorders can be treated with nipple hygiene, warm compresses, and topical antibiotics, if necessary. When nipple discharge is described as serosanguinous or frankly bloody, or when it tests positive for occult blood, the potential for surgical pathology increases, particularly when a mass is palpable below the nipple. However, surgical etiologies are rare, with malignancy only present in 6% of bloody nipple discharges. More common causes include mammary duct ectasia, intraductal papillomas, intraductal cysts, chronic cystic mastitis, and pregnancy. Any pediatric patient with spontaneous nipple discharge not explained by an obvious cause (e.g., jogger's nipples) should be referred to a breast or surgical specialist for close follow-up and further diagnostic and therapeutic evaluation.

Lesions Associated with Pregnancy and Lactation

Significant changes occur in the female breast as a result of pregnancy, most prominently an increase in breast size and weight. Although pregnant patients may have any of the breast lesions seen in nonpregnant patients, they are prone to develop some unique conditions. The most frequent of these is puerperal (lactational) mastitis, which develops in up to one-third of lactating women, usually within the first few weeks postpartum. Lactational mastitis is likely to result from infection with *S. aureus*, with an increasing incidence of CA-MRSA. *Streptococcus* species, gram-negative organisms, mycobacteria, *Candida*, and *Cryptococcus* have all been implicated as causative organisms of lactational mastitis. Breast abscess may also occur secondary to mastitis and frequently requires drainage of purulent material. Treatment of lactational mastitis consists of warm compresses, antistaphylococcal antibiotic therapy, and frequent evacuation of breast milk. Breast engorgement may exacerbate the symptoms of breast infection; therefore, continued feeding or pumping is recommended. The risk of mother-to-infant transmission of infection is rare and breastfeeding can typically continue. In cases where there is substantial pain, or the infant does not like the taste of infected milk, feeding can proceed in the opposite breast. Mastitis within the first 2 weeks postpartum is often a result of cracked nipples, infant attachment difficulties, and anatomic abnormalities (e.g., cleft lip or palate); later onset is usually a result of poor hygiene or inadequate emptying of the breast with subsequent milk stasis, engorgement, and colonization of bacteria within the milk.

Pregnant patients may also have simple milk-filled cysts called galactoceles, which are often tender and located on the periphery of the breast. Ice packs, breast support, and aspiration may be needed to relieve the obstruction of the milk-filled ducts.

Nonlactating pregnant patients may develop bloody discharge from the nipple during the second or third trimester, representing a benign condition from epithelial cell proliferation. If the discharge persists after delivery, a more thorough investigation for alternate etiologies is recommended. Fibroadenomas often increase in size during pregnancy to the point of infracting and may result in significant pain. Excision is often advised for any solitary mass and the patient should be expediently referred to a breast surgeon. The number of cases of breast malignancy diagnosed during pregnancy is very low.

Miscellaneous Breast Lesions

Congenital Lesions

Supernumerary breasts (polymastia) and supernumerary nipples (polythelia) are congenital conditions that are unlikely to present as chief complaints in the ED, but that may be discovered incidentally on examination. The incidence of polymastia is unknown, but it is more common in girls and results from failure of the embryonic mammary ridges to regress. Polymastia is present at birth, often resembling skin tags or nevi, and may not be noticed until the tissue is hormonally influenced during puberty, pregnancy, or lactation. Supernumerary breasts are most commonly found in the axillae but have been reported to occur in several locations. This ectopic tissue may become tender with menses and has been reported to develop the same range of pathology as normal breast tissue, necessitating excision under certain circumstances.

Polythelia is present in 0.6% of Caucasians and 1.5% of African Americans. It is both sporadic and familial. Polythelia is most commonly found on the left, inferior to the normal nipple. In newborns, polythelia may appear as small, wrinkled lesions with or without pigmentation. The significance of polythelia is questionable. One series of patients with polythelia had a 23% incidence of associated unsuspected urologic anomalies. For this reason, patients with polythelia should be referred for at least a primary screening of underlying urologic disease. Other reported associations include pyloric stenosis, hypertension, congenital heart disease, and cardiac conduction defects. Otherwise, this disorder requires no treatment unless the diagnosis is uncertain (e.g., the lesion looks like a possible melanoma) or is perceived as a cosmetic problem.

Premature Thelarche

Premature thelarche refers to isolated breast development without other signs of puberty. Minimum acceptable ages for thelarche are 7 years for Caucasian females and 6 years for African American females. Typically appearing within the first 2 years of life in its most common form, premature thelarche is a benign, transient condition of unknown etiology. Cases of premature thelarche usually present to the ED secondary to concern raised by parents of prepubertal girls, and reassurance is usually all that is required. However, premature thelarche may be the first sign of true precocious puberty or pseudopuberty, or exposure to exogenous estrogens, and careful follow-up with the primary physician is required.

Juvenile Breast Hypertrophy

Juvenile breast hypertrophy is a rare disorder characterized by sudden, rapid, massive breast enlargement at a time of intense endocrine stimulation, usually between 8 and 16 years of age, after onset of menarche. It is believed to result from end-organ hypersensitivity to estrogen. The hypertrophy is usually bilateral and asymmetric and may progress at an alarming rate over 36 months. The differential diagnosis of this lesion includes cystosarcoma phylloides, juvenile fibroadenoma, and precocious puberty; however, true endocrine or neoplastic lesions are uncommon. In some cases, the hypertrophy regresses in 1 to 3 years, but referral to a breast surgeon is always indicated; breast reduction or even total ablation may become necessary. This disorder is often associated with extreme emotional and psychosocial distress for patients and families.

Gynecomastia

Gynecomastia is a term commonly used to describe a broad spectrum of clinical breast lesions in boys, including excess breast tissue, breast enlargement, and masses of tissue below the nipple that are discrete and nonadherent to the chest wall. Some authorities assert that it is almost always unilateral; others claim it is exclusively bilateral. Additionally, gynecomastia has been described as the male equivalent of fibrocystic changes in the female breast. Despite the confusion in the literature, histologically, there is a proliferation of dense periductal connective tissue with hyperplasia of ductal epithelial cells, which is the result of an increased effective estrogen–testosterone ratio in the serum or in the breast tissue. Causes of this relative hormone imbalance include physiologic changes (neonatal, puberty, aging); exogenous medications; tumors of the testes, adrenal glands, and lungs; metabolic conditions (cirrhosis, hyperthyroidism, renal disease); and hypogonadism.

From a clinical perspective, gynecomastia occurs in about 50% of all boys between the ages of 11 and 18 years and typically lasts about 2 years. It can be associated with growth spurts and can also cause a significant degree of pain. The glandular enlargement is about 4 cm and resembles the early stages of female breast budding. More commonly, gynecomastia will present to the emergency physician because of the anxiety in adolescent boys. If the patient with gynecomastia has normal-size genitalia and none of the predisposing conditions listed earlier, reassurance is all that is required. There is often particular concern about gynecomastia in obese boys, since they may appear to have an overabundance of fatty tissue in the breast region. Surrounding fatty tissue may also give the illusion of small genitalia; however, these patients have no higher incidence of gynecomastia than their nonobese counterparts. Rarely, a few conditions can be mistaken for physiologic gynecomastia, such as lipomastia, a round adipose tissue mass, or neoplasm. If there is any concern for these entities or systemic diseases, then the patient should be urgently referred to an endocrinologist. Overall, gynecomastia is best managed by referral to the primary care physician for continued follow-up.

Physiologic Mastalgia

During the first trimester of pregnancy, some teenage girls may complain of breast fullness. Occasionally, nongravid patients may have breast pain for which no underlying cause is grossly apparent or suspected. These patients may have mastalgia that is likely related to the hormonal milieu of the breast throughout the menstrual cycle. Mastalgia is often described as a bilateral, poorly localized, heavy, dull, achy pain that radiates to the axillae. The pain is often worse with activity and relieved with the onset of menses. In general, there are no abnormal physical findings, except tender, nodular breasts. The differential diagnosis includes costochondritis, Tietze's syndrome, cervical root syndromes, old breast trauma that has resulted in fat necrosis or hematoma, lung disease, and gallstones. Once these possibilities can be reasonably ruled out, mastalgia is the likely diagnosis. Most patients will improve with reassurance, analgesics such as nonsteroidal antiinflammatory medications, warm compresses, and breast support. If the pain is refractory to these measures, other suggested therapies include caffeine avoidance, salt restriction, and diuretics. Danazol, a synthetic androgen, is reserved for severe, debilitating pain.

EVALUATION AND DECISION

History and Physical Examination

Initial evaluation of a breast lesion begins with a careful history and physical examination (Table 11.4). The two most common categories of breast lesions presenting in children are infections and structural or mass lesions. When infection is suspected, especially in neonates or infants, particular attention should be given to the presence of systemic symptoms such as fever, chills, malaise, poor appetite, and lethargy. For the evaluation of mass lesions, it is imperative to obtain a detailed menstrual history and a chronology of the development

TABLE 11.4

IMPORTANT HISTORICAL AND PHYSICAL EXAMINATION COMPONENTS IN THE EVALUATION OF A BREAST LESION

History
Onset and duration of lesion
Pain
Nipple discharge
Relationship of lesion with menses
Complete menstrual and sexual development history, including sexual activity and previous pregnancies
Family history of breast disease
Diet
Medications
Concomitant medical disorders
Systemic symptoms: fever, weight loss, sweating, headaches, visual changes

Physical Examination
Breasts: symmetry, skin appearance, temperature, areola, nipples, secretions, masses, chest wall, axillae
Lymph nodes
Hair distribution
Genitalia

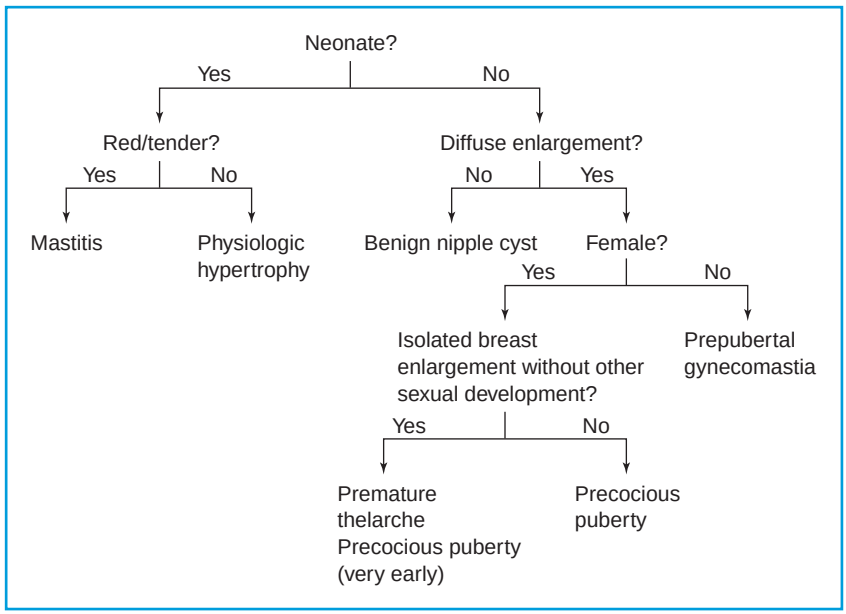

FIGURE 11.1 Approach to breast complaints in the prepubertal child.

of secondary sexual characteristics. Features of intracranial masses, including headaches or visual changes, should be assessed. Pregnant or lactating patients may also present to a pediatric ED. These patients should be queried regarding breastfeeding or breastfeeding attempts, as well as about general symptoms related to changes in the breast tissue. Medications may have an effect on the growth of certain breast lesions and may also affect hormonal pathways, leading to abnormal breast secretions. Therefore, a detailed medication history should be obtained. Few breast disorders may have a familial pattern; however, a careful family history can be helpful.

A comprehensive physical examination should be performed on any pediatric patient who complains of a breast mass or lesion. Premature appearance of secondary sexual characteristics, hirsutism, or abnormal skin coloring may indicate the presence of an endocrinopathy. A detailed evaluation of the breasts and adjacent structures is essential. The chest wall should be inspected for any gross deformities, asymmetry, or skin changes. The physician should have the patient lean forward with hands on hips and again observe for any asymmetry or skin retraction. With the patient supine with arms above the head, the physician should palpate each breast in a series of concentric circles radiating outward from the nipple, looking and feeling for nodules, cysts, masses, or inconsistencies in the breast tissue. Each areola should be gently compressed to assess for masses or nipple discharge. If present, the color, character, and odor of any discharge should be noted. The physician should feel for the presence of any masses or lymphadenopathy in both axillae.

Diagnostic Testing

The majority of patients presenting to the ED will not require intensive laboratory or radiologic testing. All postmenarchal girls should have a pregnancy test performed; breast tenderness and swelling are among the earliest signs of pregnancy. The most helpful test in the emergency setting is breast ultrasonography, which is useful in distinguishing between masses and cystic lesions as well as the presence of abscess with mastitis. Other imaging studies are rarely helpful. Mammography is of little value in children and adolescents, owing to the high proportion of fibroglandular tissue within the breast. Chest radiography is rarely helpful, except when the examiner believes that signs and symptoms from the lungs or chest wall are referred to the breast. If nipple discharge is present, Gram stain, culture, and rarely cytology can be of value. Fine needle aspiration is used in a limited fashion in children and adults, since the majority of lesions are typically benign. Serum endocrinology testing may be indicated for some breast lesions, although these generally take place outside the ED.

Approach

The approach to the patient with complaints related to the breast primarily depends first on whether the patient is prepubertal or pubertal/postpubertal. Among patients who are pubertal/postpubertal, the considerations vary greatly between boys and girls. Finally, unique considerations pertain to the pregnant or lactating girl, as discussed earlier in this chapter.

Prepubertal Child

Among prepubertal children (Fig. 11.1), the most common breast disorders are physiologic hypertrophy in the newborn period and premature thelarche in young girls. When physiologic hypertrophy is noted in newborns, erythema or tenderness should be assessed, and mastitis and potential serious bacterial infection should be considered. Breast development in prepubertal girls, without other signs of puberty, particularly in

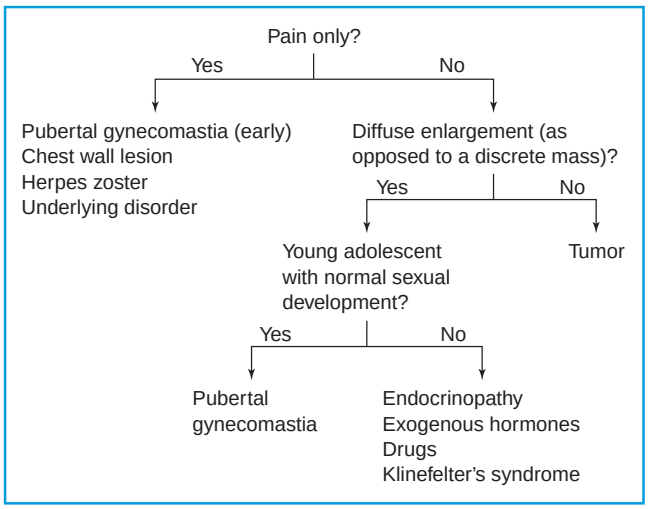

FIGURE 11.2 Approach to breast complaints in the pubertal/postpubertal boy.

those younger than 2 years of age, is likely due to the common and benign condition of premature thelarche. Nevertheless, since this may be the first sign of precocious puberty, urgent follow-up with the primary care physician and/or an endocrinologist for additional testing is recommended. Also among prepubertal children, isolated lesions underneath the nipple may be noted and are usually benign cysts.

Pubertal/Postpubertal Male

The adolescent male (Fig. 11.2) may complain of breast pain, yet have no clearly palpable breast enlargement. This sensation may be caused by minor chest trauma in a boy with early pubertal gynecomastia or may represent underlying chest pain (see Chapter 51). Most often, adolescent males will present for bilateral (sometimes asymmetric) enlargement diffusely throughout the breast tissue, which usually represents (physiologic) pubertal gynecomastia, in the setting of normal sexual development. Unilateral, discrete masses or bilateral, diffuse enlargement with abnormal sexual development require subspecialty referral and additional diagnostic evaluation.

Pubertal/Postpubertal Female

The initial step in evaluating the adolescent girl (Fig. 11.3) is to obtain a pregnancy test, which, when positive, points to a number of conditions that are specific to the gravid state (see earlier discussion). Both pregnant and nonpregnant girls may experience a myriad of disorders related to the breast. The emergency physician's primary goal is to distinguish underlying disorders that are causing chest rather than breast pain (see Chapter 51) and to assess for a few relatively minor problems, including cellulitis, abscess, hematoma, and traumatic erosions. In cases where there is concern for deeper infection or an irregular or large breast mass, breast ultrasonography can be used to rule out severe, life-threatening etiologies. Less severe causes of breast enlargement, masses, and discharge require outpatient follow-up and evaluation by an appropriate specialist.

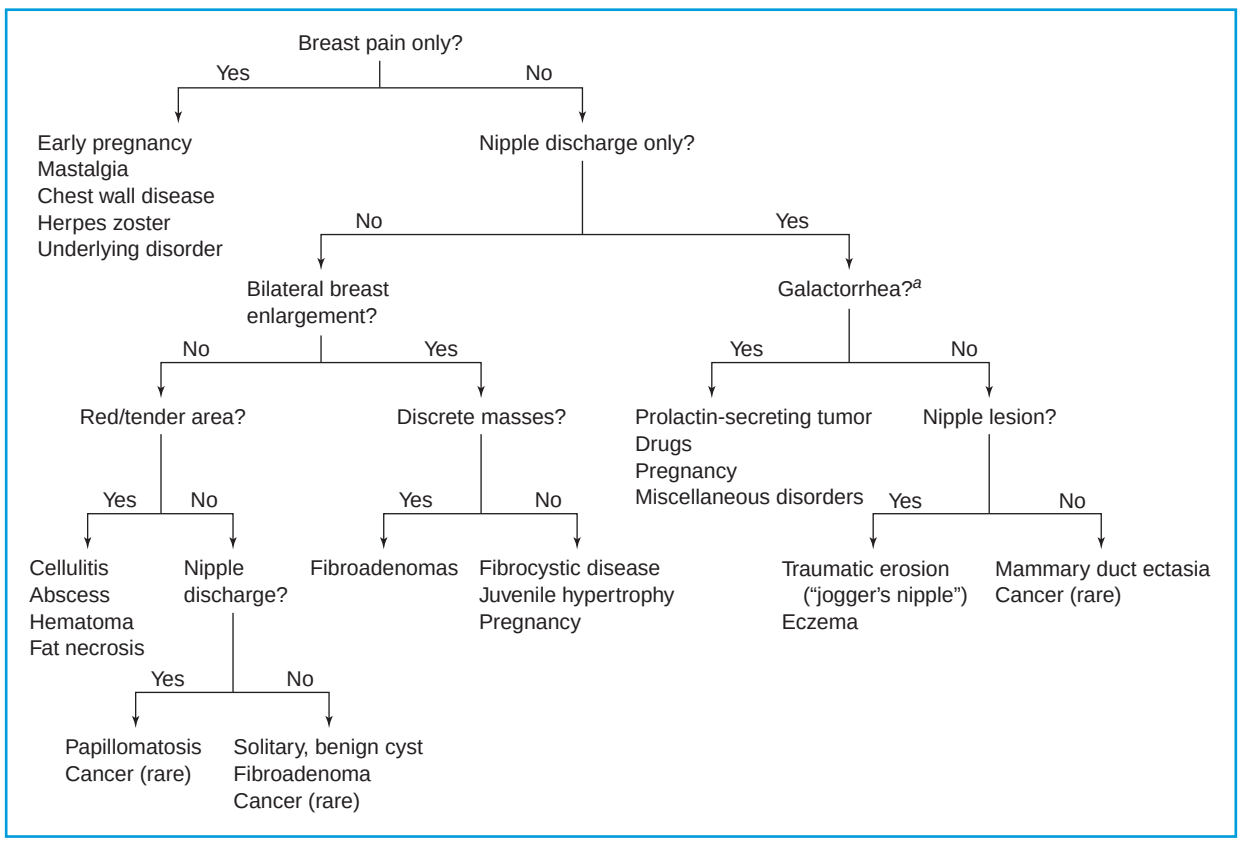

FIGURE 11.3 Approach to breast complaints in the pubertal/postpubertal girl. [a]Galactorrhea refers to milky, as opposed to bloody, serous, or purulent discharge.

ACKNOWLEDGMENT

CHAPTER 12 ■ COMA AND ALTERED LEVEL OF CONSCIOUSNESS

DOUGLAS S. NELSON, MD

Consciousness refers to the state of being awake and aware of oneself and one's surroundings. It is a basic cerebral function that is not easily compromised; impairment of this faculty may therefore signal the presence of a life-threatening condition. An altered level of consciousness (ALOC) is not in itself a disease. It is a state caused by an underlying disease process, which must be addressed quickly to maximize a patient's chance of recovery. *Coma* refers to a state of complete unawareness and unresponsiveness (e.g., unconsciousness) from which a patient cannot be roused; this represents the most extreme form of ALOC. The term *coma* is often modified with descriptors such as light or deep. Lesser levels of impairment are described using other terms whose meanings may overlap. *Lethargy* refers to depressed consciousness resembling a deep sleep from which a patient can be aroused but into which he or she immediately returns. A patient is said to be stuporous or obtunded when he or she is not totally asleep but demonstrates greatly diminished responses to external stimuli. Because neurologic status may vary dramatically over time, it may be difficult to describe such symptoms using a single descriptor. Recording the comatose patient's specific response (body movement, type of vocalization) to a defined stimulus (e.g., a sternal rub) is usually preferable (Table 12.1).

PATHOPHYSIOLOGY

The state of wakefulness is mediated by neurons of the ascending reticular activating system (ARAS) located in the brainstem and pons. Neural pathways from these locations project throughout the cortex, which is responsible for awareness. If the function of these neurons is compromised or if both cerebral hemispheres are sufficiently affected by disease, an ALOC will result.

Proper function of the ARAS and cerebral hemispheres depends on many factors, including the presence of substrates needed for energy production, adequate blood flow to deliver these substrates, absence of abnormal serum concentrations of metabolic waste products or extraneous toxins, maintenance of body temperature within normal ranges, and the absence of abnormal neuronal excitation or irritation from seizure activity or central nervous system (CNS) infection.

Disorders that produce coma by raising intracranial pressure (ICP) increase the volume of an existing intracerebral component such as brain, blood, or cerebrospinal fluid (CSF). Alternatively, a new component such as a tumor may be introduced. The brain can initially compensate for this altered volume relationship by regulating blood flow and CSF production. When the limits of these compensatory mechanisms are reached, ICP will rise abruptly, decreasing cerebral perfusion pressure (defined as mean arterial pressure minus ICP) and placing the patient at risk for herniation.

Herniation, the displacement of a part of the brain from its usual position into an unfamiliar intracranial compartment, can occur in several locations within the cranium, as shown in Figure 12.1. Central herniation results from an increase in volume and pressure in both cerebral hemispheres, compressing and displacing the midbrain and upper brainstem downward through the tentorium. Cingulate gyrus herniation occurs as a result of unilateral cerebral hemisphere volume increase when the gyrus is displaced laterally underneath the falx, crossing the midline of the cranium. This unilateral volume increase may instead cause uncal herniation because the lower midline portion of a cerebral hemisphere and adjoining hippocampal gyrus are directed downward through the tentorium. Foramen magnum (or tonsillar) herniation is a consequence of increased pressure in the posterior fossa, forcing the cerebellar tonsils through the foramen magnum at the base of the skull.

DIFFERENTIAL DIAGNOSIS

A differential diagnosis for children presenting in or near coma is shown in Table 12.2. Conditions arising from trauma or disease within the CNS are separated from those affecting the brain diffusely due to extracranial problems. The more commonly encountered causes of coma are listed in Table 12.3. These most likely causes of coma should be considered in every patient presenting in this condition. Life-threatening causes of ALOC are listed in Table 12.4 and must be considered in every patient. If present, these disorders require emergent treatment. More than one problem may be present simultaneously; for example, a drowning victim may incur a head injury when falling into a swimming pool, or a deeply postictal patient with known seizure disorder may have ingested a toxin.

Primary Central Nervous System Disorders

Trauma

Coma-producing brain lesions that result from trauma include subdural and epidural hematomas, intraparenchymal and subarachnoid hemorrhage, penetrating injuries, cerebral contusion, diffuse cerebral edema, and concussion (see Chapter 116). Penetrating injuries are rare and of obvious origin. Most

cases of pediatric head injury are blunt in nature, involving rapid deceleration against an automobile interior or the ground. Inflicted injury is also common in young children. The site of hemorrhage may be located opposite external signs of trauma due to the rebounding of the brain within the skull after impact (contrecoup injury). Patients may present in a comatose state or may be alert for variable periods after impact. All traumatic lesions of the brain may increase ICP, which is the chief cause of the resulting vomiting, lethargy, and/or coma seen in these patients. Increased ICP reduces cerebral perfusion pressure initially and may eventually result in herniation.

Epidural hematomas are caused by bleeding from cerebral arteries or veins; 85% are associated with an overlying skull fracture. Epidural hematomas may occur after relatively minor trauma; in one series, 24 of 53 children with epidural hematoma had fallen less than 5 feet. The classic location of the injury is the temporal lobe, due to tearing of the middle meningeal artery. Such arterial bleeding produces a faster onset of symptoms such as headache, vomiting, and decreased level of consciousness (LOC) than venous hemorrhage. Approximately 40% of these patients may appear neurologically normal on presentation, during the classically described "lucid interval." On computed tomography (CT) scan, epidural hematomas usually appear sharply localized and are unilateral with a lenticular (lenslike) shape.

Subdural hematomas, produced by tearing of cortical bridging veins between the dura and arachnoid, can occur bilaterally and are five to ten times more common than epidural bleeding. They may occur on a chronic basis in young, abused children and are associated with skull fractures in 30% of cases. When imaged, these lesions are classically crescent shaped. Retinal hemorrhages may be found in 75% of abused patients with subdural hematomas.

Diffuse cerebral edema is more common than focal lesions after brain trauma and is unfortunately less amenable to neurosurgical intervention. Characteristic CT findings of loss of gray–white interface may not be visible for 12 to 24 hours after the trauma was sustained. When radiographic abnormalities appear, they may be similar to those produced by hypoxia. *Concussion* is an inexact term for a transient alteration in normal neurologic function after experiencing head trauma. A postconcussion syndrome may last for hours to days and is characterized by nausea, vomiting, dizziness, headache, and lethargy. Neuroimaging studies are normal, yet patients may be symptomatic enough to require admission for observation and intravenous (IV) hydration.

Seizures

LOC is greatly diminished both during and after periods of seizure activity. Although generalized seizure activity is readily recognizable by the rhythmic motor activity accompanying an ALOC, partial or absence seizure activity may present in a

more subtle fashion with staring, tremors, eye blinking, rhythmic nodding, or other inappropriate repetitive motor activity. Seizures of all types, except absence and simple partial seizures, are usually followed by a postictal period, during which obtunded patients gradually regain responsiveness to and awareness of their surroundings. Patients in nonconvulsive status epilepticus may present in coma, and if other causes have been ruled out, comatose patients should have an electroencephalogram (EEG) performed.

The diagnostic approach toward a patient with ALOC from seizure activity varies based on whether seizures have occurred in the past and the progression or resolution of his or her neurologic abnormalities (see Chapter 69). Posttraumatic or new focal seizures are assumed to reflect an intracranial lesion until proven otherwise. Children taking anticonvulsants for known seizure disorders benefit from drug-level measurement (if available for the medication) during an observation period. Subtherapeutic anticonvulsant levels result in convulsions with postictal ALOC, whereas supratherapeutic levels can result in seizure, but often produce ALOC of a different appearance based on the medication involved. The presence of fever may indicate that a febrile seizure has occurred or that the patient

has contracted a CNS infection such as meningitis or encephalitis (see Chapters 92 and 96). The new onset of afebrile generalized seizures requires a more elaborate evaluation, as detailed in Chapter 69.

Infection

Coma-inducing infections of the CNS may involve large areas of the brain and surrounding structures, as in meningitis or encephalitis, or they may be confined to a smaller region, as in the case of cerebral abscess or empyema (see Chapter 92). Bacterial meningitis remains the most common infection severe enough to produce profoundly diminished LOC. Despite the overall decrease in cases since the introduction of vaccines effective against *Haemophilus influenzae* and *Streptococcus pneumoniae*, infections with the latter organism and *Neisseria meningitidis* still occur and are now the most common etiologic agents after the neonatal period. Meningitis may also be caused by viral (enteroviruses, herpes), fungal (*Candida*, *Cryptococcus*), mycobacterial (tuberculosis), and parasitic (cysticercosis) organisms. These nonbacterial infections usually have a slower onset of symptoms. The incidence of viral meningitis peaks in late summer, when enterovirus infections are most common.

Encephalitis, or inflammation of brain parenchyma, may also involve the meninges (see Chapter 92). It occurs most commonly as a result of viral infection or immunologic mechanisms. Mumps and measles viruses were common etiologic agents before immunizations against these diseases, and they still occur in unimmunized individuals. Varicella encephalitis occurs 2 to 9 days after the onset of rash. The incidence of arthropod-borne encephalitides varies by geographic location but usually peaks in late summer and early fall. The herpes simplex virus remains the most common devastating cause of encephalitis, causing death or permanent neurologic sequelae in more than 70% of patients. It affects the temporal lobes most severely (outside the neonatal period), leading to seizures and parenchymal swelling, which can cause uncal herniation.

Focal CNS infections include brain abscesses, subdural empyemas, and epidural abscesses (see Chapter 92). Brain abscesses occur most often in patients with chronic sinusitis, chronic ear infection, dental infection, endocarditis, or uncorrected cyanotic congenital heart disease. One-fourth of the cases of brain abscess occur in children younger than 15 years of age, with a peak incidence between 4 and 7 years of age. Subdural empyema also occurs secondary to chronic ear or sinus infection, but it is most commonly seen as a sequela of bacterial meningitis. Cranial epidural abscess is rare, but most cases occur from extension of sinusitis, otitis, orbital cellulitis, or calvarial osteomyelitis.

Neoplasms

Alterations in consciousness as a result of intracranial neoplasms (see Chapter 97) may be caused by seizure, hemorrhage, increases in ICP caused by interruption of CSF flow, or direct invasion of the ARAS by the malignancy (which is unlikely to cause coma of rapid onset). The location of the tumor determines additional symptoms: ataxia and vomiting for infratentorial lesions versus seizures, hemiparesis, and speech or intellectual difficulties resulting from supratentorial neoplasms. Acute hydrocephalus secondary to tumor growth most commonly presents with headache, lethargy, and vomiting.

Vascular

Coma of cerebrovascular origin is caused by interruption of cerebral blood flow (stroke) as a result of hemorrhage, thrombosis, or embolism (see Chapter 96). Hemorrhage is often nontraumatic, stemming from an abnormal vascular structure such as an arteriovenous malformation (AVM), aneurysm, or cavernous hemangioma. Rupture of an AVM is the most common cause of spontaneous intracranial bleeding among pediatric patients. The hemorrhage is arterial in origin and located within the parenchyma, but it can rupture into a ventricle or the subarachnoid space. Aneurysm rupture is less common and is unusual in that repetitive episodes of bleeding may occur ("sentinel bleeds"), with rising morbidity and mortality from each subsequent episode of bleeding. Subarachnoid blood may be present in either case, although more commonly with aneurysm rupture. Cavernous and venous hemangiomas are lower-flow lesions that produce a less acute onset of symptoms.

Stroke may also occur from thrombosis or embolism of a normal vessel. Cerebral infarction caused by occlusion of the anterior, middle, or posterior cerebral artery usually produces focal neurologic deficit, not coma. Acute occlusion of the carotid artery, however, may produce sufficient unilateral hemispheric swelling that herniation and coma may ensue; infarction may also lead to hemorrhage. Central venous thrombosis is most commonly seen with hypercoagulable states or as a sequela of infections of the ear or sinus.

Swelling or hemorrhage from infarcted brain can cause increased ICP, leading to interruption of blood flow to the ARAS and resultant coma. Focal symptoms vary based on the size and location of brain denied adequate blood supply. Vascular accidents in the cerebellum present with combinations of ataxia, vertigo, nausea, occipital headache, and resistance to neck flexion. Coma is an unusual early sign of infarction of cerebral structures but becomes more common as lower anatomic centers are affected. Occlusion of the basilar artery may result in upper brainstem infarction, resulting in rapid onset of coma, as does hemorrhage or infarction of the pons.

Cerebrospinal Fluid Shunt Problems

Children with congenital or acquired hydrocephalus as a result of prematurity, neoplasm, or trauma depend on the continued function of a neurosurgically placed shunt to drain CSF and to prevent rises in ICP (see Chapter 126). The most common shunt type is ventriculoperitoneal (VP), draining CSF from a lateral cerebral ventricle, up through a small hole in the skull, through a valve with an attached reservoir located beneath the scalp and into the peritoneum via tubing placed under the skin of the neck, chest, and abdomen. CSF shunts may malfunction for many reasons, including tubing rupture, valve malfunction, tubing blockage, tubing disconnection, and shunt infection. The risk of failure is greatest during the first 6 months after shunt placement or revision. Coma in children has also been noted after intrathecal baclofen overdose resulting from intrathecal pump misuse, or in the immediate postoperative setting after receipt of an inadvertent intraoperative bolus of baclofen.

Systemic Abnormalities

The second major category of disorders causing coma listed in Table 12.2 arises in organs other than the CNS and affects the

brain diffusely. These abnormalities alter neuronal activity by a variety of means, including decreasing metabolic substrates required for normal function (e.g., hypoxia, hypotension, hypoglycemia, other electrolyte abnormalities), altering the rate of intracellular chemical reactions (e.g., hypothermia, hyperthermia), and introducing extraneous toxins into the CNS.

Hypoxia

Oxygen delivery to the brain may be adversely affected by disorders that compromise a patient's airway, breathing, or circulation. Neurons are the cells most sensitive to oxygen deprivation, and they will cease to function within seconds after being deprived of adequate levels of oxygen. Hypoxic coma may result from airway obstruction, pulmonary disease, severe acute anemia, severe methemoglobinemia, carbon monoxide poisoning, or asphyxia (e.g., drowning). Permanent CNS dysfunction results from total anoxia lasting more than 4 to 5 minutes at normal body temperatures; lesser degrees of hypoxia may be tolerated for longer periods. Submersion in cold water may cool the brain sufficiently to exert a neuroprotective effect. It is usually unclear in the emergency department how much permanent neurologic damage has taken place as a result of hypoxia. Hypercarbia may accompany hypoxia and also be responsible for neurologic depression and coma.

Cardiovascular Abnormalities

Hypotension may be the product of numerous causes, including hemorrhage, dehydration, sepsis, arrhythmia, and intoxication. The end result is poor cerebral perfusion, which produces diminished mental status (see Chapter 3). Hypertensive encephalopathy is distinguished by headache, nausea, vomiting, visual disturbance, ALOC, or coma in the presence of a blood pressure greater than the 95th percentile for age and gender (see Chapter 34). The acute onset of severe hypertension may reflect ongoing renal (e.g., unilateral renal artery stenosis, acute glomerulonephritis), endocrine (e.g., pheochromocytoma), or cardiac (e.g., aortic coarctation) pathology, or it may be the result of a toxic ingestion (e.g., cocaine). Cerebral hemorrhage may result. Hypertension or hypotension accompanied by bradycardia may indicate increased ICP.

Disorders of Thermoregulation

Hypothermia or hyperthermia in the pediatric patient is usually caused by prolonged environmental exposure to temperature extremes, such as those found in cold water or in a closed car in sunlight (see Chapter 87). The child who becomes comatose as a result of abnormal core temperature will have multiple organ system abnormalities in addition to CNS dysfunction. Mental impairment is progressive as body temperature is lowered because each fall of 1°C produces a 6% decline in cerebral blood flow. At 29°C to 31°C, confusion or delirium is present, as is muscular rigidity. Patients with core temperatures of 25°C to 29°C are comatose with absent deep tendon reflexes and fixed, dilated pupils. CNS findings in hyperthermia include headache, vomiting, and obtundation, leading to coma and/or seizures, especially above 41°C.

Toxic Ingestions

Pediatric toxic ingestions are often not witnessed, may involve a large dose on a milligram per kilogram basis, may be intentionally inflicted, and are usually complicated by the young patient's inability to provide information on the quantity or identity of the substance ingested (see Chapter 102). Table 12.2 lists many drug classes that cause coma when an overdose is taken. Exogenous toxins may impair neuronal function directly or by causing hypoxia, acidosis, enzyme inhibition, hypoglycemia, or seizures. Overdoses of street drugs, resulting in coma, have been reported in young children coerced into "body packing" drugs in their intestines.

Metabolic Alterations

Abnormal serum concentrations of any substrate or product involved in neuronal metabolism can produce ALOC leading to coma. Hypoglycemia is the most common disorder in this category, especially in infants and young children, whose capacity for hepatic gluconeogenesis is limited. Disorders known to produce hypoglycemia include serious bacterial infections, sepsis, dehydration, and toxic ingestions (especially ethanol, beta blockers, and oral hypoglycemics). Diabetes mellitus, especially of new onset, may present with profoundly depressed consciousness from the combination of hyperosmolarity, dehydration, hypotension, and lactic acidosis and ketoacidosis. Patients under treatment for diabetic ketoacidosis may also develop ALOC due to cerebral edema. Patients with type 2 diabetes may present in a hyperglycemic hyperosmolar nonketotic coma, which can be complicated by malignant hyperthermia.

Metabolic acidosis or alkalosis of sufficient degree produces ALOC. Severe dehydration that leads to significant metabolic acidosis is the most common disorder of this type seen in children. Abnormal concentrations of any serum electrolyte, including sodium, calcium, magnesium, and phosphorus, can also produce altered mental status. The degree of resulting neurologic compromise will be affected by the duration of the problem and concurrent disorders. Severe dehydration alone may also produce profound lethargy in infants and children, even in the absence of significant electrolyte abnormalities.

Other causes of metabolic coma in the pediatric age group include kidney or hepatic failure, both of which may result in progressive apathy, confusion, and lethargy. Urea cycle defects may present with ALOC and hyperammonemia in young infants (see Chapter 94). Acute toxic encephalopathy (Reye's syndrome) is a rare but devastating illness caused by mitochondrial injury of unknown origin that affects all organs of the body, particularly the brain and liver (see Chapter 96). An epidemiologic association exists between the disorder and an antecedent viral illness (including varicella) from which a patient is recovering. Patients with Reye's syndrome typically develop severe vomiting, followed by combative delirium that progresses to coma. Cerebral edema, increased ICP, and central herniation may occur with typically poor outcome.

Miscellaneous Conditions

Other causes of coma or ALOC in children are less easily categorized. Children with intussusception, the most common cause of bowel obstruction in childhood, may have significant apathy and lethargy in addition to vomiting, intermittent abdominal pain, and bloody stools. As a result, they are often treated for dehydration, sepsis, or meningitis before the appropriate diagnosis is discovered. CNS involvement in hemolytic uremic syndrome may produce a comatose state secondary to cerebral infarction, most commonly occurring in the basal ganglia. Breastfed infants of

vegan mothers have presented in coma, suffering from severe vitamin B_{12} deficiency. Children with adrenoleukodystrophy may present acutely with coma, as can those with rheumatologic diseases such as systemic lupus erythematosus and Beçhet's disease.

Psychiatric disorders may produce a true stuporous state. More commonly, neurologically intact patients attempt to feign unresponsiveness for reasons known only to them, and they may be remarkably successful at remaining immobile despite painful stimuli. The nature of their "impairment" may be discovered by a detailed neurologic examination. Conscious patients will usually avoid hitting their face with a dropped arm, may resist eyelid opening, will raise their heart rate to auditory or painful stimuli, and will have intact deep tendon, oculovestibular, and oculocephalic reflexes.

A useful mnemonic incorporating the common causes of coma in children has been proposed by Schunk and is listed in Table 12.5. It is based on the names of childhood immunizations: DPT (for *d*ehydration, *p*oisoning, *t*rauma), OPV (*o*ccult trauma, *p*ostictal or *p*ostanoxia, *v*entriculoperitoneal shunt problem), HIB (*h*ypoxia or *h*yperthermia, *i*ntussusception, *b*rain masses), and MMR (*m*eningitis or encephalitis, *m*etabolic, *R*eye's syndrome, other *r*arities).

EVALUATION AND DECISION

An approach for the evaluation of pediatric patients presenting with coma is summarized in Figure 12.2. All patients need rapid assessment of their airway, breathing, and circulation, followed by a focused history, physical examination, and consideration of laboratory and imaging studies. This approach is based on the selective use of the following critical clinical and laboratory findings: (i) vital signs; (ii) a history of recent head trauma, seizure activity, or ingestion; (iii) signs of increased ICP or focal neurologic abnormality; (iv) fever; (v) laboratory results; (vi) brain CT scan results; and (vii) CSF analysis. The evaluation of the comatose patient should follow an orderly series of steps, addressing the more life-threatening problems of hypoxia, hypotension, or increased ICP before investigating less urgent disorders. If one or more of the former are present, immediate resuscitative efforts are begun.

History and Physical Examination

Although open-ended questions have merit in medicine, goal-directed questioning pertaining to suspected diagnoses is required in cases of coma of unknown origin. Specific queries regarding current medications, medications and substances available to ingest, seizures, fever, headache, irritability, vomiting, changes in gait, and behavioral abnormalities should be made. The most important historical finding in a comatose patient is a history of recent head trauma. If no history of head trauma is present, it should continue to be considered as a potential cause of ALOC if a pediatric patient was unsupervised at any time within 24 hours of presentation, if all caregivers are not available, or if the veracity of caregivers seems questionable.

A patient's vital signs will reveal the presence of fever, hypotension, or hypertension. The LOC of a neurologically impaired patient may initially be evaluated using a simple AVPU scale, representing four major levels of alertness: *a*lert, responsive to *v*erbal stimuli, responsive to *p*ainful stimuli, and *u*nresponsive. Elements of a more detailed neurologic evaluation are discussed in the following section.

The patient should be carefully examined for physical findings consistent with head trauma, including retinal hemorrhage, hemotympanum, CSF otorrhea or rhinorrhea, postauricular hematoma (Battle's sign), palpable or visual damage to scalp or skull, and periorbital hematoma ("raccoon eyes"). Child abuse should be suspected if unexplained bruising is present or the stated mechanism of injury is disproportionate to the degree of physical damage present. Other significant physical findings include anisocoria, absent or reduced pupil reactivity, papilledema, and nuchal rigidity. Purpuric or varicelliform rashes may signify the presence of systemic infections with CNS involvement. Incontinence of urine or stool may indicate that an unwitnessed seizure has occurred.

Neurologic Examination and Scoring

The neurologic examination of the comatose patient should include standard tests of eye opening, responsiveness to verbal and tactile stimuli, and deep tendon reflexes as well as the more specialized examinations described in this section. Any focal (unilateral) abnormal finding is always significant because it may indicate a structural CNS lesion. Abnormal findings on neurologic examination reflect the underlying pathologic condition causing coma and may allow localization of a lesion within the brain.

Patients with ALOC benefit from quantification of their impairment using standard measurements. This allows evaluation of patients' changing neurologic status over time and the recording of this information in the medical record. The effect of medical interventions may then be more easily assessed. The use of accepted scoring systems also facilitates communication

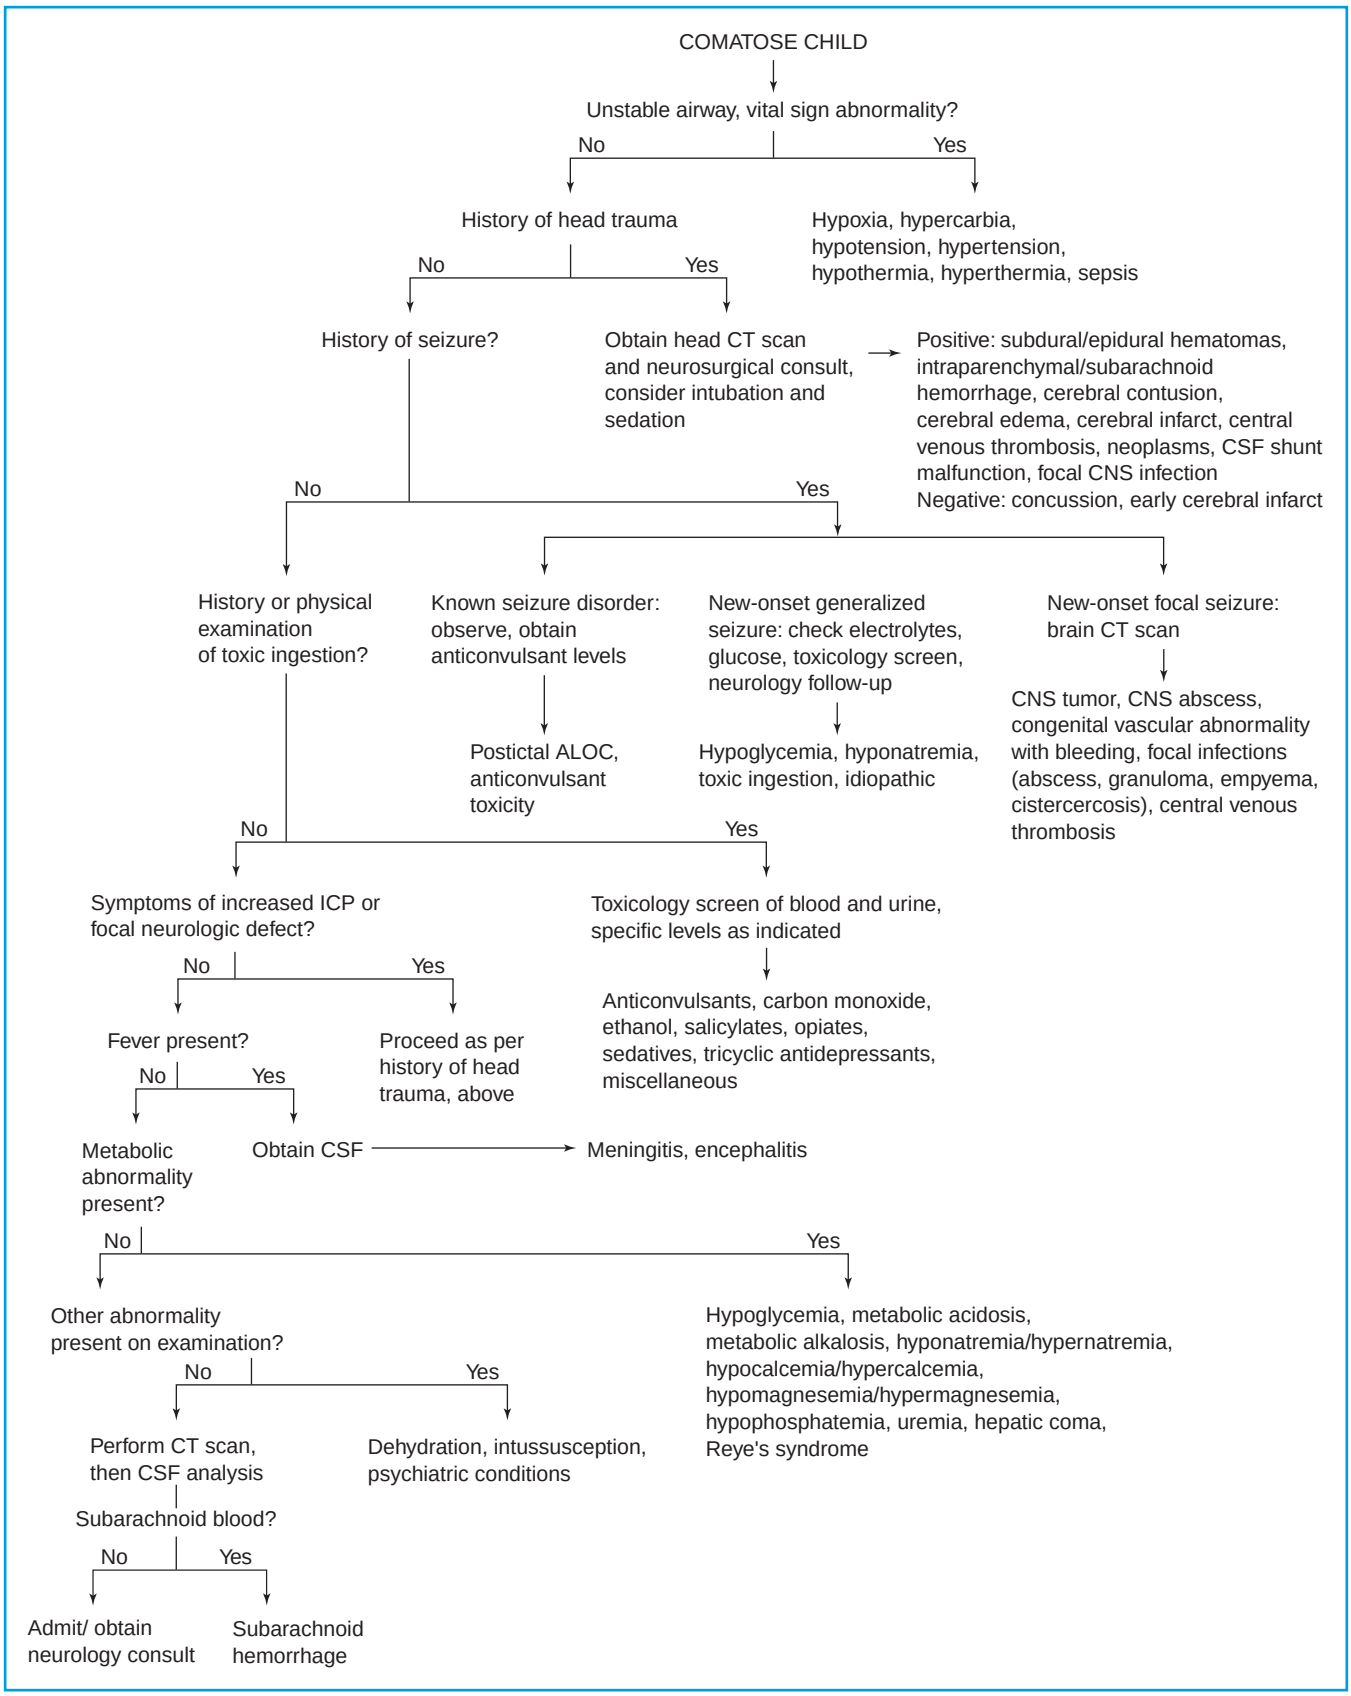

FIGURE 12.2 Evaluation of the comatose child. CT, computed tomography; CSF, cerebrospinal fluid; CNS, central nervous system; ALOC, altered level of consciousness; ICP, intracranial pressure.

with consultants such as neurologists and neurosurgeons. In addition, many outcome measures of neurologically injured patients rely on scales used to assess neurologic function. Although originally developed for trauma, a widely used measurement of consciousness is the Glasgow Coma Scale (GCS) shown in Table 12.1. Patients are graded on three areas of neurologic function: eye opening, motor response, and verbal responsiveness. A GCS score of 3 is the minimum score possible and represents complete unresponsiveness; a GCS score of 15 is assigned to fully alert patients.

Pupillary responses provide the most direct window to the brain of a comatose patient. A unilaterally enlarging pupil (greater than 5 mm) that becomes progressively less reactive to light indicates either progressive displacement of the midbrain or medial temporal lobe, or downward displacement of the upper brainstem. Bilateral enlarged and unreactive ("blown") pupils indicate massive CNS dysfunction and are most commonly seen with posttraumatic increases in ICP. Conditions affecting the brain diffusely usually spare pupillary responses. Exceptions include opiate intoxication, which may cause pinpoint pupils whose constriction is so subtle that it may be detected only with an ophthalmoscope. Intoxication with substances having anticholinergic effects, such as scopolamine, is accompanied by widely dilated pupils that may not react to light.

Other ocular signs noted in patients with depressed LOC are the roving side-to-side conjugate eye movements seen in lighter stages of metabolic coma. Persistent conjugate deviation of the eyes to one side may be caused by focal seizure activity, its resultant postictal state, or focal lesions within the brain. Ongoing seizure activity is usually apparent because of the jerking ocular movements present. Most structural brainstem lesions abolish conjugate eye movements, but it is rare for a metabolic disorder to do so. Oculocephalic reflexes (doll's eye movements) consist of conjugate turning of the eyes in the direction opposite brisk head rotation. They should not be checked in any patient who has suffered a traumatic injury because cervical spine injury may be exacerbated. In the comatose patient, the presence of this reflex implies an intact brainstem and cranial nerves. Deepening ALOC may also be measured by the reduction and loss of spontaneous blinking, then loss of blinking caused by touching the eyelashes, and finally loss of blink with corneal touch. Both eyes should always be tested to detect asymmetry. Neurologically normal patients with 30 degrees of head elevation exhibit an oculovestibular (caloric) response to irrigation of each ear with 10 mL of ice water, consisting of slow conjugate deviation of the eyes toward the irrigated ear with fast beats of nystagmus away from that side. Comatose patients with intact brainstem lose the nystagmic component and have eyes that remain deviated toward the irrigated side for several minutes.

Limb movement and postural changes seen in comatose patients include the bilateral restless movements of the limbs of patients in light coma. Unilateral jerking muscular movements may indicate focal seizure activity or generalized convulsions in a patient with hemiparesis. Decerebrate rigidity refers to stiff extension of limbs with internal rotation of the arms and plantar flexion of the feet. It is not a posture that is held constantly; it usually occurs intermittently in patients with midbrain compression, cerebellar lesions, or metabolic disorders. Decorticate rigidity, when arms are held in flexion and adduction and legs are extended, indicates CNS dysfunction at a higher anatomic level, usually in cerebral white matter or internal capsule and thalamus. Signs of meningeal irritation include Kernig's sign, resistance to bent knee extension with the hip in 90 degrees flexion, and Brudzinski's sign, involuntary knee and hip flexion with passive neck flexion.

The abnormal breathing pattern most commonly seen in comatose patients is Cheyne-Stokes respirations, where intervals of waxing and waning hyperpnea alternate with short periods of apnea. Other abnormal breathing patterns that occur with brainstem lesions include central neurogenic hyperventilation, which can produce respiratory alkalosis, and apneustic breathing, in which a 2- to 3-second pause occurs during each full inspiration.

Laboratory and Radiologic Studies

Laboratory tests commonly obtained on comatose patients include electrolytes, blood urea nitrogen, creatinine, glucose, blood gas, hemoglobin, hematocrit, osmolality, ammonia, and anticonvulsant levels. Toxicologic screening of both blood and urine should be obtained in patients with ALOC of unknown origin. If bedside glucose determination is available, it should be performed on every patient with nontraumatic ALOC. Comatose patients need IV access, and laboratory tests may often be obtained at the time of IV catheter placement. A noncontrast CT scan of the brain can reveal many of the lesions associated with coma, such as cerebral edema, hydrocephalus, malignancy, hematomas, and abscesses. Infarction and thromboses may require the addition of contrast or the use of magnetic resonance imaging scanning to be fully defined.

Vital Sign Abnormalities

Evaluation and treatment of airway, breathing, and circulatory compromise always take precedence over neurologic problems in the child with ALOC. Airway patency and respiratory effort are both compromised by decreased mental status and may result in hypoxia and/or hypercarbia. The former may be readily measured using pulse oximetry, although values will be inaccurate if a toxic hemoglobinopathy, such as methemoglobinemia or carboxyhemoglobinemia, is present. Hypoxia is usually evident by cyanosis of the lips and nailbeds and pulse oximetry values below 90% (see Chapter 15). Arterial blood gas analysis with co-oximetry is useful to quantify respiratory status and identify altered hemoglobin states. The treatment of hypoxia, regardless of the cause, always begins with supplemental oxygen.

The numerical definition of hypotension varies with age, but pallor and evidence of poor peripheral perfusion, with capillary refill time greater than 4 seconds, is recognizable even before placement of a sphygmomanometer cuff. Immediate administration of IV crystalloid therapy starting with 20 mL per kg of normal saline or lactated Ringer's solution is indicated, followed by additional boluses and vasopressors if needed (see Chapter 3). Efforts should be made during IV placement to draw blood for laboratory tests. Of the empiric antidotal therapies often used in adults, only glucose (0.25 to 0.5 g per kg) is routinely administered to children. An empiric trial of naloxone (0.1 mg per kg, max 2 mg per dose) is sometimes justified, whereas

flumazenil and thiamine are given only when specific indications for their use exist (see Chapter 102).

Severe hypertension is less easily discerned on physical examination. If confirmed in more than one extremity, antihypertensives should be administered via the IV route (see Chapters 34 and 100). Mental status should improve after blood pressure is lowered to high normal levels. Patients in hypertensive crises are at risk for hemorrhagic stroke and should be evaluated with a head CT scan if they are neurologically abnormal after blood pressure lowering. Moderate hypertension in the comatose patient with increased ICP may represent a physiologic response to maintain cerebral perfusion pressure (by raising mean arterial pressure), and in this context, should not be treated with antihypertensives.

Hypothermia and hyperthermia are readily recognized once a core (rectal) temperature less than 35°C or greater than 41°C is obtained. The mental status of these patients should begin to improve as body temperature approaches the normal range. A significant percentage of patients with abnormal core temperatures have drowned, fallen through ice, or were engaged in sporting activities in extreme environments. Adolescents with hypothermia may have associated ethanol toxicity. Head trauma, hypoxia, and/or cervical spine injury may be present in these patients.

History of Head Trauma

The patient with deeply depressed consciousness (GCS score less than 9) after head trauma is presumed to have increased ICP until proven otherwise. Rapid sequence intubation with 1 mg per kg of lidocaine added to standard paralytics and sedatives (to blunt rises in ICP caused by laryngeal manipulation) is indicated. Cervical spine injury should be assumed and cervical immobilization maintained at all times. An emergent noncontrast brain CT scan should be obtained and neurosurgery consulted.

History of Seizures

The patient with ALOC in the absence of trauma should be evaluated for recent seizure activity with current postictal state (see Chapters 69 and 96). A history of previous seizures, witnessed convulsive activity, and ALOC consistent with previous postictal periods are valuable clues to this etiology of coma. Ongoing seizure activity may be revealed by the presence of muscular twitching, increased tonicity, nystagmus, or eyelid fluttering. Subtle or completely nonconvulsive forms of status epilepticus may require an EEG to diagnose. The mental status examination of the postictal patient should gradually improve over several hours. Although temporary focal neurologic deficits may follow seizures of any cause, they must be presumed to indicate the presence of focal CNS lesions until proven otherwise.

The evaluation of neurologically depressed patients with seizures varies based on the patient's history, type of seizure, and presence or absence of fever. Patients with a history of seizures should have serum anticonvulsant concentrations measured and be observed until they approach their neurologic baseline. Children who have had a simple febrile seizure (see Chapter 69) should return to their baseline state soon, usually within 1 hour. Those who remain lethargic or irritable past this point (especially after antipyretics have been administered) should be suspected of having meningitis and are candidates for lumbar puncture. Patients with new-onset generalized seizures who do not meet criteria for simple febrile seizures (see Chapters 27, 69, and 96) require more extensive evaluation, which may include measurements of electrolytes (especially sodium, glucose, and calcium), toxicologic screening, examination of CSF, and neurology consultation.

The new onset of focal seizures, with or without the presence of fever, should be evaluated with a head CT scan (using contrast when indicated) to determine the presence of a focal lesion such as a tumor, abscess, or hemorrhage. Only after the results of this study are known should a lumbar puncture be performed. If neuroimaging is unavailable and meningitis or encephalitis is a concern, empiric treatment for bacterial meningitis or herpetic encephalitis may be administered and lumbar puncture deferred (see Chapter 92).

History of Toxic Ingestions

If no history or physical examination findings suggestive of head trauma or seizures are present, a toxic ingestion should be considered, especially in toddlers and adolescents. The availability in the home of any substances capable of depressing CNS function should be thoroughly explored. In general, coma from toxic ingestions is of slower onset than that from trauma and may be preceded by delirium or other abnormal behaviors.

Chapter 102 lists major toxidromes that result from ingestions that produce CNS depression. The pupils of a poisoned comatose patient are a particularly valuable source of information. Miosis occurs with ingestions of narcotics, clonidine, organophosphates, gamma-hydroxybutyrate (GHB), phencyclidine, phenothiazines, and occasionally, barbiturates and ethanol. Mydriasis is produced by ingestions of anticholinergic agents (e.g., atropine, antihistamines, and tricyclic antidepressants) and sympathomimetic compounds (e.g., amphetamines, caffeine, cocaine, LSD, and nicotine). Nystagmus may indicate the ingestion of barbiturates, ketamine, phencyclidine, or phenytoin. Pupillary responses are more likely to be preserved in toxic or metabolic comas. Systemic toxins do not cause unequal pupils; anisocoria in the setting of ALOC should be pursued with neuroimaging.

A toxicologic screen of blood and urine should be considered in all children with coma of unknown origin. Specific assays for other chemicals may be ordered as suspected. A serum acetaminophen level should be ordered in all children with significant ingestions. Table 12.6 lists compounds capable of causing coma that are not typically detected by drug screening; the compounds are grouped by pupillary effects.

The poisoned patient with depressed consciousness should be intubated with a cuffed endotracheal tube for airway protection before decontamination efforts are made. Naloxone may be administered as empiric antidotal therapy for coma-producing toxic ingestions involving unknown medications. Flumazenil should not be given routinely to these patients because seizures may result. Its use is limited to

pure benzodiazepine overdoses in patients with no history of seizures or drug habituation.

Increased Intracranial Pressure or Focal Neurologic Defect

Nontraumatic causes of increased ICP or focal neurologic deficits include neoplasms, CSF shunt malfunction, and hemorrhage secondary to cerebrovascular disease (see Chapters 96 and 126). These patients may present with a history of headache, vomiting, confusion, lethargy, meningismus, focal neurologic dysfunction, seizure activity, or deep coma. Initial physical signs of increased ICP include a bulging fontanelle in infants and sluggishly reactive pupils. More severe and prolonged increases in ICP produce a unilaterally enlarged pupil, other cranial nerve palsies (III, IV, VI), papilledema, and Cushing's triad of hypertension, bradycardia, and periodic breathing. All may signal impending or progressive herniation. From the standpoint of the emergency physician, which type of herniation is present is unimportant; all are life threatening, and the initial treatment is identical for all. Endotracheal intubation using rapid sequence induction (with lidocaine administration and cervical immobilization) is performed to minimize increases in ICP while gaining airway control. Evaluation should parallel that for traumatic head injury, bearing in mind the increased desirability of using IV contrast for CT imaging. Urgent neurosurgical consultation is recommended for all patients in this category regardless of focality of scan findings. Comatose patients with a CSF shunt may need their shunt reservoir or ventricle tapped emergently to treat increased ICP.

Fever

Coma accompanied by fever indicates that CNS infection may be present (see Chapters 27 and 92). Resistance to neck flexion is the most important physical finding in meningitis, the most common infection of this type, although children younger than 2 years of age may lack this finding. Historical data may also include a steadily increasing headache, irritability, vomiting, and worsening oral intake. Kernig's and Brudzinski's signs may be present. Other useful physical clues to CNS infection are the rashes that accompany meningococcemia, varicella, and Rocky Mountain spotted fever. The historical and physical findings in encephalitis are similar to those in meningitis; meningismus may be absent, however. Seizures are particularly common if herpes simplex is the causative agent.

A history of localized CNS dysfunction or seizures before the onset of febrile coma or the presence of concomitant focal neurologic signs may indicate the presence of a focal cerebral infection such as an abscess, granuloma, or subdural empyema. In addition, either diffuse or focal infections may present with signs of increased ICP secondary to abscess formation, cerebral edema, or blockage of CSF flow. If this is the case, a head CT scan should be obtained before lumbar puncture is performed. A contrast-enhanced study is desirable if concern about focal infection is present. The ill-appearing patient should receive antibiotics before neuroimaging is performed.

CSF analysis remains the key to establishing the diagnosis of CNS infection. Abnormalities of CSF white blood cell count (pleocytosis), glucose, and protein occur in roughly predictable patterns with bacterial or viral meningitis, and pathogens may be visible using Gram and other stains (see Chapter 92). Rapid testing with agglutination studies or polymerase chain reaction tests might also be used to identify pathogens. CSF pleocytosis in encephalitis is variable and, if present, is usually mild (less than 500 cells per mm^3), with normal levels of glucose and protein being common. CSF in herpes simplex encephalitis contains red blood cells in 50% of cases. Bloody or xanthochromic CSF under increased pressure in the absence of signs of infection indicates subarachnoid hemorrhage.

Metabolic Abnormalities

The presence of a metabolic disorder leading to coma is usually apparent once the results of routine laboratory tests are available. These values for glucose, sodium, potassium, bicarbonate, calcium, magnesium, and phosphorus make any deficiency or excess of these serum components readily apparent and treatable. Blood gas analysis for evaluation of acidosis or alkalosis from metabolic or respiratory causes may also be indicated. Decreased LOC caused by diabetic ketoacidosis may initially worsen because of a paradoxical temporary decrease in CSF pH and/or cerebral edema complicating therapy.

Renal and hepatic function should be quantified with analysis of blood urea nitrogen, creatinine, and ammonia. Markedly elevated serum blood urea nitrogen and creatinine, oliguria, hypertension, anemia, acidosis, and hypocalcemia indicate the presence of uremic coma as a result of renal failure. Hyperammonemia with decreased mental status may be caused by hepatic failure, acetaminophen ingestion with resultant hepatotoxicity, valproic acid toxicity, Reye's syndrome, or inborn metabolic errors. The hyperammonemia of Reye's syndrome is accompanied by a history of antecedent viral illness (possibly varicella) resolving within the past week and likely treated with aspirin (see Chapter 96). Unremitting vomiting is soon accompanied by encephalopathy, in the absence of jaundice, scleral icterus, focal neurologic signs, or meningeal irritation. Hyperammonemia without accompanying liver failure in the young infant may indicate the presence of a congenital urea cycle defect.

TABLE 12.7

COMMON ERRORS IN THE EVALUATION AND MANAGEMENT OF CHILDREN WITH COMA

Assuming no head trauma has taken place if no such history is given
Neglecting to secure the airway before imaging studies are performed
Hyperventilating intubated patients to a P_{CO_2} well below 35 mm Hg
Not sedating patients once they are paralyzed and intubated
Believing that a toxic ingestion has not occurred because the "tox screen" is negative

Coma of Unknown Origin

Patients with coma of unknown origin not falling into any of the diagnostic categories discussed previously usually benefit from a noncontrast brain CT scan, CSF analysis, and neurologic consultation, in that order. If meningeal irritation is present without fever or other signs of infection, a subarachnoid hemorrhage may be the cause. Common avoidable errors in the evaluation and management of children with coma are listed in Table 12.7. Patients presenting in a comatose state usually need admission for continuing treatment, observation, and specialized care, except when there is an easily recognized and reversible cause, such as hypoglycemia in an individual with known diabetes.

CHAPTER 13 ■ CONSTIPATION

ROSE C. GRAHAM, MD, MSCE, AND STEPHEN LUDWIG, MD

Constipation is an important problem in the pediatric emergency department for many reasons. It is one of the most common pediatric complaints, accounting for 3% of primary care visits. There are many causes for constipation (Table 13.1), some rare and some very common (Table 13.2). Occasionally, the presentation of constipation is atypical, with chief complaints that superficially seem unrelated to the gastrointestinal tract (Table 13.3). Although relatively rare, some causes of constipation are potentially life threatening and need to be recognized promptly by the emergency physician (Table 13.4). In addition, constipation may produce symptoms that mimic other serious illnesses such as appendicitis.

DEFINITION

Although constipation most commonly is defined as decreased stool frequency, there is not one simple definition. The stooling pattern of children changes based on age, diet, and other factors. Average stooling frequency in infants is approximately 4 stools per day during the first week of life, decreasing to 1.7 stools per day by 2 years of age, and approaching the adult frequency of 1.2 stools per day by 4 years of age. Nevertheless, normal infants can range from 7 stools per day to 1 stool per week. Older children can defecate every 2 to 3 days and be normal.

It is easier to define constipation as a problem with defecation. This may encompass infrequent stooling, passage of large and/or hard stools associated with pain, incomplete evacuation of rectal contents, involuntary soiling (encopresis), or inability to pass stool at all.

PHYSIOLOGY

The passage of food from mouth to anus is a complex process. The intestine relies on input from intrinsic nerves, extrinsic nerves, and hormones to function properly. Normal defecation involves voluntary and involuntary components. Disruption of any of these can result in constipation.

The colon is specialized to transport fecal material and balance water and electrolytes contained in the feces. When all is functioning well, the fecal bolus arrives in the rectum formed but soft enough for easy passage through the anus.

Normal defecation requires the coordination of the autonomic and somatic nervous systems and normal anatomy of the anorectal region. The internal anal sphincter is a smooth muscle, which is innervated by the autonomic nervous system. It is tonically contracted at baseline. It relaxes in response to the arrival of a fecal bolus in the rectum, allowing stool to descend to the portion of the anus innervated by somatic nerves. At this point, the external anal sphincter, striated muscle under voluntary control, tightens until the appropriate time for fecal passage. Before defecation, squatting straightens the angle between the rectum and the anal canal, allowing easier passage. Voluntary relaxation of the external anal sphincter allows passage of the feces, and increasing intraabdominal pressure via Valsalva aids the process.

EVALUATION AND DECISION

The evaluation of the child presumed to have constipation should begin with a thorough history and physical examination. Special attention should be paid to the age of the patient, duration of symptoms, timing of first meconium passage after birth, changes in frequency and consistency of stool, stool incontinence, pain with defecation, rectal bleeding, presence of abdominal distention and/or palpable feces, and a rectal exam to assess anal position, sphincter tone, widening of the rectal vault, and presence of hard stool.

A complaint of constipation is not sufficient for diagnosis. A decrease in stool frequency or the appearance of straining is often interpreted as constipation. The physician should be aware of the grunting baby syndrome, or infant dyschezia, in which an infant grunts, turns red, strains, and may cry while passing a soft stool. This is the result of poor coordination between Valsalva and relaxation of the voluntary sphincter muscles. Examination reveals the absence of palpable stool in the rectum or abdomen. Complaints of constipation not supported by history or physical examination are called pseudoconstipation (Fig. 13.1).

Acute Constipation

Constipation is not a disease; it is a symptom of a problem. Constipation is acute when it has occurred for less than 1 month's duration. The patient's age and the duration of the constipation are important when determining the cause and significance of the problem.

The infant younger than 1 year of age with true constipation is particularly concerning. Potential causes include serious diseases such as dehydration, malnutrition, and infant botulism. A recent viral illness accompanied by dehydration from excessive water loss through vomiting, diarrhea, fever, and increased respiratory rate can precipitate acute constipation in an infant. Adynamic ileus or decreased intake after gastroenteritis may cause slower transit time through the colon, which can also lead to hard stools. Anal fissures and/or diaper rash

TABLE 13.1

ETIOLOGY OF CONSTIPATION

after a bout of diarrhea may precipitate painful defecation, resulting in stool retention. In this case, the infant may assume a retentive posture consisting of extension of the body with contraction of the gluteal and anal muscles.

Excessive intake of cow's milk, inadequate fluid intake, and malnutrition should all be uncovered by a complete dietary history. Recent courses of medication cannot be overlooked because many can cause constipation (Table 13.5). Ingestion of lead is also a potential and serious reason for constipation.

Infantile botulism commonly presents with acute constipation, weak cry, poor feeding, and decreasing muscle tone (see Chapter 96). Acute constipation can also be a symptom of a bowel obstruction, but is normally a less prominent feature than other symptoms (see Chapter 121).

Acute constipation in the child older than 1 year of age occurs for many of the same reasons as in the infant. History may reveal recent viral illness or use of medication, as well as the presence of underlying illness, such as neuromuscular disease. Physical examination suffices to rule out anal malformations and other physical problems that could result in trouble defecating.

Chronic Constipation

Constipation of more than 1 month's duration in an infant, although probably a functional problem, is especially concerning and should prompt consideration of an underlying illness. Spinal muscular atrophy, amyotonia, congenital absence of abdominal muscles, dystonic states, and spinal dysraphism, which cause problems with defecation, can be readily diagnosed with history and physical examination.

TABLE 13.4

LIFE-THREATENING CAUSES OF CONSTIPATION

Acute Constipation
Mechanical obstruction
Dehydration
Infantile botulism

Chronic Constipation
Hirschsprung's disease
Abdominal/pelvic mass
Anorexia nervosa

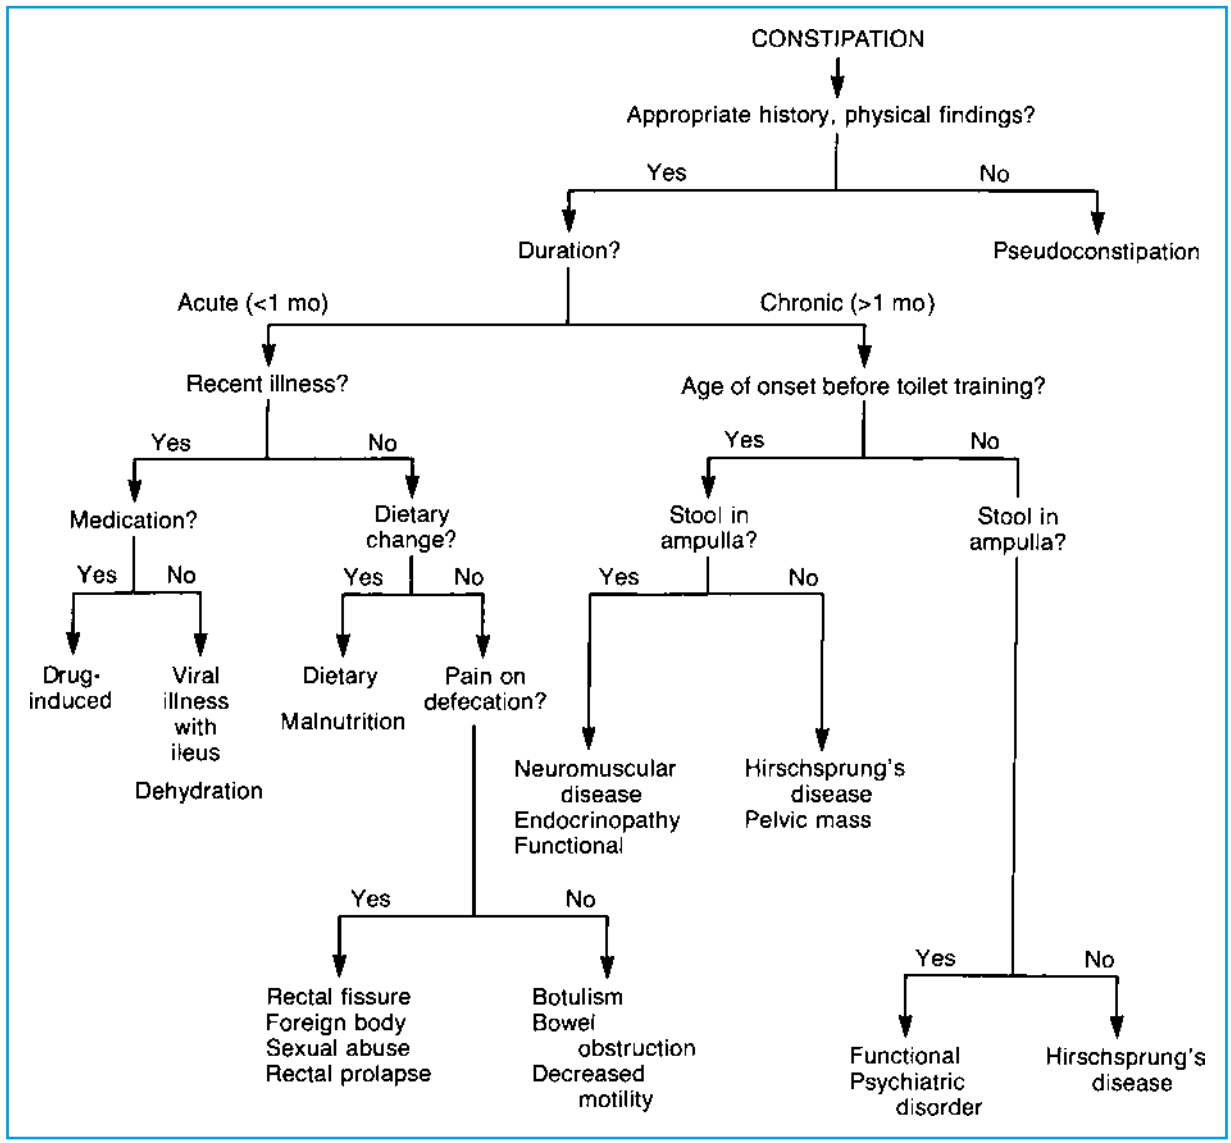

FIGURE 13.1 Approach to constipation.

Anorectal anomalies occur in approximately 1 in 2,500 live births. Anal stenosis causes the passage of ribbonlike stools with intense effort. Diagnosis is made by anal examination, which demonstrates a tight, constricted canal. The condition is treated by repeated anal dilations, sometimes over several months. The anus can be covered by a flap of skin, leaving only a portion open for passage of stool. This "covered anus" may require anoplasty with dilation. Anterior displacement of the anus is believed to cause constipation by creating a pouch at the posterior portion of the distal rectum that catches the stool and allows only overflow to be expelled after great straining. The treatment may be medical or surgical.

Hirschsprung's disease, or congenital intestinal aganglionosis, is rare but must be considered in the constipated infant because it has the potential to cause life-threatening complications. The incidence is 1 in 5,000 live births, with a male:female predominance of 4:1. As a result of failure of migration of ganglion cell precursors along the gastrointestinal tract, there is the absence of ganglion cells in the submucosal and myenteric plexuses of the affected segment. The absence of ganglion cells leaves the affected segment tonically contracted, blocking passage of stool. The segment proximal to the blockage dilates as the buildup of stool progresses. In most cases, the child never feels the urge to defecate because the blockage is proximal to the internal sphincter and anal canal.

In Hirschsprung's disease, abdominal examination often yields a suprapubic mass of stool that may extend throughout the abdomen. Rectal examination reveals a constricted anal canal with the absence of stool in the rectal vault, commonly followed by expulsion of stool when the finger is removed. The combination of palpable abdominal feces and an empty rectal vault is abnormal and must be further investigated.

Megacolon in Hirschsprung's disease can lead to enterocolitis characterized by abdominal distension; explosive stools, which are sometimes bloody; and fever progressing to sepsis and hypovolemic shock. Enterocolitis represents a major cause of mortality in this condition.

TABLE 13.5

SOME MEDICATIONS ASSOCIATED WITH CONSTIPATION

Aluminum
Amiodarone
Amitriptyline
Anticholinergic agents (benztropine, glycopyrrolate, promethazine)
Antineoplastic agents (procarbazine, vincristine)
Benzodiazepines
β-Blockers
Calcium salts
Calcium-channel blockers
Cholestyramine
Diazoxide
Iron
Mesalamine
Omeprazole
Ondansetron
Opioids
Phenobarbital
Phenothiazines and derivatives (prochlorperazine, promethazine, haloperidol)
Phenytoin
Ranitidine
Sucralfate
Ursodiol

Of infants with Hirschsprung's disease, 80% are diagnosed within the first year of life. A history of late passage of meconium is often found (Table 13.6). However, if the involved segment is relatively short, the diagnosis may be delayed. If suspected, diagnosis is supported by unprepped barium enema, which typically demonstrates narrow bowel rapidly expanding to a dilated area. This transition zone represents the location where the aganglionic, tonically contracted bowel meets the dilated, innervated bowel. In disease where only a short segment of bowel is involved, barium enema may miss the transition zone and anal manometry aids in diagnosis. Confirmation is achieved by demonstration of aganglionosis on biopsy (see also Chapter 121).

Hypothyroidism in the infant may present with constipation. Water-losing disorders such as diabetes insipidus and renal tubular acidosis may also contribute to this condition. Cystic fibrosis can present with constipation alone; when there is a history of delayed passage of meconium and Hirschsprung's disease has been ruled out, evaluation by a sweat test is indicated.

TABLE 13.6

FINDINGS IN HIRSCHSPRUNG'S DISEASE AND FUNCTIONAL CONSTIPATION

	Hirschsprung's	Functional
Onset in infancy	Common	Rare
Delayed passage of meconium	Common	Rare
Painful defecation	Rare	Common
Stool-withholding behavior	Rare	Common
Soiling	Rare	Common
Stool in rectal vault	Rare	Common
Failure to thrive	Common	Rare

Chronic constipation in the older child is overwhelmingly likely to be functional constipation. Typically, a cycle of stool-withholding starts when the child disregards the signal to defecate and strikes a retentive posture—rising on the toes and stiffening the legs and buttocks. This maneuver forces the stool out of the anal canal and back into the rectum, which subjects the fecal bolus to further absorption of water. The longer the stool sits, the more likely defecation is to be painful and traumatic. This reinforces stool-withholding behavior, creating larger and harder stool in the rectum.

Over time, in functional constipation, the rectum dilates and sensation diminishes. Eventually, the child loses the urge to defecate altogether. Watery stool from higher in the gastrointestinal tract can leak around the large fecal mass, causing involuntary soiling, or encopresis. This may be misconstrued as diarrhea or as regression in the toilet-trained child. Many parents consult a physician at this point. Other reasons parents seek medical attention for their children are abdominal pain, anorexia, vomiting, and irritability.

Peak times for constipation to develop are when routines change. Toilet training represents a major alteration in the toddler's routine. It is also a time when the child and caregiver battle for control. Another problematic time is after starting school, when a child may be uncomfortable using an unfamiliar bathroom or unable to adapt to a lack of privacy. Involvement with friends or games may distract a child from the signal to defecate. Painful defecation from streptococcal perianal disease or sexual abuse must be remembered as potential precipitants of stool withholding. In addition, functional constipation can be associated with dysfunctional urinary voiding and urinary tract infections.

A history supportive of functional constipation includes retentive posturing, infrequent passage of very large stools, and involuntary soiling during the peak ages. Physical examination typically reveals palpable stool in the abdomen. The back should be inspected for skin changes over the sacral area, which would suggest spinal dysraphism. Normal deep tendon reflexes and strength in the lower extremities in conjunction with a normal anal-wink reflex virtually excludes neurologic impairment. The anus should be normal in placement and appearance. Rectal examination typically yields a dilated vault filled with stool. Abdominal flat-plate x-ray can be helpful but is not necessary (Fig. 13.2). Failure to thrive is not associated with functional constipation and, if present, should prompt further investigation.

Although functional constipation encompasses most cases of chronic constipation in the child older than 1 year of age, the less common causes must always be considered.

As in the infant, endocrine abnormalities and other disorders can cause and present as constipation. Hypothyroidism is often associated with constipation, as well as with sluggishness, somnolence, hypothermia, weight gain, and peripheral edema. Diabetes mellitus produces increased urinary water loss and, in the long term, intestinal dysmotility, which can lead to constipation. Hyperparathyroidism and hypervitaminosis D, which lead to increased serum calcium, cause

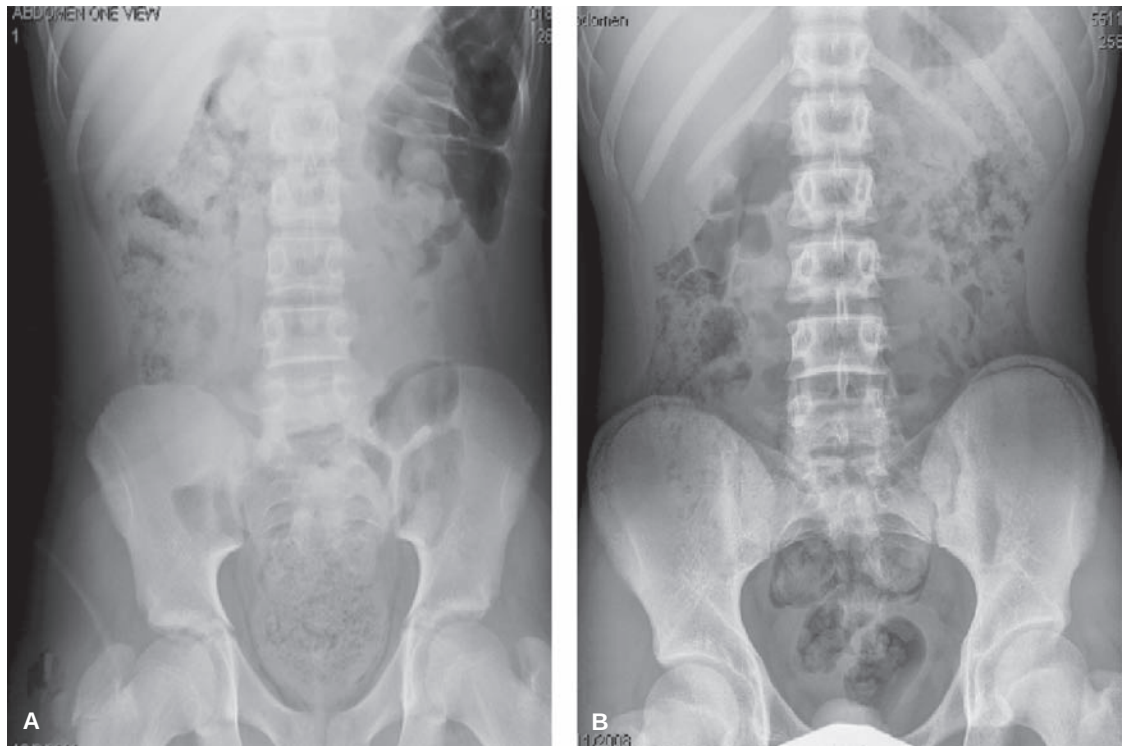

FIGURE 13.2 Both abdominal radiographs demonstrate evidence of constipation with extensive retained fecal material throughout the colon and rectum. The rectum in figure (**A**) is widened and contains a large fecal impaction while that in figure (**B**) is less widened and the stool is less compacted.

constipation through decreased peristalsis. Celiac disease is also recognized as a cause of chronic constipation.

Rarely, an abdominal or pelvic mass may present with chronic constipation. Careful abdominal examination will demonstrate the mass. Rectal masses may present similarly. Follow-up again is emphasized because a mass that does not resolve after clearance of impaction needs further evaluation. Hydrometrocolpos can present with constipation and urinary frequency; therefore, a genital examination is indicated in girls to document a perforated hymen. One must also remember that intrauterine pregnancy is a common cause of pelvic mass and constipation in adolescent girls.

Children with neuromuscular disorders often develop chronic constipation. Myasthenia gravis, the muscular dystrophies, and other dystonic states can predispose children to constipation through a number of mechanisms. A detailed history and physical examination should recognize most neuromuscular problems, allowing symptomatic treatment to be provided.

Psychiatric problems must not be forgotten in the evaluation of constipation. Depression can be associated with constipation secondary to decreased intake, irregular diet, and decreased activity. Many psychotropic drugs can cause constipation. Anorexia nervosa may present with constipation because of decreased intake or metabolic abnormalities, and laxative abuse can cause paradoxical constipation.

TREATMENT

Simple acute constipation in an infant should be treated initially with dietary changes (Table 13.7). Decreasing consumption of cow's milk, possible formula change, and increasing fluid intake when appropriate may be enough to alleviate the symptoms. In addition, supplementing the diet with sorbitol as found in prune, pear, white grape, and apple juice can be helpful to soften the stool and improve stool passage. If dietary measures are not sufficient, lactulose or barley malt soup extract (Maltsupex®) may be useful as osmotic agents. Historically, Karo® corn syrup had been used as an osmotic agent, but its use has fallen out of favor after concerns that the syrup may contain spores of *Clostridium botulinum*. Stool lubricants such as mineral oil should not be used in children younger than 3 years of age and should also be avoided in some older children when aspiration is a risk. Polyethylene glycol solutions such as MiraLax® have gained increased use in the outpatient setting (see discussion below). When perianal irritation or anal fissures are present, local perianal care may decrease the risk of painful defecation, which, in turn, may decrease stool-retentive behavior. Follow-up is the most important aspect of treating simple constipation.

Therapy for acute functional constipation in the child older than 1 year of age should be the same as that for the infant, with dietary changes and stool softeners as mainstays; however, attention should also be paid to psychological factors such as recent stress that may be complicating the situation.

Treatment for chronic constipation in the infant younger than 1 year of age should include ongoing dietary measures including several daily servings of pureed fruits and vegetables, sorbitol-containing juices, and possible formula change. If dietary measures alone are insufficient to control symptoms, a

daily stool softener such as lactulose can be used to help maintain soft stool passage and a glycerin suppository can be used on occasion to disimpact the rectum, although this should not be used regularly. Although safety data are still emerging, polyethylene glycol (PEG) 3350 (MiraLax®, GlycoLax®) may also be a safe and effective treatment for chronic constipation in infants. Loening-Baucke and colleagues studied 20 children and Michail and colleagues studied 12 children younger than 1 year of age, who were safely and successfully treated with PEG 3350 used for several months or more. Although more safety data is needed to make specific recommendations, this will likely become one of the therapeutic options for this age range.

Treatment (Table 13.7) for chronic functional constipation in the child older than 1 year of age begins with disimpaction and evacuation of the stool remaining in the colon. This is accomplished with either oral or rectal therapy or a combination of the two. A study by Youssef et al. demonstrated that in fecally impacted children whose palpable stool mass did not extend above the level of the umbilicus, PEG 3350 at a dose of 1 to 1.5 g per kg per day (up to a maximum of 100 g per day) given for 3 days was an effective method of disimpaction and evacuation. Other oral options include lactulose, sorbitol, senna, bisacodyl, PEG electrolyte solution, magnesium hydroxide, and magnesium citrate. Rectal disimpaction can be accomplished with hypertonic phosphate (Fleet®) enemas or bisocodyl suppositories. A mineral oil enema administered the night before the first phosphate enema may soften existing stool, allowing less painful passage. Phosphate enemas are typically dosed at one adult-sized enema (133 mL) for patients 3 years and older, and one pediatric-sized enema (66 mL) for those 1 to 3 years of age. Phosphate enemas should not be used in children younger than 1 year. The enema may be repeated, spaced 24 hours apart, with a maximum of three total doses. Subsequent doses should only be given if evacuation of the previous dose has occurred. Phosphate enemas should be used with caution in patients with dehydration, prolonged enema retention, or renal impairment because such use has rarely been associated with severe hyperphosphatemia, hypocalcemia, and tetany, and consequent life-threatening complications. Tap water and soapsuds enemas should be avoided because of the possibility of water intoxication. Enemas will disimpact but oral agents are often needed in addition to produce full bowel evacuation. If there is no response after 2 days, more aggressive disimpaction under physician supervision is indicated. Oral phospho-soda preparations should never be used in children and have been removed from the market secondary to serious electrolyte abnormalities.

The long-term maintenance phase of therapy, which is equally as important as the disimpaction and evacuation phase, involves nonstimulant osmotic laxatives, lubricants, fluids, fiber, and behavioral therapy. Laxatives include hyperosmolar agents such as lactulose and PEG 3350. Lubricants such as mineral oil and Kondremul® are helpful to lubricate the intestine for easier passage of stool. These should only be used in children older than 3 years of age and those without a high risk for aspiration. Some have advocated the use of fat-soluble vitamin supplementation when mineral oil products are used, but there is little evidence to suggest this is truly necessary. Increasing fluid and fiber intake is also critical to long-term success in treating constipation. Table 13.8 outlines the recommended daily fiber intake for different ages. Fiber should be increased gradually toward the goal to minimize side effects of flatulence. Regular toileting should be encouraged with positive reinforcement in the school-age child. Toilet training should be discontinued in the training toddler until retentive behaviors have improved. Education of patients and parents about the pathophysiology of constipation, the etiology of encopresis when present, and the expectations of therapy are vital. Close follow-up is a mainstay of treatment. Successful therapy may take months to years to complete.

TABLE 13.7

TREATMENT STEPS FOR FUNCTIONAL CONSTIPATION: "DEFECATE"

D—Disimpact
- oral route: PEG 3350, PEG electrolyte solution, magnesium hydroxide, magnesium citrate, lactulose, sorbitol, senna, or bisacodyl
- rectal route: hypertonic phosphate enema (Fleet®), mineral oil enema, glycerin suppository (infants), bisocodyl suppository (children)

E—Evacuate/empty bowel
- PEG 3350 (MiraLax®)
- PEG electrolyte solution (GoLYTELY®)
- lactulose
- senna
- bisocodyl

F—Fluids
- increase fluid intake
- decrease caffeine intake

E—Eat fiber
- foods high in fiber
- fiber supplements such as FiberCon®, Metamucil®, Benefiber®, Konsyl®, and high-fiber juices (Optimize™)
  - increase nonabsorbable carbohydrates (i.e., sorbitol)

C—Cathartics, softeners, and lubricants
- PEG 3350 (MiraLax)
- lactulose
- barley malt (Maltsupex®)
- lubricants such as mineral oil, Kondremul®, and Milkinol®

A—Album (diary/journal)
- daily record of bowel movements with details

T—Toileting
- set bathroom time after meals
- proper height of toilet with foot support
- reward systems/positive reinforcement
- local perineal care, ointment, sitz baths

E—Education and early follow-up
- critical for success of therapy

TABLE 13.8

RECOMMENDED FIBER DOSE IN GRAMS PER DAY

Toddler	8–10
Preschool	12–14
School-age	14–16
Adult	20–35

Approach to the Patient with Severe Chronic Constipation

Disimpaction and evacuation of stool in the patient with severe chronic constipation or one who has failed simple therapy presents a challenge, particularly in the emergency department setting. A series of phosphate enemas may not be sufficient to disimpact a larger stool mass. Use of PEG with electrolytes solution (GoLYTELY®) as a lavage either orally or via nasogastric tube at a dose of 10 to 25 mL per kg per hour up to 1000 mL per hour until stool is clear may be helpful to treat more severe impactions. This method should be done in the hospital under supervision of a physician with close monitoring of the patient's volume and cardiovascular status and electrolytes. Risks may be higher in patients with complex medical conditions such as cardiac disease. Gastrografin or *N*-acetylcysteine enemas may be an additional method of disimpaction, especially in the case of distal intestinal obstructive syndrome as occurs in patients with cystic fibrosis. In cases of very severe fecal impaction, surgical disimpaction may be necessary. The use of milk and molasses enemas in children is falling out of favor in many institutions as a result of safety concerns following several case reports of serious adverse events, including one death, after administration. The other components of constipation therapy apply as already outlined previously and in Table 13.7.

CHAPTER 14 ■ COUGH

RICHARD G. BACHUR, MD

Cough is a common pediatric complaint with a variety of causes. Although cough is usually a self-limited symptom associated with upper respiratory illnesses, it occasionally indicates a more serious process. Under most circumstances, history and physical examination can accurately determine the cause.

PATHOPHYSIOLOGY

Cough is a reflex designed to clear the airway. Although a cough can be initiated voluntarily, it is usually elicited by stimulation of receptors located throughout the respiratory tract, from the pharynx to the bronchioles. The receptors are triggered by inflammatory, chemical, mechanical, and thermal stimuli. Direct (central) stimulation of a cough center in the brain occurs more rarely. The reflex consists of a forced expiration and sudden opening of the glottis, which rapidly forces air through the airway to expel any mucus or foreign material.

DIFFERENTIAL DIAGNOSIS

The causes of cough differ in the type of stimulus and the site of involvement in the respiratory tract (Table 14.1). The common causes of cough are listed in Table 14.2. Potentially life-threatening causes are listed in Table 14.3.

In distinguishing the etiologies of cough, the clinician must consider features that are atypical for simple upper respiratory infections (URIs) or routine asthma. Although pertussis exists as a URI in the catarrhal phase, infants with paroxysms of coughing, color change, significant posttussive emesis or apneic episodes should be tested and managed as possible pertussis. Similarly, toddlers and young children with new onset wheezing following a choking episode, those infants with wheezing unresponsive to usual therapy, and those with persistent lobar pneumonia should be evaluated for a foreign body. Finally, children who present with cough and associated stridor may have croup, but recurrent stridor, associated dysphagia, or chronic hoarseness must be evaluated for a foreign body, extrinsic compression of the trachea (vascular ring, tumor), or laryngeal pathology (papilloma, hemangioma).

EVALUATION AND DECISION

The history and physical examination are the keys to establishing a diagnosis for cough. The first priority is to recognize and treat any life-threatening conditions. Patients with significant respiratory distress should receive supplemental oxygen and rapid assessment of their airway and breathing (Fig. 14.1).

History

Cough can occur as an acute or chronic symptom, depending on the underlying process. Most common and serious causes of cough have an acute onset (Fig. 14.1). Certain conditions, such as asthma, may present with an acute or a chronic history of cough.

The relationship of the cough to other factors is helpful. Cough in the neonate must raise the possibility of congenital anomalies, gastroesophageal reflux, congestive heart failure, and atypical pneumonia (e.g., *Chlamydia*). If the cough began with other upper respiratory tract symptoms or fever, an infectious cause is likely. A cough that started with a choking episode, especially in an older infant or toddler, suggests a foreign-body aspiration. Cough associated with exercise or cold exposure, even in the absence of wheezing, may be a sign of reactive airway disease. A primarily nocturnal cough often stems from allergy, sinusitis, or reactive airway disease. Systemic complaints should also be considered in patients with a cough: headache, fever, facial pain or pressure (sinusitis), acute dyspnea (asthma, pneumonia, cardiac disease), chest pain (asthma, pleuritis, pneumonia), dysphagia (esophageal or pharyngeal foreign body), dysphonia (laryngeal edema or tracheal mass), or weight loss (malignancy or tuberculosis).

The quality of the cough may also be helpful in localizing the process. A barking, seal-like cough with or without stridor supports the diagnosis of laryngotracheitis. A paroxysmal cough associated with an inspiratory "whoop," cyanosis, or apnea is characteristic of pertussis. Tracheitis gives a deep "brassy" cough, whereas conditions accompanied by wheezing (asthma or bronchiolitis) typically produce a high-pitched "tight" (often termed *bronchospastic*) cough. Determining whether a cough is productive can be difficult in young children who often swallow, rather than expectorate, their sputum. However, many parents can convey whether the cough is "dry" or "wet." Although a productive-sounding cough may be seen with uncomplicated URIs, sinusitis and lower respiratory tract infections are commonly accompanied by a productive cough.

Typically, the onset of cough with rhinorrhea suggests a viral URI. However, if a child with an apparent URI becomes more ill or has persistent symptoms, secondary bacterial infections and pertussis as well as other noninfectious etiologies should be considered.

Physical Examination

Patients with a cough require evaluation of the entire respiratory system. Older patients may be able to initiate a typical cough for assessing the quality, and with younger children,

TABLE 14.1

CAUSES OF COUGH IN CHILDREN

Infection
Upper respiratory infection
Sinusitis
Tonsillitis
Laryngitis
Laryngotracheitis (croup)

LIFE-THREATENING CAUSES OF COUGH

Reactive airway disease	Laryngeal edema
Croup	Pertussis
Bronchiolitis	Toxic inhalation
Foreign body	Congestive heart failure
Pneumonia	Bacterial tracheitis

and pharyngitis are all signs of upper respiratory tract involvement. Allergic features include boggy nasal mucosa, an allergic nasal crease, and allergic "shiners." An otoscopic exam may reveal a small foreign body (e.g., hair) in the otic canal, which may cause chronic cough. Laryngitis and/or stridor generally imply inflammation or obstruction at the level of the trachea or larynx. Unequal breath sounds, wheezes, ronchi, and rales are signs of lower respiratory tract disease. A careful cardiac evaluation should be performed to detect evidence of congestive heart failure, and any clubbing should be noted, as this finding is suggestive of a chronic, cyanotic condition such as cystic fibrosis. Young infants may have respiratory distress with localized upper airway congestion, but older infants and children usually have lower respiratory tract disease if significantly distressed (except in the obvious case of stridor).

Ancillary Studies

For most children with a cough, the history and physical examination should be sufficient to make a diagnosis. In patients with unexplained cough or significant or persistent pulmonary signs, a chest radiograph is warranted. In children with an uncomplicated exacerbation of their asthma, a radiograph is unnecessary. If a radiolucent foreign body is suspected, inspiratory and expiratory films or decubitus films should be obtained to detect air trapping; in cases where the imaging studies are negative, bronchoscopy may be warranted if the suspicion for aspiration is high, particularly in the case of peanuts (see Chapter 28). Other studies that could be useful in selected patients include sinus films, lateral neck radiographs, barium swallow, and computed tomography of the sinuses, neck, or chest.

In addition, laboratory tests may be necessary for specific diagnoses. Such tests include a complete blood count and differential, blood culture, tuberculin test, nasopharyngeal swab for rapid assays or culture (commonly for pertussis, respiratory syncytial virus, and influenza), Wright stain of nasal secretions (eosinophils with allergic rhinitis, neutrophils with sinusitis), and sputum culture and Gram stain (neutrophils and gram-positive diplococci with pneumococcal pneumonia). Pulmonary function testing can be useful to diagnose or follow obstructive airway disease. In cases of airway masses, airway anomalies, foreign bodies, or atypical pneumonias, bronchoscopy may be necessary.

Approach

The major considerations in evaluating a child with cough include the quality of the cough, associated choking or emesis,

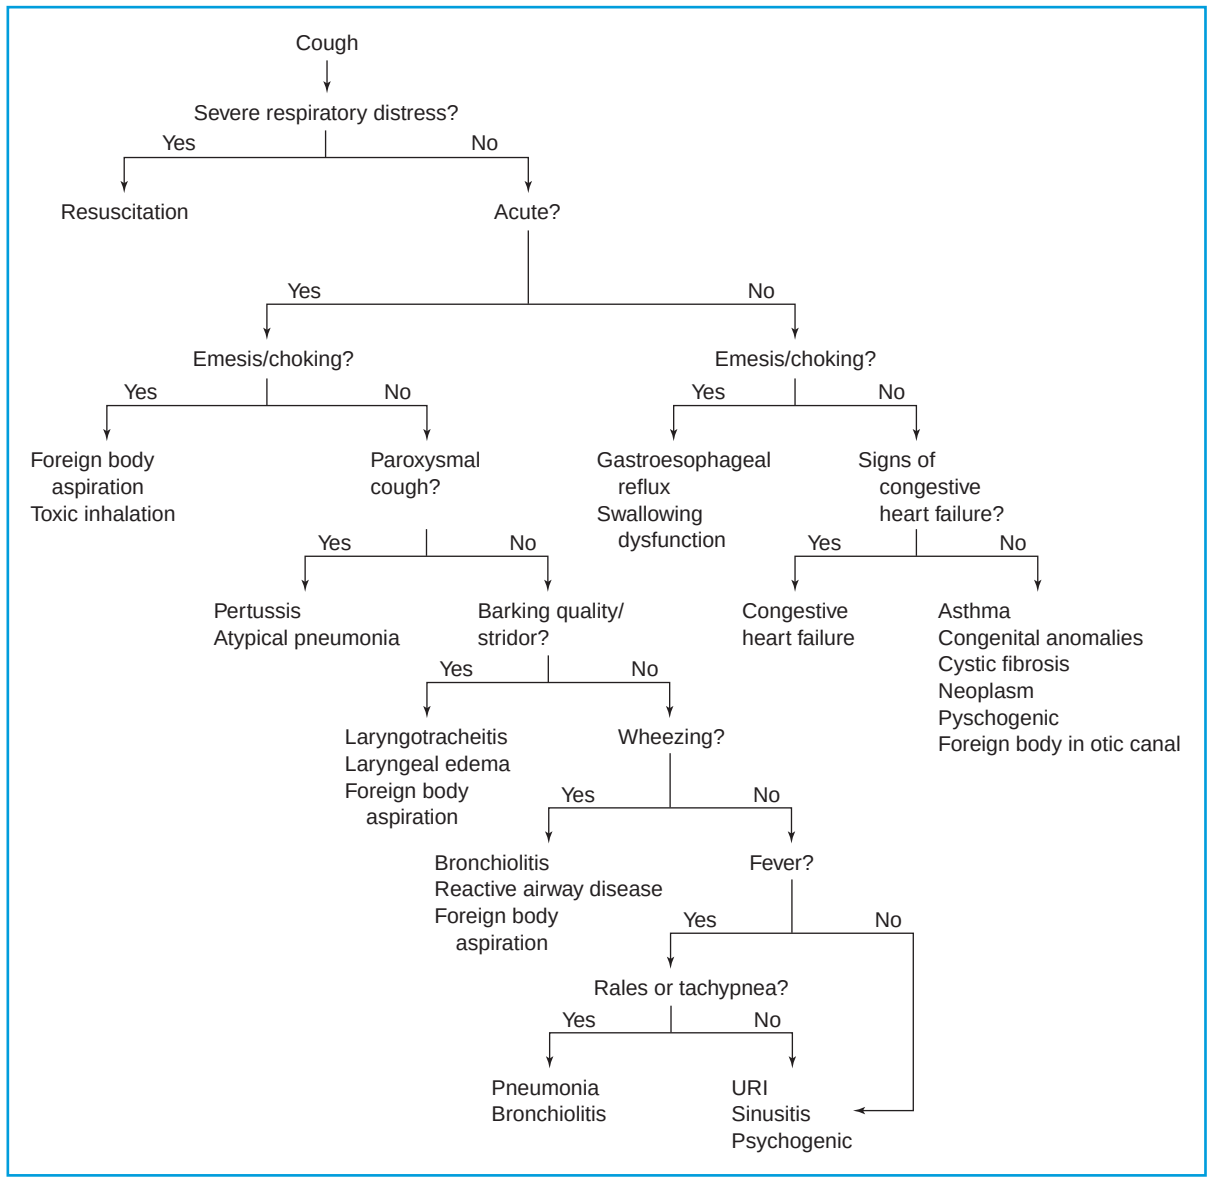

FIGURE 14.1 Approach to the child with cough.

and the findings of lower respiratory tract signs or fever (Fig. 14.1). Any child with respiratory distress needs immediate attention to their oxygenation and ventilation.

Most patients with cough of acute onset will have a simple URI, asthma, bronchiolitis, or pneumonia. A sudden onset with choking or gagging, especially in the preverbal child, is suspicious for a foreign-body aspiration (see Chapter 28). A barky cough, with or without stridor, in a child 3 months to 3 years of age suggests laryngotracheitis. Paroxysms of coughing associated with perioral cyanosis, posttussive emesis, or apnea points to pertussis. Visualizing the posterior pharynx with a tongue blade will often elicit an episode of coughing.

Physical examination should include inspection of the nares, otic canal, and oropharynx and auscultation of the chest. Wheezing indicates bronchiolitis, asthma, or, rarely, foreign-body aspiration. Patients with asthma may complain only of cough and deny any wheezing. Careful auscultation during forced exhalation may detect wheezing or a prolonged expiratory phase. In an older child, significant lower airway obstruction can be measured with a handheld peak flow meter. Asymmetric, or focal, wheezing is seen with lower airway masses and foreign bodies. Rales, ronchi, and decreased breath sounds are characteristic of lower respiratory tract infection.

The remaining patients with a cough of acute onset will have pneumonia or a URI such as viral nasopharyngitis, sinusitis, pharyngitis, or tracheitis. Although rales, decreased breath sounds, or focal wheezing are signs associated with pneumonia, a small proportion of patients with pneumonia may not have any findings by auscultation. Therefore, in cases of significant cough, especially in very young children and those with high fever or elevated white blood cell counts, a chest radiograph is useful to exclude the diagnosis of pneumonia.

Children with chronic cough are likely to have reactive airway disease, allergic rhinitis, or sinusitis. In young children

with failure to thrive or recurrent pulmonary infections, cystic fibrosis (see Chapter 99) should be considered. Chronic cough with a history of recurrent pneumonias or chronic bronchitis can also be suggestive of immunodeficiency or anatomic lesions (see Chapters 98 and 128). Choking with feeding or emesis followed by cough or wheezing in young infants is typical of gastroesophageal reflux. Newborns who exhibit a cough deserve special consideration for airway anomalies, atypical pneumonias, and congestive heart failure (see Chapters 84, 92, 98, and 123). Persistent cough during the day that stops with distraction or sleep is supportive of a psychogenic cause.

TREATMENT

The primary goal should be to treat the underlying process rather than to attempt to suppress the cough. Patients with any distress need supplemental oxygen and immediate assessment of the airway and breathing. Wheezing from asthma is primarily treated with inhaled beta-2 agonists (see Chapter 82). The treatment for bronchiolitis is mainly supportive; a trial of a bronchodilator may be beneficial in a fraction of infants. In children with suspected reactive airway disease based on history alone, a trial of bronchodilator therapy is warranted. Follow-up with the primary care physician is crucial for establishing a treatment plan. Children with suspected foreign bodies or airway masses (intrinsic or extrinsic to the airway) need appropriate intervention for their removal. Croup treatment consists of mist therapy in mild cases, and racemic epinephrine, steroids, and oxygen for more severe episodes. Treatment of pneumonia depends on the age and suspected pathogen. Patients with pertussis require antibiotics for eradication of the organism, and young infants or any child with significant paroxysms need hospitalization.

Antitussive medications have limited value and should not be used routinely in young infants. It is better to give specific therapy (bronchodilators in asthma, antibiotics in sinusitis) and avoid suppressing a cough in conditions with increased sputum production (e.g., asthma, pneumonia). In older children with a nonproductive cough that interrupts sleep, antitussives can be prescribed. Using cool mist humidifiers and elevating the head during sleep can be beneficial for coughs associated with viral URIs.

CHAPTER 15 ■ CYANOSIS

ANNE M. STACK, MD

Cyanosis, a bluish-purple discoloration of the tissues, is a disturbing condition commonly confronted by the pediatric emergency physician. It is most easily appreciated in the lips, nail beds, earlobes, mucous membranes, and locations where the skin is thin and may be enhanced or obscured by lighting conditions and skin pigmentation.

PATHOPHYSIOLOGY

The three factors that ultimately determine the occurrence of cyanosis are the total amount of hemoglobin (Hb) in the blood, the degree of Hb oxygen saturation or qualitative changes in the Hb, and the state of the circulation.

Oxygenated Hb is bright red, and deoxygenated Hb is purple. Cyanosis is evident when the reduced or deoxygenated Hb in the blood exceeds 5 g per 100 mL or when oxygen saturation approaches 85%. When the total amount of Hb in the blood is increased, as in polycythemia, this substantial contribution is evident in the overall appearance of the patient from the increased red blood cell mass, and the patient may appear ruddy. The relative increase in the amount of unsaturated Hb in the polycythemic patient will add a blue hue to the skin. Conversely, when the total amount of Hb is decreased, as in anemia, the patient appears pale, and even if Hb is desaturated, cyanosis may not appear.

The degree of Hb saturation is determined by several factors, including the partial pressure of oxygen (P_{O_2}) in the alveolus, the ability of oxygen (O_2) to diffuse across the alveolar epithelial cell wall into the capillary bed and subsequently into the red cell itself, and the Hb molecule. First, because the P_{O_2} in the alveolus is determined by a balance between the amount of O_2 added during alveolar ventilation and that removed by blood flow throughout the alveolar capillary bed, if the level of alveolar ventilation falls, so does the P_{O_2} of alveolar gas, causing a fall in arterial P_{O_2} and desaturation. Second, the ability of O_2 to diffuse across the alveolar wall into the red cell, or gas–blood barrier, is greatly affected by the circumstances of the barrier itself. According to *Fick's law,* the volume of gas per unit time moving across a tissue sheet is directly proportional to the area of the sheet and the difference in partial pressures between the two sides but inversely proportional to the thickness. Any condition that diminishes surface area or increases the thickness will decrease the amount of O_2 in the blood. Third, the Hb molecule itself has unique properties that affect the amount of oxygen it can carry. Although the complexities of Hb and its ability to carry O_2 are beyond the scope of this chapter, to understand cyanosis it is critical to note that the color of whole blood is in part determined by the state of the Hb molecule. Oxygen binds reversibly to the iron molecule of the Hb subunit, changing its conformation, and oxygenated Hb is bright red. Consequently, factors that affect O_2 binding to Hb will affect the color of the blood. For example, carbon monoxide competitively binds to the ferrous portion of heme, but at an affinity 200 times more than that of oxygen. The change in conformation of Hb with carbon monoxide occupying all the iron in the heme tetramer gives carboxyhemoglobin a cherry red hue, despite the fact that little oxygen is bound to the Hb molecule. In addition, when heme iron is oxidized to the ferric state (it is normally in the ferrous state, even when bound to O_2), known as methemoglobin, it is also incapable of binding O_2. Therefore, Hb will remain deoxygenated, and methemoglobin itself is a brownish-purple color.

The state of the circulation plays an important role in the presence and degree of cyanosis. If a shunt is present, cyanosis can result. A *shunt* is defined as a mechanism by which blood that has not traveled through the ventilated alveolar capillary bed mixes with arterial blood. Deoxygenated blood mixing with oxygenated blood reduces the arterial P_{O_2}, and if the shunt is large, the reduction in P_{O_2} can be severe, leading to marked cyanosis. Another contribution from the state of the circulation on presence of cyanosis concerns blood as it travels through a capillary bed. Oxygen is unloaded to the tissues as blood travels through a capillary, with the relative concentration of unsaturated Hb increasing from one end of the capillary bed to the other. Factors that slow blood flow, such as poor perfusion states and cold temperature, favor the unloading of oxygen and thus increase the amount of unsaturated Hb in the tissue capillaries. A third contribution from the circulation concerns the ratio of blood flow to ventilation within the lung. Simply stated, in an upright lung, the apex is ventilated more than the base, and the base is perfused more than the apex. Because most of the blood flow in the lung then comes from the relatively less ventilated areas of the lung, depression of the blood P_{O_2} is inevitable. In normal healthy subjects, this depression is only a few millimeters of mercury; however, in patients with diseased lungs, the contribution of ventilation/perfusion inequality to lowering of blood P_{O_2} can be significant.

DIFFERENTIAL DIAGNOSIS

The most common causes of cyanosis are cardiac and respiratory diseases that lead to a decrease in the arterial P_{O_2}, but many other conditions can also cause a patient to appear blue (Tables 15.1 and 15.2). Therefore, consideration of the pathophysiologic framework outlined previously allows an orderly approach to the differential diagnosis of cyanosis. Life-threatening causes of cyanosis are summarized in Table 15.3.

TABLE 15.1

CAUSES OF CYANOSIS

    3. Epiglottitis
    4. Bacterial tracheitis
    5. Traumatic disruption
    6. Congenital anomalies (e.g., vascular malformation, hypoplastic mandible, laryngotracheomalacia)
  C. Chest wall
    1. External compression
    2. Flail chest
  D. Pleura
    1. Pneumothorax
    2. Hemothorax
    3. Empyema/effusion
    4. Diaphragmatic hernia
  E. Lower airway
    1. Asthma
    2. Bronchiolitis
    3. Cystic fibrosis
    4. Pneumonia
    5. Hyaline membrane disease
    6. Adult respiratory distress syndrome
    7. Bronchopulmonary dysplasia
    8. Foreign body/aspiration
    9. Congenital hypoplasia
II. Vascular
  A. Cardiac
    1. Cyanotic congenital defects
      a. Tetralogy of Fallot
      b. Transposition of the great vessels
      c. Truncus arteriosus
      d. Pulmonary atresia
      e. Severe pulmonary stenosis with patent foramen
      f. Tricuspid atresia
      g. Ebstein's anomaly
      h. Total anomalous pulmonary venous drainage
      i. Atrioventricular canal defect
    2. Congestive cardiac failure
    3. Cardiogenic shock
  B. Pulmonary
    1. Pulmonary edema
    2. Primary pulmonary hypertension of the newborn
    3. Pulmonary hypertension
    4. Pulmonary embolism
    5. Pulmonary hemorrhage
  C. Peripheral
    1. Moderate cold exposure
    2. Shock: septic/cardiogenic
    3. Acrocyanosis of the newborn
III. Neurologic
  A. Drug or toxin-induced respiratory depression (e.g., morphine, barbiturates)
  B. Central nervous system lesions (e.g., intracranial hemorrhage, contusion)
  C. Seizure
  D. Breath holding
  E. Neuromuscular disease (e.g., Guillain-Barré, spinal muscular atrophy)
IV. Hematologic
  A. Polycythemia
  B. Methemoglobinemia
V. Dermatologic
  A. Blue dye
  B. Pigmentary lesions
  C. Tattoos
  D. Amiodarone therapy

With regard to the amount of Hb, polycythemia, as in newborns with twin–twin transfusion, infants of diabetic mothers, children with high erythropoietin states, or other conditions associated with increased red cell mass, may give the appearance of cyanosis because of the relative increase in the amount of unsaturated Hb.

The degree of Hb saturation is affected by many factors, which can be grouped conveniently by systems. First is the significant contribution from respiratory conditions. Any circumstance leading to a decrease in the concentration of inspired oxygen, such as a house fire where oxygen is consumed by combustion, confinement to a small unventilated space such as being locked inside a discarded refrigerator, or high altitude, can eventually lead to diminished P_{O_2} and cyanosis. Likewise, upper airway obstruction, as with a foreign body, croup, epiglottitis, bacterial tracheitis, tracheal/bronchial disruption, or congenital airway abnormalities, quickly leads to decreased alveolar ventilation and hypoxemia. Age, events leading to presentation, and examination features, such as barking cough, can help distinguish these. Cyanosis ensues rapidly when chest wall movement or lung inflation is impeded. This condition is often a result of trauma and includes external chest compression, flail chest, or hemothorax. Tension pneumothorax, whether traumatic or as a result of preexisting lung disease such as asthma or cystic fibrosis, is diagnosed by dyspnea, deviated trachea, and possibly distended neck veins with diminished breath sounds on the affected side. Empyema or pleural effusion caused by infection, malignancy, or large chylothorax may be associated with fever, respiratory distress, dullness to percussion, and an asymmetric examination on auscultation. Importantly, any lung dysfunction that directly affects pulmonary gas exchange can lead to cyanosis. The most common conditions in children are asthma, bronchiolitis, pneumonia, cystic fibrosis, pulmonary edema, and hyaline

  A. Neurologic conditions leading to hypoxemia
  B. Severe methemoglobinemia

membrane disease. Other causes include bronchopulmonary dysplasia, foreign body or substance aspiration, and congenital pulmonary lesions, to list a few.

Circulatory or vascular conditions leading to diminished arterial P_{O_2} are also associated with cyanosis. One of the most common causes of cyanosis in children is congenital heart disease. Although most newborns with cyanotic congenital heart disease are discovered while still in the newborn nursery, on occasion, such a newborn will initially present to the emergency department (ED) in the first few days or weeks of life with cyanosis. One condition particularly prone to such late presentation is tetralogy of Fallot, specifically in those infants with concomitant pulmonary atresia who have patent ductus arteriosis–dependent pulmonary blood flow. When the ductus closes, profound cyanosis ensues. Rarely, an infant with mild tetralogy of Fallot (or "pink tet") may present with intermittent cyanosis during a "tet spell," which is a 15- to 30-minute self-limited episode of cyanosis caused by increased right-to-left shunting and decrease in pulmonary blood flow. Diagnosis in the pink tet is facilitated by presence of a loud systolic murmur. The causes of cyanotic congenital heart disease are listed in Table 15.1 (II, A). Although many mixing lesions are correctable, several congenital lesions remain with significant shunting of blood from right to left, and these cyanotic children will inevitably be seen in the ED over the course of their lives. Cyanosis may also be caused by pulmonary congestion from cardiac failure or left-to-right cardiac lesions leading to increased pulmonary blood flow and diminished diffusion of O_2 across the gas–blood barrier. (For a detailed discussion of cardiac disease, see Chapter 84.) Several pulmonary vascular abnormalities can also lead to cyanosis. These include primary pulmonary hypertension of the newborn or pulmonary hypertension from other causes where, because of high pulmonary pressures, blood is shunted away from the lungs and the child becomes hypoxemic. Pulmonary embolism and pulmonary hemorrhage, although rare in children, also impair lung perfusion and must be considered.

Low perfusion states may lead to local cyanosis, particularly of the hands, feet, and lips. Moderate cold exposure slows transit time for red cells across capillary beds, leading to greater unloading of oxygen to the tissues and local blueness. Patients in septic or cardiogenic shock may have perfusion-related cyanosis with long capillary refill times as a result of vascular collapse of sepsis or pump failure. Poor perfusion can also result from hyperviscous states such as polycythemia or leukemia. Acrocyanosis, or blueness of the hands and feet with preserved pinkness in the mucous membranes and elsewhere, is seen commonly in newborns and is related to variable perfusion in the extremities. It is seen in well-appearing babies and resolves within the first few days of life.

Neurologic conditions can also lead to Hb desaturation and cyanosis. Patients who hypoventilate because of central nervous system (CNS) depression, whether from primary CNS lesions or drugs/toxins that depress the respiratory center, are often centrally cyanotic at presentation to the ED. Episodic blue spells in infants and young children who are otherwise well may be caused by breath holding, especially when associated with a sudden insult such as fright, pain, frustration, or anger. Vigorous crying is believed to cause cerebral ischemia via vasoconstriction from decreased P_{CO_2}, decreased cardiac output from Valsalva maneuver, and hypoxemia from apnea (see Chapter 131). Seizures are often associated with cyanosis from inadequate respiration during the convulsion. A variety of neuromuscular diseases that affect chest wall or diaphragmatic function may ultimately lead to hypoventilation.

With respect to the Hb molecule itself, methemoglobinemia is an unusual but not rare reason for presentation to the pediatric ED. Methemoglobin can be either congenital or acquired. Congenital methemoglobinemia is caused by either Hb variants designated M hemoglobins or deficiency of NADH-dependent methemoglobin reductase. The more commonly acquired form occurs when red blood cells are exposed to oxidant chemicals and drugs. Young infants with gastroenteritis or oxidant toxin exposure are particularly susceptible to the development of methemoglobinemia as a result of immature enzyme systems required to reduce Hb. Symptoms, caused by decreased blood oxygen content and cellular hypoxia, include headache, dizziness, nausea, dyspnea, confusion, seizure, and coma. Even at low levels, skin discoloration is prominent, often with intense or "slate gray" cyanosis from the presence of methemoglobin as perceived through the skin. (For a more detailed discussion of methemoglobinemia, see Chapter 91.)

Other conditions leading to a blue appearance of the skin may be confused with cyanosis. A rare but perplexing presentation is that of the well-appearing child with unusually localized cyanosis, which after some head scratching, turns out to be related to blue dye of clothing. Slate blue discoloration of the face, neck, and arms has been noted in patients on chronic amiodarone therapy. Certain pigmentary lesions such as mongolian spots can be confused with cyanosis, especially when uncharacteristically large or in unusual locations. Adolescents will occasionally "tattoo" areas of the body that may appear as local cyanosis.

EVALUATION AND DECISION

A careful yet rapid history and physical examination are critical to the approach to the cyanotic patient because timely correction may be lifesaving. Many historical features can help narrow the differential diagnosis and lead to prompt evaluation and treatment. The onset and pattern, location, quality, temporal nature, and presence of palliative or provocative features must be explored. Age of the patient with respect to onset of cyanosis, whether at birth, shortly after birth, or acquired later, is critical. In newborns, congenital cardiac and respiratory diseases are the most common causes of cyanosis. Special attention must also be paid to known preexisting heart or lung disease that may predispose to the acute onset of cyanosis. History of exposure to environmental conditions or toxins, such as cold, trauma, clothing dye, smoke inhalation, confinement to an airtight space, drugs, or chemicals, is crucial. Known history or family history of M hemoglobin or deficiency of NADH-dependent methemoglobin reductase may lead directly to the cause of cyanosis. A history of sudden pain or fright with crying or seizure occurrence should be sought.

The physical examination must include a complete general examination, with special attention paid to the vital signs, oxygen saturation, and cardiovascular and pulmonary systems. An immediate and key physical examination feature is the presence or absence of respiratory distress. In general, children with respiratory distress are likely to have *respiratory* dysfunction, and careful examination of the airway, breathing, and circulation should be rapidly initiated. Presence of cough, "sniffing position," stridor, retractions, or fever should be determined. Lung examination may reveal adventitious (e.g., wheezing or rales) or diminished breath sounds. Presence of a cardiac murmur suggests cardiac disease. Careful attention to the peripheral circulation, including pulses, capillary refill, and temperature, is also helpful. A rapid neurologic examination should be performed. Hypoventilation and subsequent hypoxemia can be the result of many conditions affecting the CNS.

Location of cyanosis helps determine its cause. Central cyanosis is noted in the mucous membranes, tongue, trunk, and upper extremities. It is most often the result of decreased arterial P_{O_2} but can also result from severe methemoglobinemia or polycythemia. If the cyanosis is peripheral only (hands, feet,

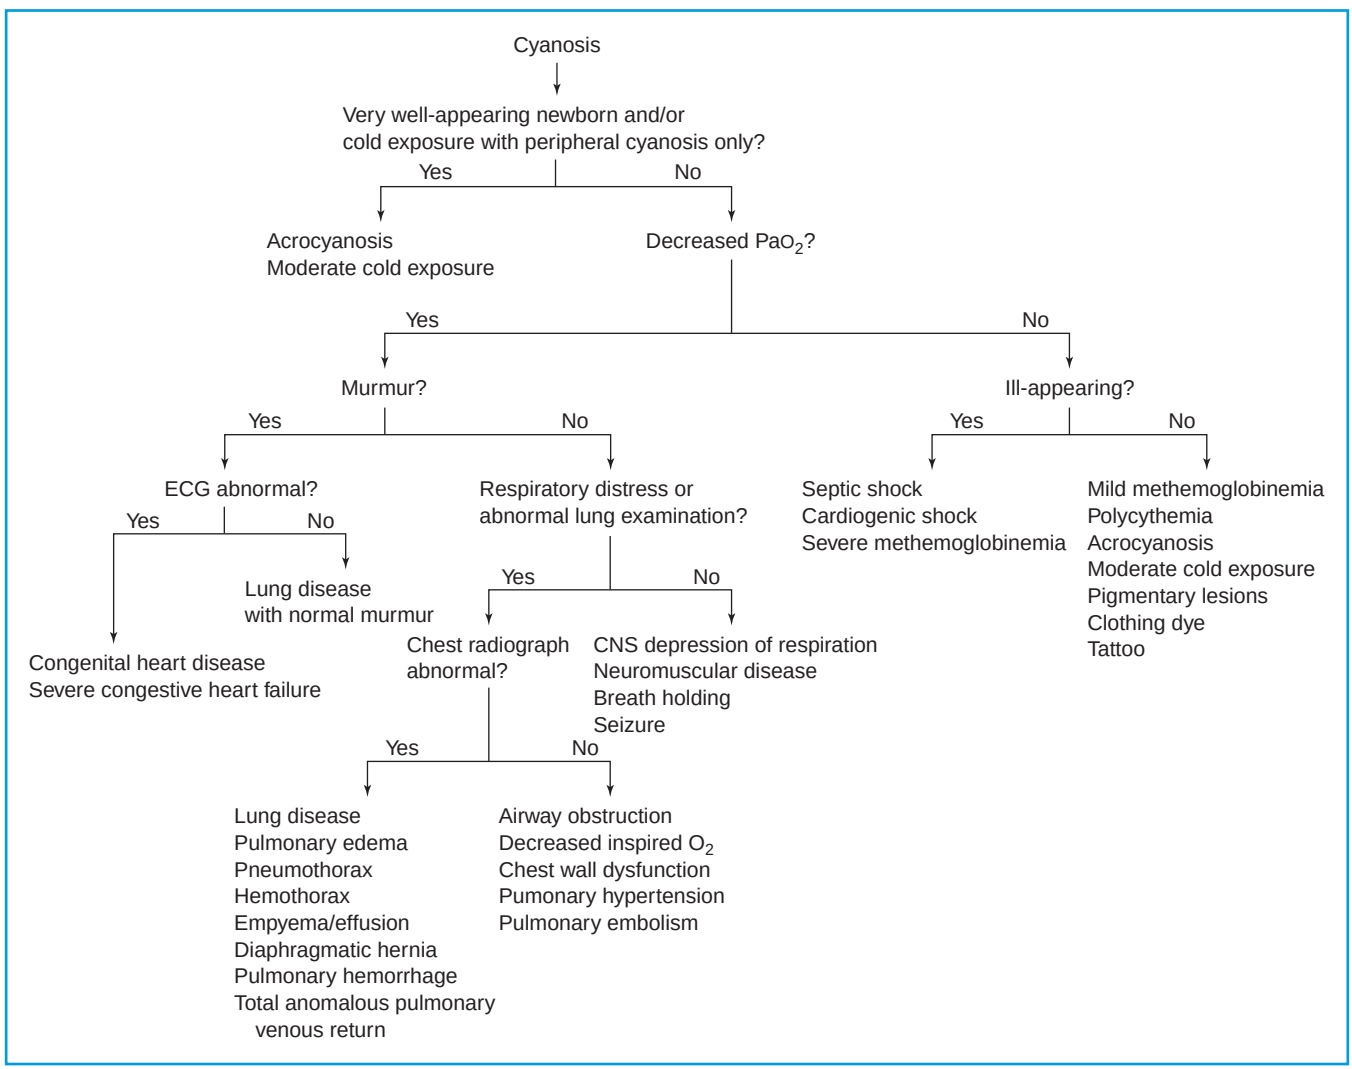

FIGURE 15.1 Laboratory evaluation of cyanosis. EKG, electrocardiogram; CNS, central nervous system.

lips), moderate cold exposure, newborn acrocyanosis, shock states, or mild methemoglobinemia may be the cause. Local blue discoloration of a single extremity corresponds to compromise of distal circulation or autonomic tone as seen in traumatic vascular lesions or reflex sympathetic dystrophy. Cyanosis and swelling of just the head may be seen with superior vena cava syndrome. In addition, a local blue hue to the skin may also be a result of simple phenomena such as pigmentary lesions or blue clothing dye. If blue coloring appears on an alcohol swab wiped across the discolored area of skin, dye is responsible. Differential cyanosis of the lower body versus the upper body may indicate high pulmonary vascular resistance with right-to-left shunting via the ductus arteriosis. Transposition of the great arteries with pulmonary-to-aortic shunt of oxygenated blood through the ductus arteriosis is represented in the rare instance that the upper body is blue and the lower body pink.

The path of the laboratory evaluation depends on the historical features and physical findings established on initial encounter (Fig. 15.1). All patients, except very well-appearing newborns and well-appearing cold-exposed patients with peripheral cyanosis only, require measurement of arterial P_{O_2}. (Oxygen saturation by pulse oximetry may be helpful in determining if hypoxemia is the cause of cyanosis, but it may also be misleading when forms of Hb are present other than oxyhemoglobin and deoxyhemoglobin.) If the P_{O_2} is normal, the laboratory evaluation is determined by the degree of ill appearance. Well-appearing oxygenated children with cyanosis usually have less urgent conditions, such as polycythemia, mild methemoglobinemia, cold exposure, newborn acrocyanosis, or dermatologic findings. In this case, laboratory evaluation might include a methemoglobin level and complete blood count, or no further investigation may be warranted. Despite a normal P_{O_2}, an ill-appearing cyanotic patient may have a more emergent condition such as severe methemoglobinemia or septic or cardiogenic shock and may require aggressive laboratory investigation, including complete blood cell count, methemoglobin level, blood cultures, and blood chemistry. Blood with high methemoglobin content may appear very dark or "chocolate brown" and fails to turn red on exposure to air, such as in a drop on filter paper. Treatment is then directed at the underlying cause. Methemoglobinemia may improve with intravenous methylene blue. If the P_{O_2} is decreased, oxygen therapy should be instituted. In general, cyanosis caused by decreased alveolar ventilation or diffusional abnormalities often improves with delivery of 100% O_2. However, hypoxemia caused by decreased pulmonary perfusion or shunt responds little to oxygen therapy. Next, a chest radiograph should be obtained. Abnormalities of the lungs may confirm pulmonary disease as a major contributor to hypoxemia, and changes in the cardiac size or silhouette may suggest cardiac causes. If the chest radiograph is normal, other reasons for diminished arterial P_{O_2}, such as CNS- or chest wall–related respiratory depression, upper airway obstruction, or pulmonary perfusion abnormalities, must be entertained. If a concomitant murmur or other concern for cardiac disease exists, an electrocardiogram (EKG) is essential. Abnormal EKGs suggest cardiac dysfunction, either congenital or acquired (Table 15.1), and the addition of echocardiography will help establish the definitive diagnosis.

CHAPTER 16 ■ CRYING AND COLIC IN EARLY INFANCY

BARBARA B. PAWEL, MD, AND FRED M. HENRETIG, MD

Crying is the means by which an infant may express discomfort, ranging from normal hunger and desire for company to severe, life-threatening illness. Many common minor irritations and illnesses are excluded by careful history and physical examination. Often, however, a normal, thriving baby will develop a chronic pattern of daily paroxysms of irritability and crying known as colic. The attacks usually have their onset in the second to third week of life and may last for several hours, more commonly in the late afternoon or evening. The typical episode is described as paroxysmal crying that develops into a piercing scream, as if the baby were in pain. The child may draw up the legs, the abdomen may appear distended, bowel sounds are increased, and flatus may be passed, leading parents to conclude that their child has abdominal distress. The emergency physician may be confronted with such a patient and the worried, occasionally hostile parents (usually no earlier than midnight). Colic cannot be cured in the emergency department (ED), and only when crying episodes are repeated and stereotypical and other causes of crying are excluded can the diagnosis of colic be considered. Establishing an orderly approach to the infant with unexplained crying is important to rule out the occasional physical illness and to provide preliminary guidance to the family.

PATHOPHYSIOLOGY

Any unpleasant sensation can cause an infant to cry. Pain or an altered threshold for discomfort (irritability) may be caused by diverse physical illnesses. Those most likely to present abruptly in a young infant are listed in Table 16.1. Numerous unproven theories abound about the etiology of colic. Cow's milk allergy, immaturity of the gastrointestinal tract or central nervous system, parental anxiety, maternal smoking during pregnancy, poor feeding technique, and individual temperament characteristics all have been invoked. The search for a specific cause of colic continues. Gastroesophageal reflux has been suggested as a possible etiology of infant colic; however, studies have shown placebos to be equivalent to antireflux medications in reducing colicky crying. Moreover there is poor correlation between irritability/crying and pH probe documented reflux episodes.

Two polypeptides produced in the gastrointestinal tract (motilin and ghrelin) have been found to be elevated in colicky infants and may play a role by affecting gastrointestinal motility.

No single theory (or concomitant therapy) has gained uniform acceptance. Colic may be a syndrome that represents the manifestations of some or all these factors in varying degrees in a normal population of babies whose tendency to cry varies along a normal distribution. Brazelton's original data on infant crying patterns have been supplemented by larger-scale studies in Canada and England. All studies revealed crying levels to increase from birth to a peak of approximately 3 hours per day at 6 to 8 weeks, followed by a rapid decline.

Early infant crying was also shown to cluster more commonly in afternoon and evening hours. These estimates of crying time over the first 12 weeks of life seem to reflect a certain degree of inconsolable crying behavior that normal infants are destined to exhibit in the first 3 months of life. An encounter with a health-care provider is more likely if the infant is difficult to console or if the crying episode is believed to be associated with pain. Although there are variations in the literature, most agree that a reasonable definition for colic embraces Wessel's criteria: An infant younger than 3 months of age with more than 3 hours of crying per day occurring more than 3 times per week for more than 3 weeks.

EVALUATION AND DECISION

A careful history and physical examination with emphasis on the head, eyes, ears, skin, abdomen, genitalia, and extremities, plus analysis and culture of a urine specimen, will usually enable the physician to diagnose identifiable illnesses or injuries causing severe paroxysms of crying (Table 16.1). Initially, this clinical evaluation must focus on those conditions that are potentially life-threatening: meningitis, child abuse, intussusception, incarcerated hernia, severe intoxication, and metabolic disturbance. Other less critical but more common conditions should be sought next; corneal abrasion or foreign body, otitis media, aerophagia, teething, gastroenteritis, and anal fissure are most commonly seen. As noted in Table 16.1, other diagnoses are encountered occasionally.

The history should include special attention to the onset of crying and any associated events—particularly recent immunization ("screaming spells" lasting up to 24 hours have been described after pertussis vaccine), trauma, fever, or use of medications. Physical examination must be thorough, with the baby completely undressed. Vital signs may reveal fever, suggesting infection (although not always present in young infants with serious infections), or hyperpnea, suggesting metabolic acidosis.

The head should be explored for evidence of trauma and the fontanel should be palpated. Eyes must be examined with fluorescein to look for corneal abrasion, even in infants with no symptoms referable to the eyes. In addition, eversion of the

[b]Common causes.

upper eyelids can exclude a foreign body. Fundoscopy should be attempted (retinal hemorrhages are common signs of abuse, especially in shaken baby syndrome). Careful otoscopy is required to visualize the tympanic membranes. The heart should be evaluated for signs of congestive failure, arrhythmia, or rare ischemia-producing lesions (Table 16.1, I.C). Abdominal and rectal examinations must be performed to look for signs of anal fissure or intussusception. The diaper must be removed, and a careful search should be made for incarcerated hernia, testicular torsion, or strangulation of the penis or clitoris by an encircling hair. Crying may be the primary symptom of an occult urinary infection, so a suitable specimen of urine should be obtained for urinalysis and culture. Careful palpation of all long bones despite the absence of obvious signs of trauma can detect fracture sites that might otherwise have been overlooked. Each finger and toe should be inspected closely to rule out strangulation by hair or thread. Further consideration of laboratory or radiographic evaluation is made in light of the clinical findings. A low threshold for urine toxicology screening is warranted in the persistently irritable baby, given the prevalence of illicit drug use. Infants with unexplained, incessant crying may have a limited physical examination necessitating an extensive evaluation and hospitalization.

Many infants will have a completely negative examination, and the history (or subsequent follow-up) will be suggestive of colic. Over the time in which the crying attacks recur, the infant must demonstrate adequate weight gain (average 5 to 7 oz per week in the first months of life) and absence of physical disorders on several examinations before underlying illnesses can be excluded and colic can be diagnosed confidently (Fig. 16.1). When it becomes clear that a given infant is experiencing colic, the practitioner faces a vexing problem. No dramatic cure is currently available, but the symptoms almost invariably resolve within 3 months of onset. Many studies on the etiology and treatment of colic have methodologic weaknesses, making it difficult for clinicians to use and compare results. In general, no safe and effective medical treatment for colic is available. The efficacy of simethicone is not supported by good quality trials but there have been no reported side effects and it is widely used by physicians who treat colic. Methylscopolamine is neither effective nor safe. Dicyclomine, once believed to be effective, is no longer recommended in infants younger than 6 months because of its dangerous anticholinergic side effects. Elimination of cow's milk protein through formula changes is only useful in the small subset of cases (4%) with cow's milk protein intolerance. Maternal hypoallergenic diets while breast-feeding have yielded mixed results. Herbal tea mixtures appear to reduce crying times, however, there are multiple drawbacks, including compromised nutrition due to the large volume required for symptomatic relief and lack of standardized dosing and strength. In addition, there is a potential for GI or neurotoxicity if certain ingredients with similar names are inadvertently added. A recent study adding a probiotic dietary supplement to breast-fed infants' diets showed decreased crying times in 95% of patients within 28 days. There is not enough support at present to recommend practice changes but further research may be promising. A study by Taubman found that parental counseling (to be more responsive to infant crying with immediate efforts at consoling) was far more effective than dietary manipulation. Interestingly chiropractic manipulation has gained some popularity and although studies have shown no benefit to colicky infants, visits were associated with an overall increase in parent satisfaction. The safest and most effective course of treatment at this time seems to be counseling and empathy. The physician can reassure the parents that their baby is thriving and will outgrow the colic and develop normally.

The emergency physician must be aware of colic as an entity to initiate the evaluation already described, rule out acute treatable illness, and refer the family to a pediatrician for follow-up. Colic is not serious and does not last forever, but it probably will be a nuisance for several weeks to come. The physician should stress to all family members the importance of sharing in the baby's care, so the mother can get

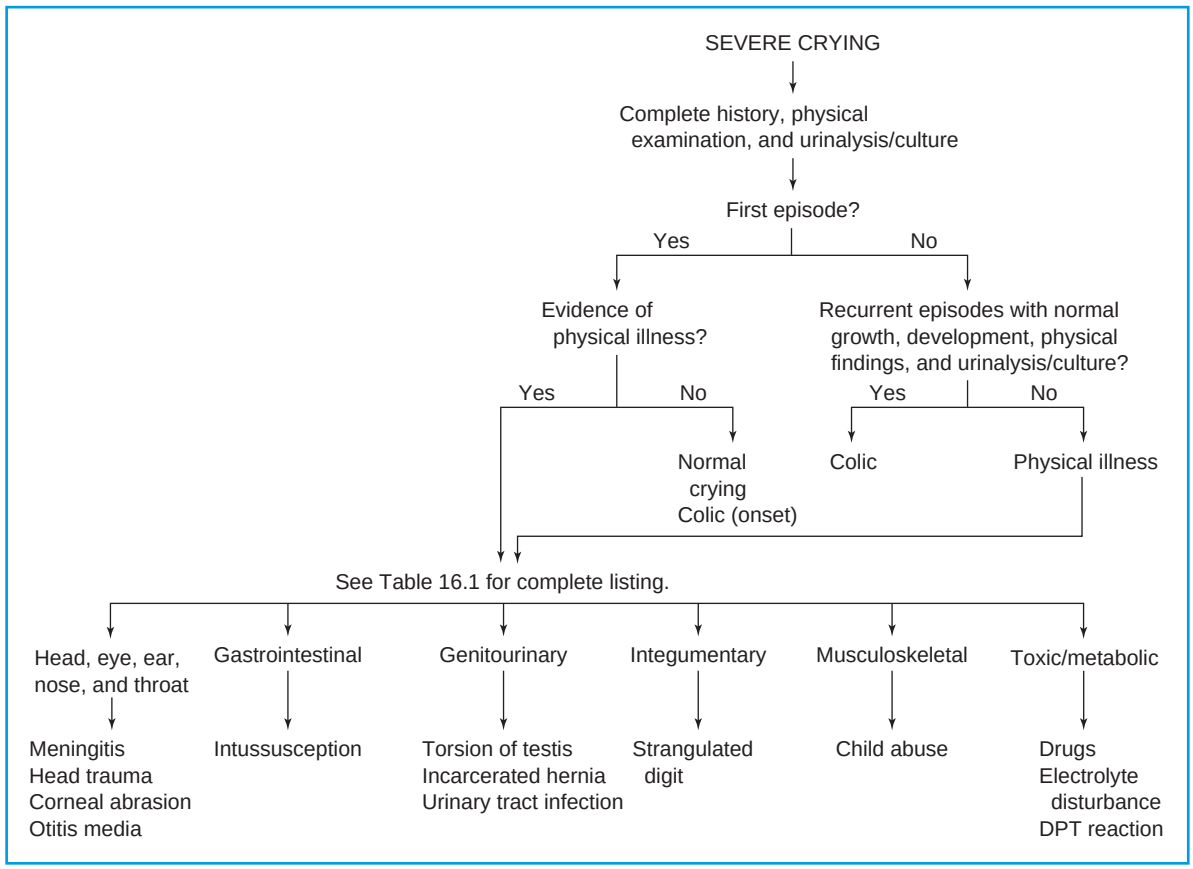

FIGURE 16.1 Approach to abrupt onset of severe crying in infancy. DPT, diphtheria-pertussis-tetanus (vaccine).

some periods of rest and relief from full-time responsibility for the infant. The emergency physician is responsible for investigating the vulnerability of families and children who present with excessive crying. Assessment of the parents' emotional state and the status of available support systems are mandatory. Exhaustion of the parents may be dangerous for the infant, both psychologically and physically. The National Center for Shaken Baby Syndrome acknowledges that excessive crying is a risk factor for abuse. They have launched a prevention campaign, including a website that provides helpful tips for parents on how to safely cope with the frustration and despair often associated with colic. For immediate amelioration of crying at the time of the ED visit, no drug therapy or feeding change is recommended. Rather, most colicky babies derive some temporary relief from rhythmic motion, such as rocking, being carried, or riding in a car, and from continual monotonous sounds, such as those from a washing machine or electric fan. A purposefully chosen circuitous route for the car ride home (one that combines motion and sound) should suffice as therapy for the first visit.

CHAPTER 17 ■ DEHYDRATION

KATHY N. SHAW, MD, MSCE, AND PHILIP R. SPANDORFER, MD, MSCE

Dehydration is a physiologic disturbance caused by the reduction or translocation of body fluids and is a type of hypovolemic shock. Infants have higher morbidity and mortality and are more susceptible to dehydration because of their larger water content, higher metabolic turnover rate of water (three times the rate for adults), renal immaturity, and inability to meet their own needs independently. Dehydration is not a disease itself, rather a symptom of another process. Children with various illnesses and circumstances will present to the emergency department (ED) with signs of dehydration (Table 17.1).

PATHOPHYSIOLOGY

Dehydration is a reduction in the water content of the body. Over two-thirds of the total body water is intracellular and one-third is in the extracellular space. Of the extracellular fluid, three-fourths is interstitial and only 25% is in the intravascular space as plasma. Early in the process of dehydration, the majority of the water loss is from the extracellular compartment, which contains 135 mEq per L of sodium and negligible potassium. However, with time, there is an equilibration from the intracellular compartment to the extracellular compartment, which has 150 mEq per L of potassium and negligible sodium. As the electrolyte composition of extracellular fluid and intracellular fluid vary greatly, an understanding of this process helps the clinician gauge the optimal composition and rate of fluid deficit correction (see Chapter 100).

Dehydration is often categorized by the serum osmolarity and severity (degree of fluid deficit), which is helpful in determining fluid therapy. Based on the initial serum sodium, most children have isonatremic dehydration (also referred to as isotonic dehydration, serum sodium 130 to 150 mEq per L), whereas others have hypernatremic dehydration (hypertonic dehydration, serum sodium greater than 150 mEq per L) or hyponatremic dehydration (hypotonic dehydration, serum sodium less than 130 mEq per L). Severity is judged by the amount of body fluid lost or the percentage of weight loss, and is typically characterized as mild (less than 50 mL per kg, or less than 5% of total body weight), moderate (50 to 100 mL per kg, or 5% to 10% of total body weight), and severe (greater than 100 mL per kg, or greater than 10% of total body weight).

DIFFERENTIAL DIAGNOSIS

Fluid imbalance in dehydration results from (i) decreased intake; (ii) increased output secondary to insensible, renal, or gastrointestinal (GI) losses; or (iii) translocation of fluid such as occurs with major burns or ascites (Table 17.1). Gastroenteritis is the most common cause of dehydration in infants and children, and is the leading cause of death worldwide in children younger than 4 years of age. In the United States, an average of 300 children younger than 5 years of age die each year, and an additional 200,000 are hospitalized, secondary to diarrheal illnesses with dehydration. In 2006, prior to widespread use of the rotavirus vaccine, rotavirus gastroenteritis was responsible for approximately 22 hospitalizations, 300 ED visits, and 300 primary care office visits per 10,000 children under the age of 3 years. Rotavirus was responsible for about half of the gastroenteritis cases and is generally more severe than non-rotavirus cases. Other common causes of dehydration in children include vomiting, stomatitis, or pharyngitis with poor intake secondary to pain, febrile illnesses with increased insensible losses and decreased intake, and diabetic ketoacidosis (Table 17.2). More severe or life-threatening causes are listed in Table 17.3.

EVALUATION AND DECISION

The first step in evaluating a child with dehydration is to assess the severity or degree of dehydration, regardless of the cause (Table 17.4). Most children with clinically significant dehydration will have two of the following four clinical findings: (i) capillary refill greater than 2 seconds, (ii) dry mucous membranes, (iii) no tears, and (iv) ill appearance. Dehydration is a type of hypovolemic shock. Mild, moderate, and severe dehydration correspond to impending, compensated, and uncompensated states of shock, respectively (see Chapter 3). If there is severe dehydration or uncompensated shock, the child must be treated immediately with isotonic fluids to restore intravascular volume, as detailed later in this chapter.

History

A thorough history is needed to assess the child with dehydration to determine the cause and degree of dehydration (Fig. 17.1). Particular attention should be paid to the child's output and intake of fluids and electrolytes. Overt GI losses from diarrhea and vomiting are the most common causes of dehydration in children, therefore, information about the amount and character of these losses is critical in determining a cause (see Chapters 18 and 78). The child may not be drinking because of physical restriction (e.g., dependence on a caregiver, pain, altered consciousness, anorexia). Fever, high ambient temperatures or bundling a baby, sweating, and hyperventilation may cause increased insensible losses. It is important to note whether there is any underlying disease that would contribute

TABLE 17.1

CAUSES OF DEHYDRATION

- Decreased Intake
  - Physical restriction
    - Infant
    - Central nervous system depression
  - Anorexia
  - Voluntary or imposed cessation of drinking
    - Pharyngitis, stomatitis
    - Respiratory distress
    - Child abuse
  - Hypothalamic hypodipsia
- Increased Output
  - Insensible losses
    - Fever
    - Sweating
    - Heat prostration
    - High ambient temperature/low humidity
    - Hyperventilation
    - Cystic fibrosis
    - Thyrotoxicosis
  - Renal losses
    - Osmotic
    - Diabetic ketoacidosis
    - Acute tubular necrosis
    - High protein feeds
    - Mannitol usage
  - Nonosmotic
    - Diabetes insipidus
    - Sustained hypokalemia-hypercalcemia
    - Sickle cell disease
    - Chronic renal disease
    - Bartter's syndrome
  - Sodium-losing
    - Congenital adrenal hypoplasia
    - Diuretics
    - Sodium-losing nephropathy
    - Pseudohypoaldosteronism
  - Gastrointestinal losses
    - Diarrhea (see Chapter 18)
      - Secretory vs. nonsecretory
    - Vomiting (see Chapter 78)
      - Obstructive vs. nonobstructive
- Translocation of Fluids
  - Burns
  - Ascites (e.g., nephrotic syndrome)
  - Intraintestinal
    - Paralytic ileus
    - Postabdominal surgery

to dehydration (e.g., cystic fibrosis, diabetes, hyperthyroidism, renal disease).

Asking the parents about documented weight loss, amount of urine output, and the presence or absence of tears is helpful in determining the severity of the dehydration. Although decreased urine output is an early sign of dehydration, only 20% of patients with the complaint of decreased urine output will be dehydrated. All ingested fluids should be noted because diluted juices or water can be associated with hyponatremic dehydration, whereas excess salt intake or low liquid intake may indicate hypernatremic dehydration. Further, inquiring how the infant formula is prepared may lead to the discovery of electrolyte abnormalities with dehydration if too little or too much water is added.

TABLE 17.2

COMMON CAUSES OF DEHYDRATION

Gastroenteritis	Febrile illness
Stomatitis/pharyngitis	Diabetic ketoacidosis

TABLE 17.3

LIFE-THREATENING CAUSES OF DEHYDRATION

Gastroenteritis (especially infants)	Heat prostration
Diabetic ketoacidosis	Gastrointestinal obstruction
Burns over 25% of body surface area	Cystic fibrosis
Thyrotoxicosis	Diabetes insipidus
Congenital adrenal hyperplasia	Child abuse

Physical Examination

Measurement of vital signs is an important and objective part of the evaluation of the child with dehydration (Table 17.4). The first sign of mild dehydration is tachycardia, whereas hypotension is a very late sign of severe dehydration. In mild to moderate dehydration, the respiratory rate is usually normal. As a child becomes more acidotic and fluid is depleted, the respiratory rate increases and the breathing pattern becomes hyperpneic. Unfortunately, vital signs alone are not always reliable. Tachycardia also may be caused by fever, agitation, or pain; respiratory illness affects respiratory rates; and orthostatic signs are difficult to obtain in babies and young children.

Age of the child, nutritional status, and type of dehydration may also affect clinical assessment, which is critical to effective management of the acutely dehydrated child. In general, older children show signs of dehydration sooner than babies do because of their lower levels of extracellular water. Babies with excess subcutaneous fat may look less dehydrated than they really are, whereas severely malnourished babies may appear to be more dehydrated secondary to wasted supporting tissues. Signs of dehydration may be less evident or appear later in hypernatremic dehydration. Excessive irritability with increased muscle tone, and doughy or smooth and velvety skin, often are noted with this type of dehydration. Conversely, signs of dehydration may be more pronounced or appear sooner in hyponatremic dehydration. Keeping these caveats in mind, particular attention should be paid to the overall appearance, mental status, eyes, and skin on physical examination. The mildly dehydrated child usually appears well and may be tired, have decreased tearing and a slightly dry mouth. Dry mucous membranes are an early sign of dehydration, but this finding is affected by rapid breathing and ingestion of fluids. Conversely, the severely dehydrated baby classically appears quite ill with lethargy or irritability, a dry mouth, sunken fontanel, and absent tears. More moderate states of dehydration, however, require more careful evaluation.

TABLE 17.4

CLINICAL ESTIMATION OF DEGREE OF DEHYDRATION[a,b]

Clinical finding	PPV	NPV	Sensitivity (95% CI)	Specificity (95% CI)
Decreased skin elasticity	0.57	0.93	0.35 (0.23–0.49)	0.97 (0.92–0.99)
Capillary refill >2 s	0.57	0.94	0.48 (0.35–0.61)	0.96 (0.90–0.99)
Ill appearance (tired, listless)	0.42	0.95	0.59 (0.46–0.71)	0.91 (0.84–0.95)
Absent tears	0.40	0.96	0.67 (0.53–0.78)	0.89 (0.82–0.94)
Abnormal respirations	0.37	0.94	0.43 (0.30–0.56)	0.86 (0.78–0.91)
Dry mucous membranes	0.29	0.99	0.80 (0.67–0.89)	0.78 (0.70–0.85)
Sunken eyes	0.29	0.95	0.60 (0.47–0.72)	0.84 (0.76–0.90)
Abnormal radial pulse	0.25	0.93	0.43 (0.30–0.56)	0.86 (0.78–0.91)
Tachycardia (>150)	0.20	0.93	0.46 (0.32–0.61)	0.79 (0.72–0.87)
Decreased urine output (parental report)	0.17	0.97	0.85 (0.73–0.93)	0.53 (0.44–0.62)

[a]The 10-point dehydration score listed in descending PPV.
[b]One to two findings indicate mild dehydration <5% total body weight, three to six findings indicate moderate dehydration (5% to 10% total body weight), and seven to ten findings indicate severe dehydration (>10% total body weight).
PPV, positive predictive value; NPV, negative predictive value; CI, confidence interval.

The skin is a reliable organ to assess for signs of peripheral perfusion because it is an indicator of the child's systemic vascular resistance and degree of shunting that is occurring to maintain blood pressure. Peripheral and central pulses and skin temperature should be compared. Cool peripheral extremities are an early sign of poor perfusion, whereas weak central pulses are a very late sign. One of the more objective measures of dehydration is assessment of skin perfusion by measuring capillary refill time. Although the child's body temperature does not affect capillary refill time, it may be falsely prolonged when measured on the foot or in a cool room. Thus, the test should be performed on the fingertip or nail bed in a warm room. Light pressure is applied to blanch the fingernail bed, and the time is measured until color returns (Fig. 17.2). Delays of only 2 to 3 seconds indicate moderate dehydration, and a measurement of more than 3 seconds occurs with severe fluid losses. Skin elasticity can be assessed by determining whether there is a delay in return of skin to its original state after it is pinched into folds (tenting). This is a less reliable finding in older children and malnourished babies who have less subcutaneous tissue.

Laboratory

The quantity and quality of urine produced are also important indicators of the cause or degree of dehydration. Progressive decrease in urine output and increase in specific gravity and osmolarity are expected with increasing severity of dehydration when normal renal function is preserved. If the physical examination indicates significant dehydration and there is dilute or copious urine, a renal or adrenal origin is most likely. In addition, polyuria and the presence of glucose or ketones may indicate diabetic ketoacidosis, whereas a history of disorders of the central nervous system (CNS) suggests diabetes insipidus.

In children who are judged to have moderate to severe dehydration that requires intravenous (IV) rehydration, laboratory tests of electrolytes, glucose, blood urea nitrogen, and creatinine are usually obtained to determine osmolarity and renal function. Approximately one-third of moderately to severely dehydrated children will have hypoglycemia less than 60 mg per dL. The acid–base status may be assessed further with an arterial or venous blood gas.

Diagnostic Approach

In approaching the patient with presumed dehydration, the initial assessment serves to determine whether compensated or uncompensated shock is present. If the child appears to be in shock, resuscitation should begin and a number of life-threatening disorders need to be considered, as listed in Table 17.3 and discussed in Chapter 3. Patients with obvious burns or diseases that disrupt the integument in the same way (e.g., scalded skin syndrome) are presumed to have become dehydrated through transudation of fluid through the skin.

If the patient does not have an obvious cutaneous source for dehydration, GI losses provide the most likely explanation. A history of vomiting (see Chapter 78) or diarrhea (see Chapter 18) should be sought. Most children with vomiting or diarrhea have viral gastroenteritis, but many diseases (Tables 18.1 and 78.1) produce these symptoms. Additional history serves to establish the adequacy of oral intake. Several common minor

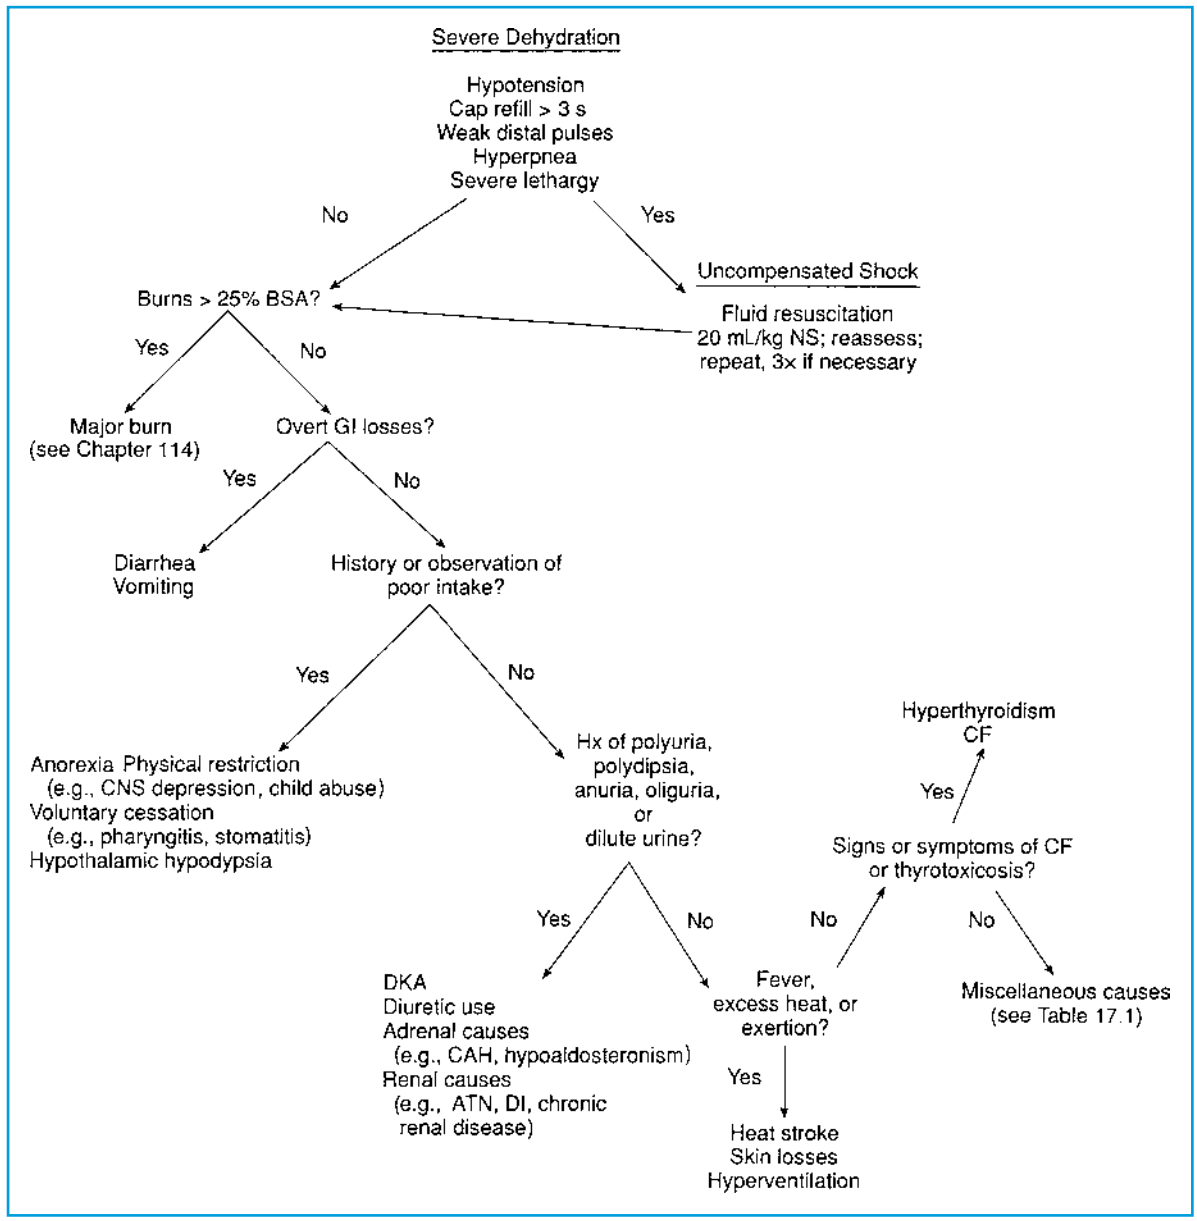

FIGURE 17.1 Suspected dehydration. BSA, body surface area; NS, normal saline; GI, gastrointestinal; CNS, central nervous system; CF, cystic fibrosis; DKA, Diabetic ketoacidosis; Hx, History; CAH, congenital adrenal hyperplasia; ATN, acute tubular necrosis; DI, diabetes insipidus.

infections, such as pharyngitis and stomatitis, as well as more serious disorders of the CNS, cause dehydration as a result of voluntary or involuntary limitation of fluids taken orally.

Next, the history should address the nature and quantity of the urine output. With dehydration, one expects to find oliguria or anuria if normal renal concentrating function remains intact. Severe oliguria or anuria may also, however, be manifest if severe dehydration and shock has led to acute renal failure (see Chapter 100). The unexpected discovery of polyuria points to diabetes mellitus or insipidus, adrenal insufficiency, diuretic use, or renal injury or disease with resultant loss of concentrating ability (Fig 17.1).

By this point, the physician will have established a diagnosis in most patients. In hot weather or when there is prolonged fever, skin losses must be considered. Patients with cystic fibrosis (see Chapter 99) are prone to dehydration because of a high concentration of sodium in the sweat (the finding of hyponatremic dehydration seemingly unexplained by the estimated fluid loss should suggest this diagnosis). Additional considerations are listed in Table 17.1.

Initial Management

The dehydrated child must be examined immediately for the degree of dehydration or state of hypovolemic shock. If there is severe dehydration or uncompensated shock, the patient is treated acutely with isotonic fluids to restore intravascular volume regardless of serum osmolarity or cause of the dehydration (Fig. 17.3). Normal saline or Ringer's lactate is given via an IV or intraosseous line in 20 mL per kg aliquots over approximately 15 to 30 minutes, or as quickly as possible if there is

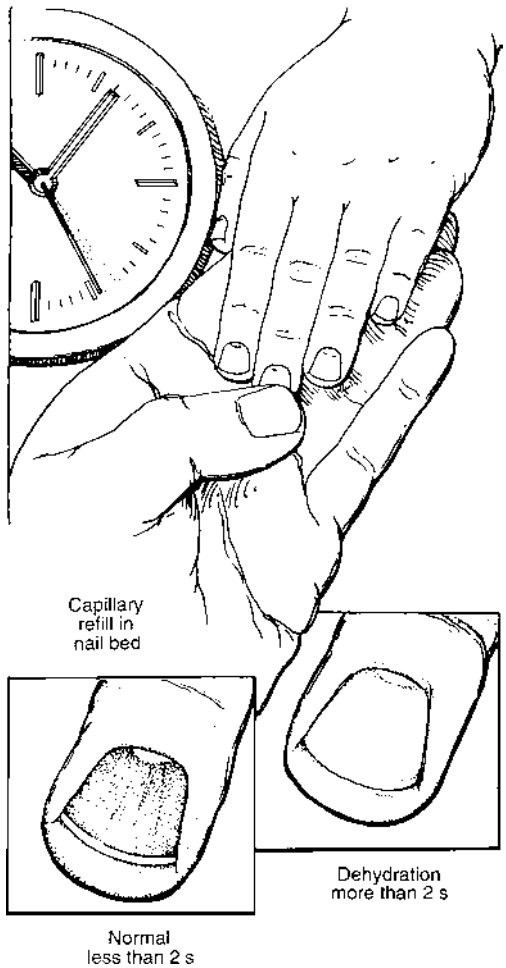

FIGURE 17.2 Assessing dehydration by capillary refill.

Step 1: Calculate degree of dehydration.
(see Table 18.4 and text)

Assume a patient is moderately dehydrated (10% dehydration).

Step 2: Obtain weight in the ED.

The patient weighs 9 kg.

Step 3: Calculate back to the predehydration baseline weight.

Take the weight obtained in the ED and divide by 1 minus the proportion dehydration.
(9 kg)/(1 – 0.1) = 10 kg baseline weight

Step 4: Calculate weight loss and deficit fluid volume.

10 kg – 9 kg = 1 kg weight loss
1 kg is equivalent to 1,000 mL deficit

This patient has a 1,000 mL fluid deficit (100 cc/kg).

Step 5: Rehydrate the child.

Oral rehydration therapy is first-line therapy for mild and moderate dehydration and should be administered as 2 cc/kg of baseline weight for the moderately dehydrated patient (1 cc/kg of baseline weight for the mildly dehydrated patient) every 5 min over a 4-h period.

2 cc/kg x 10 kg = 20 cc every 5 min orally

Administer intravenous fluids for those who were unable to tolerate oral rehydration therapy or for severe dehydration. Normal saline or lactated Ringer's boluses should be administered for the emergency phase (20 cc/kg). Half of the remaining fluid deficit is given in the first 8 h and the remainder over the next 16 h.

FIGURE 17.3 Calculation of deficit therapy using the example of a child with estimated 10% dehydration and emergency department (ED) weight of 9 kg.

uncompensated shock. Reassessment is paramount after each fluid bolus. When blood pressure is restored, heart rate returns to normal, distal pulses strengthen, and skin perfusion improves, isotonic fluids may be safely discontinued. Urine output is the most important indicator of restored intravascular volume in patients with intact renal and adrenal function, and without diabetes mellitus or insipidus, and should be a minimum of 1 mL per kg per hour. If dextrose is needed initially for low serum glucose, 0.5 to 1 g per kg is given in a single bolus of 10% or 25% dextrose and the serum level is rechecked.

Oral Rehydration Therapy

If the child is determined to be mildly or moderately dehydrated, then oral rehydration therapy (ORT) is the therapeutic option of choice. ORT is the frequent administration of small volumes of an appropriate rehydration solution, typically with an oral syringe. The use of ondansetron, a serotonin $5HT_3$ selective receptor antagonist, has clearly been shown to improve the success of rehydration with ORT (Table 17.5). An appropriate rehydration solution has the correct balance of glucose and sodium, which enables the body to absorb the water passively via the sodium glucose cotransport mechanism in the small intestine. The glucose-to-sodium ratio is an important determinant in the acceptability of these solutions. Optimal solutions have a 1:1 or a 2:1 glucose:sodium ratio. When additional sweetener is added to the rehydration solution, the ratio of glucose to sodium is distorted and may result in osmotic diarrhea or inappropriate absorption of electrolytes. There are two categories of rehydration solutions: initial rehydration solutions that contain 60 to 90 mEq per L of sodium (e.g., Rehydralyte, World Health Organization oral rehydration solutions) and maintenance solutions that contain 40 to 60 mEq per L of sodium (e.g., Pedialyte). If the etiology of the dehydration is presumed to be due to cholera, then the higher sodium concentration is appropriate because there is a large sodium loss in the diarrhea stools of cholera patients. However, if the etiology of the dehydration is presumed to be viral gastroenteritis, then the lower sodium concentration solutions would be appropriate and are more readily available. Both rehydration and maintenance solutions have approximately 20 mEq per L of potassium and a low glucose concentration of 2% to 2.5%. Soda, juice, popsicles, sports drinks, and soups are inappropriate rehydration solutions in dehydrated infants and children and should be strongly discouraged. These fluids do not have the appropriate glucose-to-sodium ratio and are not absorbed as easily as electrolyte solutions.

The amount of fluid to be administered is dependent on the degree of dehydration. Mild dehydration reflects up to 5% weight loss, so 5% of the child's body weight (50 mL per kg)

TABLE 17.5

ONDANSETRON DOSING FOR GASTROENTERITIS

Patient weight	Dose
<10 kg	1 mg liquid
10–20 kg	2 mg orally disintegrating tablet
>20 mg	4 mg orally disintegrating tablet

should be administered as small-volume frequent feeds. Likewise, moderate dehydration represents up to 10% weight loss, so 10% of the child's weight (100 mL per kg) should be administered. An easy rule of thumb to remember is that a mildly dehydrated patient can receive 1 mL per kg every 5 minutes and a moderately dehydrated patient can receive 2 mL per kg every 5 minutes. As the child tolerates the feeds, the volume can be increased as well as the frequency. The rehydration should be completed over a 4-hour time frame (Fig. 17.3). ORT has been shown to be equivalent to IV fluid therapy in terms of rehydration efficacy. Interestingly enough, it has been shown that it takes less time to institute therapy with ORT (i.e., teach the parents how to administer the fluids) than to start an IV line in a child, and there is less staff time involved in administering care to these patients as well as shorter ED stays. There are a significant number of patients with gastroenteritis that will be unable to perform ORT and will subsequently require alternative methods for rehydration. Nasogastric (NG) tube use is an acceptable alternative as it has been shown to be as effective as IV hydration. They are relatively easy to place and the patient does not need to remain awake while receiving the rehydration solution. A small feeding tube is better tolerated for fluid administration than a larger NG tube. However, they are considered one of the more noxious interventions and practitioners may choose parenteral rehydration over NG.

Parenteral Rehydration

Approximately 20% of patients will be unable to tolerate oral syringe administration of ORT because of persistent vomiting, high stool outputs, or inability to cooperate. If the patient is unable to tolerate ORT or is severely dehydrated, then administration of 20 mL per kg boluses of isotonic saline or lactated Ringer's solution intravenously would be appropriate. The number of boluses required depends on the patient's physiologic response to the fluid that has been administered. Once the initial resuscitation phase is completed, an IV fluid is determined for the maintenance phase (see Chapter 100). The initial fluid often is D51/2NS with 20 mEq per L of potassium chloride. Notable exceptions include major burn patients who continue to require isotonic fluids (see Chapter 108), children with diabetic ketoacidosis who do not require dextrose initially (see Chapter 86), and children with severe electrolyte disturbances, such as may occur with pyloric stenosis or severe hypernatremic dehydration (see Chapter 100). There are recent studies advocating for the use of isotonic fluids for all patients who require maintenance of hydration. The benefit of isotonic solutions (such as normal saline) is to avoid fatal hyponatremia.

The fluid rate is determined by the estimated fluid deficit and ongoing losses (Fig. 17.3). Usually, 50% of the child's fluid deficit is given over the first 8 hours in addition to one-third of the daily maintenance fluid requirements. In hypertonic states, after initial stabilization with isotonic fluids, the replacement solution is given more slowly to allow equilibration across the blood–brain barrier (see Chapter 100).

Parenteral rehydration via an IV catheter has been used extensively. The advantages of IV rehydration are numerous including familiarity with the procedure, widespread acceptance, and direct vascular access to rehydrate a patient. There are disadvantages associated with IV catheter use, primarily difficulty in obtaining access in dehydrated children, particularly those younger than 3 years, pain associated with placement, and the time and resources required for placement. Subcutaneous rehydration was common prior to the widespread use of IV catheters. There is evidence that using human recombinate hyaluronidase (Hylenex®) with a subcutaneous catheter may be an alternative for mild and moderately dehydrated children who have failed ORT. Hyaluronidase temporarily dissolves hyaluronic acid and allows fluid to be administered subcutaneously, which is subsequently absorbed into the vascular system. Advantages of subcutaneous fluid administration include ease of placement and decreased pain with insertion. More research in this new modality is required.

In all types of dehydration and their methods of treatment, the patient must be monitored closely. Physical exam and vital signs should be reassessed continually, urine output monitored closely, ongoing losses quantified and replaced, and therapy individualized.

CHAPTER 18 ■ DIARRHEA

GARY R. FLEISHER, MD

Diarrhea refers to a softening in the consistency of the stool with or without an increase in the number of stools. Although the World Health Organization defines diarrhea as the passage of three or more loose or watery stools per day, because of the variability in the frequency and type of stools among children, absolute limits of normalcy are difficult to define. Rather, any deviation from the child's usual pattern should arouse at least a mild concern, regardless of the actual number of stools or their water content. Some infants, particularly those who are breastfed, often have five or six loose stools daily routinely; other healthy infants may produce only one formed stool every other day.

DIFFERENTIAL DIAGNOSIS

Diarrhea, with or without vomiting, often prompts a visit to the emergency department (ED). An estimated 15 to 20 million children younger than 5 years of age have between 20 and 40 million episodes of diarrhea annually in the United States. Approximately 12% of all hospitalizations of children 1 month through 4 years of age include diarrhea as one of the top three discharge diagnoses. Although most bouts of diarrhea seen in the ED in developed countries result from self-limiting infections, diarrhea may be the initial manifestation of a wide spectrum of disorders, as outlined in Table 18.1.

Of the many causes of diarrhea, a few are particularly common: infections with viruses and bacteria, parenteral diarrhea (diarrhea due to a nongastrointestinal infection), and diarrhea induced by antibiotic administration (Table 18.2). The single most common disorder seen in the ED is viral gastroenteritis.

Any cause of diarrhea may produce, on rare occasions in developed countries, a fatality secondary to dehydration or electrolyte disturbance. Several hundred young children die annually in the United States from gastroenteritis; however, most of the disorders, particularly viral gastroenteritis, are mild. The emergency physician must be vigilant in recognizing the few children who have diseases that are likely to be life threatening from among the majority of children who have self-limiting infections. Particularly urgent are intussusception, pseudomembranous colitis, hemolytic uremic syndrome (HUS), and appendicitis (Table 18.3). In addition, children may develop severe dehydration with diarrhea secondary to any pathogen.

Intussusception, although not typified by presentation with diarrhea, is the most common of these serious disorders to have diarrhea as a symptom. Most children with intussusception primarily have severe, episodic abdominal pain, but a few are brought to the hospital with the complaint of bloody diarrhea. Intussusception peaks in frequency between 5 and 10 months of age and tapers off rapidly after 2 years of age, unless there is a predisposing pathologic condition. Although the child may be febrile, the temperature is usually normal. Classically, intussusception causes colicky abdominal pain, vomiting, and an abdominal mass, in addition to a "currant jelly" stool. The finding of a mass in association with colicky abdominal pain, vomiting, and blood in the stool is highly suggestive of intussusception, but a mass actually is palpable in fewer than 20% of cases. Thus, the physician should consider this diagnosis even in the absence of a mass when a child in the first year or two of life has the combination of bloody diarrhea and severe, colicky abdominal pain. In addition, the child who is flaccid or lethargic out of proportion to the degree of dehydration should raise suspicion, as intussusception can evoke "neurologic" signs. Plain films of the abdomen may be diagnostic (intussusceptum seen on the basis of air contrast), suggestive (mechanical obstruction), or nonspecific (normal or ileus); thus, a high index of suspicion mandates either an ultrasound or a contrast enema with air or barium.

HUS, although uncommon, merits consideration in any child with bloody diarrhea because it is a potentially fatal illness. Children are affected most often in the first 3 years of life. Typically, over the course of several days, an initially mild gastroenteritis becomes complicated first by hematochezia and then by pallor (anemia), purpura (thrombocytopenia), and oliguria (acute renal failure). When HUS is suspected, a complete blood count, urinalysis, and coagulation studies should be performed. The peripheral blood smear, in addition to reduced numbers of platelets, shows evidence of intravascular hemolysis, including helmet cells and red blood cell fragments. The urine tests positive for blood (both hemoglobin and red cells).

Another serious disorder that may cause bloody diarrhea is pseudomembranous colitis. This disease results from an overgrowth of toxin-producing clostridial organisms in the bowel and must be considered after a course of antibiotic therapy, which can decimate the normal gut flora. It may occur at any age but is uncommon in early childhood. Although the incidence of pseudomembranous colitis is highest after treatment with clindamycin, a less frequently prescribed antibiotic, any of the antibacterial drugs may be the culprit. In fact, because of its common use, amoxicillin is responsible for most cases of pseudomembranous colitis in childhood, even though the incidence after therapy with this agent is low. Occasional cases occur in children with no recent usage of antibiotics. Clinically, the patient with pseudomembranous colitis usually appears ill with prostration, abdominal distension, and significant amounts of blood in the stool. Stool toxin analysis provides the mainstay of diagnosis.

TABLE 18.1

CAUSES OF DIARRHEA

Infections
Enteral
- Viruses: rotavirus, Calciviruses (Norwalk and sapporo viruses), enteroviruses, adenoviruses, astroviruses
- Bacteria: *Salmonella, Shigella, Yersinia, Campylobacter,* pathogenic *Escherichia coli, Aeromonas hydrophila, Vibrio* spp., *Clostridium difficile,* tuberculosis
- Parasites: *Giardia lamblia, Entamoeba histolytica, Cryptosporidia*

Nongastrointestinal (parenteral diarrhea)

Dietary Disturbances
Overfeeding, food allergy, starvation stools

Anatomic Abnormalities
Intussusception, Hirschsprung's disease, partial obstruction, appendicitis, blind loop syndrome, intestinal lymphangiectasia, short bowel syndrome

Inflammatory Bowel Disease
Ulcerative colitis, Crohn's disease

Malabsorption or Increased Secretion
Cystic fibrosis, celiac disease, disaccharidase deficiency, acrodermatitis enteropathica, secretory neoplasms

Systemic Illnesses
Immunodeficiency
Endocrinopathy: hyperthyroidism, hypoparathyroidism, congenital adrenal hyperplasia

Psychogenic Disturbances (Irritable Bowel Syndrome)

Miscellaneous
Antibiotic-induced diarrhea, secondary lactase deficiency, neonatal drug withdrawal, toxins (e.g., organophosphate ingestion), hemolytic-uremic syndrome

Appendicitis manifests primarily with abdominal pain, followed by anorexia, vomiting, or fever. Less commonly, appendicitis may cause diarrhea. The presumed mechanism for the diarrhea is irritation of the colon by the inflamed appendix. In most cases, careful questioning about the nature of the diarrhea will reveal a description of frequent, very low volume stools, with mucus. Particularly in very young children or among patients of any age who have a perforated appendix and a long duration of illness, the diagnosis of appendicitis as the cause of diarrhea may be delayed because the classic constellation of findings is often absent. However, the examiner will usually be able to elicit abdominal tenderness greater than would be expected with gastroenteritis.

LIFE-THREATENING CAUSES OF DIARRHEA

Intussusception
Hemolytic uremic syndrome
Pseudomembranous colitis
Appendicitis
Salmonella gastroenteritis (with bacteremia in the neonate or immunocompromised host)
Hirschsprung's disease (with toxic megacolon)
Inflammatory bowel disease (with toxic megacolon)

EVALUATION AND DECISION

The initial evaluation of the child with diarrhea should serve the dual purpose of exploring the possible causes and assessing the degree of illness. Preexisting conditions in the child may account for the diarrhea or predispose him or her to unusual causes; in particular, the emergency physician should search for a history of gastrointestinal surgery or chronic illnesses, such as ulcerative colitis or regional enteritis. Immunodeficiency syndromes, neoplasms, and immunosuppressive therapy all lead to an increased susceptibility to infection. Institutionalized children and those recently returning from underdeveloped countries are more likely to harbor bacterial or parasitic pathogens.

A history of abdominal pain, particularly if severe, raises the index of suspicion for intussusception and appendicitis. Bloody diarrhea points particularly to bacterial enteritis but occasionally occurs with viral infections and may also herald the onset of HUS or pseudomembranous colitis. The combination of episodic abdominal pain and blood in the stool characterizes intussusception. Vomiting in association with diarrhea is very suggestive of viral gastroenteritis, whereas vomiting in isolation (see Chapter 78) is more concerning for intestinal obstruction.

With the initial interview, the physician should attempt to reconstruct historically the child's intake and output during the course of the illness. Detailed questions about the number and size of stools, the frequency of emesis, and the amount of liquid taken orally allow for an estimate of fluid balance. Decreases in the frequency or volume of urination (or the number of diaper changes in the infant) suggest an inadequate output, reflecting the development of dehydration.

The general physical examination can provide clues to an underlying illness in the child who appears malnourished or small for his or her age. The body weight should be measured and compared to a premorbid weight. If fever is present, infectious causes are most likely. The pulse and blood pressure, together with the turgor of the skin and mucous membranes, are useful in assessing the degree of dehydration (Table 18.4), except in the child who has hypernatremia, as relatively normal skin turgor is preserved in this condition even with dehydration. On abdominal examination, the finding of a mass (regional enteritis, intussusception) or evidence of obstruction

TABLE 18.4

CLINICAL FINDINGS IN DEHYDRATION

Degree of dehydration (%)	Skin	Mucosa	Pulse	Blood pressure
0	Good turgor	Moist	Normal	Normal
5	Dry	Dry, no tears	Mildly increased	Orthostatic decrease
10	Tenting present	Very dry	Moderately increased, weak	Mildly decreased
15	Poorly perfused	Parched	Markedly increased, thready	Markedly decreased

is important. A rectal examination should be performed in the child who has chronic diarrhea. With overflow stools secondary to prolonged constipation, the rectal ampulla often contains a large amount of hard stool, but it is usually empty in the patient with Hirschsprung's disease. For selected children, laboratory measurements may assist in the evaluation of dehydration, but they often fall in the normal range despite marked loss of fluids.

A diagnostic approach to the pediatric patient with diarrhea is outlined in Fig. 18.1. The physician should first determine

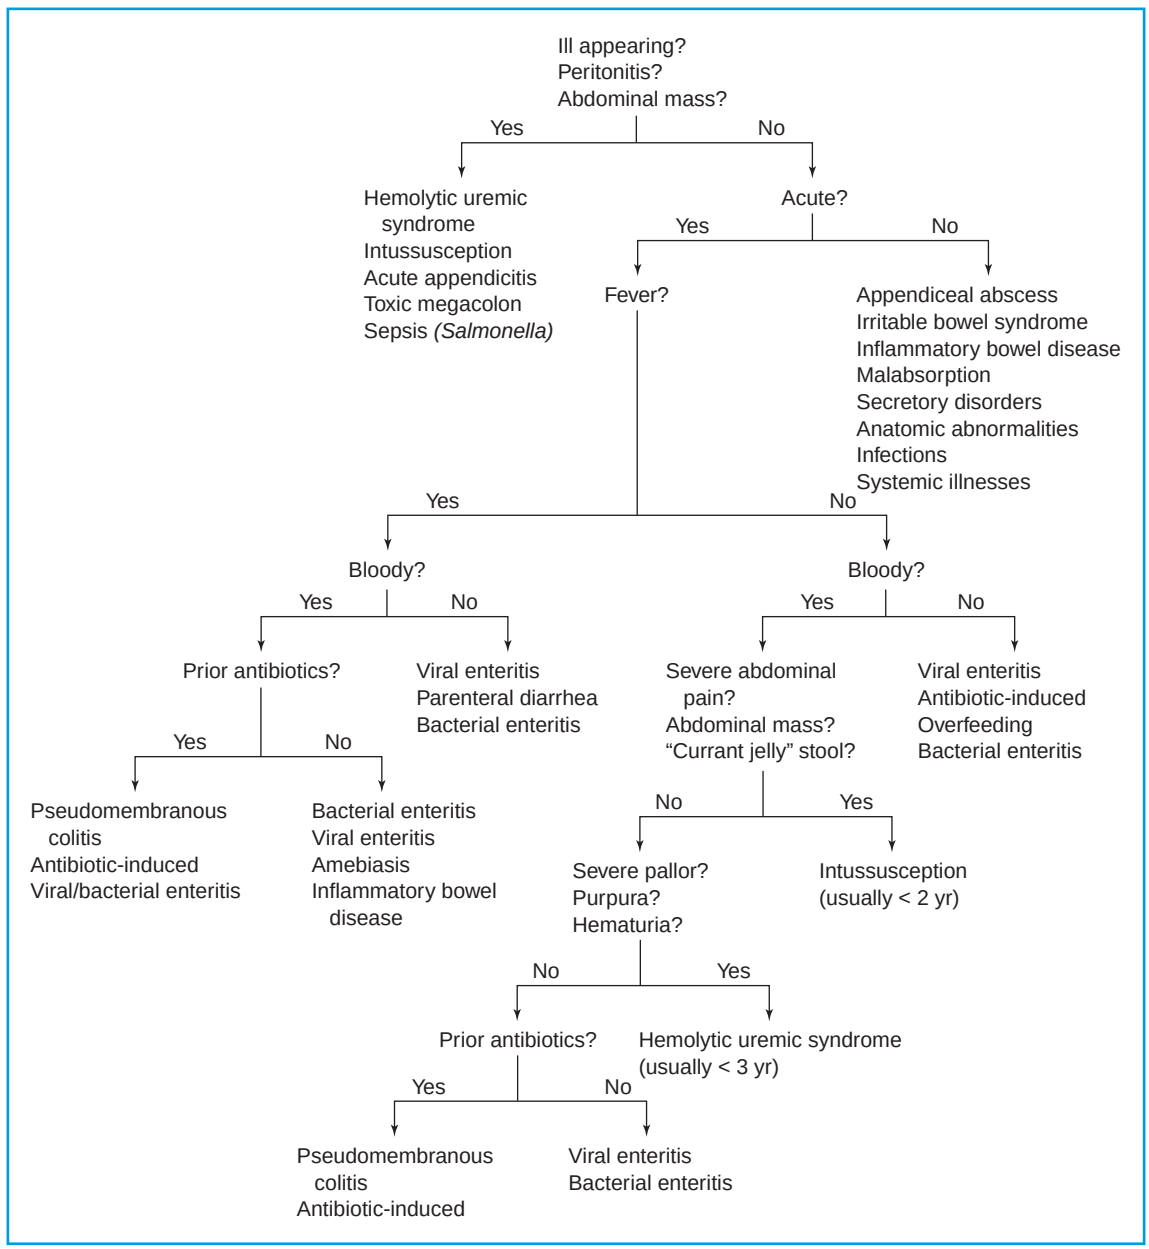

FIGURE 18.1 Diagnostic approach to the immunocompetent child with diarrhea.

whether the child appears seriously ill or has signs of a surgical abdominal process. Once it has been determined that immediate signs of a life-threatening condition are absent, more than any other feature, the duration of diarrhea dictates the initial diagnostic considerations. Children with chronic diarrhea (more than 5 days) are more likely than their counterparts with illnesses of briefer duration to have irritable bowel syndrome, bacterial infections, inflammatory bowel disease, or various malabsorptive disorders. Such conditions, if uncomplicated, do not require a definitive diagnosis emergently, with the possible exception of bacterial enteritis in a febrile or toxic-appearing patient, but rather an evaluation over time.

Acute Diarrhea

With the acute onset of diarrhea, most children have an infectious cause for their disorder and will require at least a brief evaluation in the ED. Fever, the hallmark of infection, serves as the first branch point in the approach to such patients. Although not all children with infectious enteritis have fevers, the finding of an elevated temperature points strongly in this direction. At the same time, the absence of fever, particularly in the presence of bloody stools, should alert the physician to the possibility of one of several serious noninfectious diseases, particularly intussusception and HUS.

The next question is whether hematochezia (bloody stool) is present. Blood is seen in the stool of approximately 10% of children with diarrhea. In most cases, the blood appears in small quantities as drops on the surface of the stool and should not be construed as ominous. A small percentage of children with diarrhea, however, have more profuse rectal bleeding. In these patients, one must exclude life-threatening disorders such as intussusception, HUS, and pseudomembranous colitis.

Febrile children with bloody diarrhea (Fig. 18.1) almost invariably have an infectious enteritis. Pseudomembranous colitis should be considered particularly in patients who have received antibiotic therapy, but this diagnosis usually can be discarded on clinical grounds in the absence of systemic toxicity, abdominal distension, and gross blood in the stools. If pseudomembranous colitis is strongly suspected, admission to the hospital and a full diagnostic evaluation should be considered. Bacterial diarrhea should be sought by culture in febrile children with frankly bloody diarrhea but will be found only in 15% to 20% of cases; viral enteritis is much more common. In the first few months of life, in the infant for whom *Salmonella* gastroenteritis represents a more serious illness, a stool smear for polymorphonuclear leukocytes is useful because the finding of sheets of inflammatory cells strongly points to a bacterial origin. Amebiasis merits consideration only in endemic areas and among travelers. Finally, an occasional child with inflammatory bowel disease may present with an initial episode of acute, bloody diarrhea. In most of these cases, the physician can elicit a preceding history of weight loss or recurrent abdominal pain; in the remainder, the diagnosis emerges only over time, when bloody diarrhea persists in the face of negative cultures.

Most febrile children with nonbloody diarrhea (Fig. 18.1) have viral enteritis. The physician must perform a thorough examination because nonenteric infections, particularly otitis media, may cause "parenteral" diarrhea. For similar reasons, a urine culture is indicated if any historical factors point to an infection of the urinary tract. Although a small percentage of these patients have a bacterial enteritis, routine cultures of stool are not recommended for nonbloody diarrhea of brief duration in otherwise healthy children. Immunocompromised patients, such as those with acquired immunodeficiency syndrome (HIV/AIDS) (see Chapter 93), require a more thorough evaluation, including bacterial cultures and examination for ova and parasites.

Afebrile children with bloody diarrhea (Fig. 18.1) represent the most worrisome category because most patients with intussusception, HUS, and pseudomembranous colitis have this symptom constellation. In particular, intussusception should be considered carefully in any child younger than 1 year of age with grossly bloody diarrhea that does not appear to have an infectious cause. Although the finding of a mass or a currant jelly stool is pathognomonic, a history of severe, colicky abdominal pain in a lethargic child warrants an abdominal ultrasound or contrast enema. Obvious pallor, purpura, and hematuria point to HUS, an unusual but potentially life-threatening disease. Once again, prior antibiotic therapy raises the possibility of pseudomembranous colitis. The most common diagnosis, infectious enteritis, should be assigned only after exclusion of the more serious disorders by history, physical examination, and occasionally, laboratory or imaging studies.

Afebrile children with nonbloody diarrhea (Fig. 18.1) are usually judged to have viral enteritis. Those who receive antibiotic agents, such as amoxicillin, may be suffering from a drug-related gastrointestinal disturbance (antibiotic-induced diarrhea) but not usually from pseudomembranous colitis. During the first 6 to 12 months of life, overfeeding may manifest as diarrhea. The tip-off to this diagnosis is the history of excessive intake in the overweight child. Bacterial enteritis, although a possibility, does not merit a stool culture in the usual clinical circumstances.

Chronic Diarrhea

Chronic diarrhea precipitates a visit to an ED by a child less often than does acute gastroenteritis. An apparent worsening of a long-standing disease may be a final frustration on the part of the parents, however, particularly on a weekend when the family's usual physician may be unavailable. The evaluation of chronic diarrhea usually requires a period of observation and laboratory evaluation beyond the scope of the ED. In the management of these children, the role of the emergency physician is to identify those few individuals who have urgent conditions and refer the remainder to their regular source of care. Particularly in the infant, consideration must be given to Hirschsprung's disease and to cystic fibrosis. A history of delayed passage of meconium, constipation since birth, and abdominal distension are compatible with Hirschsprung's disease. Malabsorptive stools and respiratory infections suggest cystic fibrosis. Failure to thrive, thrush, and pneumonia occur in association with human immunodeficiency virus (HIV) infection. A stool culture and examination for parasites serve to diagnose the serious infections of the gastrointestinal tract and provide a head start on the evaluation for the physician who subsequently sees the child.

The child who returns to the ED with the persistence of an acute diarrheal illness, presumed to be viral in origin and with no evidence of malnutrition or dehydration, often may be managed without an extensive evaluation. Three causes are common: (i) bacterial infections, (ii) secondary lactase deficiency from mucosal sloughing, and (iii) starvation stools in the child who inadvertently has been continued on a clear liquid diet for several days. A stool culture should be obtained, and testing for clostridial toxin is indicated in the presence of recent or ongoing antibiotic therapy. If the child has remained on a clear liquid diet, gradual refeeding is recommended. Milk and all milk products should be proscribed temporarily when secondary lactase deficiency is suspected.

TREATMENT

The treatments for the myriad causes of diarrhea are covered in the medical and surgical sections of this book; however, the therapy for viral gastroenteritis or parenteral diarrhea merits a brief summary. Although all children with circulatory compromise and many children with moderate to severe dehydration need intravenous fluids, the majority of patients with gastroenteritis can be managed with oral solutions. Most children, even those with vomiting, will tolerate frequent, small feedings, but occasionally delivery of fluids via a nasogastric tube may be helpful.

Optimal oral therapy emphasizes the use of appropriate glucose and electrolyte solutions, as well as the early reintroduction of feeding. The ideal solutions, based on formulas carefully tested by the World Health Organization (WHO), have a carbohydrate:sodium ratio that approaches 1:1. Although some recommend, particularly for young infants, initial rehydration with a solution that contains 75 to 90 mEq/L of sodium (i.e., Rehydralyte®) and subsequent maintenance with a more hypotonic formulation (i.e., Pedialyte®), most clinicians use a single preparation during the course of routine, brief illnesses. Older children with mild gastroenteritis tolerate juices and other commercial products, even though the carbohydrate:sodium ratio deviates from the WHO standard.

In general, antidiarrheal agents are ineffective and have no role in the treatment of infectious gastroenteritis during childhood; agents that decrease intestinal mobility (i.e., Lomotil®) carry an additional risk of toxicity. Preliminary studies that pointed to a decrease in stool output with bismuth subsalicylate (Pepto-Bismol®) have not been replicated to a point where routine utilization can be recommended. When selected bacterial or parasitic pathogens are isolated or strongly suspected, appropriate antimicrobial agents should be prescribed (see Chapter 92).

CHAPTER 19 ■ DISTURBED CHILD

LAURA L. CHAPMAN, MD, EMILY R. KATZ, MD, AND THOMAS H. CHUN, MD

This chapter presents an approach for the diagnosis of the acutely disturbed child who manifests agitation and aggression. Additional details of management of the conditions discussed here are found in Chapter 133.

At times, the child's ways of responding to external events and changes in the environment are inadequate. In other situations, a previously supportive environment no longer provides security and protection. As a result, the child may no longer be in control of his or her social and emotional responses. It is usually at this point of crisis that the emergency physician meets the child and his or her caregivers.

The agitated child is typically anxious, upset, and unresponsive to attempts at support. The child may pace back and forth and may threaten staff or family. Speech is often loud and may be abusive. Some children may also be disoriented and out of contact with reality. When agitated, younger children may be out of control, running about the examining room and having severe temper tantrums. They may cry or strike out at the parent or physician. Older children and adolescents may be distraught, sullen, and angry as they meet the examiner. Some children or adolescents, however, may appear to be calm and under control when seen in the emergency department (ED). Information from the parents may reveal significant destructiveness at home before coming to the hospital. In many cases, the improvement in the child's behavior in the ED is a response to the structure provided and the sense that help will be forthcoming.

DIFFERENTIAL DIAGNOSIS

A wide variety of medical and psychiatric conditions can lead to a child's development of significant agitation and aggression. These disorders are listed in Table 19.1 and include severe psychiatric disturbances, life-threatening medical conditions, and minor aberrations in the child's ability to respond to stressful events.

Medical Conditions

Agitation, especially in the presence of disorientation, abnormal vital signs, or decreased level of consciousness, should be considered due to an emergent medical cause until proven otherwise. Clinicians should resist the temptation to immediately ascribe agitation or aggression to psychiatric causes, even in children with a preexisting psychiatric diagnosis. These children remain susceptible to medical illness and are at even higher risk than their peers for engaging in substance use and high-risk behaviors. The first step in evaluating a child with a chief complaint of sudden personality change or confusion is to rule out any potentially life-threatening medical causes.

The history and physical exam can provide multiple diagnostic clues to help the emergency physician differentiate medical from psychiatric causes (Table 19.2). In general, medical causes of agitation have an acute onset and the patient is likely to be disoriented, particularly with regard to time and place. Recent memory can be impaired. In addition, hallucinations may be visual, tactile, or gustatory, rather than auditory in nature (auditory hallucinations are less common). In contrast, psychiatric causes of agitation and confusion have a gradual onset, often following a prolonged period of progressive social and emotional withdrawal. Hallucinations with psychiatric conditions are most frequently auditory. On physical exam, it is important to review vital signs, complete a full exam including a complete neurologic exam, and to consider medical etiologies if abnormalities are found. Further discussion of the evaluation of the agitated child can be found later in this chapter.

Table 19.3 lists medical conditions that can induce agitation in a child. Most of these diagnoses present acutely. For example, a patient with closed head trauma or a cerebral hemorrhage will present with an acute change in mental status and agitation that worsens over a period of minutes to hours. These patients may also be acutely intoxicated, making the evaluation challenging. Careful assessment of vital signs, and in this case, head imaging and toxicologic screening will lead to the correct diagnosis. Other medical conditions, such as thyroid disease, diabetes mellitus, and electrolyte imbalances, will present subacutely. These disorders are usually preceded by medication changes or by a period of weeks to months of symptoms such as weight change, hair loss, diarrhea or vomiting, or fatigue. A patient with a chronic condition such as heart or renal disease can present with agitation during a period of acute worsening of their chronic illness. It is therefore critically important to obtain an accurate history of current and previous medical problems.

A special consideration in pediatrics, especially in the preverbal, autistic or mentally delayed child, is pain. These children may appear agitated, when in fact they have an acute medical condition or an acute injury. A careful physical exam and a broad diagnostic workup is necessary to fully evaluate these children. Child abuse should always be considered, especially in the autistic or mentally delayed child, as these children have been shown to be at higher risk.

Toxicologic Ingestion or Withdrawal

Acute ingestion of a toxicologic substance, or in the case of a chronic user, withdrawal from a substance, commonly leads to

TABLE 19.1

DIFFERENTIAL DIAGNOSIS OF AGITATION AND AGGRESSION IN CHILDHOOD

- Psychosis, caused by
  - Medical illness
  - Ingestion of toxic substance
  - Pervasive developmental disorder (e.g., autism)
  - Adult type schizophrenia
  - Manic-depressive illness
- Depression
- Conduct disorder
- Adjustment reaction of childhood or adolescence
- Attention-deficit disorder
- Medical illness in the absence of psychosis (e.g., thyrotoxicosis, temporal lobe epilepsy)
- Sensory deficit: blindness, deafness
- Severe communication disorder (e.g., childhood aphasia)

agitation and may lead to psychosis (Table 19.4). In obtaining a history, a frequent important clue in drug intoxication is the acute onset of disordered thinking in the presence of visual hallucinations. A history of drug abuse and the availability of toxic substances are other important historical clues. Intoxication with alcohol, sedatives, antidepressants, anticholinergic agents, and heavy metals can be life threatening if enough of the agent has been ingested. Withdrawal syndrome in patients habituated to alcohol or sedative-hypnotic agents may likewise result in severe agitation, psychosis, seizure, and death.

Delirium

Delirium can be broadly defined as acute, fluctuating global cerebral dysfunction due to a medical condition. The presentation can be quite variable but the core feature is a disturbance in consciousness with a decreased ability to focus, sustain, or shift attention (Table 19.5). While many delirious patients may be agitated or suffering from hallucinations, others can appear hypoactive, quiet, and withdrawn.

TABLE 19.3

MEDICAL CONDITIONS THAT MAY LEAD TO AGITATION AND DELIRIUM

- Central Nervous System Lesions
  - Tumor
  - Brain abscess
  - Cerebral hemorrhage
  - Meningitis or encephalitis
  - Temporal lobe epilepsy
  - Closed head trauma
- Cerebral Hypoxia
  - Pulmonary insufficiency
  - Severe anemia
  - Cardiac failure
  - Carbon monoxide poisoning
- Metabolic and Endocrine Disorders
  - Electrolyte imbalance
  - Hypoglycemia
  - Hypocalcemia
  - Thyroid disease (hyper- and hypo-)
  - Adrenal disease (hyper- and hypo-)
  - Uremia
  - Hepatic failure
  - Diabetes mellitus
  - Porphyria
  - Reye's syndrome
  - Wilson's disease
- Collagen-vascular Diseases
  - Systemic lupus erythematosus
  - Polyarteritis nodosa
- Infections
  - Malaria
  - Typhoid fever
  - Subacute bacterial endocarditis
  - HIV and complicating infections
  - Pain

Irritability, mood fluctuation, and anxiety are common findings in pediatric patients suffering from delirium. If delirium is present, priorities should be maintaining the patient's safety while evaluating and treating the underlying cause (Table 19.6).

TABLE 19.2

DIFFERENTIATING FEATURES OF ORGANIC AND PSYCHIATRIC PSYCHOSIS[a]

Evaluation feature	Organic psychosis	Psychiatric psychosis
Onset	Acute	Gradual
Pathologic autonomic signs[b]	May be present	Absent
Vital signs	May be abnormal	Normal
Orientation	Impaired	Intact
Recent memory	Impaired	Intact
Intellectual ability	May be impaired	Intact
Hallucinations	Visual	Auditory

[a]Children with both functional and organic psychoses will have impaired reality testing, inappropriate affect, thought disorder, poor behavior control, and disturbed relating ability.
[b]Increase or decrease in heart rate, respiratory rate, blood pressure, and temperature; miosis or mydriasis; and skin color changes.

TABLE 19.4

EXOGENOUS SUBSTANCES CAUSING AGITATION AFTER INGESTION OF SIGNIFICANT QUANTITY OR OVERDOSE, OR DURING WITHDRAWAL WHEN HABITUATED

Intoxication/Overdose
Alcohol
Marijuana
Cocaine
Opioids (e.g., heroin, methadone)
Amphetamines
Methamphetamines/MDMA(ADHD medications, ecstacy)
Hallucinogens—LSD, peyote, mescaline
Corticosteroids (adverse therapeutic effect)
Phencyclidene (PCP)
Barbiturates
Methaqualone (Quaalude)
Anticholinergic compounds
Antipsychotics (e.g., phenothiazines)
Opioids (e.g., heroin, methadone)

Withdrawal
Alcohol
Barbiturates
Benzodiazepines
Other sedative-hypnotic agents

Psychiatric Conditions

A number of psychiatric conditions can present with agitation or aggression. Agitation or aggressive behavior may be the final common pathway for a number of psychiatric conditions. These conditions are discussed below and in greater detail in Chapter 133.

Psychotic Disorders

Psychosis refers to a mental state in which major disturbances in thinking, relating, and reality testing occur. They

TABLE 19.5

CLINICAL DISTURBANCES OF DELIRIUM

Consciousness	Decreased awareness of the environment
Attention	Impaired ability to focus, sustain, or shift attention
Cognition	Disorientation, disorganization, thought disturbance (e.g., paranoia, confusion, language, or memory deficit)
Perception	Hallucinations (especially tactile and visual), illusions, misperceptions
Sleep	Sleep–wake cycle disturbances, fluctuating symptoms (i.e., "sundowning"—waxing and waning symptoms)
Behavior	Agitation, hyper- or hypoactivity, restlessness
Mood/affect	Anxious, depressed, irritable, labile
Neurologic	Diffuse EEG slowing, myoclonus, asterixis, abnormal tone

TABLE 19.6

"I WATCH DEATH" MNEMONIC FOR DELIRIUM

Infection	Meningoencephalitis, HIV, sepsis, abscess
Withdrawal	Alcohol, barbiturates, benzodiazepines, other sedative hypnotics
Acute Metabolic Disturbance	Acidosis, alkalosis, electrolyte abnormality, hepatic or renal failure
Trauma	Head injuries, heatstroke, postoperative complications, severe burns
CNS Pathology	Increased intracranial pressure (e.g., hydrocephalus), seizures, neoplasms, vasculitis
Hypoxia	Anemia, carbon monoxide poisoning, cardiopulmonary failure, impaired cerebral circulation
Deficiencies	Vitamins B_{12}, B_1 (thiamine), B_3 (niacin), folate
Endocrine Disturbances	Hyper- and hypocortisol states, hyper- and hypoglycemia, myxedema, hyperparathyroidism
Acute Vascular Events	Stroke, arrhythmia, shock, hypertensive encephalopathy
Toxins/Drugs	Illicit drug use, prescription drugs, pesticides, solvents
Heavy Metals	Lead, mercury, manganese

Adapted from Wise MG, Terrell CD. In: Hall JB, Schmidt GA, Wood LD, eds. Delirium in the Intensive Care Unit. Principles of Critical Care. 2nd ed. New York: McGraw-Hill; 1998;969–72

may have hallucinations, delusions (fixed, false beliefs), and/or grossly disorganized behavior and speech. Psychotic patients do not express themselves clearly and have difficulty answering direct questions. They also may be extremely suspicious and hostile. In children, psychosis is less likely to be due to a primary psychotic disorder such as schizophrenia and more likely due to a medical illness or another psychiatric disorder that can present with psychotic symptoms [e.g., severe anxiety, posttraumatic stress disorder (PTSD), depression, or mania].

Primary psychotic disorders include brief psychotic disorder, schizophreniform disorder, schizophrenia, delusional disorder, and schizoaffective disorder. These illnesses share core diagnostic criteria but differ primarily based on duration of symptoms. Brief psychotic disorder requires the presence of psychotic symptoms for greater than 1 day but less than one month. Schizophreniform disorder requires active psychotic symptoms for 1 to 6 months. The diagnosis of schizophrenia is reserved for patients who have demonstrated active, prodromal, and/or residual symptoms lasting greater than 6 months. Delusional disorder is diagnosed in otherwise well-functioning children who have non-bizarre delusions and no hallucinations or disorganization. Schizoaffective disorder is diagnosed when patients have bipolar or major depressive episodes superimposed on symptoms consistent with a diagnosis of schizophrenia.

It is useful to assess the child presenting with psychotic symptoms for their level of premorbid functioning as well as any recent stressors. Primary psychotic disorders can present

in children who have been previously well adjusted or may have had mild to moderate emotional problems but have been exposed to acute or chronic unmanageable stressor(s) such as trauma or abuse. For children who present with a prolonged prodromal period of progressive social and emotional withdrawal, an eventual diagnosis of a chronic disorder such as schizophrenia is more likely.

It is important for clinicians to reserve the use of the term schizophrenia for patients meeting full diagnostic criteria, since the prognosis for brief psychotic disorder, schizophreniform disorder, and the other psychiatric disorders that can present with psychosis can often be good. Using the term schizophrenia in the ED setting, before it has been determined that full diagnostic criteria have been met, can be unduly devastating and demoralizing for patients and their families. Liberal use of this term may also lead to insufficient evaluation for alternative and potentially treatable diagnoses.

Depression

The depressed child who presents to the ED may appear sad, hopeless, anxious, anhedonic, or withdrawn. However, some depressed children present with irritability as their main symptom and deny feeling sad. This irritability can, in turn, lead to agitated and aggressive behavior. Thus, the emergency physician should ask about other common symptoms of depression including depressed mood and a disturbance in "SIGECAPS" (Table 19.7), a family history of mood disorders, and any major recent changes in the child's life. While depression and resulting irritability can occur in the absence of any major apparent stressors, common precipitants of depression and a sense of hopelessness may include parental divorce or separation, loss of a parent through death, a recent devaluation of personal abilities through poor academic performance, peer rejection, or the onset of significant physical illness. Once depression is identified, it is extremely important to inquire about the presence and nature of any suicidal ideation.

Manic/Mixed Episodes

While mania is primarily associated with elation or elevated mood, the main symptom, especially in children, can be irritability. In fact, signs of elation may be completely absent. As with depression, the irritability can be severe and judgment can be so impaired that children can become aggressive and violent. A manic episode is defined as a 7-day period (or shorter if hospitalization is required) of a persistently elevated or irritable mood along with symptoms of distractibility, indiscretions/hypersexuality, grandiosity, flight of ideas, increased goal-directed activity, rapid or pressured speech, and decreased need for sleep (Table 19.8). Some children will have a mixed episode, simultaneously meeting criteria for mania and depression. Irritability, agitation, violent acts, and suicidality are more likely to occur when mixed symptoms are present. Children and adolescents experiencing mixed or manic symptoms may be difficult to engage in an interview. They tend to speak rapidly and have pressured speech, have difficulty staying still, and find it difficult or impossible to concentrate long enough to answer questions. As with all presentations of psychiatric symptoms, a high suspicion for an organic etiology should be maintained, especially if abnormal vital signs, confusion, and/or disorientation exist.

TABLE 19.7

"SIGECAPS" MNEMONIC FOR DEPRESSION

Sleep (decreased, increased, or disturbed sleep)
Interests (loss of interests, morbid preoccupations)
Guilt (excessive guilt)
Energy (decreased energy)
Concentration (decreased or problems with concentration)
Appetite (decrease or increase in appetite)
Psychomotor functioning (decreased or problems with functioning)
Suicidal ideation

Adapted from Caplan JP, Stern TA. Mnemonics in a mnutshell: 32 aids to psychiatric diagnosis. Current Psychiatr 2008;7:27.

TABLE 19.8

"DIG FAST" MNEMONIC FOR MANIA

Distractibility (attention too easily drawn to unimportant or irrelevant external stimuli)
Indiscretion (excessive involvement in pleasurable activities that have a high potential for painful consequences such as buying sprees/shoplifting, sexual indiscretions, or driving recklessly)
Grandiosity (excessively inflated self-esteem, feeling invincible, reporting they have or are planning to achieve wildly unrealistic goals)
Flight of ideas (rapidly leaping from one idea to the next or subjective experience that thoughts are racing)
Activity increase (socially, at school, or at home) or psychomotor agitation
Sleep deficit (decreased need for sleep while still feeling rested or energized)
Talkativeness/pressured speech (difficult or impossible to interrupt)

Adapted from Caplan JP, Stern TA. Mnemonics in a mnutshell: 32 aids to psychiatric diagnosis. Current Psychiatr 2008;7:27.

Anxiety

Children with anxiety disorders can become quite agitated and even aggressive in an effort to avoid something they are afraid of. For example, children with separation anxiety may become violent—kicking and punching caregivers, destroying property—in their increasingly desperate attempts to prevent their parents from dropping them off at daycare. Children with obsessive–compulsive disorder (OCD) can become agitated and/or aggressive when they are kept from carrying out a compulsion. Agitation and aggression tend to escalate as the fear of the event or activity draws near and may resolve rather precipitously when the event has passed. For example, the child with a school phobia may become increasingly irritable as the weekend draws to a close. It may worsen to the point of trying to jump out

of a moving school bus. However, that same child may then appear perfectly safe and happy within 15 minutes of starting the school day. Typically, children whose anxiety leads to severe irritability or aggression will have a long-standing history of anxiety symptoms, and the patient or their parents are usually able to give a clear history of precipitating events. In the absence of such a history and/or a clear precipitating event, suspicion for an organic contribution should be raised.

Trauma

Children and adolescents who have been victims of past or ongoing physical or sexual abuse or other severe trauma may develop acute agitation brought on by posttraumatic stress disorder. The symptoms of this disorder include fluctuating behavior with episodes of excitement, fearfulness, or irritability; recurrent nightmares or flashbacks; and lack of involvement in usual friendships or activities. Children who experience posttraumatic reactions often avoid or refuse to talk about the trauma, and thus, parents may be confused about the reasons for the child's disturbed behavior. If parents are aware of the traumatic event, they may be upset or feel guilty about its occurrence.

Alternatively, one or more of the child's parents may be the perpetrators of the trauma. Parents and children should thus be asked about trauma separately, as part of the diagnostic assessment. Children who are upset about a previous trauma may be particularly difficult to evaluate. They will appear frightened, may behave erratically, and may be uncomfortable with discussing previous traumatic events. A quiet environment and gentle support from the physician may help these children express their thoughts and fears. Younger children who are frightened and who do not easily separate from their parents should raise the possibility of past or current trauma.

Disruptive Behavior Disorders

Disruptive behavior disorders include attention-deficit/hyperactivity disorder, oppositional defiant disorder, and conduct disorder; these disorders are discussed in greater length in Chapter 133. Children with each of these disorders commonly present with out-of-control, agitated, and/or violent behavior. Acute agitation or aggression that requires an ED visit is likely to result from some consequence of the child's difficulties at school or at home. Usually their presenting symptoms fit into a long-standing pattern of similar behaviors. Children with disruptive behavior disorders are at increased risk for substance abuse and suffering trauma-related injuries. Therefore, any acute change in behaviors, especially if accompanied by any physical symptoms or abnormal vital signs, should raise suspicion of a medical contribution to the patient's presentation.

Adjustment Disorders

Adjustment disorder is characterized by a deterioration of functioning from a previously higher level. The decline in function occurs in the presence of some precipitating event or situation that leads to significant emotional or behavioral distress or a symptomatic response in excess of what would be expected given the specific stressor. At times, the precipitant may be a developmental event, such as enrollment in a new school, increased peer pressure, or the emergence of secondary sexual characteristics during puberty. The precipitant also may be an acute event such as the loss of a parent through death or divorce. Children with adjustment reactions can present with anxiety, depressed mood, and/or behavioral disturbances. Behaviors that may fall under this category include those that violate the rights of others or other major age-appropriate societal norms and rules (truancy, vandalism, fighting, etc.).

The child with an adjustment reaction is oriented and usually can explain his or her problems well, although those who present with behavioral disturbances may be quite angry and difficult to engage. In order for a diagnosis of adjustment disorder to be made, the patient's symptoms must not meet criteria for any other major psychiatric disorder. The agitation and aggression of an adjustment reaction can be as dangerous and require intensive intervention as other psychiatric disorders. As such, patients with adjustment reactions need to be screened for suicidality, homicidality, and safety to return home.

Pervasive Developmental Disorders Including Autism

These disorders are discussed in greater length in Chapter 133. Children with pervasive developmental disorders (PDD) who present with agitation or aggression can pose a significant diagnostic and treatment challenge. The range of causes of such behavior is extremely broad, and the patient's ability to report his or her current symptoms can be severely impaired. Clinicians should pay special attention to questioning caregivers about any recent changes in the patient's life or behaviors, no matter how insignificant they may initially appear. Small changes in the patient's routine or apparently minor medical ailments such as constipation can lead to severe behavioral disturbances including self-injurious behavior. Suspicion for medical causes/contributions to the patient's presentation must be extremely high and consultation with the patient's primary clinicians should be sought whenever available. While interventions for agitated and aggressive behavior will be discussed in detail later in this chapter and in Chapter 133, it should be noted that special care should be taken with PDD spectrum patients. Caregivers should be consulted in order to ascertain what calming/distracting techniques have been useful for the patient in the past, and clinicians should use caution when dosing sedative medications, as patients with PDD spectrum often require smaller doses than other children and are especially sensitive to medication side effects.

EVALUATION AND DECISION

The emergency assessment of the agitated or withdrawn child or adolescent involves three complementary areas. The first area involves determination of whether the problematic behavior is caused by some medical condition or organic state. Potential life-threatening effects of the medical condition must be recognized and treated. Second, the psychiatric manifestations of the

presenting condition, whether organic or psychiatric, are assessed. Third, the family system and social support for the child are assessed. Once these three areas have been evaluated, the physician can make an appropriate decision regarding disposition and further treatment.

General Approach/Initial Stabilization

The first priority when approaching an agitated and/or aggressive patient is to ensure the safety of both the patient and the ED staff. Pharmacologic and non-pharmacologic interventions that can be employed are discussed in Chapter 133.

Medical Conditions

First, to determine whether the child's agitation or withdrawal is organically based, the physician should bear in mind the differential diagnosis of these behaviors, which include psychiatric as well as organic origins (Table 19.1). A complete history of the acute events that led up to the ED visit, including any changes in behavior or functioning of the child, should be obtained. The possibility of drug use or ingestions should be explored with the parents and with the child. The child's medical history should be documented carefully, and any previous episodes of the current behavior should be reviewed. In general, organically based problems are acute in onset and result from an ingestion, an injury, or the worsening of a medical condition. The differentiating features of organic psychoses and psychiatric psychoses have already been discussed and are listed in Table 19.2.

The medical evaluation of agitation and withdrawal requires that each child who presents to the ED with these behaviors receive a complete physical examination, including full neurologic evaluation. This makes it possible to detect most significant ongoing organic illnesses and neurologic disease of traumatic, infectious, or structural origin. Mild incoordination, abnormalities of rapid alternating movements, and impaired tandem gait may be present in children with an attention-deficit disorder. In situations in which an acute intoxication is being considered, blood and urine should be obtained and sent for specific drug determination or toxic screening, as appropriate. Additional laboratory studies should be pursued in accordance with the findings of the physical examination and may include a complete blood count, sedimentation rate, urinalysis, electrolytes, blood glucose, calcium, blood urea nitrogen, ammonia, and liver function tests. Thyroid studies are indicated when ongoing thyroid disease is suspected. A computed tomography scan or magnetic resonance imaging examination may be helpful when trauma or a mass lesion is being considered (Table 19.9).

TABLE 19.9

MEDICAL EVALUATION OF THE AGITATED CHILD

Baseline evaluation
Physical examination including neurological exam

If intoxication suspected
Toxicologic screening
Specific drug testing
Anion/osmolar gap
Blood gas

If suggested by history or physical exam
CBC
ESR
Urinalysis
Electrolytes
Blood glucose
BUN
Ammonia
LFTs
Pregnancy test
Thyroid function tests
EKG

If trauma or mass lesion suspected
Head CT or MRI

CBC, complete blood cell count; ESR, erythrocyte sedimentation rate; BUN, blood urea nitrogen; LFTs, liver functions tests; EKG, electrocardiogram; CT, computed tomography; MRI, magnetic resonance imaging.

Psychiatric Evaluation

The second major area in the ED approach to an agitated or withdrawn child involves assessment of psychiatric manifestations of the presenting condition. This is achieved through a thorough history of present illness (HPI), mental status examination (MSE), in conjunction with an evaluation of the child's previous level of adjustment, past psychiatric history, and family psychiatric history. In older children and adolescents, the Folstein "Mini-Mental Status Examination" (MMSE) can be a useful screening tool. In younger children who cannot complete the tasks of the MMSE, bedside observation and questioning of parents (or nursing staff) will be the mainstay of assessment. All patients should be asked whether their thinking is confused, whether they are seeing or hearing any strange things, and about the any homicidal or suicidal ideation. The ED physician can obtain much of the MSE during the history and physical examination. Other areas will require direct questioning of the child by the physician.

The categories of the MSE, as described in Chapter 133, are also summarized here. The child's appearance will have already been noted. Orientation to person, place, time, and situation should be determined. Short- and long-term memory should be tested, as should cognitive functions, which include intelligence, fund of knowledge, and the ability to reason and think (much of this information can be determined from the flow of the interview). The child's behavior should be assessed for activity level and age appropriateness. Particularly important in the emergency assessment of the child are affect and thinking. Affect refers to the predominant feelings displayed by the child. The examiner should observe the nature of the affect (e.g., happy, sad, angry, flat), its degree of appropriateness to the situation, and how it changes as various subjects are discussed. Thinking includes thought processes and thought content. The coherence and goal directedness of verbal communication are assessed, and loose associations and speech that lack internal consistency are noted.

Evaluation of thought content involves identifying the child's major themes and concerns. Preoccupations, such as hallucinations, delusions, and ideas of reference (present in psychosis), or sadness, hopelessness, and feelings of depression (present in depression) should also be sought. The child's strengths can be assessed from spontaneous statements and from forthrightness in answering specific questions. The child's insight into the current problem should be noted, and their capacity to suggest a plan for the present crisis should be evaluated.

Determining the presence or absence of suicidal or homicidal ideation and intent is an essential part of the MSE and provides an opportunity to ask about past attempts. The circumstances and intent of any previous suicidal or homicidal attempts should be explored thoroughly and should include questioning about how the patient feels about the fact that prior attempts have failed. If the patient reports suicidal or homicidal ideation, they should be asked whether they have a plan, if they have the means to carry out that plan, what they think will happen if they carry it out, and what, if anything, has kept them from acting on their plan already. The most effective way of determining such intent is by asking the child directly. Such an approach opens the subject in a way that is often reassuring, thereby enabling the discussion to proceed.

As the MSE is carried out, the physician develops a picture of the child that leads to certain diagnostic possibilities. For example, the psychotic child will have bizarre or inappropriate affect, speech that is not goal directed, and possibly, hallucinations or delusions. Such a child typically relates poorly to the physician, avoiding eye contact, failing to respond to the physician's attempts to empathize, and perhaps, engendering in the physician feelings of confusion and uneasiness. If the psychotic child is oriented with intact memory and cognitive functions, it is likely that the psychosis is psychiatric in origin. If the child's orientation, memory, and cognitive functions are significantly impaired, the psychosis is more likely organic in nature. When the child's thinking is coherent and the affect is not bizarre or inappropriate, it is likely that psychosis is not present.

While interviewing the patient, physicians should pay attention to the feelings they experience when interacting with the child, as this can be a rich source of useful information. For example, an interview with a depressed child will often leave the physician feeling sorry for the patient. The manic patient may leave the physician feeling either stressed or more cheerful and talkative. With disruptive behavior disorders, child's manner of relating may be distant or manipulative. The physician may feel angry at such children. Psychotic children may seem odd or absent and leave the physician feeling disconnected or uneasy. Most importantly, the physician should pay close attention to any threatening feelings, as this may be the first sign that a patient may become violent. While awareness of this emotional response to a patient is not, in and of itself, diagnostic, it can still be clinically useful—especially when the patient or family members are reluctant or unreliable historians, or difficult to engage. Recognition of the feelings engendered by a patient can be useful in helping physicians summon empathy and prevent themselves from acting in a counter-therapeutic or unnecessary manner (i.e., being overly aggressive with physical restraints).

Evaluation of Support Systems

Finally, emergency evaluation includes assessment of the family and social support system. Information about who lives at home with the child, the nature of their relationships with each other, and any recent changes in family composition or in the child's living situation help in understanding the current problem and in determining treatment.

The physician can gain information about the family through observation and direct questioning. Information about family relationships, including the parents' level of concern and their ability to appreciate the child's current situation, is obtained. The parents' description of the child during the history taking offers insight into how the child is perceived in the family. The extent to which the parents try to engage a withdrawn child or to calm and set limits with an agitated child should be noted, as well as the child's response to these efforts.

As the child is questioned by the physician, the parents' responses are also informative. Do the parents answer for the child and interrupt when he or she tries to speak? The parental response suggests the degree to which the child's independent thinking and behavior are encouraged. If the child is not cooperative during the psychiatric or physical examinations, how effective are the parents in telling the child that he or she must cooperate? The parents' success in gaining the child's cooperation during the ED visit may offer a valuable clue about their ability to manage their child effectively at home.

The physician can assess the degree of coping by the family in part by the way in which the family members describe problems. Responses that suggest that the parents are overwhelmed and disorganized should lead the physician to consider psychiatric consultation and possible hospitalization. The openness of the family in discussing recent difficulties also is important. Some families are extremely guarded and deny problems, despite the presence of a major crisis that they are unable to manage. Other families offer a more balanced view of family functioning, instilling greater confidence in the physician. If the child's parents are divorced, assessing the relationship between the parents is important. Arguments and disagreements, as well as the possibility of violence, lead to a lack of safety and security for the child in crisis. The degree of support that a single parent receives from extended family and neighbors is also an important factor in evaluating family support and capacity.

Before discharge, the physician should be confident that the child is safe; otherwise, social work or psychiatric consultation should be obtained.

Disposition

In determining the disposition of a child with a psychiatric problem in the ED (Fig. 19.1), the physician should be guided by the severity of the problem and by the ability of the family to manage the child on an outpatient basis. The physician should inquire about what social supports are available to the parents. If extended family or close friends are available and the parents believe that their participation would be helpful, the physician should encourage the parents to enlist such help. If other agencies are working with the family, their efforts

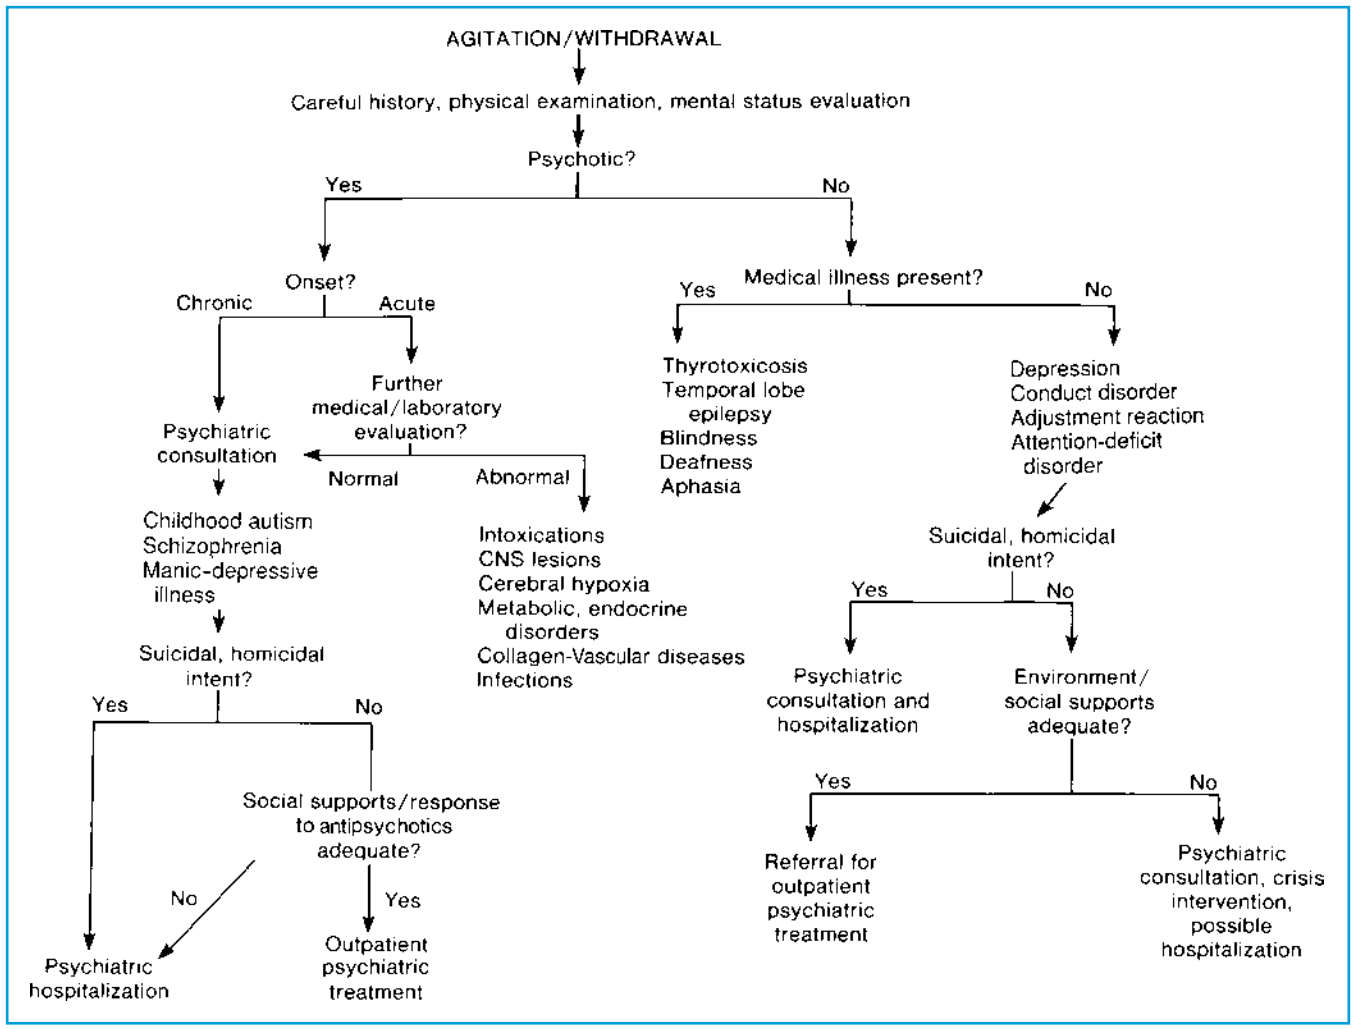

FIGURE 19.1 Approach to the diagnosis and initial disposition of the acutely disturbed child. CNS, central nervous system.

should be coordinated with those of the hospital or mental health facility at which the child receives treatment. Many families express a clear preference about whether their child should be hospitalized. The physician should keep this preference in mind, but should make the decision based on the data about the child's physical and emotional well-being and the assessment of the family support system.

When organic etiologies are suspected or delirium is present, full medical evaluation, observation, and treatment of the underlying condition is required. This is best accomplished through medical hospitalization. Psychiatric consultation is indicated in all cases of psychiatric psychosis, mania, and/or suicidal or homicidal intent. Social work or child protection team consultation is indicated whenever abuse or neglect are suspected.

Psychotic patients who are not suicidal, homicidal, or aggressive and who are able to engage in normal activities of daily living may be referred for ongoing outpatient treatment after a positive response to antipsychotic medication (see Chapter 133).

Patients who have suicidal or homicidal intent are usually hospitalized, as are patients who are unable to maintain their own safety due to mania. Patients with disruptive behavior disorders sometimes require brief inpatient hospitalization when current outpatient and community supports are inadequate to prevent further violence. In the absence of suicidal ideation, homicidal ideation, impaired decision making leading to unsafe behaviors, inability to carry out basic daily functions, or extreme acts of aggression, the ability of the family and social support system to control the child's behavior and prevent further emotional and physical harm should be assessed. If the support system is adequate and timely and appropriate treatment is available, referral to outpatient treatment may be appropriate. When the support system is not adequate and/or appropriate outpatient treatment options are not available, psychiatric hospitalization may be necessary, especially with such behaviors as fire setting, persistent aggressiveness, or failure of prior or current outpatient treatment.

If a child is already in treatment, every effort should be made to contact the child's providers in order to obtain their assessment as to the appropriate disposition and to attempt to arrange for follow-up as close to ED discharge as possible. The physician who discharges a child for outpatient psychiatric

treatment should help the family develop short-term measures to manage the child and relieve his or her distress until outpatient psychiatric treatment begins.

CHAPTER 20 ■ DIZZINESS

STEPHEN J. TEACH, MD, MPH

Patients may present with "dizziness" as an isolated complaint or as part of a constellation of symptoms related to an underlying illness. True vertigo, the perception that the environment is rotating relative to the patient or that the patient is rotating relative to the environment, arises in the peripheral or central vestibular system. It can be immensely disturbing, even frightening, to patients and their families. Preverbal children, unable to articulate the sensation, may merely be irritable, vomit, and prefer to lie still. Older children and adults may have difficulty describing the sensation.

Unfortunately, most patients who use the term "dizziness" are in fact describing one of numerous nonvertiginous disturbances (pseudovertigo), which may be difficult for the practitioner to distinguish from true vertigo. Light-headedness, presyncope, intoxication, ataxia, visual disturbances, unsteadiness, weakness, stress, anxiety, hyperventilation, depression, and fear can initially all present with a complaint of dizziness.

Therefore, when evaluating a child complaining of dizziness, the practitioner should listen carefully to the details of the history as these may allow him or her to distinguish true vertigo from pseudovertigo. The key element in the history that strongly suggests true vertigo is the subjective sense of rotation. Often, the best response to a chief complaint of being dizzy is to say, "Tell me what you mean by 'dizzy.'" Initially vague complaints often become increasingly concrete, and the underlying diagnosis may become increasingly clear.

PATHOPHYSIOLOGY

True vertigo arises from a disturbance in either the peripheral or central components of the vestibular system. The two peripheral sensory organs of the system (together known as the labyrinth) are the semicircular canals (stimulated by rotary motion of the head) and the vestibule (stimulated by gravity). Both organs lie near the cochlea within the petrous portion of the temporal bone. The proximity of the vestibular and cochlear apparatus explains the frequent association of vertigo with hearing impairment.

Afferent impulses from these organs travel via the vestibular portion of the eighth cranial nerve to the vestibular nuclei in the brainstem and in the cerebellum. Cortical projections terminate in the superior temporal gyrus and the frontal lobe. Efferents from the cerebellum and vestibulospinal tract to the peripheral muscles complete the circuit by which the vestibular system helps maintain balance and position sense. Additional impulses from the vestibular nuclei ascend within the medial longitudinal fasciculus to cranial nerves III, IV, and VI, accounting for the oculovestibular reflexes. Almost all patients complaining of true vertigo should have nystagmus, at least when the vertiginous symptoms are peaking. If not, then a vestibular defect is much less likely. When present with true vertigo, the fast component of the nystagmus is almost always in the same direction as the perceived rotation.

DIFFERENTIAL DIAGNOSIS

As discussed earlier, dizziness is best divided into vertiginous conditions (true vertigo) and nonvertiginous conditions (pseudovertigo). Table 20.1 lists the differential diagnosis of true vertigo and highlights the life-threatening causes. Table 20.2 lists the most common causes of vertigo. Table 20.3 lists numerous nonvertiginous conditions that may initially be described as dizziness. Because the spectrum of nonvertiginous conditions is so broad, the following discussion will concentrate on true vertigo.

Vertigo follows a dysfunction of the vestibular system within the semicircular canals, vestibule, or vestibular nerve (peripheral vertigo), or within the brainstem, cerebellum, or cortex (central vertigo). It can also be divided into conditions in which hearing is impaired (usually peripheral causes) and into conditions in which hearing is spared (usually central causes). Finally, vertigo can be divided into acute (usually infectious, postinfectious, traumatic, or toxic) and chronic-recurrent groups (usually caused by seizures, migraine, or benign paroxysmal vertigo of childhood).

Infections

Both acute and chronic bacterial and viral infections of the middle ear with or without associated mastoiditis may cause both vestibular and auditory impairment (see Chapter 31). Severe, untreated, acute suppurative otitis media with effusion may extend directly into the labyrinth. Even without direct invasion of the pathogens, inflammatory toxins can cause a serous labyrinthitis.

Chronic and recurrent otitis media can produce a cholesteatoma of the tympanic membrane, an abnormal collection of keratin caused by repeated cycles of perforation and healing. Cholesteatomas can erode the temporal bone and the labyrinth, producing a draining fistula from the labyrinth that presents as vertigo, nausea, and hearing impairment. Computed tomography (CT) scans show destruction of the temporal bone.

Viral infections can directly affect the labyrinth or the vestibular nerve; together these conditions are known as *vestibular neuronitis*. Known pathogens include mumps, measles, and the Epstein-Barr virus. Herpes zoster infection of the ear canal and facial palsy (Ramsay Hunt syndrome) may

TABLE 20.1

CAUSES OF VERTIGO IN CHILDREN

Peripheral causes	Central causes
Suppurative or serous labyrinthitis	Tumor[a]
External ear impaction (especially cerumen)	Meningitis[a]

Cholesteatoma	Increased intracranial pressure[a]
Perilymphatic fistula	Multiple sclerosis
Vestibular neuronitis	Trauma[a]
Benign paroxysmal vertigo	Seizure (usually complex partial)
Ingestions[a]	Migraine
Temporal bone fracture[a]	Stroke[a]
Posttraumatic vestibular concussion	Motion sickness
Ménière's disease	Paroxysmal torticollis of infancy

[a]Life-threatening causes of vertigo.

also involve the 8th nerve. More commonly, a nonspecific upper respiratory tract infection may precede the illness. Onset is usually acute and can be severe. Nystagmus is usually present. Patients prefer to lie motionless with their eyes closed. Recovery is from 1 to 3 weeks. Early use of prednisone may shorten the course.

Migraine

Vertigo may be a prominent feature of classic migraine or migraine equivalent, in which there is no associated headache (see Chapters 55 and 96). Up to 19% of children with migraine may have vertiginous symptoms during their aura. Basilar migraine presents as a throbbing occipital headache following signs and symptoms of brainstem dysfunction (including vertigo, ataxia, tinnitus, and dysarthria). Vertigo from migraine equivalent (without pain) is typically seen in patients with a family history of migraine headache and is associated with other transient neurologic complaints (e.g., weakness, dysarthria). Symptoms may suggest temporal lobe epilepsy. The latter is distinguished by altered consciousness.

The differential diagnosis of headache and vertigo includes a brainstem or cerebellar mass, hemorrhage, and infarction.

Hyperventilation	Hypoglycemia
Orthostatic hypotension	Pregnancy
Hypertension	Ataxia
Heat stroke	Visual disturbances
Arrhythmia	Psychogenic disturbance

These uncommon disorders are best assessed by magnetic resonance imaging (MRI).

Benign Paroxysmal Vertigo

Considered by many to be a form of migraine, benign paroxysmal vertigo is most common in children between the ages of 1 and 5 years. Patients have recurrent attacks, usually one to four per month, and occasionally in clusters. Onset is sudden—the child often cries out at the start of each episode—and is associated with emesis, pallor, sweating, and nystagmus. Episodes are brief, lasting up to a few minutes, and may be mistaken for seizures. In fact, the electroencephalogram (EEG) is normal. Consciousness and hearing are preserved, and the neurologic examination is otherwise normal. The disorder spontaneously remits after 2 to 3 years.

Ototoxic Drugs

Most agents that disturb vestibular function will also disturb auditory function. Specific agents include aminoglycoside antibiotics, furosemide, ethacrynic acid, streptomycin, minocycline, salicylates, and ethanol. Toxic doses of certain anticonvulsants and neuroleptics can produce measurable disturbances of vestibular function, although associated complaints of vertigo are rare.

Posttraumatic Vertigo

Several mechanisms account for posttraumatic vertigo. The most obvious is fracture through the temporal bone with damage to the labyrinth. Presentation includes vertigo, hearing loss, and hemotympanum. CT scanning of the temporal bone should be obtained when there is hemotympanum or posttraumatic evidence of vestibular dysfunction.

More subtle causes of posttraumatic vertigo include trauma-induced seizures, migraine, or a postconcussive syndrome. The latter disorder (vestibular concussion) typically follows blows to parietooccipital or temporoparietal regions and presents with headache, nausea, vertigo, and nystagmus. Although it generally remits with time, intermittent and recurrent episodes can occur. Hyperextension and flexion ("whiplash") injuries can be associated with vestibular dysfunction, probably caused by basilar artery spasm with subsequent impairment of their labyrinth and cochlear connections. Symptoms may mimic basilar artery migraine.

Seizures

Two types of seizures are associated with vertigo: vestibular seizures (seizures causing vertigo) and vestibulogenic seizures ("reflex" seizures brought on by stimulating the semicircular canals or vestibules by sudden rotation or caloric testing). Vestibular seizures, the more common type, consist of sudden onset of vertigo with or without nausea, emesis, and headache, and are invariably followed by loss or alteration of consciousness. The EEG is abnormal. Anticonvulsants may be of benefit.

Motion Sickness

Motion sickness is precipitated by a mismatch in information provided to the brain by the visual and vestibular systems during unfamiliar rotations and accelerations. The most common situation occurs when a child travels in a car or airplane and is deprived of a visual stimulus that confirms movement. Symptoms include vertigo, nausea, and nystagmus. Attacks can be prevented by allowing patients to watch the environment move in a direction opposite to the direction of body movement. In car travel, encouraging children to "look out the window" is helpful.

Ménière's Disease

Uncommon in children younger than 10 years, Ménière's disease is characterized by episodic attacks of vertigo, hearing loss, tinnitus, nystagmus, and autonomic symptoms of pallor, nausea, and emesis. Between episodes, patients may complain of impaired balance. The underlying cause is believed to be an overaccumulation of endolymph within the labyrinth, which causes a rupture (endolymphatic hydrops). Typical attacks last from 1 to 3 hours and usually begin with tinnitus, a sense of fullness within the ear, and increasing hearing impairment. Attacks are intermittent and unpredictable, often lasting for years and, at times, evolving to permanent hearing loss.

Miscellaneous Causes

Vertigo may occur at any point in the clinical course of multiple sclerosis when the central demyelination interferes with the vestibular nuclei in the brainstem or its efferents or afferents. Diagnosis is confirmed by MRI and lumbar puncture. Paroxysmal torticollis of infancy consists of spells of head tilt associated with nausea, emesis, pallor, agitation, and ataxia. Episodes are brief and self-limited and may recur for months or years. The cause is unclear, although some authors see it as a prelude to later benign paroxysmal vertigo (considered by some to be a migraine variant). Perilymphatic fistula is an abnormal communication between the labyrinth and the middle ear, with leakage of perilymphatic fluid through the defect. It may be congenital or acquired by trauma, infection, or surgery. The diagnosis may be suspected when vertigo is provoked by sneezing or coughing, actions that can increase perilymphatic drainage. Diagnosis is confirmed by middle ear exploration. Finally, vertigo may be associated with diabetes mellitus and chronic renal failure.

EVALUATION AND DECISION

Differentiation of True Vertigo and Pseudovertigo

Evaluation of children complaining of dizziness begins by separating those with true vertigo from those with pseudovertigo (Tables 20.1 and 20.3). True vertigo is always associated with a subjective sense of rotation of the environment relative to the patient or of the patient relative to the environment. All vertigo is made worse by moving the head, and acute attacks are usually accompanied by nystagmus. Pseudovertigo is suggested by complaints involving light-headedness, flushing, weakness, ataxia, unsteadiness, weakness, fatigue, pallor, anxiety, stress, hyperventilation, and fear.

True Vertigo

History and Physical Examination. Once true vertigo (Fig. 20.1) is identified, its severity, time course, and pattern must be established. In general, the most severe attacks of vertigo are due to peripheral causes, whereas central causes tend to be more recurrent, chronic, and progressive. Sudden onset of sustained vertigo suggests central or peripheral trauma, infection, stroke, or ingestion. Recurrent episodic attacks suggest seizures, migraine, or benign paroxysmal vertigo. More persistent episodes suggest brainstem or cerebellar mass lesions.

Recurrent, transient, altered mental status suggests seizure or basilar migraine. Episodes of prior head injury suggest concussion syndromes. Recent upper respiratory tract infections may suggest vestibular neuronitis. History of ototoxic drug or intoxicant use is important, as is a family history of migraine. Age of the patient is especially useful—benign paroxysmal vertigo is unusual after age 5 years, whereas Ménière's disease is unusual before age 10 years. A family history of migraine may be helpful.

The physical examination focuses on the middle ear and on neurologic and vestibular testing. Visualization of the external ear canal may reveal cerumen impaction, foreign body, or zoster lesions (Ramsay Hunt syndrome). Perforation or distortion of the tympanic membrane should be noted. A pneumatic bulb will enable the examiner to see whether abrupt changes in the middle ear pressure trigger an episode of vertigo, a suggestion that a perilymphatic fistula may be present (Hennebert's sign).

The neurologic examination must be complete, focusing closely on the auditory, vestibular, and cerebellar systems. Both vestibular and cerebellar disorders may present with an unsteady gait. In both situations, when there is a unilateral lesion, the child will fall toward the side of the lesion. The two may at times be distinguishable by the nature of the nystagmus (described below). In addition, if cerebellar dysfunction is present, there may be dysmetria and ataxia. All cases of suspected vestibular or cerebellar dysfunction require close follow-up evaluation because of the risk of a posterior fossa mass.

Nystagmus is a highly specific sign for both central and peripheral vertiginous disorders. Nystagmus from a peripheral origin usually occurs without other neurologic signs (except, perhaps, auditory changes and tinnitus). Nystagmus from

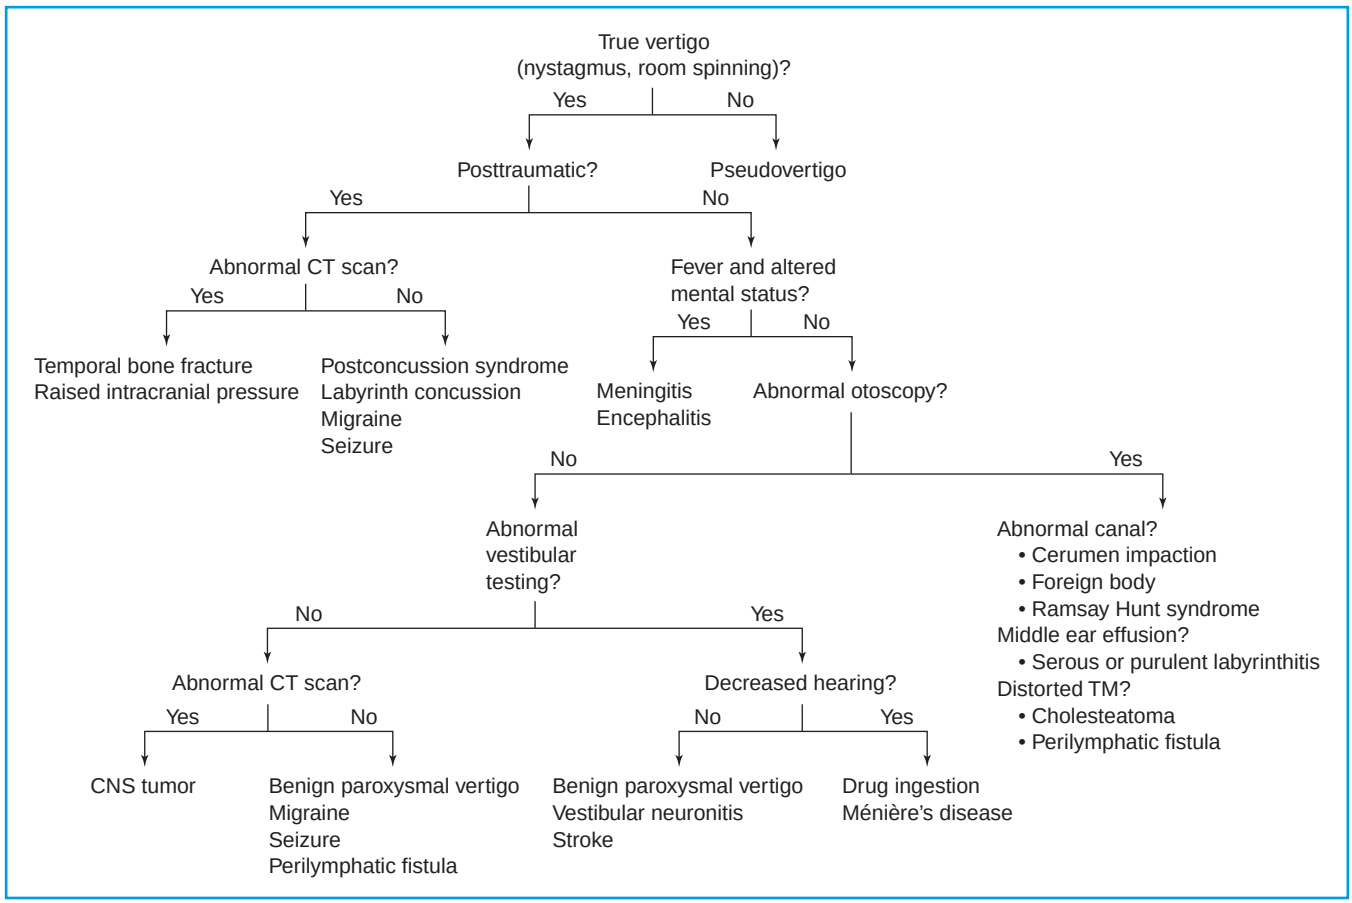

FIGURE 20.1 Approach to the child with true vertigo. CT, computed tomography; TM, tympanic membrane; CNS, central nervous system.

central causes, on the other hand, is usually accompanied by such signs. In addition, a patient complaining of dizziness with vertigo may not have nystagmus at the time that he or she is examined. Tests to elicit positional vertigo and nystagmus can therefore be helpful in identifying and even distinguishing central and peripheral vestibular dysfunction, particularly if the tests elicit or increase the patient's complaint.

Initially, nystagmus should be sought in all positions of gaze and with changes in head position. Peripheral vestibular disorders are characterized by a "jerk" nystagmus with the slow component toward the affected side. Central lesions are characterized by nystagmus with the fast component toward the affected side and reversal of the fast component when changing from right to left lateral gaze. The Nylen-Hallpike test is performed by moving a child rapidly from a sitting to a supine position with the head 45 degrees below the edge of the examining table and turned 45 degrees to one side. Nystagmus and a vertiginous sensation may result as the vestibular system is stressed. Certain features of the nystagmus elicited may be helpful in distinguishing central from peripheral vestibular dysfunction. In central dysfunction, for example, onset of nystagmus is immediate; in peripheral vestibular disorders, it is delayed. Finally, visual fixation tends to dampen peripheral nystagmus while it usually does not affect nystagmus from central causes.

The cold caloric response tests for integrity of the peripheral vestibular system. Slow and careful irrigation of either 100 mL of tap water 7°C below body temperature or 10 mL of ice water into the external ear canal through a soft plastic tube, with the child lying about 60 degrees recumbent, should induce a slow movement of the eyes toward the stimulus and a fast movement away. Instillation of warm water (44°C) will cause an inverse reaction. Vestibular damage will suppress the response on the affected side. Absence of nystagmus indicates absence of peripheral vestibular function. The test is contraindicated if the tympanic membrane is perforated.

Laboratory Data. Laboratory investigations have a limited role in the evaluation of vertigo. Useful initial tests include a complete blood count, a serum glucose, and an electrocardiogram. Together, these may help identify patients with pseudovertiginous conditions caused by anemia, hypoglycemia, and rhythm abnormalities. Further laboratory testing may reveal diabetes or renal failure, both of which have been associated with vertigo. Toxicologic testing including specific anticonvulsant levels and an ethanol level, if indicated, may be helpful. A lumbar puncture is indicated in cases of suspected meningitis or encephalitis.

Radiologic imaging of the central nervous system, preferably by MRI for adequate visualization of the posterior fossa

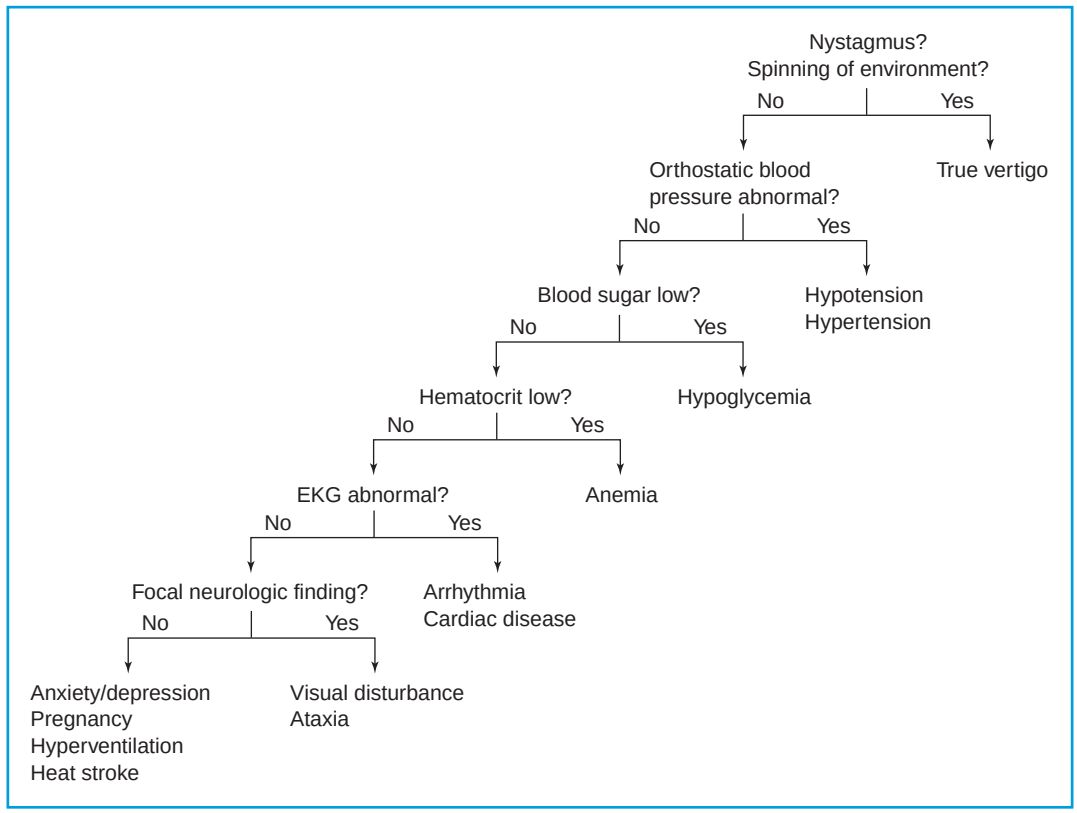

FIGURE 20.2 Approach to the child with pseudovertigo. EKG, electrocardiogram.

and brainstem, is indicated in cases of chronic and recurrent vertigo to exclude mass lesions. Children with vertigo and an underlying bleeding diathesis or a predisposition toward ischemic stroke (i.e., sickle cell disease) may also need an emergent cranial CT or MRI. Posttraumatic vertigo, especially when accompanied by hearing loss or facial nerve paralysis, is best assessed by CT including adequate images of the temporal bone.

Some children with true vertigo will require referral for more extensive testing. An EEG is indicated when vertigo accompanies loss of consciousness or other manifestations of a seizure. Audiometry is indicated when vertigo accompanies otalgia, hearing loss, or tinnitus. Specialized testing for nystagmus, including electronystagmography, which measures eye movements at rest and at extremes of gaze, can separate central from peripheral vestibular disorders. It may be combined with caloric and positional testing.

Management. Specific disorders causing vertigo are treated directly. Suppurative or serous labyrinthitis, for example, is treated with antibiotics. An erosive cholesteatoma may require surgical removal. Anticonvulsants may diminish vestibular and vestibulogenic seizures. Motion sickness may respond to simple behavioral changes (e.g., encouraging children to look out the window). Other causes of vertigo spontaneously remit without therapy and merit only close monitoring. Vestibular neuronitis and benign paroxysmal vertigo are examples.

Subspecialist consultation is indicated in certain situations. Neurosurgical evaluation after trauma may be indicated in cases of suspected basilar skull fracture. Suspected perilymphatic fistula, cholesteatoma, or complicated otitis media may merit otorhinolaryngologic evaluation. Neurologists may be helpful in cases of suspected seizure or migraine.

Children with severe or recurrent attacks of vertigo may require treatment with specific antivertiginous medications. The antihistamines dimenhydrinate (12.5 mg to 25 mg orally every 6 to 8 hours, maximum dose 75 mg per day for ages 2 to 6 years and 25 mg to 50 mg every 6 to 8 hours for ages 6 to 12 years, maximum dose 150 mg per day) and meclizine (12.5 mg to 25 mg orally every 12 hours in children older than 12 years of age) may be helpful. Concomitant use of a benzodiazepine such as diazepam (0.1 to 0.3 mg per kg per day orally divided every 6 to 8 hours, maximum 10 mg per dose) as a sedative may be necessary in severe cases.

Pseudovertigo

Pseudovertigo (Fig. 20.2) refers to a broad array of diagnoses that present with symptoms such as light-headedness, presyncope, intoxication, ataxia, visual disturbances, unsteadiness, stress, anxiety, and fear. Uniformly absent are a sense of rotation and ocular nystagmus. Underlying causes are numerous; several of the most common causes are listed in Table 20.3 (see also discussions of syncope in Chapter 73). Careful consideration of the patient's age, gender, detailed history, and physical examination, together with a limited number of ancillary tests, may help establish the specific diagnosis.

CHAPTER 21 ■ EDEMA

LINDA L. BROWN, MD, MSCE

Edema may be defined as the abnormal swelling of tissues from the accumulation of fluid in the extravascular space. In children presenting for medical care, this fluid may appear as generalized or localized swelling. When significant edema is present, collections of fluid may be visualized as pericardial or pleural effusions or as ascites. When edema is profound and generalized, the patient is described as having anasarca. However, the initial presentation of generalized edema may be subtle. Often the swelling is most prominent in the dependent portions of the extremities or lower back or in distensible tissues such as the eyelids, scrotum, or labia. Obtaining a careful history and completing a physical examination will help to identify these patients and may lead to a definitive diagnosis.

PATHOPHYSIOLOGY

The occurrence of edema in healthy individuals is usually prevented by the balance of oncotic and hydrostatic pressures between the intravascular and interstitial spaces, as well as the normal function of the lymphatic system. Any imbalance in this system may lead to increased interstitial fluid and resultant tissue swelling. Edema may occur as a result of decreased intravascular oncotic pressure, increased venous or lymphatic pressure, or from the loss of normal vascular permeability, as seen with vasculitis from an allergic or hypersensitivity reaction. Tightly controlled serum levels of albumin and sodium maintain normal intravascular oncotic pressure. Hypoalbuminemia may arise from decreased production of proteins caused by hepatic disease, as a result of protein malnutrition or, more commonly from losses of protein through gastrointestinal (GI), renal, or dermal (e.g., burns) conditions. When the albumin level is less than 2.5 g/dL, the oncotic pressure in the vascular space is reduced enough for fluid to move freely into the soft tissues and, if not corrected, generalized edema may result.

When the intravascular albumin and sodium levels are within the normal range and vascular permeability is preserved, the formation of edema requires increased hydrostatic pressures to overcome the oncotic pressure, forcing fluid out of the vascular space. This can occur as a result of hypervolemia from cardiac failure, renal failure, salt retention, estrogen–progesterone excess, or renal tubular insensitivity to the natriuretic and diuretic actions of atrial natriuretic peptide.

In the event of a hypersensitivity reaction, the formation of edema may be rapid, localized, and potentially life threatening. In such patients with a severe allergic reaction associated with anaphylaxis, edema may involve the tissues adjacent to the airway leading to potential airway compromise. More commonly, this allergic reaction is merely uncomfortable with localized swelling of the affected area and occasional pruritis, as seen with insect bites. The onset of symptoms is usually more gradual for causes of generalized edema. In fact, a 10% to 15% weight gain may be accumulated, with symptoms existing for weeks to months, before a patient presents for medical care.

DIFFERENTIAL DIAGNOSIS

A myriad of disease processes can result in either localized or generalized edema (Table 21.1). Localized edema in children is often caused by an allergic reaction, with the most severe reactions resulting from exposure to nuts, shellfish, or hymenoptera venom. Idiopathic nephrotic syndrome, although rare (occurring in just 2 to 3 of every 100,000 children annually), is the most common cause of generalized edema (Table 21.2). Overall, most children who develop edema will have a benign diagnosis and self-limited course. However, potentially life-threatening conditions (Table 21.3) can occur, including severe allergic reactions, soft tissue infections with associated bacteremia (see Chapter 92), deep venous thrombosis, and kidney, liver, or cardiac disease.

EVALUATION AND DECISION

When evaluating the child with edema, it is helpful to classify the swelling as localized or generalized. As with any complaint, it is necessary to perform a complete and thorough history and physical examination. It is important to include information on the location of the edema (facial vs. extremities), and the duration of the symptoms (hours vs. weeks), as well as associated symptoms including fever, shortness of breath, or recent illness. Past medical history, including a dietary history and family history is helpful to identify patients with chronic conditions or inherited disorders such as hereditary angioedema. Current and recent medications or allergies may also help to clarify the diagnosis. Overall, the duration of the symptoms and the patient's age may help to narrow down your differential, as certain disorders will present in the newborn period (congenital lymphedema, Turner's syndrome) while others occur more frequently in school-age children or adolescents (nephrotic syndrome, vasculitis). It is particularly important to inspect for edema around the eyes, scrotum or labia, as well as the distal extremities, as these areas may be the only locations with perceptible swelling.

A urinalysis to rule out proteinuria should be included in the initial evaluation of any patient presenting with generalized edema. It is important to realize that this edema may be the only physical finding of renal disease, the most common cause of hypoalbuminemia. Acquired hypoproteinemia from

Hepatic failure

LOCALIZED EDEMA

Localized edema is a more common presenting complaint in pediatrics than generalized edema (Fig. 21.1). Usually, these areas of localized swelling are caused by minor trauma, infection, or secondary to an allergic reaction. Historical factors and physical examination findings will often lead to a particular diagnosis without the need for further testing. Tenderness to palpation points to trauma or infection, while fever, erythema, and overlying warmth more commonly occur with an infectious cause (Table 21.4). On the face and distal extremities, insect bites may produce swelling and warmth, which can be difficult to distinguish from cellulitis. A therapeutic response to an oral antihistamine or to an intramuscular dose of epinephrine can help to differentiate an allergic reaction from other causes of localized swelling.

Interestingly, localized bilateral upper eyelid edema may be found in patients with Epstein-Barr virus (EBV) infectious mononucleosis. This swelling (Hoagland's sign) may be present in up to 50% of patients, is notable only for the first few days of the illness, and does not lead to any significant discomfort. Although transient, this finding is thought to be very specific for the diagnosis of EBV and may be used to trigger further laboratory evaluation to confirm the diagnosis.

As previously mentioned, when localized edema occurs on the face, it is important that the physician evaluate the child carefully for concurrent airway involvement. When a child presents with severe or recurrent facial edema, especially if there is a family history of a similar problem, the diagnosis of hereditary angioedema (see Chapter 82) should be investigated. Facial edema may also be caused by oral, dental, or sinus infections, including acute sinusitis, orbital cellulitis, or dental abscess. Often these patients will present with a history of dental or facial pain, sinus congestion, erythema, or fever. A history of environmental exposure should lead to the diagnosis of other common causes of localized swelling, including sunburn, frostbite, and plant-induced dermatitis (poison ivy). Although rarely seen, pit viper envenomation may cause rapid onset of painful swelling at the site of injury (see Chapter 83).

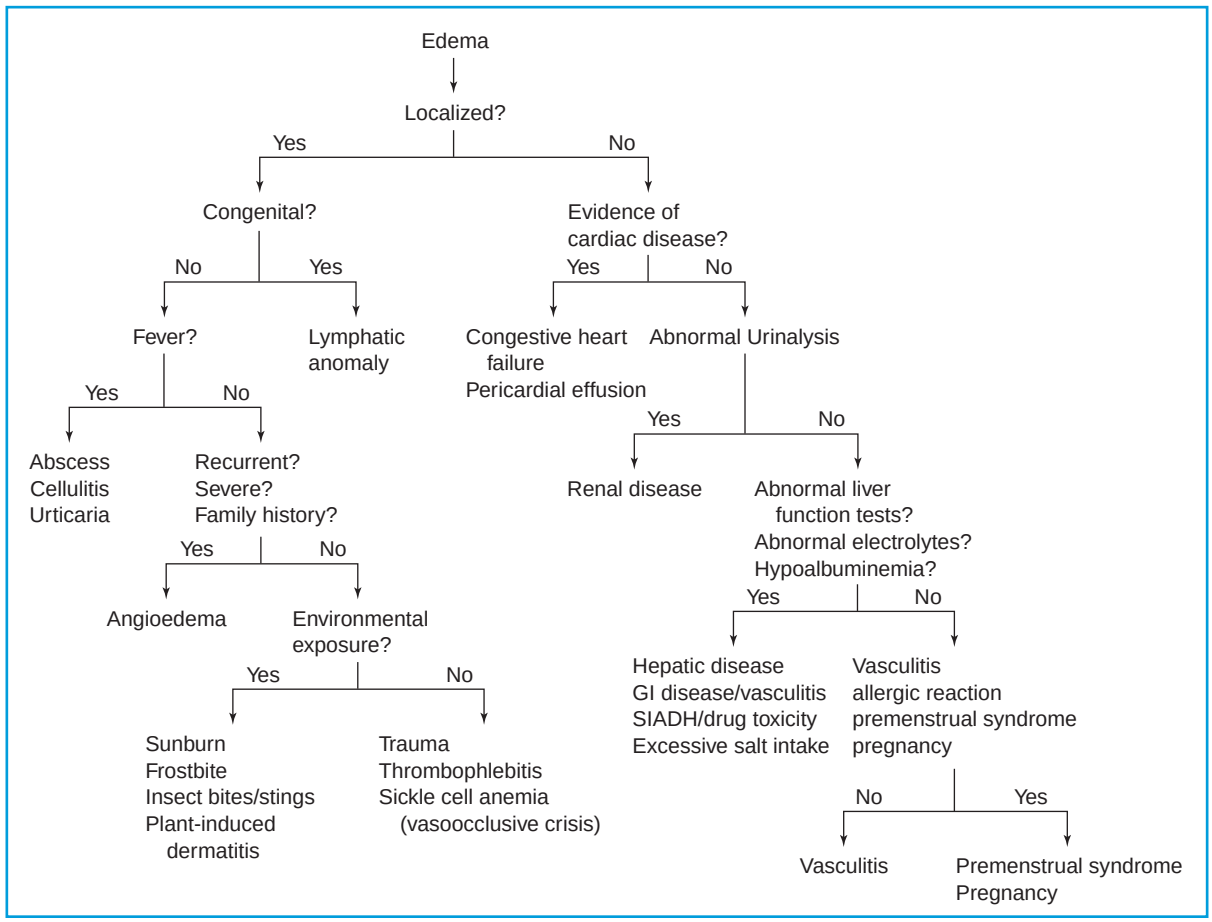

FIGURE 21.1 Edema in children. GI, gastrointestinal; SIADH, syndrome of inappropriate secretion of antidiuretic hormone.

Occasionally, an infant will present with unexplained, localized swelling of an extremity present since birth. In this situation, the possibility of an injury secondary to birth trauma should be explored. Less commonly, congenital lymphedema (Milroy's disease), Turner's syndrome (bilateral leg edema), and Noonan's syndrome (pedal edema) should be considered. Sickle cell anemia may cause swollen and painful digits in young children, referred to as dactylitis (see Chapter 91). Thrombophlebitis or deep venous thrombosis rarely occurs in the prepubertal child but may affect adolescents; inherited hypercoagulable states, weightlifting, and the use of oral contraceptive pills predispose teenagers to this condition. Evaluation of these patients should include an ultrasound of the venous system of the affected limb and a thorough laboratory evaluation. Superior vena cava syndrome may also present as facial swelling, often with some degree of facial cyanosis or plethora.

GENERALIZED EDEMA

The evaluation of the child presenting with generalized edema must include a complete and thorough cardiovascular examination. Patients with CHF, pericarditis, myocarditis, or cardiomyopathy may present with edema, but these children will usually have additional signs and symptoms. An edematous child presenting with a gallop, tachycardia, tachypnea, inspiratory crackles, or hepatomegaly should be evaluated for cardiac disease (see Chapter 84). For patients with complex heart disease, right-sided failure will lead to generalized edema without

TABLE 21.4

DIFFERENTIATION AMONG THE COMMON CAUSES OF LOCALIZED EDEMA

	Fever	Local tenderness	Local warmth	Lesion/color
Allergic Reaction	No	No	Yes	Erythematous
Trauma	No	Yes	No	Violaceous
Infection	Usually	Yes	Yes	Erythematous or violaceous

the pulmonary findings. In the child with a pericardial effusion, the classic findings of pulsus paradoxus, muffled heart sounds, and jugular venous distension may occur. However, in several studies of patients with cardiac tamponade visible on echocardiography, these findings were absent in 30% to 50% of patients. Evaluation of these children should therefore also include a chest radiograph, which may show an enlarged cardiac silhouette, and an electrocardiogram (EKG). Findings on the EKG will vary greatly with the etiology of the heart failure, including ST-segment elevation and generalized T-wave inversion suggestive of pericarditis or diffusely low voltages suggestive of myocarditis. Ultimately, echocardiography is diagnostic.

Generalized edema, with an otherwise normal exam, occurs most commonly in patients with renal disease, particularly nephrotic syndrome (see Chapter 100). Other forms of renal disease or vasculitis, including glomerulonephritis, hemolytic uremic syndrome, or Henoch-Schönlein purpura (HSP) may also be responsible. In contrast to patients with nephrotic syndrome and edema from low oncotic pressure, edema associated with acute renal failure results from the hypervolemic state. The initial diagnosis of nephrotic syndrome is based on significant proteinuria (3+ or 4+ or >300 mg/dL on a urinalysis). The presence or absence of urine red blood cells, white blood cells, or casts in the urine, along with further laboratory testing including chemistries, albumin and total protein, and complement and triglyceride levels may help to confirm the diagnosis. Various factors, including the presence of hypertension or significant fluid collections in the pleural or peritoneal spaces, must be considered to determine the appropriate initial management of these patients. In the child with HSP, the location of the edema may be helpful. The swelling primarily affects the lower extremities, where the purpuric rash predominates, or is isolated to specific joints when arthritis is present. The purpuric rash, despite normal platelet count and coagulation studies (consistent with a vasculitis), is usually, but not universally, present.

In an edematous patient with a normal cardiac exam and no proteinuria, further evaluation should include a search for hepatic and other GI diseases, as well as other forms of vasculitis. Patients with protein-losing enteropathy, from milk protein allergy, celiac disease, giardiasis, or inflammatory bowel disease, can present with generalized edema with few other physical findings. These patients may have significant protein loss through the GI tract and will often present with hypoalbuminemia. An initial laboratory evaluation, including liver function tests, electrolytes, erythrocyte sedimentation rate, and measurement of total protein and albumin, may reveal abnormalities. However, further evaluation, including more specific blood, urine, and stool testing, is often required to definitively diagnose the etiology of edema in this subset of patients.

As noted throughout this chapter, generalized edema may be a sign of a serious underlying disease. However, less serious conditions may be causative as well. Certain drugs (oral contraceptive pills, corticosteroids, lithium, nonsteroidal antiinflammatory agents, calcium channel blockers, and others) may cause some people to become edematous. This swelling usually resolves when the medication is discontinued. Cyclical edema related to menstruation occurs frequently in young women. The etiology of this edema is likely hormonally mediated, although the exact mechanisms are unclear. Pregnancy may result in edema as well.

In conclusion, it is important to remember that a complete history and physical examination of the patient with either localized or generalized edema may be enough to arrive at a likely diagnosis. It is of particular importance to focus on the cardiovascular, renal, and GI systems when searching for an etiology for generalized edema. Commonly, patients presenting with symptoms of localized edema will have an allergic, traumatic, or infectious etiology and, with appropriate management, will have resolution of their symptoms without serious sequelae.

CHAPTER 22 ■ EPISTAXIS

FRAN NADEL, MD, MSCE, AND FRED M. HENRETIG, MD

Epistaxis (nosebleeding) is a common symptom in young children and may be alarming to parents who often overestimate the amount of blood loss. It usually is noted first at about age 3 years and increases in frequency with age, until peaking before or in adolescence. An orderly approach to the history and physical examination is necessary to identify the small minority of patients who require emergent hemorrhage control, laboratory investigation, or consultation with an otorhinolaryngologist (ORL) for further management.

PATHOPHYSIOLOGY

Minor trauma, nasal inflammation, desiccation, and congestion, as well as the rich vascular supply of the nose, contribute to the frequency of nosebleeds in otherwise normal children. The nose is a favored site for recurrent minor trauma, especially habitual, often absent-minded, picking. The small vessels that supply the nasal mucous membrane have little structural support because the mucosa is closely applied to the perichondrium and periosteum of the nasal septum and lateral nasal walls. Furthermore, the nasal mucosa is richly supplied with vessels that form plexiform networks. One such anastomosis of common etiologic significance is Kiesselbach's plexus in Little's area of the anterior nasal septum, about 0.5 cm from the tip of the nose (see Fig. 127.4). Any factors that tend to cause congestion of the nasal vessels or drying of the mucosa will enhance the likelihood of epistaxis, resulting from a given degree of trauma.

DIFFERENTIAL DIAGNOSIS

Many types of local and systemic disorders may cause epistaxis (Table 22.1). Local factors predominate in etiologic importance (Table 22.2). In addition to minor accidental trauma and habitual picking, any cause of acute inflammation will predispose the nose to bleeding. Acute upper respiratory infections, whether localized as in colds or secondary to more generalized infections such as measles, infectious mononucleosis, and influenzal illnesses, contribute to the onset of epistaxis. Nasal colonization with *Staphylococcus aureus* may predispose to a more friable mucosa and epistaxis.

Allergic rhinitis may also be a factor. *Rhinitis sicca* refers to a condition that is common in northern latitudes during the winter, in which low ambient humidity, exacerbated by dry hot-air heating systems, leads to desiccation of the nasal mucosa with concurrent tendency to frequent bleeding. Staphylococcal furuncles, foreign bodies, telangiectasias (Osler-Weber-Rendu disease), hemangiomas, or evidence of other uncommon tumors may be found on inspection. Juvenile nasopharyngeal angiofibroma is usually seen in adolescent boys with nasal obstruction, mucopurulent discharge, and severe epistaxis. These tumors may bulge into the nasal cavity but often require examination of the nasopharynx to be identified. Although benign, they can cause severe problems through local invasion of adjacent structures. A rare childhood malignant tumor, nasopharyngeal lymphoepithelioma, may cause a syndrome of epistaxis, torticollis, trismus, and unilateral cervical lymphadenopathy. Other rare local causes of epistaxis include nasal diphtheria and Wegener's granulomatosis.

Children rarely present with a nosebleed as their only manifestation of a more systemic disease. In children with severe or recurrent nosebleeds, a concerning family history, or constitutional signs and symptoms, the physician should consider a systemic process. von Willebrand's disease and platelet dysfunction are two of the more common systemic diseases that cause recurrent or severe nosebleeds. Other less common systemic factors include hematologic diseases such as leukemia, hemophilia, and clotting disorders associated with severe hepatic dysfunction or uremia. Arterial hypertension rarely is a cause of epistaxis in children. Increased nasal venous pressure secondary to paroxysmal coughing, which can occur in pertussis or cystic fibrosis, occasionally may cause nosebleeds. *Vicarious menstruation* refers to a condition occasionally found in adolescent girls in whom monthly epistaxis related to vascular congestion of the nasal mucosa occurs concordant with menses and is presumably related to cyclic changes in hormone levels. Nosebleeds in infants are rare and one should consider the possibility of child abuse.

EVALUATION AND DECISION

Rarely are nosebleeds in children life threatening or require more than simple measures to gain control of hemorrhage. However, one's evaluation should begin with hemorrhage control and identification of children who are unstable by noting alterations in the patient's general appearance, vital signs, airway, color, and mental status. Perhaps the most crucial step in gaining hemorrhage control is calming the child and family. Success in this effort may be enhanced by having a child sit on a parent's lap while the adult provides pressure to the nose and the child is distracted by a toy or video.

Most childhood nosebleeds are anterior in origin. However, because posterior bleeds may require more extensive therapy, it is important to identify the site of bleeding. In general, posterior sites bleed more profusely, although parents may underestimate the volume because much of the blood is often swallowed. Blood seen in the oropharynx, blood in both nares, difficulty

TABLE 22.1

DIFFERENTIAL DIAGNOSIS OF EPISTAXIS

Local Predisposing Factors
Trauma, direct and picking
Local inflammation
- Acute viral upper respiratory tract infection (common cold)
- Bacterial rhinitis/sinusitis
- Congenital syphilis
- β-Hemolytic streptococcus
- Foreign body
- Acute systemic illnesses accompanied by nasal congestion
- Measles, infectious mononucleosis, acute rheumatic fever
- Allergic rhinitis
- Nasal polyps (cystic fibrosis, allergic, generalized)
- Staphylococcal furuncle

Vascular malformations (telangiectasias as in Osler-Weber-Rendu disease, hemangiomas)
Juvenile angiofibroma[a]
Other tumors, granulomatosis (rare)[a]
Rhinitis sicca

Systemic Predisposing Factors
Hematologic diseases[a]
- Platelet disorders
- Quantitative: idiopathic thrombocytopenic purpura, leukemia, aplastic anemia
- Qualitative: von Willebrand's disease, Glanzmann's disease, uremia
- Hemophilias
- Clotting disorders associated with severe hepatic disease, disseminated intravascular coagulation (DIC), vitamin K deficiency
- Drugs: aspirin, nonsteroidal antiinflammatory drugs, warfarin, valproic acid rodenticide

Vicarious menstruation
Hypertension[a]
- Arterial (unusual cause of epistaxis in children)
- Venous: superior vena cava syndrome or with paroxysmal coughing seen in pertussis and cystic fibrosis

[a]Life-threatening condition.

controlling bleeding despite adequate anterior pressure, and a normal anterior exam are more characteristic of a posterior nasal bleed but can be found with an anterior causative site.

After treating any emergent problems, the evaluation of the child with epistaxis begins with a thorough history. Specific features to be sought include frequency of occurrence, difficulty in control (and adequacy of simple at-home first aid), history of trauma, nose picking, frequent upper respiratory infection, allergic and chronic discharge, and obstructive symptoms. Often, asking children which finger they pick their noses with will elicit a more honest answer.

TABLE 22.2

COMMON CAUSES OF EPISTAXIS

Trauma
Foreign body
Allergic rhinitis
Rhinitis sicca
Viral rhinitis

Commonly, parents will note hematemesis or melena, prompting them to seek urgent medical attention. Specific questions regarding evidence for any systemic hemorrhagic disorder or family history of bleeding are asked. In adolescent girls, relation to menses is noted.

Physical examination must include a complete general examination with special attention paid to vital signs, including blood pressure, evidence of hematologic disease (enlarged nodes, organomegaly, petechiae, or pallor), and of course, inspection of the nasal cavity after reasonable efforts to stop the bleeding. When examining a child with a nosebleed, one will need a good light source, suction, and adequate body fluid precautions. Nasal inspection begins with clearing the passages by having the child blow his or her nose or by using gentle suction. On examination, one is looking for the site of bleeding, mucosal color, excoriations, discharge, a foreign body or other mass, and septal hematomas. Using one's thumb, the tip of the nose is pushed upward to allow examination of the vestibule, the anterior portion of the septum, and anterior portion of the inferior turbinate. If the mucosa is too boggy for adequate visualization, a topical vasoconstrictor or decongestant may be beneficial. A more thorough examination requires the use of a nasal speculum. Using one's nondominant hand, the speculum is passed vertically into the nares and opened, allowing examination of the septum, turbinates, and middle meatus. A topical anesthetic and restraints may be necessary for such an examination in young children.

Because most cases of bleeding in children are from the anterior nasal septum, the simplest way to stop the hemorrhage is to apply direct pressure on the bleeding site for 5 to 10 minutes by external compression of the nares between two fingers. In addition, a cotton (dental) roll may be placed under the upper lip to compress the labial artery. Occasionally, the addition of cotton pledgets moistened with a few drops of epinephrine (1:1,000) or application of topical thrombin will help achieve hemostasis. The child should be sitting up, with his or her head tilted slightly forward during these procedures. If an anterior site of bleeding is identified and there is no evidence of a hemorrhagic diathesis—and particularly if bleeding has been recurrent—cautery with a silver nitrate stick may be warranted (see Chapter 135). For management of severe epistaxis not responsive to such measures, nasal packing or surgical ligation of vessels may be necessary (see Chapter 135, Procedure 7.2). The recent advent of expandable nasal tampons has simplified the procedure of anterior nasal packing for the emergency physician, especially in patients who relapse after a successful cautery.

However, nasal tampons pose the risk of toxic shock syndrome, necessitating careful patient instructions and follow-up. For children with nosebleeds from a hemorrhagic diathesis, one must also correct the underlying disorder. No laboratory workup is indicated in children without clinical evidence of severe blood loss in whom systemic factors are not suspected, and for whom an anterior site of bleeding is identified and stopped readily with local pressure. Reassurance and education about appropriate at-home management needs to be provided.

Occasionally, recurrent epistaxis during an acute upper respiratory infection or flare-up of allergic rhinitis may be lessened with use of an antihistamine-decongestant preparation, although care must be taken not to dry the nose excessively, which can cause epistaxis related to dry mucosa. However, potential side effects of these combination products argue against their use in children younger than 6 years. During the winter, especially in

the context of forced hot-air heating systems, a cool mist vaporizer may lessen crusting and drying of nasal mucosa with its subsequent predisposition to recurrent bleeding. An emollient, such as petroleum jelly or a topical antibiotic cream, placed in the nostrils twice daily, and saline nasal spray also are useful for maintaining normal moistness of the nasal mucosa. Instructing parents to keep the child's fingernails short is also helpful.

All patients discharged from the emergency department (ED) after evaluation for significant epistaxis should be given specific instructions on nares compression and indications for repeat evaluation. For patients with specific local abnormalities, such as tumors, polyps, or telangiectasias, referral to an ORL is necessary. Such referral might also be considered, even with questionable findings on the ED nasal examination, if bleeding was severe, recurrent, or suspected to be posterior in origin.

Finally, evaluation for hemorrhagic diathesis should be performed in any child with pertinent positive findings on history, family history, or physical examination. This usually would include prothrombin time, partial thromboplastin time, complete blood cell count, and screening study for von Willebrand's disease. Although the yield would be low in the absence of corroborative clinical features, some children with isolated epistaxis that seems particularly severe or frequently recurrent might also deserve such screening. Children with isolated recurrent epistaxis may have mild bleeding abnormalities; however, the diagnosis of these patients may be difficult, requiring more sophisticated laboratory evaluation (e.g., postaspirin bleeding time, factor VIII–related antigen, ristocetin aggregation study) and referral to a hematologist may be helpful. More recently, epistaxis and mild coagulopathy (thrombocytopenia) suggestive

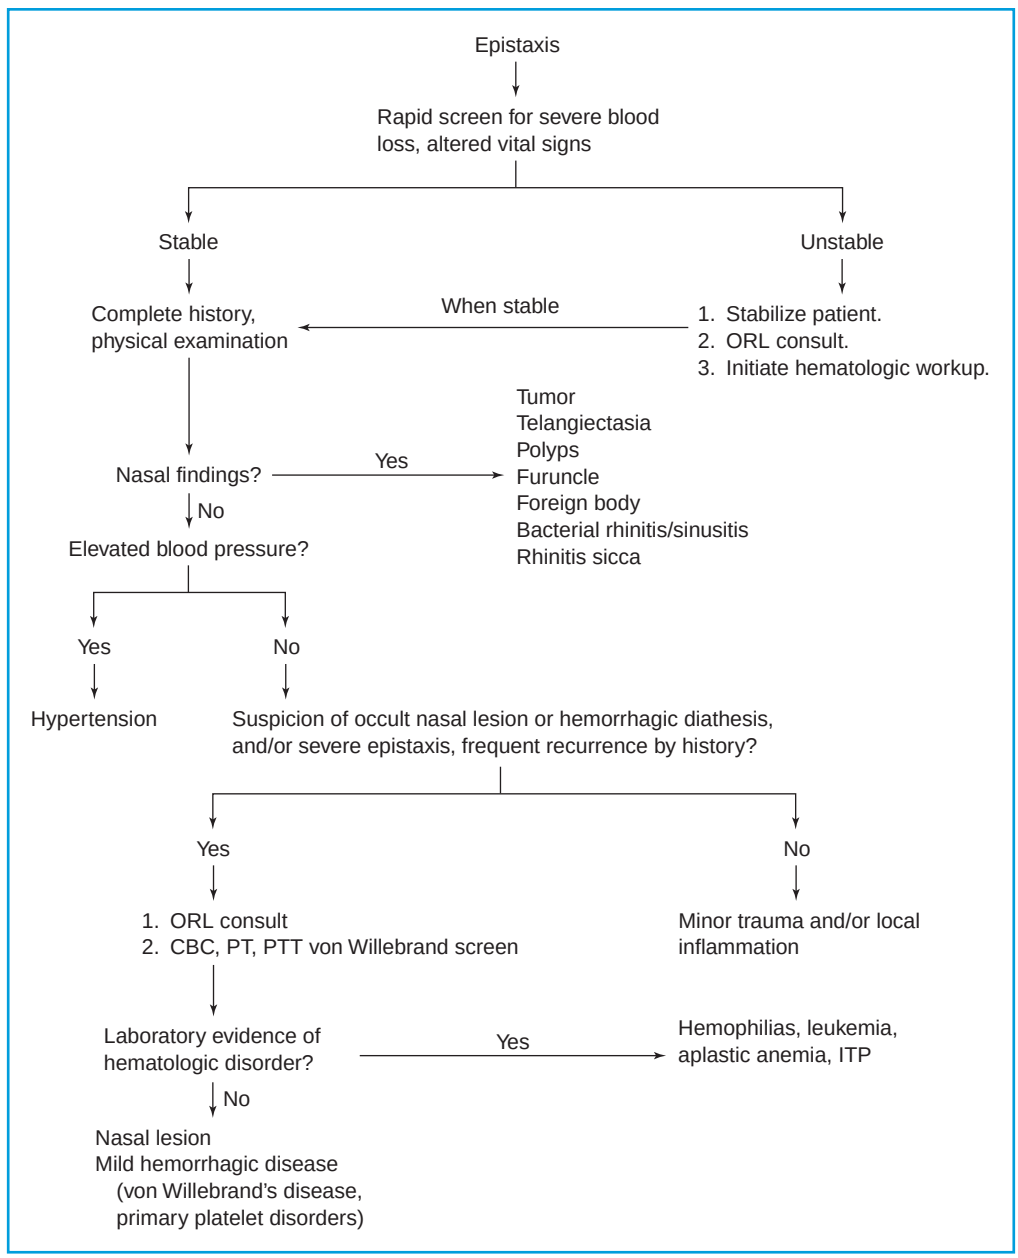

FIGURE 22.1 Approach to diagnosis of epistaxis. ORL, otorhinolaryngologist; CBC, complete blood count; PT, prothrombin time; PTT, partial thromboplastin time; ITP, idiopathic thrombocytopenic purpura.

of acquired von Willebrand's disease has been reported rarely in children receiving chronic valproic acid therapy. These considerations are outlined in the epistaxis algorithm (Fig. 22.1).

CHAPTER 23 ■ EYE—RED

ALEX V. LEVIN, MD, MHSC, FRCSC

"Red eye" is a generic term that refers to any condition in which the "white of the eye" appears red or pink. A red eye may be caused by local factors, intraocular disease, or systemic problems. Tables 23.1, 23.2, and 23.3 list common and life-threatening causes of red eye. Often, the cause of a red eye can be identified based on the history alone. Discussion here, of chemical conjunctivitis or irritation caused by agents such as smoke or trauma, is limited because the history is almost always known in these situations, making the diagnosis clear. The management of these disorders is discussed in Chapters 117 and 127.

When approaching the problem of "red eye," it is important to determine which tissues are involved. This chapter is confined to disorders in which the conjunctiva, episclera, or sclera are inflamed. Attention must be paid to documenting whether the inflammation is unilateral or bilateral, diffuse or sectorial, and acute or chronic. When bilateral, it is helpful to know whether both eyes were involved simultaneously or sequentially.

PATHOPHYSIOLOGY

With the exception of the cornea, the eye is covered by conjunctiva, a modified mucous membrane covered by nonkeratinized stratified squamous epithelium with goblet cells overlying a substantia propria. The conjunctival epithelium is contiguous with the corneal epithelium. The conjunctiva extends from the surface of the eyeball above and below onto the inner surface of the upper and lower eyelids, creating an upper and lower fornix as it reflects off the eyeball onto the lids (palpebral conjunctiva). These fornices may become repositories for foreign material or exudate. The conjunctiva overlying the sclera (bulbar conjunctiva) may become inflamed without involvement of the palpebral conjunctiva and vice versa. The palpebral conjunctiva contains lymphoid follicular tissues that may become particularly prominent during ages when benign lymphoid hypertrophy (e.g., tonsils, adenopathy) is common. Benign lymphoid hypertrophy appears as small bumps on the palpebral conjunctiva, particularly of the lower lid, best visualized with magnification. A follicular reaction may also occur in some forms of red eye—in particular, viral conjunctivitis. The conjunctiva also covers the caruncle, a small mass of tissue, containing glands, located in the medial corner of the eye at the junction of the upper and lower eyelids.

The sclera (the true "white of the eye") is a largely avascular dense collagenous tissue that provides a tough fibrous outer wall for the eyeball. Four of the six extraocular muscles insert into the anterior sclera, 4 to 8 mm away from the cornea: the superior, medial, inferior, and lateral rectus muscles (see Chapter 24). Although these insertions are not easily visible on the normal eye, inflammation of the muscles makes them apparent. Knowledge of this anatomy may be helpful in the diagnosis of myositis.

The sclera may become inflamed (scleritis). An intermediate layer, the episclera, lies beneath the conjunctiva's substantia propia and another largely avascular fascial layer (Tenon's fascia), where it is firmly attached to the sclera. The episclera and Tenon's fascia do not extend onto the eyelids. The episclera is more vascularized than the sclera and may become inflamed either in a diffuse or localized fashion (diffuse, sectorial, or nodular episcleritis).

The term *conjunctivitis* should be reserved for disorders in which the conjunctiva is inflamed. Inflammation may be caused by direct irritation, infection, inflammation of underlying or contiguous structures (e.g. cornea), immune phenomena, or processes secondary to abnormalities of the lid and lashes. Inflammation within the anterior chamber affecting the iris (iritis) may also result in secondary inflammation of the conjunctiva.

A tear film, which prevents desiccation, is constantly present over the surface of the eye. The tear film is made up of three components: an inner mucinous layer secreted by the goblet cells of the conjunctiva; a middle aqueous layer secreted by the lacrimal glands within the superior temporal anterior orbit and superior conjunctival fornix; and an outer layer secreted by glands in the body of the eyelids, which empty at the eyelid margins (each eyelid contains 20 to 30 glands). A disruption in the function of any three of these anatomic structures may result in an abnormal tear film with secondary desiccation of the ocular surface, resulting in irritation and inflammation (dry eye syndrome).

Innervation of the conjunctiva and cornea comes from the first division of the trigeminal nerve (V1). Abnormalities on the ocular surface may give rise to pain or a foreign-body sensation. The reflex arc that involves the afferent trigeminal nerve and the efferent facial nerve results in a rapid blink, with contraction of the orbicularis oculi muscle, to protect the surface of the eye in response to noxious stimuli. Two other reactions to noxious stimuli may occur: tearing and discharge. Tearing (epiphora) may accompany virtually any conjunctival inflammation or irritation. Tearing may even be a part of some forms of dry eye syndrome, as the lacrimal gland attempts to compensate for ocular surface desiccation due to disruption of the other layers of the tear film. Discharge results either from conjunctival exudation or precipitation of mucus out of the tear film. The latter occurs when the tear film is not flowing smoothly (e.g., nasolacrimal duct obstruction), causing misinterpretation as infection when the problem is actually mechanical.

TABLE 23.1

COMMON CAUSES OF RED EYE[a]

Conjunctivitis
Infectious: viral (including herpes), bacterial, chlamydial
Allergic or seasonal
Chemical (or other physical agents such as smoke)
Systemic disease (Table 23.3)
Trauma
Corneal or conjunctival abrasion
Iritis
Foreign body
Dry eye syndromes
Abnormalities of the lids and/or lashes
Blepharitis
Trichiasis due to epiblepharon
Sty or chalazion (external or internal hordeolum)
Molloscum of lid margin
Periorbital or orbital cellulitis
Contact lens–related problems
Infectious keratitis (corneal ulcer)
Allergic conjunctivitis
Corneal abrasion
Poor fit
Overwear

[a]Not listed in order of frequency. List not complete.

Although discharge may be a nonspecific finding, the nature of the discharge may be helpful in determining the cause of an infection. Discharge without a red eye is by definition not conjunctivitis. The presence of membranes or pseudomembranes (Fig. 23.1, see also color plate) on the palpebral conjunctiva of an eye with conjunctivitis is also helpful in establishing a cause. For example, pseudomembranes or membranes are more common with adenovirus infection or Stevens-Johnson syndrome. These white or white-yellow plaques are caused by loosely or firmly adherent collections of inflammatory cells, cellular debris, and exudate.

EVALUATION AND DECISION

The approach to the child who presents in the emergency department with a red eye is outlined in the flowchart shown in Figure 23.2.

Any child who wears contact lenses regularly, even if the lens is not in the eye at the time of the examination, should be referred to an ophthalmologist within 12 hours if he or she has red eye. Red, and often painful, eyes of a person who wears contact lenses may represent potentially blinding corneal infection (corneal ulcer) or the breakdown of the corneal epithelium, which subsequently would predispose the person to corneal infection. Other than removing the contact lens when possible (topical anesthesia may be helpful), further diagnostic or therapeutic interventions by the pediatric emergency physician are not indicated in these patients. It is recommended that empiric antibiotics not be started because the ophthalmologist may want to culture the cornea. Rather, prompt consultation with ophthalmology is essential. The presence of a white spot on the cornea of a contact lens wearer with inflamed conjunctiva is an ominous sign that may represent an ulcer. The absence of such a spot does not rule out corneal ulcer. Other causes of red eye in a contact lens wearer include contact lens solution allergy (which may develop even after years of using the same regimen), overwear, overly tight fit, foreign body, or a damaged contact lens. Examination by an ophthalmologist is perhaps the only way to ensure that a

TABLE 23.2

LIFE-THREATENING CAUSES OF RED EYE[a]

Systemic disease (Table 23.3)
Child abuse
Blunt trauma
Covert instillation of noxious substances [medical child abuse (formerly known as Munchausen syndrome by proxy)]
Traumatic intracranial arteriovenous fistula (very rare)

[a]List not meant to be complete.

TABLE 23.3

SYSTEMIC CONDITIONS THAT MAY BE ASSOCIATED WITH RED EYE[a]

Collagen vascular disorders
Juvenile rheumatoid arthritis
Infectious diseases
Varicella, rubeola, otitis media
Kawasaki disease
Inflammatory bowel disease
Cystic fibrosis
Vitamin A deficiency
Cystinosis
Leukemia
Ectodermal dysplasia
Trisomy 21
Cornelia de Lange syndrome
Status post radiation therapy, including ocular field
Bone marrow transplantation
Stevens-Johnson syndrome

[a]Not a complete list: intended to demonstrate multiorgan representation.

FIGURE 23.1 Pseudomembrane on lower lid palpebral conjunctiva and extending into the inferior fornix in patient with epidemic keratoconjunctivitis (adenovirus).

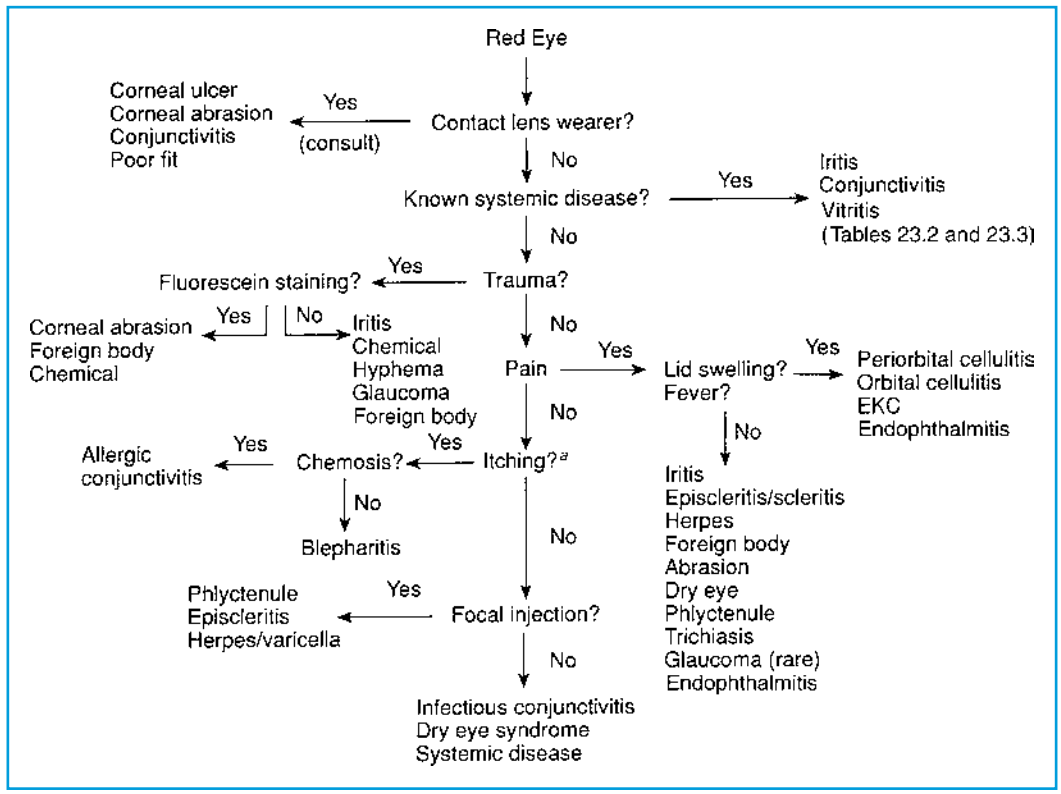

FIGURE 23.2 Diagnostic evaluation of red eye. (EKC = epidemic keratoconjunctivitis)

corneal ulcer is not missed by ascribing the red eye to one of these other etiologies. It is recommended that all contact lens wearers with a red eye be seen an ophthalmologist.

Numerous systemic diseases may be associated with ocular inflammation. A representative sample can be found in Table 23.3. In some systemic diseases, the associated ocular abnormality involves intraocular inflammation (iritis, vitritis), which can then cause secondary conjunctival infection. Patients with these diseases may also have coincidental ocular inflammation unrelated to their underlying conditions. Ophthalmologic consultation may be helpful in making this distinction. For example, in Kawasaki disease, the inflammation of the conjunctiva may be associated with mild iritis. More often, the conjunctiva is inflamed in isolation as part of the systemic mucous membrane involvement. Description of conjunctival inflammation is once again important as the conjunctivitis of Kawasaki disease is usually confined to the bulbar conjunctiva rather than the palpebral, with little, if any, discharge unlike an infective process such as viral conjunctivitis in which the entire conjunctiva is inflamed (Fig. 23.3). Very rarely, head injury may cause the development of an intracranial arteriovenous fistula that may present with proptosis, chemosis, red eye, corkscrew conjunctival blood vessels, and decreased vision.

Traumatic injury may result in a red eye because of other reasons including corneal or conjunctival abrasion, hyphema, iritis, or rarely, traumatic glaucoma. (The diagnosis and treatment of these disorders are summarized in Chapter 117.) If there is no fluorescein staining of the conjunctiva or cornea and there is no obvious evidence of severe intraocular injury (e.g., hyphema, ruptured globe), the examiner may need to consider the possibility of noxious material coming in contact with the eyeball at the time of trauma. Both acidic and alkaline substances may cause a red eye. (The treatment of these disorders is summarized in Chapter 127.) Likewise, a foreign body may cause ocular pain and inflammation. Foreign bodies often can be difficult to see on brief, superficial examination, especially if the foreign body is smaller than what the naked eye can see. To

FIGURE 23.3 Bulbar conjunctival injection in patient with Kawasaki disease.

enhance visualization, spin the focusing wheel of a direct ophthalmoscope to the black or green number 10 or more. This will turn the instrument into a self-illuminated hand-held magnifier. All the recesses and redundant folds of the conjunctiva must be inspected. The upper eyelid should be everted (see Chapter 117). The lower eyelid should be pulled down from the globe as the patient looks upward so the inferior fornix can be inspected. The patient should be asked to adduct the affected eye when the lateral canthus (junction of the upper and lower eyelid laterally) is stretched laterally to allow inspection of the lateral fornix. There is no analogous medial fornix.

It is wise to inspect the position of the eyelashes before performing lid eversion and examining the conjunctival fornices. Eyelashes that turn against the ocular surface (trichiasis) may cause a red eye that is accompanied by pain or foreign-body sensation in the absence of lid swelling. Although corneal fluorescein staining may reveal the effect on the corneal epithelium, the condition may be so mild that slit lamp biomicroscopy would be required despite significant symptoms. Trichiasis is particularly common in patients who have had prior injury or surgery to the eyelid and in patients of Asian background. In the latter case, a prominent fold of skin (epiblepharon) may be found medially just below the eyelid margin, causing the lower lid medial eyelashes, and less commonly the upper lid lashes, to rotate toward the eyeball (Fig. 23.4).

In the absence of cornea/conjunctiva abrasion, foreign body, and trichiasis, the painful red eye caused by trauma may have iritis. This may not present for up to 72 hours after the trauma was sustained. Photophobia and vision blurring may also occur. The ipsilateral pupil may be smaller. Occasionally, one will see a cloudy inferior cornea caused by the deposition of inflammatory cells and debris on the inner surface (keratoprecipitates). This finding may be easier to recognize with the direct ophthalmoscope focused as a magnifier (see above). Iritis also may occur in association with systemic disease or as an isolated idiopathic ocular finding. Iritis associated with juvenile idiopathic arthritis (formerly known as juvenile rheumatoid arthritis) is characterized by the distinct absence of signs or symptoms until the disease has progressed significantly, thus underscoring the need for routine screening of these patients. Other systemic causes of iritis include sarcoidosis, tuberculosis, inflammatory bowel disease, collagen vascular disorders, systemic lupus erythematosis, Wegener's, tubular interstitial nephritis uveitis syndrome (TINU), and leukemia. Traumatic iritis and nontraumatic iritis often are indistinguishable except by history. All causes of iritis, regardless of the etiology, require ophthalmologic consultation and follow-up if the diagnosis is not otherwise apparent. The diagnosis of iritis requires slit lamp examination by a skilled observer. Topical steroids should not be prescribed by non-ophthalmologists.

Episcleritis and scleritis may also cause a painful red eye. Although episcleritis is usually an isolated ocular abnormality, scleritis is often associated with an underlying systemic disease, particularly the collagen vascular disorders. Both entities may present with focal or diffuse inflammation. A focal nodular or diffuse elevation may be seen. The eye is often tender, especially with scleritis, where the inflamed area may have a bluish hue. There may also be pain on attempted movement of the eye. Diagnosis and treatment require slit lamp examination and ophthalmologic consultation.

Herpetic corneal infection is another cause of painful red eye. This may be caused by either the simplex or varicella-zoster viruses. Usually, there is no concomitant dermatologic manifestation except in association with chickenpox, when a unilateral or bilateral lesion may be seen on the conjunctiva (usually near or just on the edge of the cornea) with focal injection (Fig. 23.5, see also color plate). Most often, no treatment is required for a conjunctival pox lesion during chickenpox, but herpetic corneal ulcers require urgent treatment to prevent corneal scarring and vision loss. Patients with herpetic corneal ulcers may have a history of prior recurrent painful red eye, although herpes occasionally can be painless because of induced corneal hypoesthesia. Herpes simplex is virtually always unilateral. Fluorescein staining of the cornea may reveal a linear branching pattern referred to as dendrites (Fig. 120.10). If the infected area is located eccentrically on the corneal surface, the injection may be localized to the quadrant of conjunctiva adjacent to the lesion.

If eye pain is relieved by a drop of topical anesthetic (see Chapter 117), the patient most likely has a surface problem (e.g., foreign body, abrasion). If the pain is not relieved and periorbital swelling and fever are present, the red eye may be caused by periorbital or orbital cellulitis. These are emergent

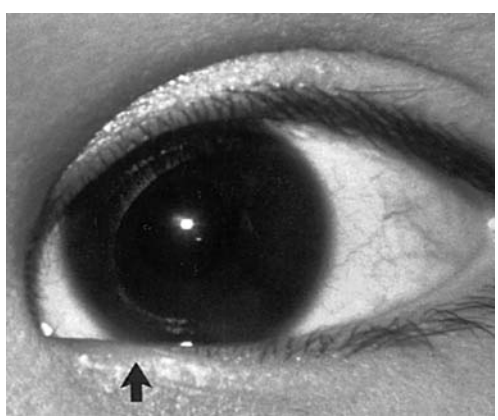

FIGURE 23.4 Epiblepharon. Extra skin fold medially on lower lid *(arrow)* rotates eyelashes back toward eyeball surface.

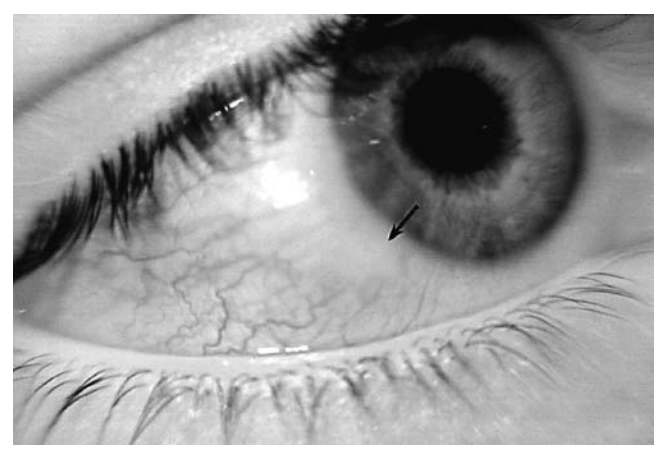

FIGURE 23.5 Red eye caused by chickenpox (varicella) involvement of conjunctiva. Note sectorial injection of conjunctiva. White area *(arrow)* at junction of conjunctiva and cornea is the pox lesion.

conditions, the treatment and diagnosis of which are reviewed in Chapter 127. Eye pain and marked lid swelling also may be associated with epidemic keratoconjunctivitis (EKC) secondary to adenovirus (Fig. 120.8). When questioned further, patients may reveal that they actually have a sandy foreign-body sensation rather than true ocular pain. Pseudomembranes are a fairly diagnostic sign when present (Fig. 23.1). Low-grade fever and tender preauricular adenopathy may also occur, making it difficult to distinguish EKC from periorbital cellulitis. EKC usually affects the eyes consecutively and bilaterally as opposed to the unilateral nature of periorbital cellulitis. There also may be associated prominent photophobia and tearing in adenoviral conjunctivitis, which is not usually seen in cellulitis.

Itching is another important diagnostic symptom. When it is associated with swelling of the conjunctiva, giving it the appearance of a blister-like elevation (chemosis, Fig. 120.9), one should suspect acute allergic conjunctivitis. Unlike chronic, recurrent, seasonal, allergic conjunctivitis, there are usually no associated systemic symptoms. Often, there is no known causative agent, and there may be associated periocular swelling. The condition may be unilateral or bilateral and usually has an acute or hyperacute onset. Photophobia, tearing, and lid swelling may also occur. The emergency physician can prescribe topical antihistamines and/or vasoconstrictors, as well as cool compresses, to relieve the symptoms. Systemic diphenhydramine may also be useful. The etiology is only rarely identified.

Itching may also accompany blepharitis, an idiopathic disorder in which there is suboptimal flow of secretions from the meibomian glands normally present in the eyelids. Because these glands participate in the formation of the lubricating tear film that normally covers the eye, the deficiency of flow may result in an abnormal tear film and rapid corneal desiccation. Symptoms are aggravated by activities associated with prolonged staring and a decreased blink rate (reading, television or computer viewing, and video games) or going outside on windy days. Patients may have photophobia and a sandy foreign-body sensation. To compensate for the tear film deficiency, reflex excess tearing may occur from the lacrimal gland. The most characteristic sign is erythema of the eyelid margins and flaking and crusting at the base of the eyelashes (Fig. 23.6). This can be well visualized with the direct ophthalmoscope as a magnifier (see above). Left untreated, the reduced flow of the meibomian glands may allow for proliferation of the coagulase-negative staphylococci, which are normally present. This overgrowth may lead to an immune response causing an inflamed elevated white spot(s) on the conjunctiva (phlyctenule) or peripheral corneal infiltrates associated with a red eye. Slit lamp examination is helpful in making these diagnoses and is most helpful to rule out the presence of corneal involvement. Erythromycin topical ointment may be useful, but more important is the use of baby shampoo eyelash scrubs once or twice daily to encourage better flow of the glands. Full strength baby shampoo is placed on a washcloth over the caretaker's finger and then used to gently scrub the base of the eyelashes. Accumulated soap is then rinsed away with a washcloth. This should be done once or twice daily and continued for some time even after the symptoms have improved or resolved.

FIGURE 23.6 Blepharitis. Note crusts and flakes at base of eyelashes.

Although itching and pain may be minor symptoms associated with several types of conjunctivitis, it is usually the absence of these symptoms that should lead one to suspect an infectious cause. Conjunctivitis usually causes diffuse inflammation of the conjunctiva, either unilaterally or bilaterally with rare exception (e.g., sectoral herpes keratitis). The differentiation of bacterial, viral, chlamydial, and other types of conjunctivitis is sometimes difficult (see Chapter 127). Purulent discharge is particularly characteristic of bacterial infection.

If the injection is localized, the examiner should consider a specific list of diagnostic possibilities. Herpes keratitis phlyctenule, episcleritis, and scleritis may present with focal involvement, as previously discussed. Localized injection of the conjunctiva may be an indicator of an imbedded foreign body, varicella, or other focal processes that require the attention of an ophthalmologic consultant.

Although much feared, glaucoma in children is very rare. Congenital glaucoma is usually not associated with a red eye or pain. Small children who have glaucoma often have enlarged eyes (buphthalmus) with tearing, photophobia, cloudy cornea and less commonly, heterochromia. Acute acquired glaucoma causes a painful red eye, perhaps associated with corneal clouding and decreased visual acuity. Acquired glaucoma, is most often associated with trauma, other anatomic abnormalities, or iritis that would be apparent on examination. Because it is difficult to determine intraocular pressure in children, ophthalmologic consultation is required in all cases.

CHAPTER 24 ■ EYE—STRABISMUS

ALEX V. LEVIN, MD, MHSC, FRCSC

Strabismus refers to any misalignment of the eyes such that they are not viewing in the same direction. *Esotropia* refers to eyes that are turned in (cross eyed). *Exotropia* refers to eyes that are turned out (wall eyed). The terms *hypertropia* and *hypotropia* refer to a higher or lower eye, respectively. By convention, vertical misalignment of the eyes is always categorized by the higher eye (e.g., right hypertropia), unless it is known that a specific abnormal process is causing one eye to be held in a lower position (e.g., left hypotropia). (Note: These terms should not be confused with *hyperopia*, the term referring to farsightedness.) Many children with strabismus require a formal evaluation by an ophthalmologist for definitive diagnosis and management, but the emergency physician should attempt to answer two questions: (i) "Is the strabismus an emergency?" and, if so, (ii) "What is the most likely cause?"

PATHOPHYSIOLOGY

Six muscles surround each eyeball (Fig. 24.1). Although several of these muscles may individually move the eye in more than one direction, knowledge of the primary action of these muscles allows for the definition of diagnostic positions of gaze (Table 24.1). This can be helpful in pinpointing specific muscle dysfunction. For example, if a muscle that primarily governs abduction (e.g., lateral rectus) is impaired, the eye is unable to abduct and will usually lie in a position of adduction (esotropia). Likewise, if a muscle that is involved with downgaze (e.g., inferior rectus) is impaired, the eye will have a tendency to remain in relative upgaze (ipsilateral hypertropia).

Although the interactions of the extraocular muscles are complex, the eyeballs should always move symmetrically, both quantitatively and qualitatively, into each direction of gaze. On lateral gaze, the abducting and adducting eye should move far enough so that no sclera is visible laterally or medially, respectively (Fig. 24.2). Both eyes should move symmetrically into upgaze and downgaze such that a straight line, parallel to the horizon, could be drawn between the most superior or inferior part of the iris (Fig. 24.3).

On upgaze, the eyelids should also move up involuntarily. Likewise, on downgaze, the eyelids should move down symmetrically. In the primary position (straight ahead), no sclera should be visible superiorly. The upper eyelid margins should just cross over the iris without crossing over a significant portion of pupil. If one or both lids droop further down, the patient has ptosis. The lower eyelid margin usually crosses within 1 mm above or below the 6 o'clock position of the inferior iris.

Strabismus is categorized into misalignment as a result of impaired muscle function or misalignment in the presence of full normal muscle function. In general, there are only two emergency reasons why the function of a particular muscle might be impaired: neurogenic palsy or muscle restriction.

Three cranial nerves are responsible for the innervation of the six extraocular muscles (Table 24.1). The sixth cranial nerve innervates the ipsilateral lateral rectus muscle. This nerve exits the ventral pons and then travels on the wall of the middle cranial fossa (clivus), reaching the sphenoid ridge, along which it travels until entering the cavernous sinus. The course of this nerve allows it to be injured by vascular or neoplastic changes in the midbrain, increased intracranial pressure (ICP), large anterior midline craniofacial tumors (e.g., nasopharyngeal carcinoma), otitis media (OM) with involvement of the petrous portion of the sphenoid (Gradenigo syndrome), and any abnormality that involves the cavernous sinus. An abnormality of the sixth cranial nerve will cause a reduction in ipsilateral abduction (Fig. 24.2), and in the straight ahead position, a possible ipsilateral esotropia.

The fourth cranial nerve innervates the superior oblique muscle. It is the only cranial nerve that completely decussates and has a dorsal projection over the midbrain. This position renders the fourth cranial nerve particularly vulnerable to blunt head trauma, one of the most common causes of fourth nerve palsy. The fourth cranial nerve also has a relatively long intracranial course, which makes it particularly susceptible to increased ICP and parenchymal shifts caused by cerebral edema. It also runs through the cavernous sinus. Fourth cranial nerve palsy may be congenital but asymptomatic for several years during childhood until the brain is no longer able to compensate. Acquired or congenital palsy of this cranial nerve causes the eyes to become misaligned vertically (ipsilateral hypertropia). Patients with congenital fourth cranial nerve paresis compensate by tilting their head to the ipsilateral side, which allows for a rebalancing of the eye muscles such that alignment may be achieved. Old photographs may demonstrate this tilt. Facial asymmetry can also be seen after years of this compensatory tilting. Ophthalmic consultation is usually needed to differentiate between congenital and acquired palsy.

The third cranial nerve supplies the remaining four extraocular muscles. It is involved with downgaze, upgaze, and adduction. Parasympathetic innervation to the pupil (see Chapter 25) and innervation to the eyelid muscle (levator palpebrae) are also carried in the third cranial nerve. A complete third cranial nerve palsy results in an eye that is positioned down (from the remaining action of the unaffected superior oblique muscle) and out (from the remaining action of the unaffected lateral rectus muscle) with ipsilateral ptosis and ipsilateral pupillary dilation (Fig. 24.4). Because the third cranial nerve divides into a superior and an inferior division just as it enters the orbit from the cavernous sinus and because the fibers to individual muscles are segregated within

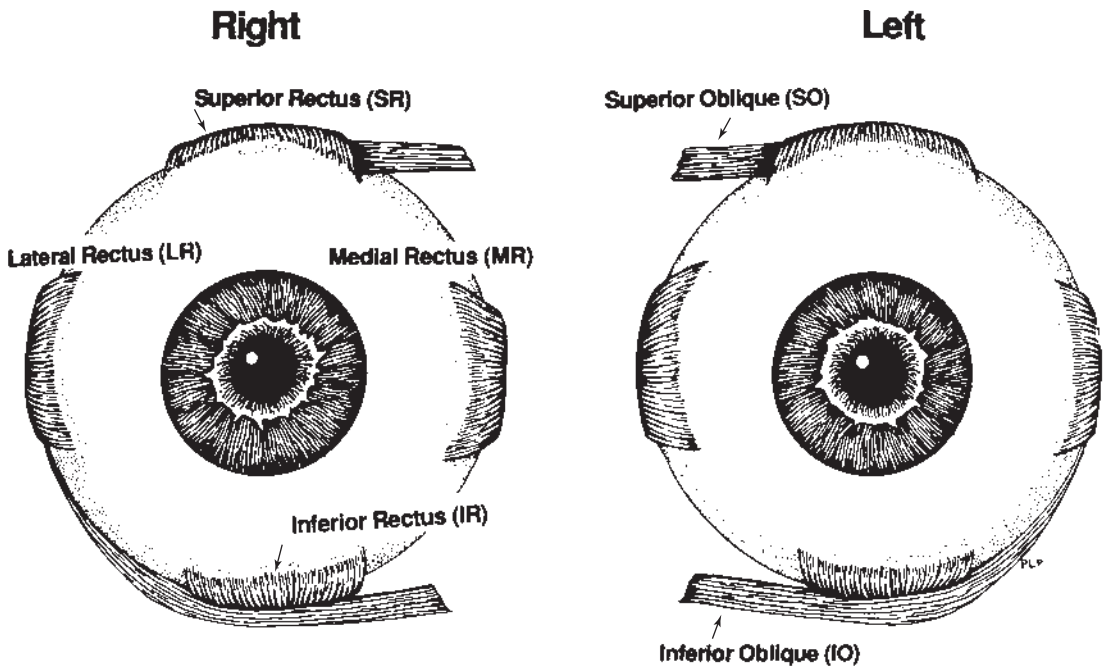

FIGURE 24.1 Normal extraocular muscle anatomy.

the nerve throughout its course, partial third cranial nerve palsies may occur with or without ptosis and/or pupillary dilation. This may leave the patient with complex strabismus, which is best left to the ophthalmologic consultant. (The differential diagnosis of third cranial nerve palsies is summarized in Chapter 25.)

The action of a muscle may also be impaired by restriction. The muscle can become infiltrated with substances that might restrict its action or cause fibrosis. Children with hyperthyroid eye disease (e.g., Graves) can have large, tight eye muscles. An eyeball may also be restricted in its movements by tumors or infection in and around the globe. Orbital tumors, cellulitis, or abscesses that cause restriction may be associated with proptosis or a displacement of the entire eyeball, either vertically or horizontally. After blunt trauma to the eyeball, the globe may be translocated posteriorly, causing an increased intraorbital pressure that may result in a "blowout" fracture of the bony orbital wall. Limitations of movement caused by blowout fractures may not be noticeable until the eye attempts to move. In other words, the eyes may be parallel in the straight ahead position but may be misaligned when they attempt to look in a direction opposite the fracture site. When an orbital wall fracture occurs, the muscle or surrounding tissues that run along that wall may become entrapped within that fracture, tethering the eyeball so the eye cannot look in the direction opposite the fracture. For example, fractures of the orbital floor may entrap the inferior rectus muscle, tethering the eye downward so upgaze is restricted (Fig. 24.5). Sometimes, the eye may also have a limitation of movement in the direction of the fracture. Orbital wall fractures may also be associated with enophthalmos, in which the eye appears to be sunken in the orbit, or proptosis caused by orbital hemorrhage. All patients with orbital fractures must receive a complete ophthalmic examination to rule out accompanying ocular injury. The most common fracture involves the inferior and/or medial walls of the orbit. The lateral wall is rarely fractured. Fracture of the superior wall (orbital roof) is particularly worrisome because it may allow communication between the subfrontal intracranial space and orbit.

TABLE 24.1

EXTRAOCULAR MUSCLES

Muscle[a]	Cranial nerve	Action[b]	Eye position in palsy
Medial rectus	III (inferior division)	Adduction	Exotropia
Inferior rectus	III (inferior division)	Downgaze	Hypertropia
Lateral rectus	VI	Abduction	Esotropia
Superior rectus	III (superior division)	Upgaze	Hypotropia
Superior oblique	IV	Downgaze	Hypertropia
Levator palpebrae[c]	III (superior division)	Eyelid	Ptosis (lid)

[a]Inferior oblique not included for simplicity. Isolated palsy of the inferior oblique is extremely rare.
[b]Action in the horizontal or vertical field only. Cyclorotatory movements not included.
[c]By definition, not truly an extraocular muscle.

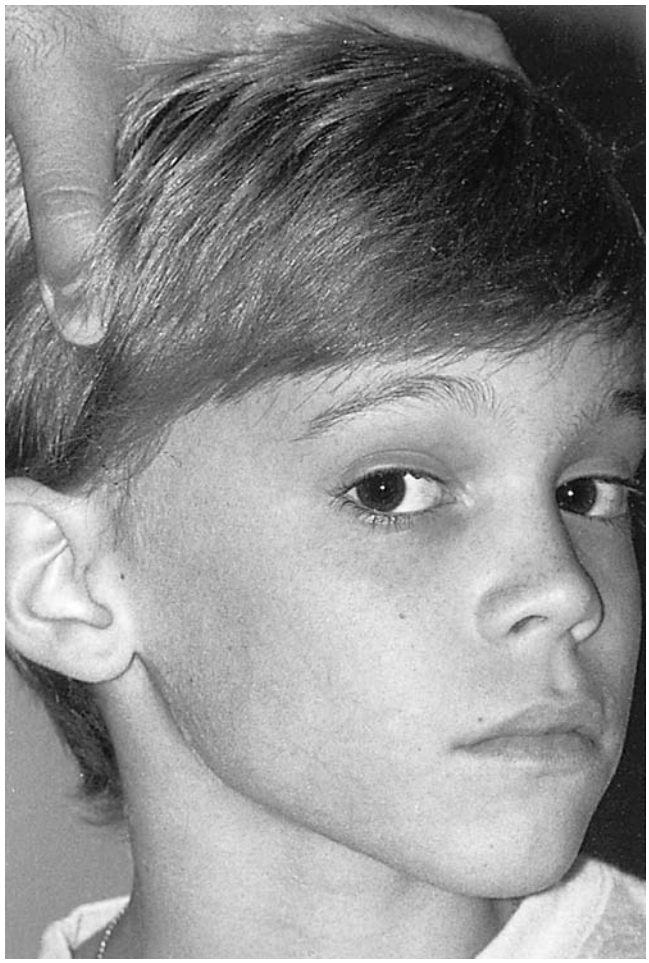

FIGURE 24.2 Patient's head is being rotated passively to patient's left as he looks straight ahead. This causes displacement of eyes into right gaze. Left eye adducts fully, showing no visible sclera medially. Subtle right sixth nerve palsy demonstrated by failure of right eye to abduct fully: sclera is still visible laterally on right eye.

The remaining types of strabismus fall into the category where eye muscle function is unimpaired (nonrestrictive and nonparalytic). These problems are not emergent. The eyes may be misaligned as a result of a failure of the brain to use both eyes simultaneously in a coordinated fashion (idiopathic), a need for glasses or the presence of poor vision in one eye. Uncorrected farsightedness (hyperopia) can result in esotropia (accommodative esotropia), which may have an acute onset, usually between the ages of 2 and 6 years, with the misalignment often worse at near viewing. Uncorrected nearsightedness (myopia) can result in exotropia, especially when the patient views in the far distance. Both types of misalignment may be treated with glasses.

Checking the vision in both eyes (see Chapter 127) is essential in all cases of strabismus with full eye movements to rule out the presence of uncorrected refractive error or a poorly seeing eye. The latter may be due to serious eye problems such as retinoblastoma or cataract.

EVALUATION AND DECISION

The Hirschberg light reflex test can be helpful in determining whether strabismus is present. The physician should shine a penlight or direct ophthalmoscope light at the patient's eyes from 2 to 3 feet while the patient is told to look at the other end of the room. In younger children, the patient may choose to look at the light itself, but all efforts should be made to distract the child with a more distant target. The examiner should observe the white dot light reflex that appears to be located on the cornea, overlying the iris or pupil of each eye. This reflex should be located in a nearly symmetric position in each eye (Fig. 24.6). In the normal state, the light reflex actually falls slightly off-center in the nasal direction in both eyes (Fig. 24.6). If the eyes are misaligned, symmetry would not be preserved (Figs. 24.5 and 24.7, see also color plate).

Two findings are helpful in assessing whether strabismus is emergent: (i) the presence or absence of double vision and

FIGURE 24.3 In normal upgaze, an imaginary line parallel to the horizon can be drawn between the most inferior point of the edge of each iris. In normal downgaze, a similar line can be drawn at the most superior point of the iris.

FIGURE 24.4 Right third cranial nerve palsy. When looking straight ahead with left eye, right eye rests in a hypotropic and exotropic position. Note right ptosis. Right pupil is involved (mydriatic), but both pupils were dilated pharmacologically by examiner just before this photograph was taken.

FIGURE 24.6 Normal Hirschberg light reflex test. Light reflexes fall symmetrically in each eye. The reflex in the patient's left eye is a bit nasal to the center, but still within normal limits.

(ii) the status of the eye movements. Although young children may not complain of diplopia, this symptom often indicates an acute or subacute onset of ocular misalignment. Nonemergent childhood strabismus is usually not associated with double vision because the brain becomes adept at suppressing the misaligned nonfixing eye. If a child complains of diplopia, ophthalmologic consultation is appropriate, even if no strabismus appears on examination by the emergency physician.

If the eye movements are completely full and symmetric, one can be virtually certain that the strabismus is not emergent. Problems that cause emergent strabismus do so by impairing the action of one or more muscles. A neurogenic palsy or restrictive phenomenon can not be present if the eye movements are full. If there are any questions about subtle reductions in extraocular movement or if there is prominent nystagmus elicited in one particular field of gaze (more than the few beats of normal end point nystagmus known as gaze paretic nystagmus), ophthalmologic consultation is most likely appropriate.

Because of fear and noncompliance, some children will not follow the examiner's target that is presented to assess eye movement. If they will not follow the target but look at the examiner only, the examiner should ask the parent to gently move the patient's head to each side and then up and down. The examiner can also do this by putting one hand on the child's head (Fig. 24.2), although this may serve only to heighten the child's anxiety. As the patient continues to look straight ahead when the head is being turned, the eyes are moving passively in reference to the head and orbit. When the head is turned to the left, the eyes move into right gaze to maintain fixation straight ahead (Fig. 24.2). If the head is tilted

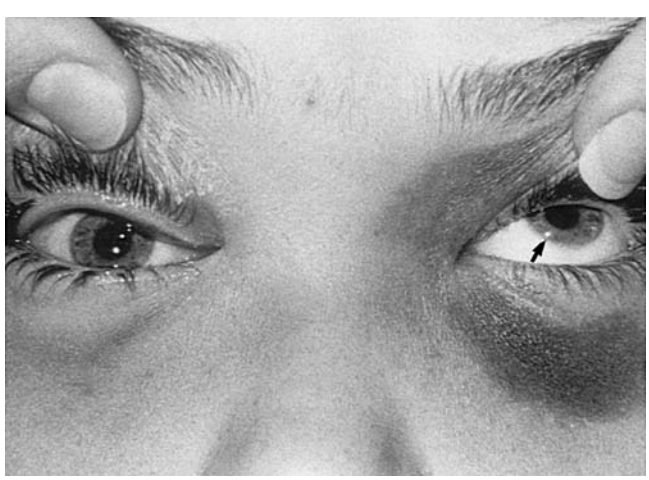

FIGURE 24.5 Patient is looking upward. Right inferior orbital wall blowout fracture causes restriction of upgaze in right eye. Note light reflexes (Hirschberg test). Left reflex *(arrow)* is lower in reference to pupil than right reflex, indicating the presence of a right hypotropia.

FIGURE 24.7 Left esotropia. Note lateral displacement of Hirschberg light reflex in the left eye. Photograph demonstrates right ptosis. Pupils are pharmacologically dilated. Asymmetry of red reflex is caused by misalignment of the eyes.

up, the eyes are moved into relative downgaze. Essentially, this is the "doll's eye" maneuver used in the assessment of comatose patients. If the eyes move symmetrically and fully on passive movement of the head, this rules out the presence of a neurogenic or restrictive problem with the same accuracy as if the patient had voluntarily followed a target. Although the neuro-ophthalmologic contributions to the assessment of the comatose patient are beyond the scope of this chapter, the presence of a cranial nerve palsy can be ruled out even in the patient who is experiencing an altered mental status related to central nervous system (CNS) disease if the eyes move fully on the doll's eye maneuver as the head is rotated by the examiner.

When an orbital blowout fracture is suspected, confirmation may be obtained by a computed tomography (CT) scan of the orbit. Some controversy exists about the need to perform this test emergently. Some ophthalmologists prefer to image only if the strabismus and diplopia do not spontaneously resolve over 1 to 2 weeks. If there is a concern about intracranial injury or orbital roof fracture as the cause of strabismus, an urgent CT scan of the head is indicated. If there is significant enophthalmos, then early imaging is also recommended. To evaluate the extraocular muscles, it is essential that coronal views be obtained. Contrast enhancement is unnecessary. Plain skull radiographs play virtually no role in the diagnosis and management of orbital fractures.

The causes of pediatric strabismus are summarized in Tables 24.2 through 24.4. The first considerations (Figs. 24.8 and 24.9) are restrictive strabismus and neurogenic palsies. Myasthenia gravis and thyroid ophthalmopathy (hyperthyroidism) can mimic virtually any strabismus with deficiency of extraocular movement and must always be considered in the differential diagnosis in any pattern of ocular misalignment. Myasthenia may cause ptosis, whereas thyroid disease causes retraction of the upper lid. The pupils are not involved in either condition.

TABLE 24.2

DIFFERENTIAL DIAGNOSIS OF STRABISMUS[a]

Neurogenic Palsies
III Cranial nerve palsy (partial or complete)
IV Cranial nerve palsy
VI Cranial nerve palsy
Traumatic extraocular muscle palsy
Myasthenia gravis
Internuclear ophthalmoplegia
Skew deviation

Restrictive Strabismus
Orbital wall fracture
Orbital hemorrhage, tumor, infection, or abscess
Thyroid eye disease
Nonthyroid extraocular muscle infiltration (e.g., metastasis)
Orbital cellulites

Nonneurogenic Nonrestrictive Strabismus
Idiopathic childhood strabismus
Strabismus caused by refractive errors (e.g., accommodative esotropia)
Sensory strabismus (unilateral visual loss)

[a]Not listed in order of frequency.

TABLE 24.3

COMMON CAUSES OF STRABISMUS[a]

Esotropia
Congenital infantile or acquired (with or without farsightedness), nonparalytic, nonrestrictive
Long-standing unilateral visual loss
Medial orbital wall fracture
VI cranial nerve palsy
Orbital mass, hemorrhage, or infection (all uncommon)

Exotropia
Nonparalytic nonrestrictive idiopathic childhood exotropia
Long-standing unilateral visual loss
III cranial nerve palsy
Orbital mass, hemorrhage, or infection (all uncommon)

Hypertropia
Dissociated vertical deviation (a nonparalytic nonrestrictive childhood deviation)
Idiopathic overaction or the inferior oblique muscle (affected eye rises in adduction)
Inferior or superior orbital wall fracture
IV Cranial nerve palsy: congenital or acquired
Orbital mass, hemorrhage, or infection (all uncommon)

Hypotropia
Brown syndrome (tight superior oblique tendon)
Inferior or superior orbital wall fracture
Orbital mass, hemorrhage, or infection (all uncommon)

[a]Not listed in order of frequency.

Esotropia Emergencies

Figure 24.8 summarizes the approach to a patient with esotropia and exotropia. Patients with a restrictive or neurogenic esotropia (deficiency of abduction) may adopt an abnormal head position to place the eyes in the position of best alignment to avoid double vision. By turning the face in the direction of the deficiency (e.g., right face turn for right sixth nerve palsy) when looking straight ahead, the eyes are aligned and appear straight. The patient's head must be held in the straight ahead position to notice that the affected eye is actually crossed.

In the presence of proptosis or a history of eye trauma, one must be concerned that an orbital process is causing the esotropia. Fracture of the medial orbital wall may cause entrapment and restriction of the medial rectus. Fracture of

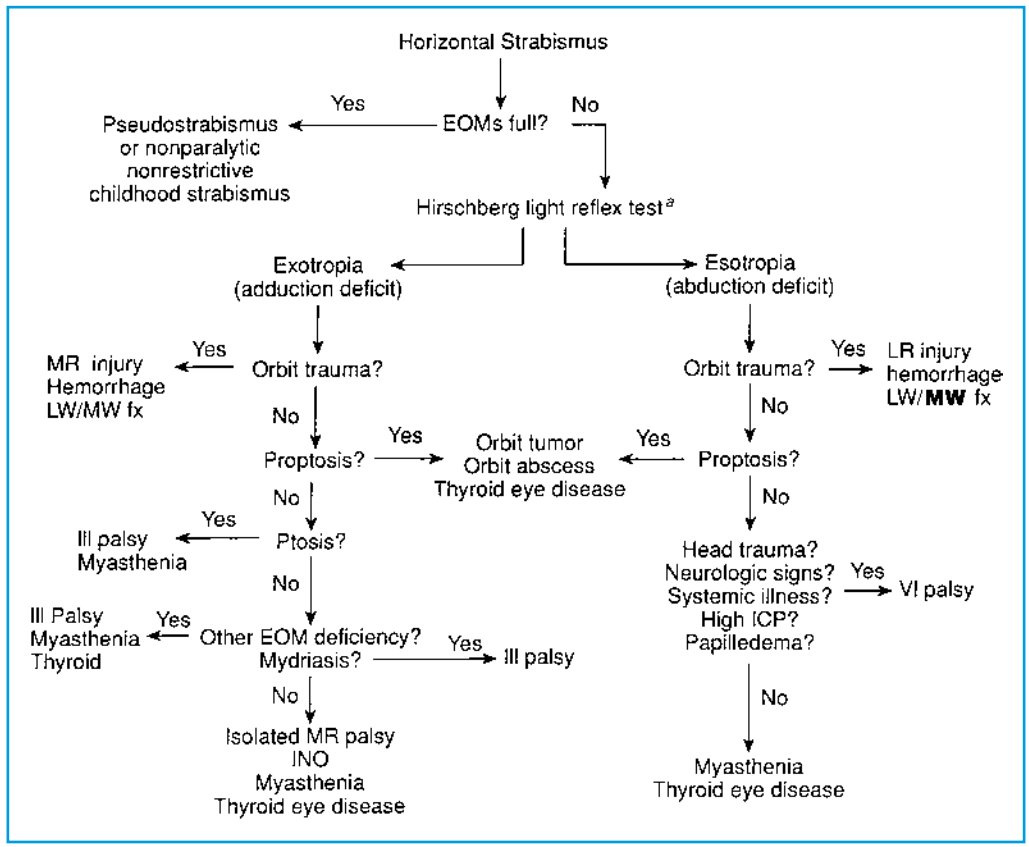

FIGURE 24.8 Evaluation of horizontal strabismus. EOM, extraocular muscle movement; MR, medial rectus; LW, lateral orbital wall; MW, medial orbital wall; fx, fracture; LR, lateral rectus; ICP, intracranial pressure; INO, internuclear ophthalmoplegia; boldface type, most likely fracture. [a]With head held in straight ahead position.

the lateral wall—usually part of a tripod fracture that involves the zygoma and inferior lateral wall—may cause orbital hemorrhage that would displace the eye medially.

Likewise, a lateral orbital tumor or abscess can push the eye toward the nose or restrict abduction. Any infiltrative process that involves the eye muscles may also cause esotropia through restriction. Orbital cellulitis can cause any type of misalignment, including esotropia, with or without abscess formation. A CT scan of the orbit with coronal and axial views is the diagnostic procedure of choice in these situations.

Lateral rectus palsy (sixth cranial nerve palsy) occurs most commonly secondary to head trauma (see Chapter 116) or increased ICP. Other CNS signs, such as papilledema, may be present. Magnetic resonance imaging (MRI) of the brain is the procedure of choice. Sixth cranial nerve palsy can also occur rather precipitously after the placement of ventricular shunts designed to relieve increased ICP even if the palsy was not obvious preoperatively. Sixth cranial nerve palsy may be bilateral, in which case both eyes will be in the crossed position with reduced ability to adduct bilaterally, although possibly asymmetrically.

Exotropia Emergencies

Orbital cellulitis, thyroid eye disease, and orbital tumors may also cause exotropia. Trauma very rarely results in exotropia because lateral wall fractures rarely cause entrapment. Orbital hemorrhage (with or without medial wall fracture) can have a mass effect, causing the eye to be turned out.

Isolated paresis of the medial rectus muscle, resulting in a deficiency of adduction and a turned out eye, is quite unusual because other muscles are also innervated by the same branch of the third cranial nerve. One should look for accompanying ptosis, pupillary dilation, or deficiencies of upgaze or downgaze to confirm third cranial nerve involvement, even if these findings are subtle.

Unilateral isolated deficiency of adduction may be the result of an intranuclear ophthalmoplegia secondary to a brainstem injury that involves the interconnecting pathways between the third and sixth cranial nerves. Bilateral isolated deficiency of adduction is virtually diagnostic of this condition. MRI of the brainstem should be ordered emergently. The observer should also look for prominent nystagmus on attempted abduction of the contralateral eye.

Hypertropia/Hypotropia Emergencies

Paretic or restrictive vertical eye muscle imbalance must be referred to an ophthalmologist. Figure 24.9 summarizes the approach to the patient with vertical ocular misalignment. To determine whether it is the higher or lower eye that is abnormal, the examiner must have the patient look upward and then downward. If one eye is unable to look downward fully,

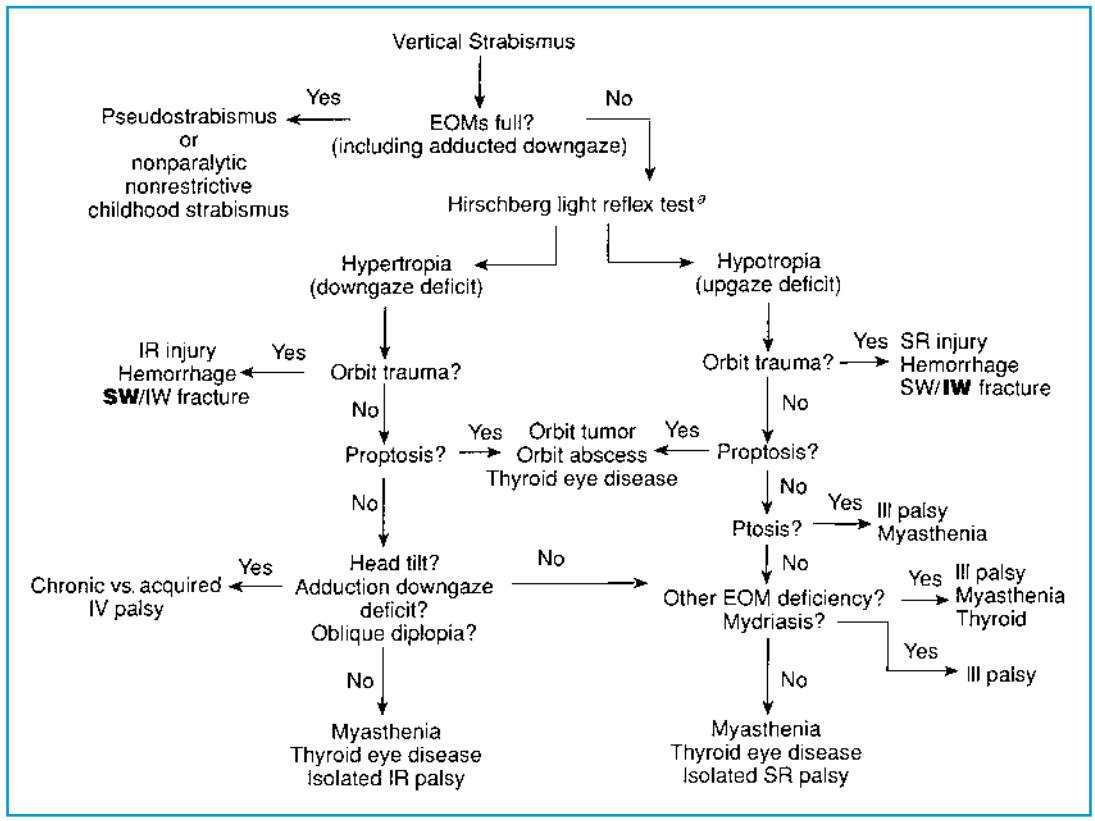

FIGURE 24.9 Evaluation of vertical strabismus. EOM, extraocular muscle movement; IR, inferior rectus; SW, superior orbital wall; IW, inferior orbital wall; SR, superior rectus; **boldface type**, most likely fracture. [a]With head held in straight ahead position.

the patient has a hypertropia of that eye. If one eye is unable to look upward fully, that eye is hypotropic (Fig. 24.5). Patients may adopt abnormal head positions to compensate for this misalignment. By lifting the chin to look straight ahead, the eyes are placed in relative downgaze, thus indicating that the strabismus is worse when the patient looks up. Likewise, the patient may adopt a chin down position to look straight ahead, indicating that the strabismus is worse in downgaze. A chin up or chin down position does not prove strabismus as there may be other causes (e.g., chin up position as compensation for ptosis, chin up or down position to lessen nystagmus). When a patient has an anomalous head position, it can be useful to examine the patient with the head in the opposite position to better highlight the abnormality for which the spontaneous head position is trying to compensate. For example, if the patient presents with a chin up position, the eyes may appear to be aligned in that position. If the head is moved by the examiner into a chin down position, the vertical misalignment of the eyes will be more apparent. An eye may become hypertropic for several reasons. Any mass underneath the eyeball—for example, an orbital tumor or a mucocele extending upward from the maxillary sinus—may push the eye upward. A tightened superior rectus is unusual but may be seen in thyroid eye disease or after trauma. An inferior orbital wall fracture could injure (weaken) the inferior rectus or cause hemorrhage that would push the eye up into a hypertropic position. A CT scan of the orbit would be the proper diagnostic modality.

Perhaps the most important cause of ipsilateral hypertropia is a lesion that involves the fourth cranial nerve. Although the eye may be able to look straight down fully, there may be a restriction of gaze in the down-and-in position relative to the other eye (which then would be looking down and out). Because of the torsional forces of the superior oblique muscle on the eyeball, the patient may adopt an abnormal head position with a face turn and a head tilt away from the affected eye. One must always consider the possibility that a new fourth nerve palsy actually represents a decompensated congenital abnormality.

Although rare, neurogenic palsies of the inferior oblique or inferior rectus with resultant vertical misalignment may occur. These have been reported after viral illnesses, including varicella. As with exotropia of neurogenic origin, it would be more likely to have other branches of the third cranial nerve involved with other findings. Another type of vertical eye muscle imbalance, skew deviation, can be the presenting sign of a midbrain lesion. Ophthalmologic consultation can be helpful in deciding whether MRI is appropriate.

Hypotropia can be caused by an orbital roof fracture with superior hematoma that pushes the eye down. Alternatively, hypertropia from a deficiency of downgaze due to tethering of the superior rectus muscle in an orbital roof fracture can also occur uncommonly. Orbital roof fracture is an emergent condition. Neuroradiologic evaluation, including coronal views, must be obtained to rule out communication between the orbit and the intracranial cavity. Pulsating proptosis is a

particularly ominous sign indicating direct contact between the intracranial and orbital compartments.

Traumatic hypotropia most commonly results from inferior wall blowout fractures (Figs. 24.5 and 24.9). The eye often is enophthalmic, and there may be associated numbness in the distribution of the infraorbital nerve as it innervates the ipsilateral infraorbital and malar region. Orbital lesions, including those that may have extended from the intracranial cavity, may push the eyeball downward and prevent it from looking upward. Thyroid eye disease also can cause hypotropia due to tightening of the inferior rectus.

CHAPTER 25 ■ EYE—UNEQUAL PUPILS

ALEX V. LEVIN, MD, MHSC, FRCSC

Abnormalities of the pupils can be helpful diagnostically when assessing central nervous system, autonomic nervous system, orbital, and ocular problems. Pupillary disorders can be divided into two categories: disorders in which the size of one or both pupils is abnormal and disorders in which the shape of one or both pupils are abnormal. The pupil can also be malpositioned (*corectopia*). Congenital or acquired (e.g., after trauma) corectopia generally requires ophthalmology consultation. When the pupils are different in size, the term applied is *anisocoria*. An abnormally dilated pupil is called *mydriasis*. *Miosis* refers to an abnormally constricted pupil. Figure 25.1 represents a flowchart for an approach to anisocoria.

PATHOPHYSIOLOGY

The pupillary dilator muscle receives sympathetic innervation. The pupillary sphincter receives parasympathetic innervation that also supplies the ciliary muscle of the eyeball that governs focusing (accommodation) of the lens.

The first-order sympathetic neurons extend from the hypothalamus through the midbrain, pons, and medulla into the spinal cord, where they synapse with the second-order neurons at the ciliospinal center of Budge-Waller, just before exiting the cord at roots C8–T2.

The cervicothoracic sympathetic trunk then travels over the apex of the lungs to the superior cervical ganglion in the neck, where synapses are made with the third-order neurons. Sympathetic innervation to the face departs from the superior cervical ganglion or at the bifurcation of the common carotid artery. Therefore, complete unilateral anhidrosis in association with unilateral miosis suggests damage to the second-order neurons or superior cervical ganglion. The third-order neurons travel with the internal carotid artery into the cranial vault, where the fibers gain access to the orbit via the nasociliary branch of the first division of the trigeminal nerve. They then travel through the ciliary ganglion in the orbit without synapse. Fibers extend to the iris dilator via the ciliary nerves. Disruption of sympathetic innervation anywhere along its course results in ipsilateral miosis (Horner syndrome) and is often accompanied by mild ptosis, enophthalmos, with or without ipsilateral anhidrosis. The lower lid may be higher than the contralateral side ("upside down ptosis").

Parasympathetic neurons originate in the Edinger-Westphal nuclei, located on the dorsal aspect of the third cranial nerve nucleus in the anterior dorsal mesencephalon at the level of the superior colliculus, ventral to the sylvian aqueduct. These neurons travel with the third cranial nerve, exiting the midbrain on its ventral aspect and passing between the posterior cerebral artery and the superior cerebellar arteries as they arise from the posterior communicating artery in the circle of Willis. The nerve then runs anteriorly and enters the cavernous sinus superiorly and laterally. Just before entering the posterior orbit through the superior orbital fissure, the third cranial nerve splits into a superior and an inferior division. The latter contains the parasympathetic fibers that then pass into the ciliary ganglion, where they synapse. Short ciliary nerves then carry the postsynaptic fibers to the pupillary sphincter muscle and the ciliary muscle (behind the iris). Unilateral mydriasis can be caused by damage to the parasympathetic fibers anywhere along their course. With the exceptions noted next, it is distinctly unusual for the parasympathetic fibers to be damaged without other evidence of third cranial nerve palsy (a deficit in the ability of the eye to adduct, look upward, and/or look downward, and/or ptosis; see Chapter 24).

Local factors can also cause physical changes in the iris or in the surrounding structures that may result in miosis or mydriasis.

EVALUATION AND DECISION

When testing pupillary size, it is essential that the patient be instructed to look at a *distant* target that does not involve reading letters or numbers. This prevents the eyes from needing to accommodate. Because the innervation for accommodation is the same as that for the pupillary sphincter, the accommodating patient also has reflex contraction of the pupils, particularly when focusing at near. Focusing on a near object also stimulates convergence of the eyes toward each other. Crying or forced eyelid closure may also induce miosis.

ANISOCORIA

When evaluating the patient with anisocoria, the emergency physician must answer two critical questions: (i) Which pupil is abnormal, the smaller or the larger? and (ii) Is this abnormality acute or chronic?

To establish which pupil is abnormal, the relative difference in pupillary size should be noted under conditions of bright illumination and dim illumination. Using the largest diameter circle of the direct ophthalmoscope or a bright penlight, both pupils should be illuminated simultaneously in a room with the lights on. The room lights should then be turned off and the handheld light source held tangentially from below or from above so the eyes are illuminated only enough that the examiner can note the pupillary size.

Normally, the pupils constrict equally in response to bright illumination and dilate equally in dim illumination. If the relative

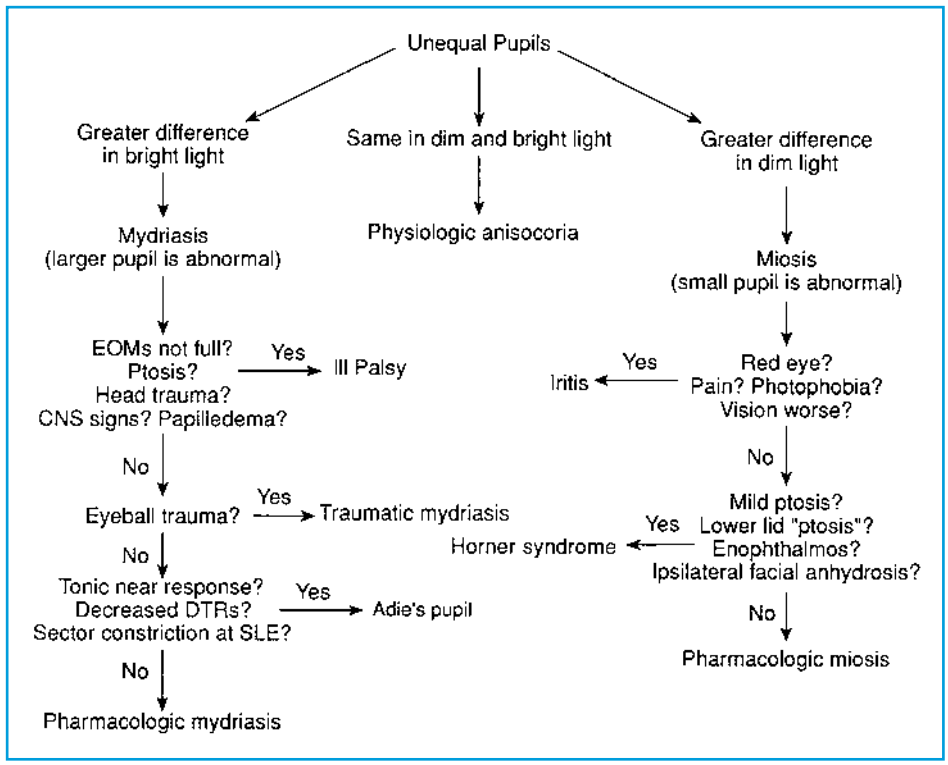

FIGURE 25.1 Unequal pupils. EOM, extraocular muscle movement; CNS, central nervous system; III, third cranial nerve; DTR, deep tendon reflex; SLE, slit lamp examination.

difference in pupillary size increases under bright illumination, the larger pupil is the abnormal pupil: the larger pupil is not constricting normally (Fig. 25.2). If the relative difference in pupillary size increases under dim illumination, the smaller pupil is the abnormal pupil: the smaller pupil is not dilating normally. If the relative difference in pupillary size is the same in both dim and bright illumination, the patient does not have an abnormal pupil (Fig. 25.3). Rather, the patient has physiologic anisocoria. Approximately 20% of people with normal pupils have a difference in the size of their pupils in excess of 0.4 mm.

When trying to establish whether the anisocoria is of relatively recent or acute onset, as opposed to long-standing anisocoria, it is helpful to view old photographs. Sometimes, chronic physiologic anisocoria will not have been noticed previously. The direct ophthalmoscope can be used to provide magnification and illumination of the photograph so the pupils can be viewed. Set the focusing dial on progressively higher black (or green) numbers until adequate magnification has been achieved while viewing through the direct ophthalmoscope. It also is important to note any other symptoms that accompanied the onset of anisocoria (headaches, pain, double vision, or blurred vision). The causes of anisocoria are summarized in Tables 25.1 to 25.3.

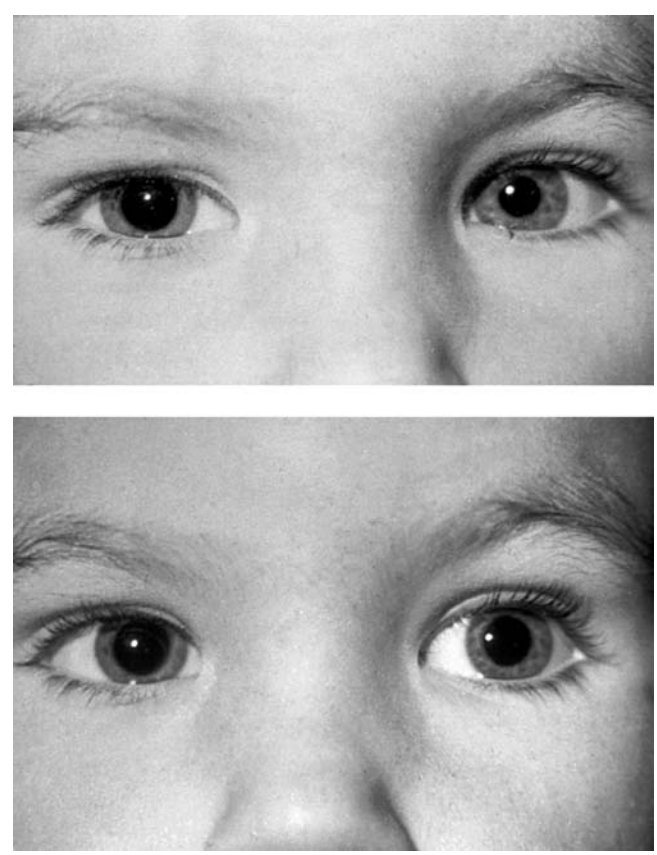

FIGURE 25.2 Patient with right mydriasis. Relative difference between the pupil size is greater in bright illumination (**top**) than in dim illumination (**bottom**).

MIOSIS

Local Factors

An irritated or inflamed iris sphincter muscle will result in miosis. Iritis, secondary to trauma or other factors, is a common cause (see Chapter 23). The eye is usually injected, and

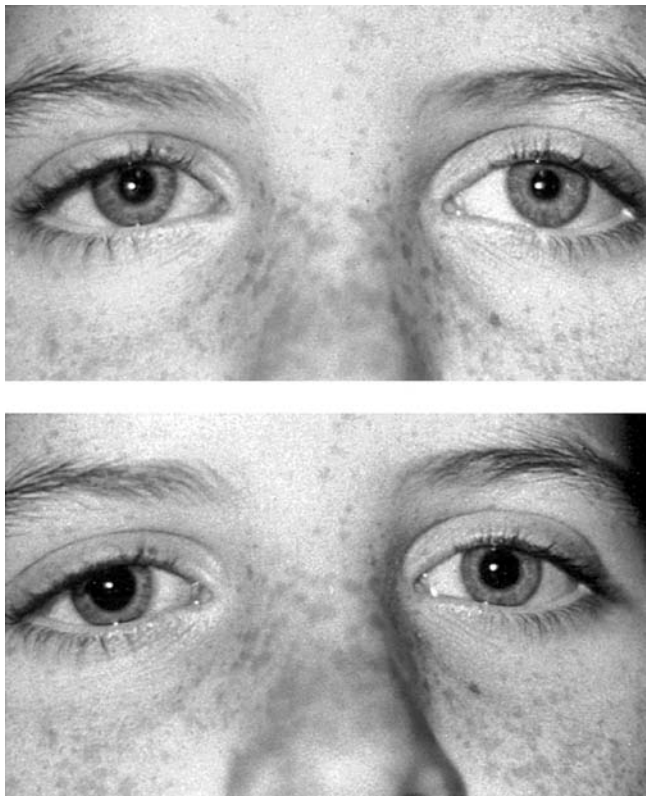

FIGURE 25.3 Physiologic anisocoria. Relative difference in pupil size is the same in bright illumination (**top**) and dim illumination (**bottom**).

there are symptoms of eye pain, photophobia, tearing, with or without decreased vision. Injection may surround the cornea for 360 degrees, creating a ring of erythema ("ciliary blush"). More diffuse injection may also occur. Children with juvenile idiopathic arthritis may not have these classic symptoms associated with their iritis; in fact, they may have no symptoms at all. Traumatic iritis is often not apparent for 12 to 72 hours after eye trauma. Iritis from any cause, especially when longstanding (as is often seen in juvenile idiopathic arthritis with asymptomatic iritis that escaped recognition), can result in scar tissues between the pupil edge and the lens just behind the pupil (posterior synechia), which prevent pupillary dilation or cause asymmetric irregular dilation of one or both pupils. The diagnosis of iritis is confirmed by slit lamp biomicroscopy. This technique is described in Chapter 117. Ophthalmologic consultation is important for evaluation and treatment.

Other local factors include surgical irritation of the iris and pharmacologically induced unilateral miosis. Mechanical contact with the iris during any intraocular surgical procedure may result in transient postoperative unilateral miosis. Parasympathomimetic or sympatholytic systemic medications and topical drops can also result in transient miosis. A list of commonly used topical miotics is found in Table 25.4. These drops are rarely used in children, with the exception of their occasional bilateral use to treat crossed eyes or unilateral or bilateral use for glaucoma. Systemic drugs from the same categories may result in bilateral miosis. It is helpful to remember that most topical ophthalmic miotics are supplied in bottles that have green caps.

TABLE 25.1

DIFFERENTIAL DIAGNOSIS OF UNEQUAL PUPILS[a]

Physiologic anisocoria
Pharmacologic (miotics or mydriatics)
Local factors
Miosis: iritis, surgical trauma
Mydriasis: trauma
Abnormal pupil shape from scar formation following prior iritis or trauma
Neurologic causes
Miosis: Horner syndrome
Mydriasis: third cranial nerve palsy, Adie's pupil
Congenital abnormalities
Iris coloboma
Anterior chamber dysgenesis syndromes (e.g., Axenfeld-Rieger)

Generic name	Trade names
Cholinergics	
Pilocarpine	Adsorbocarpine, Akarpine, Almocarpine, Isopto Carpine, Miocarpine, Pilagan, Pilocar, Pilocel, Pilogel, Pilomiotin, Piloptic, Ocusert Pilo
Carbachol	Carbacel, Isopto Carbachol
Anticholinesterases	
Physostigmine	Eserine Sulfate, Isopto Eserine
Demecarium	Humorsol
Echothiophate iodide	Echodide, Phospholine Iodide
Isoflurophate (DFP)	Floropryl

Neurologic Factors

Congenital Horner syndrome may result from brachial plexus injury and is often associated with ipsilateral iris hypopigmentation. This sign is not as helpful in the first few months of life when both eyes are normally relatively hypopigmented. More than 50% of children with congenital Horner syndrome have a history of difficult extraction at delivery. Congenital varicella infection may also be a cause.

This testing is best performed by ophthalmologic or neurologic consultants. If the presence of Horner syndrome is questioned, one drop of topical 4% cocaine can be instilled into both eyes. Because cocaine prevents reuptake of norepinephrine at the terminal myoneural junction of the sphincter muscle, pupillary dilation will occur normally. Failure of the miotic pupil to dilate is diagnostic of Horner syndrome. Knowledge of the sympathetic system anatomy can be exploited through the use of other topically applied diagnostic agents to localize the site of the lesion. Table 25.5 summarizes the causes of acquired Horner syndrome in children. All children who have Horner syndrome should receive a complete evaluation unless congenital Horner syndrome is present, based on history, old photographs, and examination.

TABLE 25.5

CAUSES OF ACQUIRED HORNER SYNDROME IN CHILDREN[a]

First-order Neuron
Brainstem glioma or other tumor
Brainstem vascular insult (aneurysm, infarct)
Spinal cord tumor

Second-order Neuron
Intrathoracic tumor (neuroblastoma, ganglioneuroma, metastatic)
Intrathoracic aneurysm
Cervical tumor or adenitis
Trauma (especially brachial plexus trauma)
Postsurgical

Third-order Neuron
Internal carotid thrombosis or aneurysm
Internal carotid or head trauma
Otitis media
Nasopharyngeal malignancy
Cavernous sinus thrombosis, tumor, or inflammation
Postsurgical

[a]Not listed in order of frequency.

MYDRIASIS

Local Factors

Both trauma and topical agents can cause unilateral mydriasis. Blunt trauma (and, less commonly, intraocular surgery) can result in a fixed dilated pupil. Traumatic mydriasis usually occurs in a setting in which a clear history of trauma and other intraocular injuries, such as hyphema, are noted. The pupil may be somewhat irregular in shape if the sphincter has irregular tears that appear as V-shaped notches in the pupil margin best seen using the direct ophthalmoscope as a magnifier. Sometimes, pigment deposition can be seen on the anterior surface of the lens.

Topical parasympatholytics and sympathomimetics can also cause mydriasis. Systemic medications from the same classes can cause bilateral pupillary dilation. A list of topical mydriatics is found in Table 25.6. Most of these drops are supplied in bottles that have red caps. Pharmacologic mydriasis can be diagnosed by the instillation of pilocarpine 1% into both eyes. The pharmacologically dilated pupil will not constrict or will constrict only minimally. Inhaled medications (e.g. ipratropium) can also cause transient mydriasis, often presenting unilaterally.

TABLE 25.6

TOPICAL OPHTHALMIC MYDRIATICS[a] (DROPS AND OINTMENTS)

Generic name	Trade names
Sympathomimetics	
Phenylephrine	AK-Dilate, Efricel, Mydfrin, Neo-Synephrine, Phenoptic
Cocaine (see text)[b]	
Parasympatholytics	
Atropine	Atropisol, Isopto Atropine, Ocu-Tropine

Homatropine	Homatrocel, Isopto Homatropine
Scopolamine	Isopto Hyoscine, Mydramide
Tropicamide	Mydriacyl, Mydriafair, Tropicacyl

[a]Combination products may also be available.
[b]Diagnostic and anesthetic use only—not prescribed for outpatient use.

Neurologic Factors

When a child with unilateral mydriasis arrives in the emergency department, the initial concern is often cerebral herniation leading to compression and stretching of the third cranial nerve. A rapid neurologic assessment usually is sufficient to diagnose herniation because most patients will have a decreased level of consciousness, focal findings in addition to a dilated pupil, and abnormal vital signs usually with deficiencies of eye movements and/or ptosis (see Chapter 24). Once the physician is certain that increased intracranial pressure (ICP) is not present, a more careful evaluation is appropriate.

Examination by an ophthalmologist is often indicated to help define patterns of extraocular muscle deficit and strabismus, as well as to assess for the possible presence of papilledema. Meningitis and increased ICP have been associated with mydriasis from third cranial nerve involvement without abnormalities of the extraocular muscles. In children, head trauma is the most common cause of acquired third cranial nerve palsy. Other causes are listed in Table 25.7. Neuroradiologic investigation is almost always indicated.

Other problems may mimic the eye muscle imbalance of third nerve palsy. For example, an inferior orbital wall blowout fracture (see Chapter 24) may cause a deficiency in the eye's ability to look up. Trauma may also result in unilateral mydriasis. Together, these findings may mimic a third cranial nerve palsy. This scenario underscores the need for ophthalmologic consultation when pathologic unilateral mydriasis and/or eye muscle deficits are present. Diagnostic clues to the presence of a long-standing third cranial nerve palsy include phenomena associated with aberrant regeneration of the oculomotor nerve. Examples include eyelid elevation when the patient looks down and pupillary constriction when the patient looks upward, downward, or into adduction.

Adie's pupil is most often unilateral. It is caused by parasympathetic denervation at the myoneural junction of the pupillary sphincter muscle. It may be associated with deep tendon hyporeflexia. Also known as tonic pupil, an Adie's pupil constricts slowly to near convergence and then redilates deliberately. Slit lamp examination may reveal serpentine microundulations or asymmetries on constriction to light. Adie's pupil usually has an acute or subacute onset. It has been reported after trauma and viral illnesses, including varicella. The denervation is best demonstrated by instillation of weak pilocarpine (0.125% or 0.1%) into both eyes. This concentration is too weak to cause constriction of the normal pupil. The denervated Adie's pupil will become miotic. Acutely, this test may be falsely negative. Perhaps it is best that this test be left to the ophthalmologist so complete ophthalmic examination can be conducted before pharmacologic alterations in pupil size are made.

A common misconception is that poorly seeing eyes have large pupils. Even an eye with very poor vision (light perception) or total blindness may have normal pupil size.

CORECTOPIA AND IRREGULAR PUPILS

Pupils that are located eccentrically rather than centrally are often bilaterally abnormal and represent congenital anomalies. A corectopic pupil can also be due to a progressive change in iris anatomy. Congenital corectopia may be associated with other holes in the iris (polycoria), abnormal iris strands that may be adherent to the cornea, or alterations in iris color. These abnormalities may also be associated with glaucoma and systemic malformations such as dental and umbilical abnormalities (Axenfeld-Rieger spectrum). Progressive changes in pupil location may be because of progressive formation of scar tissue after eye surgery or progressive posterior synechia. After trauma, the presence of corectopia, or a teardrop-shaped pupil, is particularly ominous because this may indicate an underlying associated rupture of the eyeball (see Chapter 117).

The direct ophthalmoscope can be helpful in identifying iris anomalies. The focusing dial should be turned so the iris is in focus (less than 6 in. away from the patient). The dial will be turning in the direction of increasingly higher black (or green) numbers to provide increasing magnification at shorter distances from the eye. The red reflex test (see Chapter 117) can also be helpful when the pupil does not appear as a perfect circle.

Perhaps the most familiar disorder of pupillary shape and/or location is the congenital iris coloboma. This "keyhole" pupil (Fig. 25.4) represents a failure of proper embryologic development of the iris tissue. By itself, iris coloboma is usually asymptomatic and not associated with a functional deficit. Associated colobomatous defects of the retina or optic nerve may exist, and these can result in serious visual compromise. An eye with coloboma may be smaller (microphthalmia).

Occasionally, when dilating drops are instilled initially, the pupil may begin to dilate irregularly and asymmetrically. This is of no concern provided the ultimate shape of the dilated pupil is round. Otherwise, it is wise to seek ophthalmologic consultation in all situations of corectopia or irregular pupillary shape.

UNEQUAL PUPILLARY REACTIVITY

Both pupils should be equally brisk in their constricting reaction to a penlight (or direct ophthalmoscope light). When asymmetry in pupillary reactivity is found, it is always the more sluggish pupil that is abnormal. Often, the more sluggish pupil will be a unilaterally dilated pupil (for which the previous discussion applies). If both pupils are symmetric in their baseline positions, an abnormally sluggish pupil may indicate

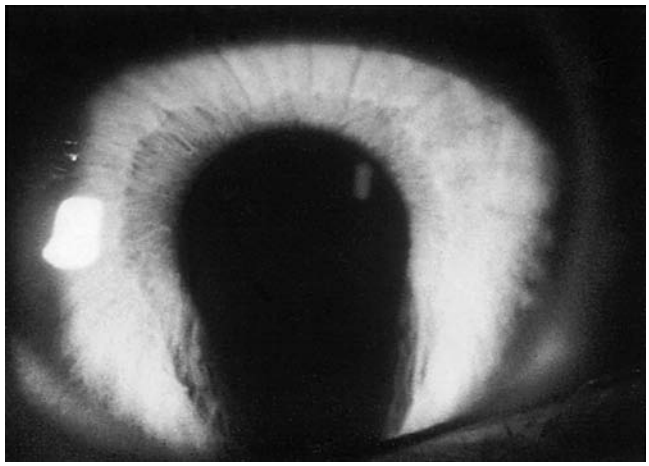

FIGURE 25.4 Iris coloboma creating a "keyhole" pupil. The iris defect is always inferior or inferior-nasal.

the presence of a serious retinal or optic nerve problem that is impairing the ability of the affected eye to perceive the light source equally. Testing visual acuity is essential under these circumstances. A Marcus Gunn pupil [also known as afferent pupillary defect (APD)] occurs when there is unequal perception of light between the two eyes, usually due to a unilateral or asymmetric optic neuropathy, which could be due to trauma, tumor (e.g., glioma in neurofibromatosis type 1), genetic optic neuropathies (e.g., Leber hereditary optic neuropathy), demyelinating disease, or inflammation of the optic nerve (papillitis). The reader is referred elsewhere (Young and Levin, 1997) for details of the "swinging flashlight test" used to evaluate for a Marcus Gunn pupil.

The pupil should not be pharmacologically manipulated in the ED if there is a concern about a pupil abnormality. Rather, direct referral to an ophthalmologist is appropriate so the pupils may be observed unaltered.

CHAPTER 26 ■ EYE—VISUAL DISTURBANCES

KAREN DULL, MD

Sudden loss or deterioration of vision (or diplopia) can be caused by numerous diseases and injuries (Tables 26.1 to 26.3). A systematic approach is necessary to reach a correct diagnosis and to minimize the risk of permanent visual impairment. The patient's age, underlying disease conditions, visual history, and history of possible injury must be determined. The extent of the visual impairment, the rapidity of its onset, and the association with other systemic findings are vital pieces of information. It is important to remember that visual acuity improves with age. The normal visual acuity for a toddler is 20/40 and gradually improves to the normal adult acuity of 20/20 by age 5 or 6 years. A careful eye examination, including gross and ophthalmoscopic examination, determination of extraocular movement, and visual acuity, together with the history, leads to correct diagnosis and management of the patient.

Few ocular conditions in the pediatric population are truly emergent (Table 26.4), but many are urgent; most can be treated by the emergency physician or can be referred for appropriate follow-up with an ophthalmologist. Many conditions seen by a pediatric ophthalmologist are not discussed here because they rarely are seen in the emergency department (ED). Such conditions include congenital eye disorders and amblyopia. Likewise, head tilt may represent a visual disturbance and requires a complete ophthalmologic evaluation, although the condition may also be caused by musculoskeletal problems in the neck. Conditions that are more likely to be seen in the ED are emphasized in this chapter.

PATHOPHYSIOLOGY

Vision may be impaired through interference at any point in the visual pathway. Light must reach the eye, pass through the cornea and the anterior chamber, be focused by the lens, pass through the posterior chamber, and reach the retina. The retina must react to the visual stimuli, generate electrical impulses, and transmit these impulses along the optic nerve and eventually to the visual cortex for interpretation. In addition, for binocular vision, the movement of both eyes must be coordinated and smooth. Loss of clarity of the visual media or damage to the conductive tissues anywhere along the visual pathway can lead to decreased vision.

DIFFERENTIAL DIAGNOSIS

Trauma and infections are the two most common causes of acute visual impairment that can interfere with any part of the visual pathway (Tables 26.1 and 26.2). The total spectrum of diseases that cause visual impairment can be understood best if the visual pathway is divided into its parts, and each part is considered sequentially (Table 26.1).

Vision may be limited by periorbital diseases such as periorbital cellulitis, tumor, infection, or allergic swelling of the eyelids. Orbital cellulitis should be considered if decreased vision, proptosis, ophthalmoplegia, or pain with eye movements is present.

Blunt trauma to the eye may cause a blowout fracture of the orbit. The weakest portion of the orbit, the floor, most commonly breaks, and this may entrap the extraocular muscles. Visual impairment may be limited to double vision when looking in a certain direction, particularly upward. Testing the extraocular movements reveals the limitation. Careful inspection of the globe is also necessary.

Diseases of the cornea that cause visual impairment are predominantly infectious or traumatic. Infections of the cornea and conjunctiva can be caused by bacteria, viruses, and fungi (see Chapters 23 and 127). All these diseases may present as a unilateral or bilateral process, usually affecting only the conjunctiva and cornea. Onset is variable but usually occurs over 1 or 2 days, and vision is not greatly impaired. In the newborn period, gonococcal, chlamydial, and herpetic infections must be considered. *Staphylococcus* species are the leading cause of bacterial keratitis. *Pseudomonas* species is the most commonly isolated bacteria in patients who wear contact lenses. In the United States, the most common corneal infection that causes permanent visual impairment is herpes simplex keratoconjunctivitis, whereas trachoma infection is the most common cause worldwide. A careful ophthalmoscopic or slit lamp examination will reveal the characteristic dendritic ulcers of herpes simplex infection after the eye has been stained with fluorescein. Unless this disease is excluded, steroid-containing medications should not be used. Herpes simplex infection may be recurrent, so if a child with a history of previous herpes simplex keratitis complains of a red eye on the previously infected side, recurrent herpes infection must be suspected. With a recent eye injury or foreign-body intrusion, fungal infections are possible.

Traumatic injuries to the cornea include one of the true ophthalmologic emergencies: alkali burns. Alkali burns in general carry a worse prognosis than acid burns. The cause of the chemical injury is usually obvious from the history. Immediate copious irrigation of the eye with normal saline is imperative to prevent permanent visual impairment and to preserve visual acuity. Both ultraviolet and infrared light can cause damage to the cornea, resulting in severe pain and photophobia within 24 hours of exposure. Lacerations with perforation of the cornea usually affect other parts of the eye as well and can lead to significant visual impairment. Careful inspection of the globe with associated lid trauma is mandatory.

TABLE 26.1

CAUSES OF ACUTE VISUAL DISTURBANCES

	Traumatic	Nontraumatic
Periorbital	Eyelid hematoma, edema from trauma	Orbital or periorbital cellulitis, tumor, allergic edema
Cornea and conjunctiva	Chemical burns, thermal burns, ultraviolet or infrared burns, laceration of cornea	Conjunctivitis (bacterial, viral, fungal)
Anterior chamber	Traumatic iritis, hyphema, posttraumatic cataract, dislocation of lens, glaucoma	Acute iritis, glaucoma, uveitis
Posterior chamber	Vitreous hemorrhage	Endophthalmitis
Retina	Severed retinal artery, retinal tears or detachment, commotio retinae	Retinal vein or artery obstruction, spontaneous
Cortex	Head trauma	Optic neuritis, toxins, hysteria, hypoglycemia, leukemia, cerebrovascular accidents, migraine, multiple sclerosis, acute disseminated encephalomyelitis, meningitis, encephalitis, seizure, cerebral venous sinus thrombosis, idiopathic intracranial hypertension
Other	Carotid artery trauma	Poisoning Shunt malfunction Vitamin A deficiencies Measles Neoplasm

The anterior chamber of the eye consists of the aqueous humor, the iris, and the lens. Acute iritis is rare in children, and the cause is often uncertain. There is a sudden onset of pain, redness, and photophobia that usually affects one eye only. The degree of visual impairment varies with the severity of inflammation. Certain diseases, such as juvenile rheumatoid arthritis, have associated iritis. Blunt trauma can also cause iritis, but vision is only slightly impaired unless other structures are involved. Traumatic iritis often presents 24 to 72 hours after the trauma.

Trauma can also cause a hyphema or hemorrhage into the anterior chamber. This can result in little to severe visual impairment in the affected eye, depending on the extent of bleeding and associated trauma. Complications of hyphema include rebleeding, which typically occurs within the first 5 days after injury, and increased intraocular pressure potentially leading to glaucoma. Previously, all patients with hyphema were hospitalized on strict bed rest. However, this was not shown to improve outcome, but close follow up with an opthamologist is recommended. Despite lack of definitive evidence, most ophthalmologists recommend cycloplegic and corticosteroid drops to reduce pain and possibly reduce inflammatory complications. Nonsteriodal antiinflammatory drugs should be avoided. The risk of vision loss is highest in patients with sickle cell disease or trait, greater than 20% of the visual field affected, rebleeding, and residual blood lasting beyond 3 to 4 days duration.

Traumatic injuries can lead to cataract formation, usually within a few days of injury, but onset may be delayed for years. Dislocation of the lens after trauma causes significant visual impairment but can be recognized easily with a careful examination. Glaucoma and a retinal detachment may be late complications of blunt trauma. Pain around the eye, blurred vision, and occasionally, nausea and vomiting in a patient with glaucoma or with a recent eye injury may represent an acute attack of glaucoma. Congenital glaucoma is a major preventable cause of blindness in children; most cases manifest within the first 6 months of life and occasionally present to the ED. Corneal clouding, buphthalmos, or asymmetry in eye size may be the chief complaint. If any one of these is noted as a primary complaint or an incidental finding, immediate referral is required.

The uvea consists of the iris, ciliary body, and choroid. One or all portions of the uvea may become inflamed, causing uveitis. Iritis and iridocyclitis may be called anterior uveitis, whereas inflammation of the choroid is often called posterior uveitis. The etiologies may be divided into infectious and noninfectious. Infectious uveitis may be caused by viruses, bacteria, fungi, or helminths. The most common cause of posterior uveitis in children is toxoplasmosis. Noninfectious causes include juvenile rheumatoid arthritis, trauma, ankylosing spondylitis, Behçet's disease, pseudotumor cerebri, peripheral uveitis, sarcoidosis, and sympathetic ophthalmia. Vogt-Koyanagi-Harada syndrome is a panuveitis with meningeal and cutaneous findings. Prompt treatment of this syndrome is necessary for optimal visual outcome.

In addition to blurred vision in one or both eyes, anterior uveitis is also associated with pain in the affected eye, headache, photophobia, and conjunctival injection. On gross examination, the pupil may be constricted and have a ring of redness surrounding the cornea. A slit lamp exam is used to confirm the diagnosis. Anterior uveitis may be confused with conjunctivitis or an acute attack of glaucoma. In posterior uveitis, the pain and photophobia may be less pronounced, but there may be a more pronounced visual impairment.

The posterior chamber is composed of the vitreous humor. The vitreous gel is usually clear, and any diseases that affect the clarity will impair vision. Certain chronic conditions such as uveitis can cause deposits in the vitreous humor, but the visual impairment is very gradual. Infections inside the eye (endophthalmitis) usually result from a penetrating injury, surgery, or an extension of a more superficial infection. Bacterial infections develop more rapidly than do fungal infections. The child will have severe pain in or around the eye and, with bacterial infections especially, may have fever and leukocytosis. The process is usually unilateral, and vision is severely compromised. Purulent exudate is formed in the vitreous humor, and ophthalmoscopic examination may reveal a greenish color with the details of the retina lost. A hypopyon—accumulation of pus in the anterior chamber—is usually present.

Either penetrating or blunt trauma (see Chapter 117) to the eye can lead to vitreous hemorrhage, but this is uncommon in children. Diabetes mellitus, hypertension, sickle cell disease, and leukemia may cause vitreous hemorrhage as well as retinal tears, central retinal vein occlusion, and tumor. There is a sudden loss or deterioration of vision in the affected eye. This may presents as strabismus and nystagmus in younger preverbal patients. Findings on examination depend on the degree of hemorrhage. Blood clots may be visible with the ophthalmoscope, or the fundus reflex may be black, obscuring the retina in more severe cases.

Retinal vein and artery obstruction are also uncommon in pediatric patients. With central retinal artery occlusion, there is a sudden, painless, total loss of vision in one eye. If only a branch is occluded, a field loss will result. Ophthalmoscopic examination reveals the cherry-red spot of the fovea, the optic nerve appears pale white, and the arteries are narrowed significantly. A Marcus Gunn pupil (relative afferent defect) may be present and may be diagnosed by shining a light in one eye, then in the other. When the light is shone in the normal eye, both pupils will constrict. When light is shone in the damaged eye, the pupil will dilate. The retinal artery may be severed by trauma or obstructed by emboli, as in a patient with endocardial thrombi or arterial obstructions in systemic lupus erythematosus (SLE) and in diseases with hypercoagulability, such as sickle cell disease. The arterial spasm associated with migraine may lead to retinal artery obstruction.

As with retinal artery occlusion, retinal vein occlusion causes a painless loss of vision. Visual loss may be severe, with total occlusion of the central retinal vein, or less pronounced, with branch obstruction. Examination of the retina reveals multiple hemorrhages with a blurred, reddened optic disc. The arteries are narrowed, the veins engorged, and patchy white exudates may be evident. These findings will be limited to one area in branch occlusion. Retinal vein obstruction, although rare, may occur with trauma or diseases such as leukemia, cystic fibrosis, or retinal phlebitis.

As mentioned, a tear in the retina may lead to vitreous hemorrhage, causing decreased vision in the affected eye. If the tear is in the macula, the visual loss will be severe. A tear in the retina may not cause immediate visual impairment. Retinal detachment from a retinal tear may be delayed for years. The visual impairment may go unnoticed if the detachment is peripheral. As the detachment progresses or when it involves more central areas, the patient will complain of cloudy vision with lightning flashes (photopsia). This may be followed by a shadow or curtain in the visual field. Visual acuity may remain normal if the macula is not involved. Examination of the eye will reveal a lighter-appearing retina in the area of detachment, and it may have folds. Flashing lights or visual field defects, after trauma, should raise the suspicion of retinal detachment. Retinoschisis, splitting of the layers of the retina, may be seen in shaken baby syndrome.

Commotio retinae, or Berlin's edema, is edema of the retina that may follow blunt ocular trauma by 24 hours. The visual loss is variable, and the retina will appear pale gray because of the edema, but the macula is usually spared.

The optic nerve transmits visual signals to the cortex. Optic neuritis is involvement of the optic nerve by inflammation or demyelination. The process is usually acute and may be unilateral or bilateral. Loss of vision may take from hours to days, and visual impairment ranges from mild loss to complete blindness. Patients often complain of disturbance of color vision. Pain may be absent or present on movement of the eye or palpation of the globe. It is rarely an isolated event in children. Causes include meningitis, viral infections, immunizations, encephalomyelitis, Lyme disease, and demyelinating diseases. Multiple sclerosis uncommonly occurs in childhood, but may present with sudden onset of intermittent episodes of optic neuritis associated with gait disturbances, paresthesisas, and dysesthesias. Pediatric neuromyelitis optica is a demyelinating disease of the central nervous system that is difficult to distinguish from multiple sclerosis. Typically it presents with optic neuritis and transverse myelitis. Visual loss ranges from mild to severe. Similarly, acute disseminated encephalomyelitis

may present acutely with hemiplegia, ataxia, cranial nerve palsies, and optic neuritis. It may follow a recent viral infection, and, unlike multiple sclerosis, does not generally reoccur. Exogenous toxins and drugs (e.g., lead poisoning, long-term chloramphenicol treatment) may also cause optic neuritis.

Idiopathic intracranial hypertension (IIH), or pseudotumor cerebri, which is characterized by increased intracranial pressure with normal cerebrospinal fluid content, normal neuroimaging, absence of neurologic signs except cranial nerve VI palsy, and often without discernable cause, can also present with visual loss. Transient visual obscurations due to optic disc edema occur in about three-fourths of IIH patients. The attacks are monocular or binocular. Visual acuity loss and/or visual field defects can be reversed with appropriate therapy.

Pressure on the optic nerve from a neoplastic lesion, such as an optic glioma or craniopharyngioma, may cause visual field loss as an early finding. Optic nerve gliomas can occur anywhere along the optic nerves, chiasm, and optic tract. Optic nerve gliomas are slow growing, and patients present with proptosis, unilateral or bilateral visual loss, strabismus, optic atrophy, or nystagmus. Children with craniopharyngiomas often present with nonspecific complaints of headaches or progressive visual loss of unknown cause. They may also present with endocrine abnormalities related to pituitary dysfunction.

Children with shunts for hydrocephalus may suffer acute visual disturbances—ranging from diplopia to complete blindness during acute shunt failure. Thus, the child with an acute visual disturbance and a shunt must be evaluated for shunt patency, function, and infection. Various toxins are capable of causing impaired vision. The loss may be gradual or sudden, depending on the particular toxin. Toxins usually act on ganglion cells of the retina or on optic nerve fibers, causing contraction of the peripheral field, central visual defect, or a combination. Methyl alcohol, when ingested, may cause bilateral sudden blindness, which may be complete and permanent or may have a more gradual onset. With methyl alcohol ingestion, associated symptoms include nausea, vomiting, abdominal pain, headache, dizziness, delirium, and convulsions. Other toxins include halogenated hydrocarbons, sulfanilamide, quinine, mercury, and quinidine. Large doses of salicylates may cause amblyopia. Digitalis may cause transient amblyopia, visual blurring, or the perception of yellow halos around light (xanthopsia).

Visual impairment may also result from interference with the visual cortex of the brain. Cortical blindness has many causes (Table 26.5). Head trauma (see Chapters 37 and 116) may cause total loss of vision soon after the event. This has been called "footballer's migraine" because of its association with head trauma in soccer. Even trivial head trauma has been known to cause blindness. The apparent hysterical reaction that follows head trauma, especially in young children, may represent complete blindness in a child who is unable to express the problem or is too frightened by the experience. The physical examination may be completely normal. There may be a delay of onset, but the entire course is usually brief, lasting minutes to hours. This form of blindness is often confused with hysterical blindness, the latter being a diagnosis of exclusion. Monocular blindness may be caused by trauma to the carotid artery on the affected side.

Cerebral venous sinus thrombosis may present with headache, diplopia, nausea, vomiting, blurred vision, and photophobia. It may be associated with hypercoagulable states secondary to oral contraceptive usage.

Postictal states
Hypertensive crisis

Migraine headaches are a common cause of visual loss in children. Opthalmoplegic migraine, which occurs primarily in children, affects the third cranial nerve causing ptosis, pupillary dilation, exotropia and diplopia, and blurred vision as the headache ends and takes days to weeks to resolve. Basilar migraine are typically occipital, associated with visual disturbances and accompanied by blurred or tunnel vision, dizziness, ataxia, diplopia, and vomiting. Retinal migraine is characterized by sudden loss of vision associated with a headache. Headache and nausea after such an episode are the rule but occasionally may be absent.

Seizures may also present with visual changes, which sometimes manifest as a migraine-like episode. Visual disturbances may also be the only clinical manifestation of childhood occipital epilepsy, but are more commonly associated with more typical seizure activity.

EVALUATION AND DECISION

The absolute ophthalmologic emergencies are alkali burns, a ruptured globe, and retinal artery occlusion. The diagnosis of the first is by history, and therapy must be initiated promptly to minimize the damage to the eye. If there is any doubt about the actual substance to which the eyes have been exposed, treatment for an alkali burn is always prudent. A ruptured globe must be suspected with any possible penetrating injury to the eye. The injury may be subtle, and the vision may be normal. If a possibility of a ruptured globe exists, the eye should be protected and the patient should have immediate evaluation by an ophthalmologist. Retinal artery thrombosis is rare in children, but it should be suspected when there is sudden, unilateral painless loss of vision and a predisposing condition. Predisposing conditions include those associated with

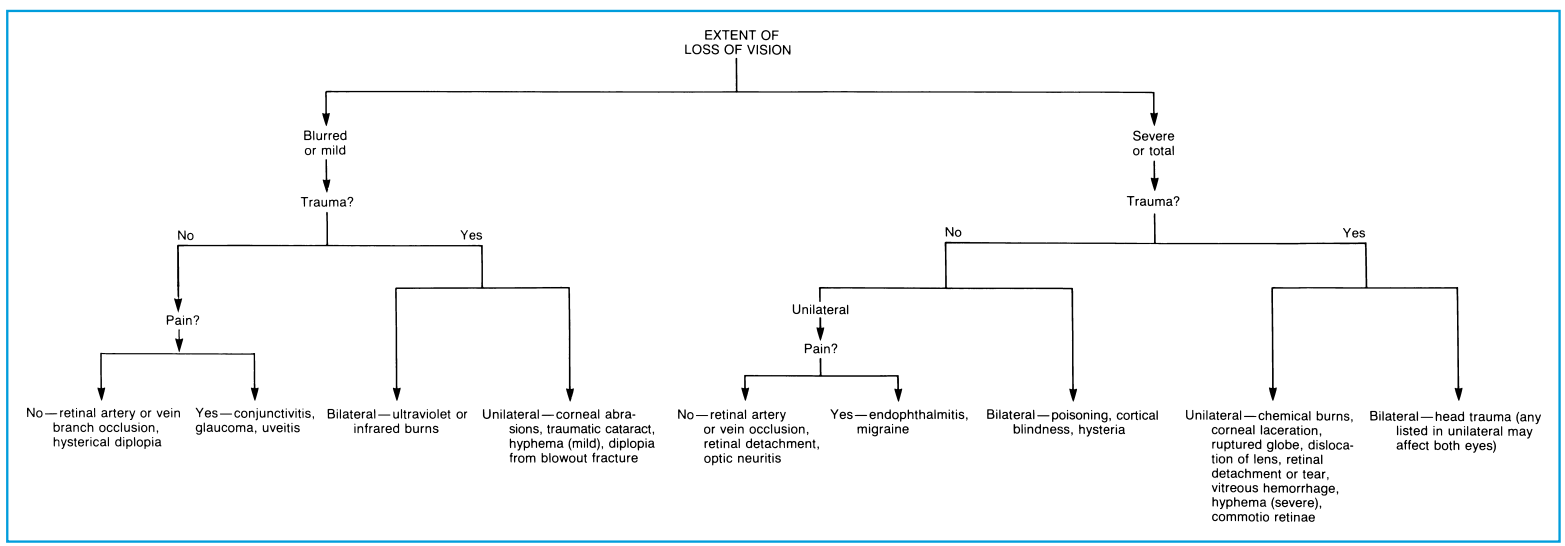

FIGURE 26.1 Diagnostic approach to visual disturbances.

emboli, such as endocardial thrombi or amniotic fluid; conditions with arteritis leading to obstruction, as in SLE; disease states associated with hypercoagulability, such as sickling hemoglobinopathies; and conditions with arterial spasm, such as severe hypertension.

If alkali burns, a ruptured globe, and retinal artery occlusion can be excluded, the patient may be evaluated more carefully before instituting therapy. Significant historical information includes episodes of recent trauma, unilateral or bilateral nature of the loss, and association of pain in or around the eye (Fig. 26.1). Child abuse may present with any of a variety of traumatic injuries. Retinal hemorrhages in a child are almost always caused by intentional trauma. Most children seen in the ED will have a traumatic or infectious process.

If hysterical blindness is suspected, the mirror test may be used. A mirror that is large enough to prevent the patient from looking around it is placed in front of the patient's face and is slowly rocked back and forth. The examiner should observe the patient from above to see if the patient is able to suppress the tendency to follow the mirror or hide a response to another visual stimulus, such as a funny face made by the examiner.

Severe Visual Loss Associated with Trauma

Severe bilateral visual loss associated with head trauma is likely cortical blindness. This condition usually is totally reversible in less than a few hours. Any of the traumatic injuries that cause severe unilateral loss of vision may cause bilateral loss if both eyes are involved. The mechanism of injury should be elicited. If there is any possibility of a penetrating injury or rupture of the globe, the involved eye should be protected from further damage by shielding until careful examination can be performed by a skilled physician. If the globe is intact and no penetration by a foreign body occurred, an ophthalmoscopic or slit lamp examination usually leads to the correct diagnosis. These conditions include chemical burns of the cornea, hyphema, dislocation of the lens, vitreous hemorrhage, detachment or tear of the retina, and commotio retinae.

Severe Visual Loss Not Associated with Trauma

With severe bilateral visual loss not associated with trauma, the possibility of toxins must be explored. Also, cortical blindness may cause a similar picture, but this is rare and generally associated with another problem, such as hypoglycemia, leukemia, and cerebrovascular or anesthetic accidents. If severe visual loss is unilateral and painful, endophthalmitis must be suspected, but once again, such loss is usually the result of a previous penetrating injury or an extension of a local infectious process. If a headache is associated with the visual loss, migraine may be implicated. If the severe loss is unilateral and painless, retinal artery or vein occlusion, or retinal detachment, may be diagnosed by ophthalmoscopic examination. Optic neuritis will also present this way.

Mild Visual Loss with Trauma

If the visual loss is unilateral, not severe, and if trauma recently occurred, corneal abrasions, traumatic cataracts, and small hyphemas should be sought. A blowout fracture may cause diplopia, but if each eye is examined individually, the visual acuity should be normal. If the process is bilateral, exposure to ultraviolet or infrared light should be considered.

Mild Visual Loss without Trauma

When the visual loss is mild and nontraumatic, and if the process is unilateral and painful, conjunctivitis, uveitis, and acute attacks of glaucoma are possible. If the process is painless, retinal vein or artery branch occlusion may be suspected. Any of these processes may also be bilateral.

CHAPTER 27 ■ FEVER

ELIZABETH R. ALPERN, MD, MSCE, AND FRED M. HENRETIG, MD

Fever, the abnormal elevation of body temperature, has been recognized for centuries by physicians as a sign of disease. Furthermore, the problem of the febrile child is one of the most commonly encountered in clinical pediatrics, accounting for as many as 20% of pediatric emergency department (ED) visits. Despite such considerable clinical experience, only recently has much progress been made in our understanding of the pathogenesis of fever. The problem of appropriate clinical and laboratory evaluation of febrile children, however, remains a major challenge. The approach outlined in this chapter helps the physician treat a febrile child in the ED and proceed systematically with the appropriate diagnostic steps and management. The principal causes of fever in children are listed in Table 27.1.

PATHOPHYSIOLOGY

Fever is a complex process, involving the highly coordinated interplay of autonomic, neuroendocrine, and behavioral responses to a variety of infectious and noninfectious inflammatory challenges. Fever is believed to be an adaptive response that is ubiquitous in animals. Exogenous pyrogens (e.g., toxins, infectious agents, antigen–antibody complexes) from many sources produce fever by inducing the production of proteins, collectively termed endogenous pyrogens, by phagocytic leukocytes. These are now identified as proteins including interleukin-B1, interleukin-6, tumor necrosis factor-α, and several interferons. These proteins enter the circulation after their synthesis and interact with specialized receptor neurons in the organum vasculosum of the preoptic, anterior hypothalamus, one of the "circumventricular organs" of the brain, which is now understood to have no blood–brain barrier and to function as a neurohumoral receptor. Signaling at this site leads to the production of prostaglandins, particularly PGE_2, monoamines, and probably cyclic adenosine monophosphate. PGE_2 is likely the critical mediator of the febrile response and impacts on preoptic neurons to reset the hypothalamic thermostat thereby initiating several responses. The principle effect is on the vasomotor center and results in peripheral vasoconstriction of cutaneous beds with redirection of blood flow to deeper tissues, thus minimizing skin heat loss. In addition, sweating is decreased; vasopressin secretion falls, which results in lowered extracellular fluid volume that requires heating; and behavioral adjustments, such as shivering and seeking a warmer environment, are stimulated. These effects all combine to elevate body temperature. There is some evidence that increased body temperature impairs replication of many microbes and may aid phagocytic bactericidal activity. The febrile response includes further adaptive neuroendocrine effects. Glucose metabolism is curtailed in favor of that based on lipolysis and proteolysis, thus depriving bacteria of their preferred substrate. Fever-induced anorexia further diminishes glucose availability to microbes. Hepatic production of acute-phase reactant proteins may result in binding of divalent cations, which are also growth factors for microorganisms. All these effects combine to further enhance the host's response to microbial invasion. Rarely, fever results from central nervous system (CNS) dysfunction (e.g., hypothalamic tumor, infarction) that alters the thermostatic set point directly, rather than via pyrogen induction. Finally, sometimes hyperpyrexia is not due to altered hypothalmic regulation, but rather to increased heat production (e.g., stimulant drug overdose—see Chapter 102) or exposure to excess environmental heat (heat stroke—see Chapter 87).

It is difficult to pinpoint the lowest temperature elevation considered to be definitely abnormal for all children under all circumstances. Some children normally have rectal temperatures as low as 36.2°C (97°F) or as high as 38°C (100.4°F). Children, like adults, also have diurnal variations in temperature, with the peak usually occurring between 5 p.m. and 7 p.m. This variation is less pronounced in infants. In the 2- to 6-year age range, the temperature may vary by 0.9°C (1.6°F), and in children older than 6 years of age, diurnal variation may span 1.1°C (2°F). Factors such as excessive clothing, physical activity, hot weather, digestion of food, and ovulation can raise temperature in the absence of disease. For the appropriately dressed child who has been at rest 30 minutes, a rectal temperature of 38°C (100.4°F) is defined as fever for this discussion. Using the proper technique to record rectal temperature is important for maximum accuracy. Optimal technique includes appropriate positioning and restraint in infants (prone, supine, or on the side with hips slightly flexed), depth of insertion (about 2 to 3 cm), and time for equilibration (2 to 3 minutes with glass thermometers or several seconds with electronic digital probes). The thermometer should not be placed directly into a fecal mass because the fecal temperature may not have equilibrated with rapid fluctuations in core temperature and thus may be falsely low as temperature rises rapidly. Oral and axillary temperatures are usually about 0.6°C (1°F) and 1.1°C (2°F) lower than rectal temperatures, respectively. More recent attempts to measure temperature with a less invasive technique include temperature-sensitive pacifiers and forehead strips, both of which have been found to be unreliable. However, infrared tympanic membrane thermometry has been more recently adopted in many settings; the tympanic membrane shares vascular supply with the hypothalamus, and it has been shown in adult intensive care settings that there is excellent correlation between core temperature (e.g., pulmonary artery catheter) and tympanic membrane

TABLE 27.1

PRINCIPAL CONDITIONS IN CHILDREN ASSOCIATED WITH FEVER

- Infections
  - Central nervous system
    - Meningitis
    - Encephalitis
    - Brain abscess
  - Ocular
    - Periorbital (preseptal) cellulitis
    - Orbital cellulitis/abscess
  - Airways and upper respiratory tract
    - Common cold (upper respiratory infection)
    - Pharyngitis/tonsillitis
    - Otitis media
    - Acute cervical adenitis
    - Acute sinusitis
    - Peritonsillar, retropharyngeal, lateral pharyngeal wall abscess
    - Croup
    - Epiglottitis
  - Oral cavity and salivary glands
    - Alveolar abscess
    - Viral stomatitis (herpangina, herpetic gingivostomatitis)
    - Parotitis (mumps, acute suppurative parotitis)
  - Pulmonary
    - Bronchiolitis
    - Pneumonia
    - Bronchitis
    - Pulmonary tuberculosis
    - Lung abscess
  - Cardiac
    - Myocarditis
    - Endocarditis
    - Pericarditis
  - Gastrointestinal
    - Acute gastroenteritis (viral, salmonella, shigella)
    - Appendicitis
    - Peritonitis
    - Pancreatitis
    - Acute mesenteric adenitis
    - Hepatitis
    - Cholangitis
    - Intraabdominal abscesses
  - Genitourinary
    - Urinary tract infection/pyelonephritis
    - Perinephric abscess
    - Acute salpingitis, tuboovarian abscess
    - Acute prostatitis
    - Epididymitis, orchitis
  - Musculoskeletal
    - Septic arthritis
    - Osteomyelitis
    - Myositis
  - Skin and soft tissue/Lymphoid
    - Abscess (methicillin-resistant *Staphylococcus aureus*, methicillin-sensitive *S. aureus*, group A *Streptrococcus*)
    - Cellulitis
    - Necrotizing fasciitis
    - Exanthems (systemic infections usually associated with prominent rashes)
      - Viral: roseola, rubeola, rubella, varicella, hand–foot–mouth disease (Coxsackievirus)
      - Bacterial toxin: scarlet fever
      - Syphilis (secondary)
      - Meningococcemia (occasionally other primary septicemia)
      - Rocky Mountain spotted fever
      - Lymphadenitis
  - Systemic infections
    - Bacterial sepsis (primary—especially meningococcemia)
    - "Occult bacteremia" (especially pneumococcal)
    - Viruses (Epstein-Barr, adenovirus)
    - Lyme disease
    - Rickettsial (Rocky Mountain spotted fever, ehrlichiosis), chlamydial, fungal, parasitic, and unusual bacterial infections
    - Toxic shock syndrome
    - Miliary tuberculosis
- Vasculitis Syndromes and Hypersensitivity Phenomena
  - Acute rheumatic fever
  - Juvenile rheumatoid arthritis
  - Systemic lupus erythematosus
  - Polyarteritis nodosa
  - Kawasaki syndrome
  - Dermatomyositis/polymyositis
  - Mixed connective tissue disease
  - Henoch-Schönlein purpura
  - Serum sickness
  - Stevens-Johnson syndrome
  - Drug and immunization reactions
- Neoplasms
  - Leukemia
  - Neuroblastoma
  - Lymphoma
  - Ewing's sarcoma
- Poisonings and Drug Reactions
  - Sympathomimetics (e.g., amphetamines, cocaine)
  - Anticholinergics (e.g., antihistamines, tricyclic antidepressants, atropinic alkaloids)
  - Salicylates
  - Malignant hyperthermia
  - Serotonin syndrome
  - Neuroleptic malignant syndrome
  - Alcohol/sedative–hypnotic withdrawal
- Central Nervous System (CNS) Disorders
  - CNS lesions in hypothalamus/brainstem
  - Prolonged seizures
  - Riley-Day syndrome
- Metabolic Diseases
  - Thyrotoxic crisis
  - Etiocholanolone fever
  - Acute intermittent porphyria
- Miscellaneous Conditions
  - Dehydration
  - Intravascular hemolysis
  - Hemorrhage into an enclosed space
  - Anhydrotic ectodermal dysplasia
  - Extreme environmental heat excess
  - Hereditary periodic fever syndromes
  - PFAPA (periodic fever, aphthous stomatitis, pharyngitis, adenitis)
  - Cyclic neutropenia
  - Sarcoidosis
  - Inflammatory bowel disease
  - Factitious
  - Major trauma (crush injuries)
  - Other rare causes

readings. Several studies in children have confirmed the reliability of this technique compared with rectal temperature, although others have questioned the accuracy of tympanic measurements in young infants, especially those younger than 3 months of age. The presence of otitis media (OM) or cerumen does not seem to affect reliability adversely. Temporal artery thermometry has also been recently studied, and though it is more accurate than tympanic thermometry in young children, it has limited sensitivity for detecting temperatures in the fever range. Because even low-grade fever may be clinically significant in young infants and there is at least some doubt about the reliability of axillary, tympanic, or temporal artery measurements in this age group, rectal temperatures should be obtained in this population.

EVALUATION AND DECISION

The importance of fever lies in its role as a sign of disease. The physicians caring for a febrile child should concentrate on discovering the cause of the fever and treating the underlying illness. Any fever may signify serious infection; however, hyperpyrexia, defined as a temperature of 41.1°C (106°F) or higher, is more often associated with diagnoses of pneumonia, bacteremia, or meningitis. As the risk of serious bacterial infection is higher with hyperpyrexia in children, a more thorough assessment for possible bacterial etiology and consideration of empiric antibiotics is indicated. However, the magnitude of reduction of fever in response to antipyretics does not distinguish children with serious bacterial illnesses from those with viral diseases. If no specific treatment for the determined diagnosis is necessary, the physician's goal is then to provide appropriate supportive care and follow-up. Because many parents have "fever phobia," instructions that explain the importance of fever as an indicator of disease, not as an inherently harmful entity, should be given.

A complete *history and physical examination* will provide the most important clues in determining the diagnosis of children with febrile illnesses. The *general impression* obtained in the first few moments of an evaluation is extremely important in the recognition of potentially life-threatening causes of fever (Table 27.2). A great deal of information can be attained by visual assessment of the child while in the arms or lap of the parent. The severity of the illness may become apparent if the child is agitated or uninterested in the surroundings while in this comfortable, safe position. If the child appears nontoxic, observation of the child while the *history* of the present illness and past medical history is being discussed may provide further insight into the diagnosis. Fever has different management implications for distinct subsets of children. Therefore, a clear understanding of the degree, mode of measurement, and duration of fever is especially important in the initial evaluation. The physician should ask questions concerning associated signs and symptoms, medications being given (including antipyretics and antibiotics), presence of ill contacts, travel history, and pet or insect exposures. The medical history should focus on recurrent febrile illnesses and the presence of any diseases or drug regimens that would compromise normal host defenses, such as sickle cell anemia, asplenia (functional, congenital, or surgical), malignancy (noting particularly chemotherapeutic or radiation treatments), human immunodeficiency virus (HIV), renal disease, prolonged steroid use, or indwelling catheters or ventriculoperitoneal shunts. Immunization status should also be determined. An understanding of prior evaluation and treatments during this illness may be helpful.

TABLE 27.2

LIFE-THREATENING ACUTE FEBRILE ILLNESSES

- Infection
  - Central nervous system
    - Acute bacterial meningitis
    - Encephalitis
  - Upper Airway
    - Acute epiglottitis
    - Retropharyngeal abscess
    - Laryngeal diphtheria (rare)
    - Croup (severe)
  - Pulmonary
    - Pneumonia (severe)
    - Tuberculosis, miliary
  - Cardiac
    - Myocarditis
    - Bacterial endocarditis
    - Suppurative pericarditis
  - Gastrointestinal
    - Acute gastroenteritis (fluid/electrolyte losses)
    - Appendicitis
    - Peritonitis (other causes)
  - Musculoskeletal
    - Necrotizing myositis (gas gangrene)/fasciitis
  - Systemic
    - Meningococcemia
    - Other bacterial sepsis
    - Rocky Mountain spotted fever
    - Toxic shock syndrome
- Collagen-vascular
  - Acute rheumatic fever
  - Kawasaki syndrome
  - Stevens-Johnson syndrome
- Miscellaneous
  - Thyrotoxicosis
  - Heat stroke
  - Acute poisonings and drug reactions: sympathomimetics, anticholinergics, salicylate, serotonin syndrome, neuroleptic malignant syndrome, malignant hyperthermia, alcohol/sedative-hypnotic withdrawal
  - Malignancy

As stated previously, the *physical examination* of the young febrile patient begins during the interview with the caregiver. The physician should note the child's alertness, responsiveness to persons and objects, work of breathing, color, feeding activity, and age-related appropriateness of social interaction and gross motor functions. The *febrile infant who appears irritable and/or lethargic* while being held by a parent before the examination has a high probability of having a serious infection such as meningitis or sepsis. The complaint or observation that a child's crying increases with parental attempts to comfort is critical because "paradoxical irritability" is an important sign of meningitis in infancy.

Other signs of severe or life-threatening infections heralded by fever should be sought early in the examination. CNS infections may be marked by fever with altered sensorium, convulsion,

meningismus, or focal neurologic deficits. However, infants younger than 2 years of age with meningitis may not have meningismus, but they may instead have irritability, somnolence, a bulging fontanel, or nonspecific symptoms such as anorexia, lethargy, or vomiting. Severe upper airway infections may present with stridor, excessive drooling, and tripod positioning. A child with pneumonia, pericarditis, endocarditis, or sepsis syndrome may display tachycardia, dyspnea or tachypnea, cyanosis or pallor, poor perfusion or hypotension, as well as altered mental status. Hemorrhagic rashes may signal bacterial or rickettsial infections such as meningococcemia or Rocky Mountain spotted fever.

Although the index of suspicion for serious febrile illness must be high throughout the evaluation of each child, most childhood illnesses with fever are minor and self-limiting. Once the physician has ascertained that the child is not in immediate danger, the examination should focus on sites of common pediatric infections, including the ears, nose, and throat; cervical lymph nodes; respiratory, gastrointestinal, and genitourinary tracts; and skin, joints, and skeletal system (Table 27.3). Evaluation of each child is developed with an understanding of the common infectious entities that affect that child's age group and the presenting signs and symptoms or lack thereof in each infectious entity (see Chapter 92 for a full discussion of infectious diseases).

Many febrile exanthems are characteristic enough to be diagnostic (see Chapters 62–67 and 92). Varicella, rubeola, scarlet fever, and coxsackievirus can all be identified by their pathognomonic rashes. However, if a child with chickenpox presents several days into the illness with a new fever, the possibility of group A β-hemolytic streptococcal or *Staphylococcus aureus* superinfection should be considered. Children with *fever and petechiae* may have invasive meningococcal disease, disseminated streptococcal infection, or Rocky Mountain spotted fever; however, they may simply have a less serious viral infection or streptococcal pharyngitis. Differentiation of these entities is crucial and is based on clinical appearance of the patient and laboratory evaluation. A child with only a few petechiae (especially if only above the nipple line), normal white blood cell (WBC) count, normal platelet count, and well appearance is less likely to have invasive disease. However, any child who appears ill, has distinctly abnormal laboratory results, or has a rapidly progressive petechial rash needs a more complete evaluation for sepsis or meningitis and should receive antibiotics. A patient with fever and diffuse erythroderma should be evaluated carefully for hemodynamic instability or other signs and symptoms of toxic shock syndrome.

On physical examination, acute otitis media is identified by the acute onset of otalgia or fever with changes in the tympanic membranes, such as redness, bulging, decreased mobility, loss of landmarks and light reflex, air–fluid level behind the tympanic membrane, or purulent drainage from a perforation. Careful examination of the head and neck may reveal rhinorrhea and signs of inflammation, suggesting a viral upper respiratory infection (URI). The oropharynx may reveal pharyngitis or stomatitis (see Chapters 48 and 71). Children with a history of a recent respiratory infection may have reactive, tender, swollen cervical lymph nodes; asymmetric enlargement of nodes especially with tenderness and overlying erythema might indicate bacterial adenitis. Croup is readily identified by a barky cough with or without stridor in young children, whereas a distinctive "hot potato voice" with unilateral tonsillar swelling in adolescents indicates a peritonsillar abscess. Wheezing, tachypnea, and fever in infants usually mark bronchiolitis. Pneumonia often presents with cough, fever, tachypnea, ausculatory findings, and hypoxemia. Mild abdominal pain or tenderness, vomiting, and/or diarrhea may suggest viral gastroenteritis or early

TABLE 27.3

COMMON CAUSES OF FEVER

- Infections
  - Central nervous system
    - Acute bacterial meningitis
    - Viral meningoencephalitis
  - Ocular
    - Periorbital cellulitis
    - Orbital cellulitis
  - Upper respiratory tract
    - Common cold
    - Pharyngitis/tonsillitis
    - Cervical adenitis
    - Croup
    - Acute sinusitis
    - Otitis media
  - Oral cavity and salivary glands
    - Alveolar abscess
    - Herpangina
    - Herpetic gingivostomatitis
    - Mumps (unimmunized child)
  - Pulmonary
    - Acute tracheobronchitis
    - Bronchiolitis
    - Pneumonia
  - Gastrointestinal
    - Acute gastroenteritis
    - Appendicitis
  - Genitourinary
    - Urinary tract infection
    - Acute salpingitis
    - Tuboovarian abcess
  - Musculoskeletal
    - Septic arthritis
    - Osteomyelitis
  - Skin and soft tissue/Lymphoid
    - Abscess
    - Cellulitis
    - Lymphadenitis
    - Miscellaneous systemic infections associated with prominent rash (e.g., meningococcemia and Rocky Mountain spotted fever)
    - Scarlet fever
    - Viral exanthems (especially varicella, measles if unimmunized)
  - Systemic
    - Primary septicemia—especially meningococcemia
    - "Occult" bacteremia
    - Viral syndromes
    - Vector-borne disease—especially Lyme disease
    - Toxic shock syndrome
- Miscellaneous
  - Drug and vaccine reactions, including serum sickness
  - Kawasaki syndrome
  - Amphetamine, cocaine, salicylate poisoning

hepatitis or pancreatitis. More severe findings, particularly the occurrence of peritoneal signs, may indicate appendicitis, intraabdominal abscess, or peritonitis from other causes (see Chapters 49 and 121). However, in children, fever with abdominal pain may also represent lower lobe pneumonia, streptococcal pharyngitis, urinary tract infection (UTI), gastroenteritis, or mesenteric adenitis. Additional findings in UTI may include suprapubic or costovertebral angle tenderness (see discussion below and in Chapter 92). Adolescent girls with pelvic or abdominal pain and fever should be evaluated for pyelonephritis and pelvic inflammatory disease (see Chapter 90). Differentiation of these diverse diagnoses depends on a thorough history, physical examination, and at times, well-directed laboratory evaluation (see Chapter 92).

Continued advancements in *immunizations* have changed the frequency and risk of certain febrile illness in children. The Centers for Disease Control and Prevention report that the *Haemophilus influenzae* type B (Hib) vaccine has drastically changed the risk and causative agents for meningitis in children. There has been a 94% reduction in the incidence of *H. influenzae* meningitis and a shift in the median age of those affected from 15 months to 25 years of age. The current rarity of epiglottitis in children is also due to this decline in *H. influenzae* infections. In addition, a heptavalent pneumococcal conjugate vaccine (PCV) was licensed in 2000. Prior to the availability of this vaccine, 70% of invasive *Streptococcus pneumoniae* infections in children younger than 5 years of age presented as bacteremia without a focus of infection. This vaccine has significantly decreased the risk of invasive pneumococcal diseases in children. However, there has been an overall small, but not inconsequential, increase in invasive bacterial infections in children due to pneumococcal serotypes not contained within the heptavalent vaccine. Recognition of these epidemiologic changes is crucial in evaluating and treating the febrile child. Children between 2 and 18 years of age who have bacterial meningitis will now most likely be infected with *Neisseria meningitides* or nonvaccine serotype *S. pneumoniae*. These findings obviously influence the evaluation and treatment of febrile children with signs of meningitis, as well as those young children without an identified source of infection after thorough historical and physical examination.

Occult bacteremia is the presence of pathogenic bacteria in the blood of a well-appearing febrile child in the absence of an identifiable focus of infection (see Chapter 92). Children with occult bacteremia may develop serious bacterial infections such as septic arthritis, osteomyelitis, meningitis, or sepsis. Children most commonly suspected to be at risk for occult bacteremia are those between the ages of 2 and 36 months with a fever of 39°C (102°F) or higher. Infants younger than 2 months of age are at increased risk for invasive disease and therefore necessitate different evaluation and treatment. The reported incidence of occult bacteremia among highly febrile young children before the initiation of the Hib vaccine program was between 3% and 10%. However, studies in the post-Hib, pre-PCV era showed that the prevalence of occult bacteremia in this group decreased to 1.6%–1.8% and was predominately due to *S. pneumoniae*. As mentioned previously, with the licensure of the PCV, rates of invasive pneumococcal infections including occult bacteremia have decreased. Studies from the post-PCV era indicate the risk of occult bacteremia in immunized children to be less than 1%.

Given these general considerations, an algorithmic *approach to the child with an acute* (less than 5 days) *febrile illness* can be formulated, using the following *key features*: overall degree of *toxicity* and presence of signs or symptoms of life-threatening disease, immunocompromised *host status*, patient's *age*, *degree of fever*, and presence of *localizing features* on history and physical examination (Fig. 27.1). Laboratory studies are indicated only for selected situations as defined by these clinical features. Most older febrile children do not need routine laboratory testing.

Infants younger than 2 months of age are at increased risk of serious bacterial infections and bacteremia and are more difficult to assess clinically than older children. Thus, for children with fevers of 38°C (100.4°F) or higher who are younger than 2 months of age, many authorities recommend a laboratory investigation for serious infection ("sepsis workup"), including complete blood cell count (CBC), blood culture, urine analysis, urine culture, and lumbar puncture with cerebrospinal fluid (CSF) for cell count, glucose, protein, Gram stain, and culture. Some of these authorities support the same evaluation for infants up to 3 months of age; regardless of the exact age parameter, most clinicians base their approach on one of the several published guidelines for managing febrile infants. Herpes simplex virus polymerase chain reaction (PCR) or culture with presumptive antiviral treatment should be considered in neonates with historical concerns or physical findings of skin, eye, or mouth lesions; respiratory distress; seizures; signs of sepsis; or CSF pleocytosis. Stool for leukocytes and culture should be obtained if diarrhea is present. Respiratory findings are good predictors of clinically significant positive chest radiographs in children younger than 3 months; therefore, chest radiographs may be obtained only when there are clinically evident respiratory signs. Clinical examination alone, without further laboratory evaluation, is generally not considered sensitive enough to identify serious illness in these very young infants. In addition, the peripheral blood WBC count has been shown to be inadequate as an indicator of young febrile infants at risk for meningitis. Biomarkers, including procalcitonin and C-reactive protein, have been recently evaluated as predictors of serious bacterial infection in febrile young infants. Further evaluations of these markers alone and in combination with existing algorithms may provide improved prediction of serious bacterial infection in newborns and young infants. Infants younger than 1 month are usually admitted to the hospital for observation with presumptive antibiotic therapy after full evaluation as noted above in the ED. Many studies (Baker et al., Baskin et al., Dagan et al., Jaskiewicz et al., Garra et al.) found that children between 1 and 2 months of age, who are not pretreated with any antibiotics and who have a pristine physical examination and completely benign laboratory evaluation, may be safely discharged home with careful observation and close follow-up. For such a disposition, parents should be able to watch the infant closely for changes in symptoms, should have ready access to health care, and should be willing to return for evaluation. These studies found that either close observation without antibiotics (e.g., Baker et al.) or after empiric intramuscular ceftriaxone (e.g., Baskin et al.) are safe and effective management strategies in this age group.

Recent work has concentrated on the evaluation of the febrile young infant or child with signs and symptoms suggestive of

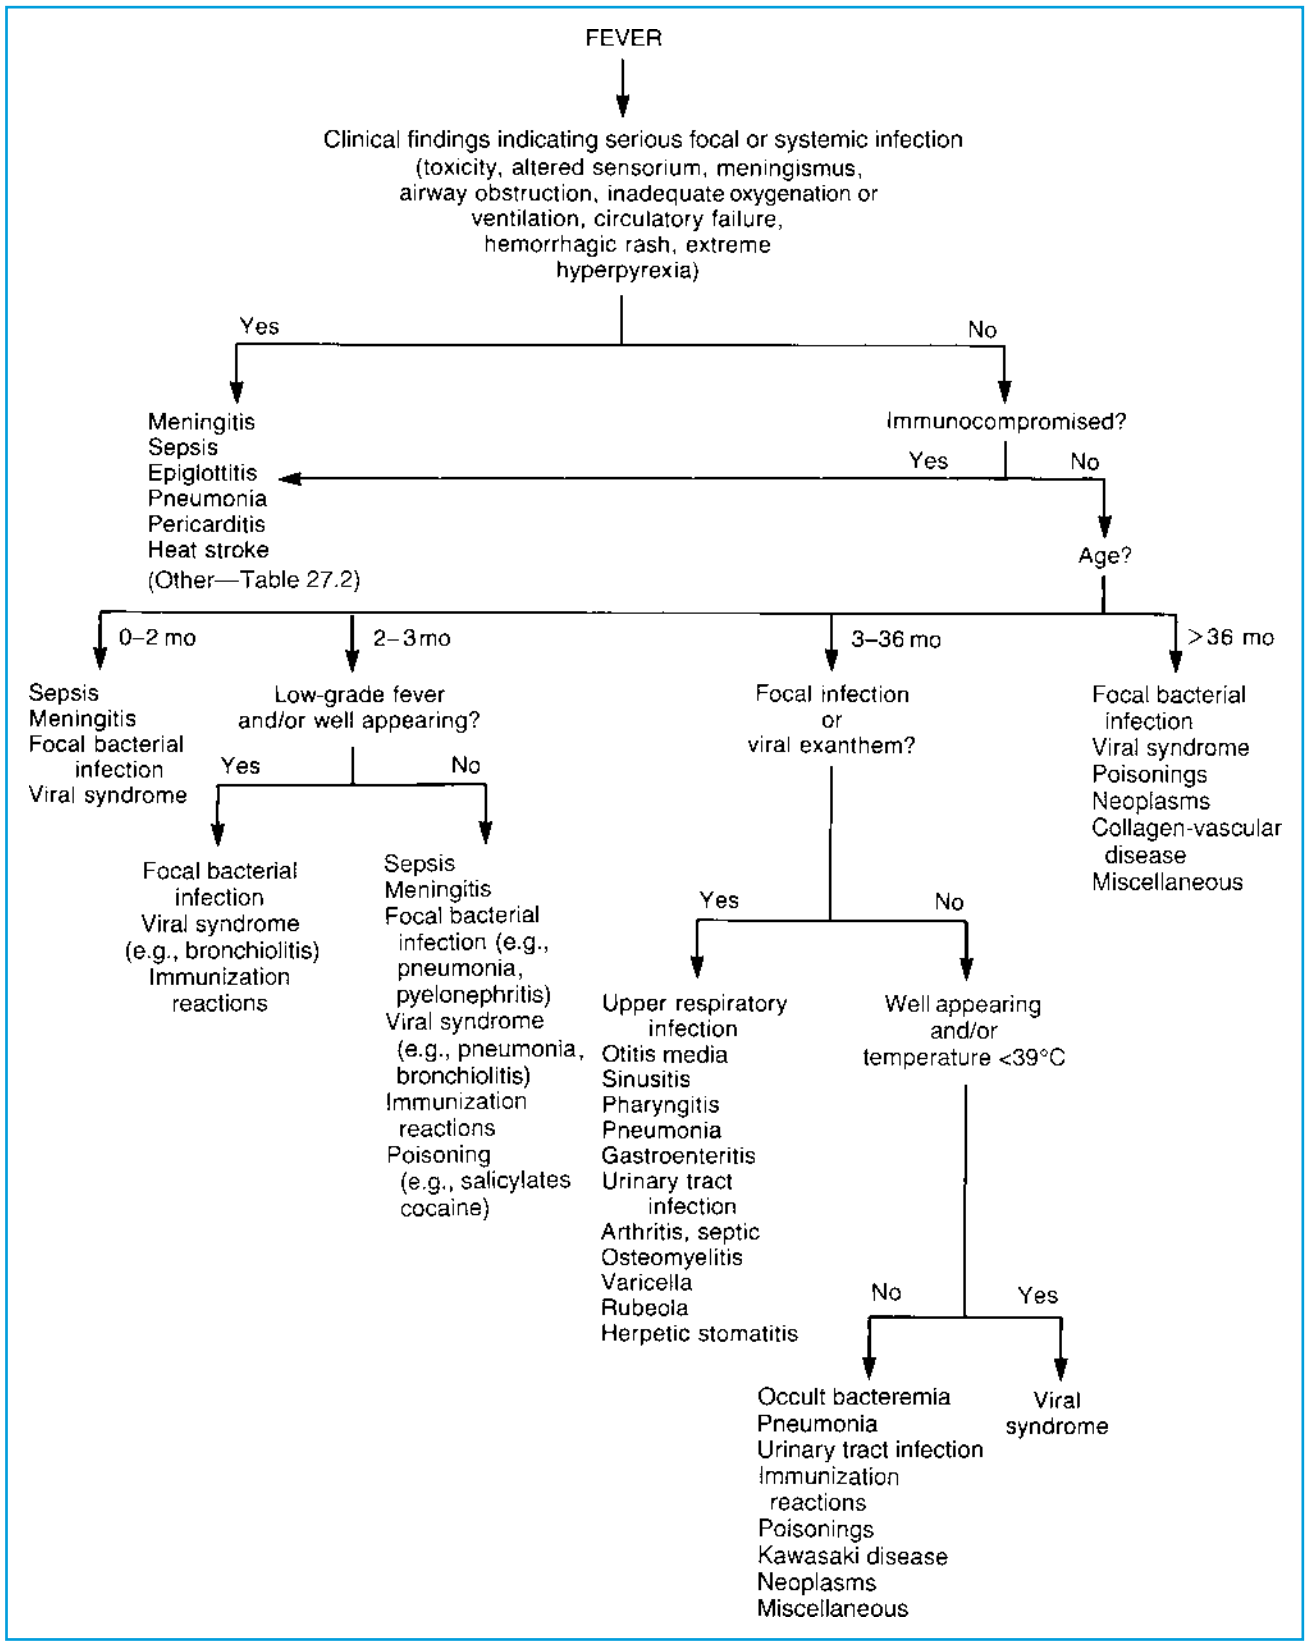

FIGURE 27.1 Approach to the evaluation of the febrile child.

bronchiolitis. Several studies showed that bacteremia is unlikely in the face of a clinical diagnosis of bronchiolitis. In the well-appearing child with bronchiolitis who is to be treated as an outpatient, the risk of occult bacteremia is exceedingly low. However, the rate of occult UTI is still significant in children with concurrent bronchiolitis, although less than in children without a source of fever. Therefore, evaluation for UTI should still be considered in the very young infant with fever and clinical signs of bronchiolitis.

An additional dilemma involves the very young baby who presents to the ED with a description of either tactile fever alone or fever confirmed by rectal temperature at home but who is afebrile on arrival. This situation was studied by Bonadio et al., who found that the history of tactile fever in such infants did not correlate with subsequent fever, whereas an elevated rectal temperature at home correlated with subsequent fever in 20% of such patients. However, all infants who were found to have serious bacterial infections (including five who were afebrile on presentation) were observed to have had an abnormal initial clinical profile and/or laboratory workup. Although there is no consensus on the approach to this situation, it seems prudent to consider a careful clinical evaluation in all young infants with a history of fever, including one or more repeat temperatures over 1 to 2 hours in the ED after the baby is unbundled. If there is a reliable history of elevated rectal temperature, a sepsis workup should be seriously considered, as described above, along with a subsequent disposition based on the clinical findings, and laboratory results. The infant with only a history of tactile fever whose repeated temperatures are normal and who has an entirely normal clinical evaluation may be assessed as not requiring laboratory studies. All such infants discharged home warrant close follow-up and appropriate short-term monitoring of rectal temperature.

The *febrile child between 2 and 36 months of age* with signs suggesting a serious focal infection (e.g., irritability, meningismus, tachypnea, flank tenderness) should be evaluated with the appropriate diagnostic tests and treated for any identified source. Of course, any child with signs or symptoms of lower pulmonary disease should be evaluated with a chest x-ray. An association between pneumonia and fever greater than 39°C with a WBC greater than 20,000 per mm^3 in the absence of signs of pulmonary disease has also been suggested. Therefore, if a CBC has been obtained and there is marked increase in WBC count, a chest x-ray should be considered. If the child has neither clinical findings of pulmonary disease nor the constellation of high fever associated with leukocytosis, there is no need to perform a chest x-ray. Consideration should be given for occult UTI (see discussion below and Chapter 92) generally with a urinalysis and culture in females younger than 2 years of age and males younger than 6 months of age (less than 12 months if uncircumsized). Risk factors for UTI include the absence of a potential alternative source, prolonged fever, female or Caucasian patient, and temperature greater than 39.0°C. Rapid viral testing can be indicated with specific symptoms or signs of a viral illness. Several recent investigations have shown a decreased risk of bacterial infections with positive rapid tests for specific viruses. Despite positive viral tests, children should be evaluated for secondary bacterial infection through careful examination, especially those patients who have an atypical course based on their duration or severity of their symptoms.

However, if the child between 2 and 36 months of age with a temperature of 39°C (102°F) or higher does not have localizing symptoms or laboratory/radiograph results (when performed) indicative of definitive focal infection, the child should be assessed for the risk of occult bacteremia especially if younger than 6 months of age or not fully immunized for Hib and *S. pneumoniae* (see Chapter 92). A "well" clinical appearance does not decrease the risk for occult bacteremia (otherwise the bacteremia would not be "occult"). Historically, some febrile children, 2 to 24 or 36 months of age, with temperatures greater than 39°C (102°F) and no clear source of infection were evaluated with a CBC and blood culture for risk of occult bacteremia. The WBC count was used by some to determine the risk of occult bacteremia and guide empiric antibiotic use. However, as the risk of occult bacteremia has decreased, the previous strategy of screening has become less valuable. Currently, in an immunized population, a detailed history and physical examination and close follow-up is advocated.

Although in older children, UTIs are accompanied by signs and symptoms such as dysuria, frequency, urgency, incontinence, vomiting, or abdominal, suprapubic, and/or flank pain, in young children fever may be the only sign of a UTI. As the risk of occult bacteremia has fallen in young children with fever without identifiable source of infection, UTIs have become the most common bacterial infection. Studies have established the overall prevalence of occult UTI in young children without an identified source of infection to be between 3% and 9%. The risk is highest in febrile non-black girls younger than 2 years of age and in uncircumcised boys younger than 1 year of age. Renal scarring is associated with a febrile UTI in young children and may lead to further sequelae such as hypertension and renal insufficiency. Therefore, laboratory testing to evaluate for occult UTI is indicated for at-risk young febrile children without an identifiable focus of infection. Certainly any febrile child with a history of UTI should be considered to be at risk for a recurrence. For children without a prior history or overt signs of UTI, one approach is to obtain a urinalysis and urine culture in febrile boys younger than 6 months of age and in any age febrile boy who is uncircumcised and not yet toilet trained. Febrile girls younger than 2 years of age should be considered for urine studies if any two of the following characteristics are present: fever of 39°C (102.2°F) or higher, 1 year of age or younger, non-black race, fever lasting 2 days or longer, or no identifiable source of infection. Aseptic urethral catheterization or suprapubic aspiration is an appropriate method to obtain urine for the diagnosis of UTIs. Urine dipstick and culture should be performed for all children at significant risk for occult UTI (see Chapter 92).

Children older than 36 months of age can usually be managed on the basis of degree of irritability, evidence of meningeal signs, and/or other foci of infection found on history and physical examination. These children need not be screened routinely for occult bacteremia or other occult infections. After excluding meningitis, there are several important infections that may be present in ill-appearing, febrile children in this age group, without obvious initial focus. These include meningococcemia, Rocky Mountain spotted fever, and pyelonephritis (see Chapter 92). Early institution of presumptive therapy may be lifesaving in some of these situations, so their possibility must be borne in mind with toxic, febrile children at any age.

Simple febrile seizures occur in 3% to 5% of all children (see Chapter 69). They are defined as generalized tonic-clonic seizures without focal neurologic findings, occurring only once per febrile illness (usually in the first 12 hours of onset of fever) in children 6 months to 5 years of age and lasting less than 15 to 20 minutes in duration. By definition, they are seizures accompanied by fever that occur in children without CNS infection or other underlying cause. The dilemma that faces the emergency physician is to decide whether a febrile seizure is truly such, or if a child presenting with a fever and seizure requires a lumbar puncture to rule out meningitis. Green et al. reviewed 503 cases of meningitis in children 2 to 15 years of age and noted that no cases of bacterial meningitis presented solely as a seizure without any other neurologic signs or symptoms (nuchal rigidity, irritability, prolonged seizure activity, or multiple seizures). Kimia reviewed more than 700 patients with first simple febrile seizure and identified no cases of bacterial meningitis. The decision to perform a lumbar puncture should be determined by the presence of signs or symptoms of meningitis or other CNS infection. As such, any child with irritability, lethargy, abnormal mental status findings after a usual postictal period, or signs of meningitis such as bulging fontanel, should have a lumbar puncture performed. Particular care should be taken in the assessment of children younger than 12 months of age (because of the difficulty in recognizing signs and symptoms of meningitis in very young infants) and in children pretreated with antibiotics (because symptoms of partially treated meningitis may be minimal or absent). Children with atypical or complex febrile seizures should be closely evaluated for CNS infection.

Other causes of acute febrile episodes should be kept in mind, including intoxications, environmental exposure, and immunization reactions. *Toxic exposures*, particularly aspirin, anticholinergics, and sympathomimetics (e.g., amphetamines, cocaine, and methylenedi-oxymethamphetamine or "ecstasy"), may present with severe hyperpyrexia (see Chapter 102). Additional uncommon febrile drug reactions include the *serotonin syndrome* occurring with the combined use of monoamine oxidase inhibitors and analgesic, antitussive, or psychotropic serotonergic medications (e.g., meperidine, dextromethorphan, fluoxetine), and the *neuroleptic malignant syndrome* (see Chapter 102). History of environmental heat exposure preceding severe hyperpyrexia may represent *heat stroke* rather than an infectious cause for the increased temperature (see Chapter 87). Therapeutic exposure to the antiepileptic drug zonisamide can result in oligohydrosis and severe resultant heat stroke. The diphtheria–pertussis–tetanus *immunization* is associated with fever that occurs within 48 hours (occurring less often with diphtheria, tetanus, acellular pertussis vaccine administration), as is the conjugate pneumococcal vaccine administration. Fever, at times accompanied by a faint rash, may occur 7 to 10 days after immunization with the live-attenuated measles vaccine or the measles–mumps–rubella vaccine.

Fevers of unknown origin (FUOs) are defined as daily temperatures of 38.5°C (101.3°F) or higher for at least 2 weeks without discernible cause. Many children evaluated for FUOs actually have consecutive unrelated viral illnesses. Infections commonly causing prolonged fever in children include Epstein-Barr virus infections, osteomyelitis, *Bartonella henselae* infections (cat-scratch disease), UTIs, Lyme disease, and HIV. Although consecutive viral illnesses are the most common etiology for recurrent fevers in a child, occasional cases are due to *periodic fever syndromes* that are marked by recurrence of fever at regular intervals, affecting the child over a period of years. PFAPA (periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis), familial Mediterranean fever, or cyclic neutropenia are in the differential for the diagnosis of the child with recurrent, intermittent fevers.

Additional noninfectious causes of prolonged fever include neoplasms, collagen vascular diseases, and inflammatory disorders (ulcerative colitis or Crohn's disease).

Symptomatic Treatment

In general, antipyretic therapy should parallel the pathophysiologic basis of the fever. When the fever is caused by altered hypothalamic set point, as in infection, antigen–antibody reactions, and malignancy, attempts to reset the "thermostat" with antipyretic medications are most likely to enhance patient comfort. Antipyretics work via the inhibition of hypothalamic prostaglandin synthesis. If fever is caused by imbalance of heat production and heat loss mechanisms, such as in heat stroke, urgent cooling by physical removal of heat is necessary, such as with ice-water baths, and antipyretics will not help (see Chapter 87). Rarely, a patient with infection will have extreme hyperpyrexia [temperature of 41.1°C (106°F) or higher] and will require urgent temperature reduction with both antipyretics and external cooling. Patients with ongoing febrile seizures also warrant rapid treatment with antipyretics and external cooling, although tepid to cool water sponging is usually sufficient. However, children at risk for recurrent febrile seizures do not, unfortunately, tend to be protected by rapid use of "prophylactic" antipyresis at first sign of fever.

Acetaminophen and ibuprofen are currently the most commonly used pediatric antipyretic medications in the United States (aspirin is no longer recommended for routine antipyretic use in children because of its potential to cause severe gastrointestinal bleeding and its implication as an etiologic risk factor for Reye's syndrome). The current dosage recommendation for acetaminophen is 10 to 15 mg per kg given every 4 to 6 hours, with a maximum of four doses per day, resulting in 40 to 60 mg per kg per day. Several reports and reviews have stressed that, although very rare, repetitive dosing of acetaminophen at the upper limit of, or just slightly above, recommended dosages may result in severe or fatal fulminant hepatic failure. This is particularly the case for children who were fasting (e.g., because of vomiting or diarrhea with febrile illness), younger than age 2 years, treated for several days, or treated with adult-intended preparations.

Ibuprofen is typically dosed at 5 to 10 mg per kg per dose, given every 6 to 8 hours, with a maximum of four doses per day (e.g., 30 to 40 mg per kg per day). Several studies have found that ibuprofen is more effective in reducing fever, especially in single-dose comparisons at 4 and 6 hours after administration, than acetaminophen at commonly used doses of each agent. However, the difference narrows and is, in our view, of little clinical significance for most patients when antipyretic therapy is used repetitively over 12 to 24 hours or more, as typically prescribed for most childhood febrile

illnesses (e.g., Hay et al, 2008). Theoretical concern that widespread use of ibuprofen in children might manifest a significantly increased incidence of serious gastrointestinal bleeding, renal failure, or allergic reactions relative to acetaminophen has not been borne out in large, prospective studies (Lesko and Mitchell, 1995). Nevertheless, ibuprofen has been rarely associated with acute renal dysfunction when it was used in children with dehydration. An additional concern with ibuprofen is that its antiinflammatory activity in the treatment of routine febrile illnesses, particularly varicella, might predispose to invasive bacterial, particularly streptococcal, disease. Although not proven to be causally related, it might still be prudent to avoid ibuprofen in such cases of suspected or at-risk streptococcal disease, as well as for children at risk of dehydration. Several studies in the past decade have evaluated the practice of combining or alternating ibuprofen and acetaminophen (Hay et al., Kramer et al, Sarrell et al.). In general, these have found modest increments in antipyretic effect without an increase in observed short-term drug toxicity. However, many commentators (Schmitt, Serwint) have noted that "real-world" safeguards are not equivalent to those enforced in prospective studies, that such complicated regimens pose considerable potential for parental confusion and overdosing, and that they may well add to unreasonable "fever phobia." Thus, our practice is to avoid prescribing such regimens for routine antipyresis, but rather to consider dual therapy in exceptional cases. If instituted, it is prudent to use sub-maximal doses of each agent (acetaminophen 12.5 mg per kg per dose alternating with ibuprofen 5 mg per kg per dose every 4 hours, with a 3 dose per day limit of each) and only with the provision of very detailed instructions and precautions. It is important to remember that many parents greatly fear even moderately high fever in their children and require reassurance that the fever itself, in its usual range of severity, does not cause damage. They need education about appropriate indications for antipyretic treatment, particularly seeking to reduce fever-associated discomfort, rather than a modestly elevated temperature itself. They need further education about appropriate, safe antipyretic dosing regimens, the lack of urgency in treating fever (unless temperature goes above 41.1°C (106°F) or there are prolonged febrile seizures), and most important, the concept that the overall well-being of the child, in context with age, is usually far more important than the temperature per se.

CHAPTER 28 ■ FOREIGN BODY—INGESTION/ASPIRATION

JEFF E. SCHUNK, MD

Through play, experimentation, and daily activities, children are likely to place foreign bodies just about anywhere. Once an object or foodstuff is in a child's mouth, it can lodge in the respiratory tract, be ingested, or end up in the nasopharynx. Young age (6 months to 4 years), a tendency to hold objects in the mouth, easy distractibility, inappropriate-for-age foods, and inappropriate playthings can place the child at risk for foreign-body aspiration or ingestion. Often, the "choking episode" will completely clear the foreign body; however, the sequelae of an aspirated object can range from an immediate life-threatening event to a slowly evolving pneumonia. The seriousness of foreign-body ingestion is determined by the nature of the object (e.g., blunt, long, sharp, battery, magnetic) and the potential level of lodgment in the gastrointestinal (GI) tract. Fortunately, children typically swallow round rather than sharp objects. Generally, most ingested foreign material is well tolerated, and many ingestions likely go unnoticed by the family and the child.

PATHOPHYSIOLOGY

There are three main pathophysiologic considerations for aspirated and ingested foreign bodies: the anatomic determinants of lodgment site, the physical properties of the foreign body (size, shape, and composition), and the local tissue reaction to the foreign body.

The respiratory tract, once distal to the larynx, gradually narrows with each airway generation, whereas the GI tract has several sites of anatomic or functional narrowing that occur throughout. An ingested foreign body may lodge in three distinct esophageal sites, may be unable to pass through the pylorus, or may become impacted in the duodenum, cecum, appendix, rectum, or any other location of congenital or acquired narrowing.

The nature of the foreign body (size, shape, and composition) determines the site of lodgment and the potential for local tissue interaction. The widest diameter of the aspirated or ingested foreign body and the ability of the tissue to distend determine, in part, where it lodges within the respiratory or GI tract. A sharp or long object may become impacted even where there is no anatomic narrowing. The aspirated object may affect air movement minimally, until the "fit" with the airway is sufficient to completely or intermittently impede airflow.

The composition of the foreign body also determines the local tissue reaction and the evolution of complications. A disc battery will erode through the esophageal wall rapidly when compared with the slow reaction to a coin. In the bronchial tree, the fatty oils in some aspirated foods (e.g., peanuts) can create a more severe pneumonia than a similarly sized plastic or metal object. While the ingestion of a single blunt magnet may cause little problem, the ingestion of more than one could lead to magnetic attraction across bowel walls, potentially resulting in necrosis and bowel perforation or volvulus.

DIFFERENTIAL DIAGNOSIS

Gastrointestinal Foreign Body

Esophagus

Impaction in the esophagus is the most common and potentially the most serious consequence of a GI foreign body. Most childhood esophageal foreign bodies are round or spherical objects. Coins account for 50% to 75% of childhood esophageal foreign bodies; pennies predominate (Fig. 28.1). This contrasts with adults, whose impacted esophageal foreign bodies tend to be foodstuffs (meat) and bones (e.g., fish or chicken). Esophageal foreign bodies in adults are often associated with underlying conditions that affect the esophagus (e.g., intrinsic strictures, motility issues, extrinsic pressure), whereas most children with esophageal impactions have a structurally and functionally normal esophagus. Children with acquired esophageal strictures (e.g., secondary to caustic ingestions) or congenital conditions, even after surgical correction (e.g., esophageal atresia, tracheoesophageal fistula), are at increased risk for recurrent esophageal impactions, even with foodstuffs (e.g., hot dogs, chicken).

Foreign bodies of the esophagus tend to lodge at three sites. The most proximal location, at the thoracic inlet (Fig. 28.1), accounts for 60% to 80% of esophageal foreign bodies. The next most common level of lodgment is at the gastroesophageal junction, accounting for 10% to 20%, and last, at the level of the aortic arch, accounting for 5% to 20%. The level of lodgment in children with underlying esophageal conditions or strictures depends on the nature and location of the constricting lesion.

Foreign bodies that remain lodged in the esophagus may lead to potentially serious complications. For example, coins can cause respiratory distress with upper airway compromise, esophageal perforation, mediastinitis, and aortic and tracheal fistula formation. Therefore, it is imperative that the physician be alert to the possibility of esophageal foreign bodies, especially in the susceptible 6-month-old to 4-year-old age group.

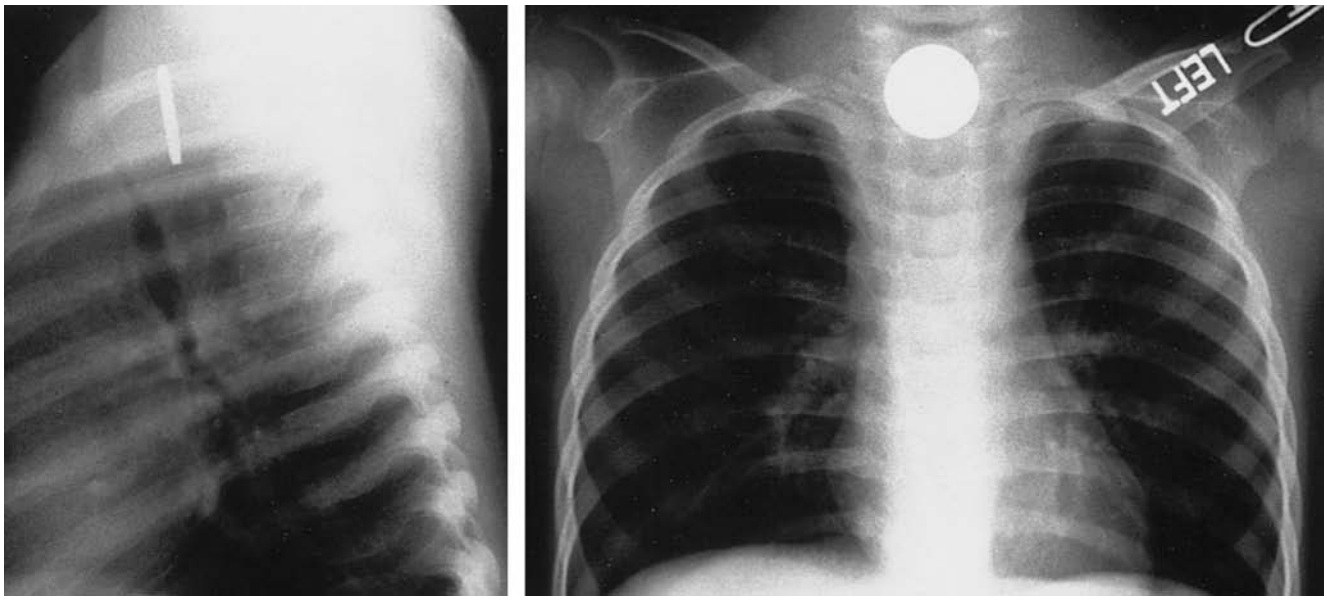

FIGURE 28.1 Two-view chest radiograph demonstrating impacted esophageal coin located at the thoracic inlet.

Stomach and Lower Gastrointestinal Tract

Objects that can pass safely into the stomach generally traverse the remainder of the GI tract without complication. Safe passage has been documented in hundreds of cases involving various foreign objects (Fig. 28.2). This includes objects such as screws, tacks, and staples. This may not be true in the younger child when long (greater than 5 cm) objects are unable to negotiate the turns of the duodenum and some other tight bends in the lower GI tract. However, no definitive age/length guidelines exist. This also may not be true of some very sharp objects that may perforate the hollow viscera and multiple magnets as discussed below. Sewing needles appear to present a relatively high risk of perforation. Bowel perforation from sharp objects has resulted in peritonitis, abscess formation, inflammatory tumors, hemorrhage, and death.

FIGURE 28.2 Abdominal radiograph demonstrating gastric radiopaque foreign body—a screw—that passed without complications.

Respiratory Foreign Body

Upper Airway

Foreign bodies that lodge in the upper airway can be immediately life threatening. Such occurrences are responsible for more than 300 childhood deaths in the United States annually. Of fatalities caused by food aspiration, 65% occur in children who are younger than 2 years. The most common foods responsible include hot dogs, candy, nuts, and grapes. Childhood fatality from aspiration of manmade objects is less common. These objects tend to be conforming objects, with balloons, small balls, and beads accounting for most cases; the majority occur in children younger than 3 years of age. Children with foreign bodies in their upper airways present with acute respiratory distress, stridor, increased respiratory effort, or complete obstruction of their upper airway. In patients with complete airway obstruction, emergency treatment depends on proper application of basic life support skills. Back blows and chest compressions are used in infants, and the Heimlich maneuver is used in toddlers, children, and adolescents while the patient remains conscious. Abdominal thrusts are used initially if the patient has lost consciousness. If these methods fail to dislodge the foreign body, rapid progression to direct visualization and manual extraction is necessary (see Chapters 1 and 5).

Lower Respiratory Tract

Because of the ubiquitous nature of the presenting symptoms (e.g., cough, wheezing, respiratory distress), the frequency of the asymptomatic presentation, and the potential for false-negative

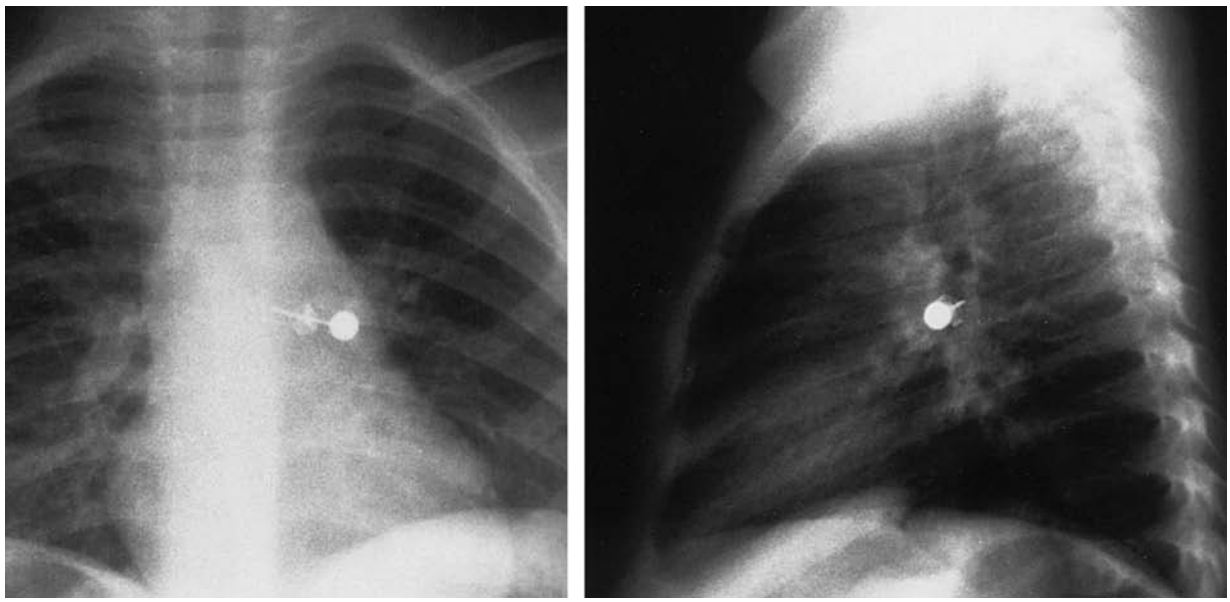

FIGURE 28.3 Two-view chest radiograph demonstrating aspirated radiopaque foreign body—an earring—located in the left bronchus.

and false-positive screening radiographs, childhood foreign bodies of the lower tracheobronchial tree represent a diagnostic challenge to all who treat children.

Foreign bodies of the lower respiratory tract occur more commonly in young children. Approximately 60% to 80% of pediatric tracheobronchial foreign bodies occur in children younger than 3 years. In children, aspirated foreign bodies show only a slight propensity to lodge in the right lung. The nature of the aspirated objects is fairly consistent throughout studies in several countries. Organic matter accounts for most aspirations. Nuts (peanuts predominate) and seeds (sunflower and watermelon) account for 40% to 70% of cases, followed by other food products (apples, carrots, and popcorn), plants, and grasses (Table 28.1). Plastics and metals make up a minority of aspirated objects (Fig. 28.3), and coin aspiration has rarely been reported.

TABLE 28.1

ASPIRATED FOREIGN BODIES IN CHILDREN RECOVERED AT BRONCHOSCOPY[a]

Foreign body	Percent
Peanuts	38
Other nuts	10
Other organic (food) material	16
Seeds, weeds, or twigs	7
Plastics	6
Popcorn	6
Pins, screws, tacks, or nails	6
Crayons	2
Rocks or stones	1
Miscellaneous[b]	8

[a]A total of 440 foreign bodies removed.
[b]Cotton/lint, earrings, bullet shell casings, tooth, staple, shirt label, pellet, spring, aluminum foil, seashell, pencil lead, screwdriver, chalk, chain, coin, chicken bone, plaster, Styrofoam cup fragment, and others.

The diagnosis of foreign-body aspiration is often delayed. Previously, diagnosis on the day of aspiration occurred in fewer than half the cases, and the diagnosis was made a week or more after the aspiration in 20% to 30% of cases. A more recent report suggests diagnosis within a day in 70% of patients. Symptoms at diagnosis include cough in 75% to 90%, wheezing in 50% to 75%, and respiratory distress in 25% to 60%. The classic clinical triad for an aspirated foreign body (wheeze, cough, and decreased breath sounds) is present in only one-third of all cases of pediatric foreign-body aspiration. This clinical triad occurs more often when the evaluation is delayed from the aspiration event. Approximately 20% of patients with aspirated foreign bodies are asymptomatic. In case series of pediatric foreign-body aspiration, a history of aspiration, if sought, is present in more than 80% to 90% of the time. Several authors emphasize the importance of ascertaining the choking history because this is the crucial clue to diagnosis.

EVALUATION AND DECISION

Unknown Location

Generally, the symptom complex and history that surround the event provide the clues necessary to decide whether to evaluate the respiratory tract or GI tract. Symptoms of cough, respiratory distress with tachypnea or retractions, stridor, wheezing, or asymmetric aeration suggest a foreign body in the airway. Symptoms of gagging, vomiting, drooling, dysphagia, pain, or localization suggest esophageal impaction. However, impacted esophageal foreign bodies may induce secondary airway symptoms, and foreign bodies in either location may induce coughing, vomiting, or gagging initially. Diagnosis is further complicated in that both types (GI and respiratory) may be asymptomatic. If the history and physical examination do not

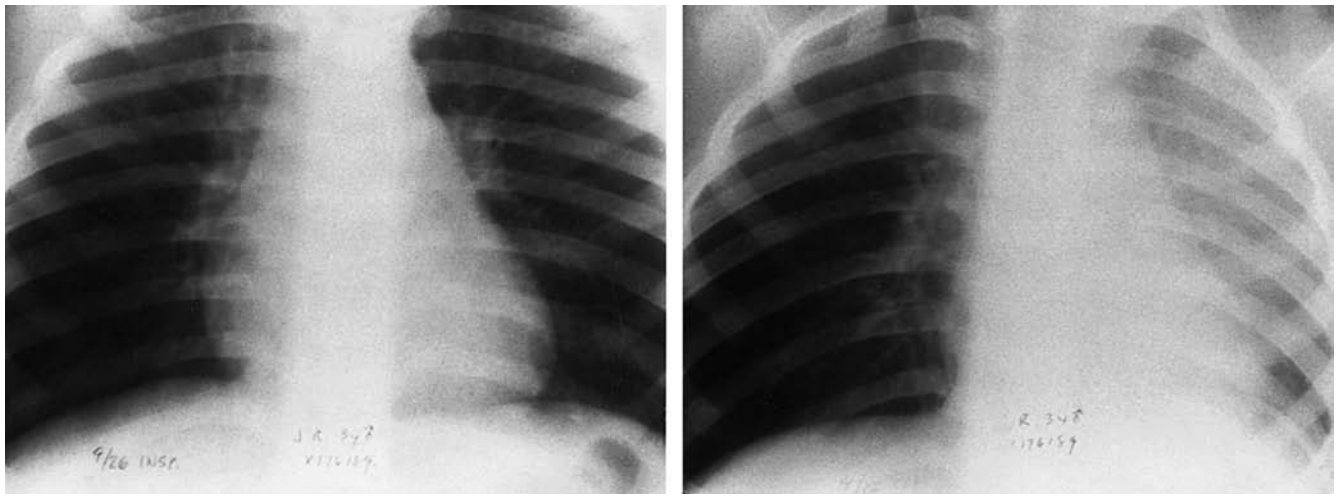

FIGURE 28.4 Inspiratory and expiratory chest radiographs demonstrating air trapping in the right lung during expiration, indicating likely right-sided foreign body. A peanut was removed at bronchoscopy.

provide the necessary clues, initial evaluation with a chest radiograph (to include the upper abdomen and oropharynx) will suffice as the first screen for a radiopaque esophageal or gastric foreign body. Coupling this with an expiratory chest radiograph (as outlined later) screens for an aspirated foreign body (Fig. 28.4). Alternatively, the combination of a soft-tissue lateral neck and a "wide" chest radiograph that includes the oropharynx and abdomen is also used as an initial "foreign body search."

Gastrointestinal Foreign Body

Esophageal Foreign Body: Diagnosis

Children with esophageal foreign bodies often have a history of having swallowed the foreign body. Symptoms associated with esophageal impaction include pain with swallowing, refusal to eat, foreign-body sensation or localization, drooling, and vomiting. When these symptoms are associated with a history of foreign-body ingestion, the diagnosis is straightforward. In the absence of an ingestion history, the diagnosis may be subtle because these same symptoms occur with such common childhood ailments as acute gastroenteritis, pharyngitis, or gingivostomatitis. Any patient with swallowing difficulty requires a thorough examination, including mouth, oropharynx, neck, chest, and abdomen. A radiographic evaluation may also be needed in some cases (see Chapter 52).

The approach to a child with foreign-body ingestion is outlined in Figure 28.5. Children may be asymptomatic with an esophageal foreign body. Since 30% to 40% of children with coins impacted in the esophagus are asymptomatic in the emergency department, it is suggested that most children with a history of ingested foreign bodies undergo radiographic evaluation. In the asymptomatic patient, this evaluation is urgent but not emergent; however, disc battery ingestions and multiple magnet ingestions are exceptions as discussed in the "Disc Battery Ingestion" and "Magnet Ingestion" sections below. The asymptomatic patient who has ingested a small (less than 1 cm in maximum diameter), nonsharp object (Fig. 28.5) does not require imaging studies. If the foreign body is not radiopaque (yet is large enough to become impacted) and the patient's symptoms suggest esophageal impaction, it is necessary to use a contrast esophagram to rule out an esophageal foreign body. Fortunately, childhood esophageal foreign bodies tend to be radiopaque (e.g., coins), so diagnosis with plain radiographs is not difficult (Fig. 28.1). Children with a predisposing condition (tracheoesophageal fistula repair, esophageal stricture) who have symptoms of an esophageal foreign body after eating should have contrast esophagrams; plain radiographs are not useful to visualize typical impacted foodstuffs. Similarly, with nonradiopaque ingestions and symptoms suggestive of impaction in children without underlying conditions, contrast esophagrams or esophagoscopy should be performed.

Handheld metal detectors may provide an alternative to conventional radiography as an initial screen when coin ingestion is suspected. In study situations, these devices compare favorably with radiography in determining presence or absence of a coin and determining coin location (esophagus or more distal GI tract). Users should gain some metal detector experience using x-ray confirmation before abandoning radiography, and patient follow-up is suggested because esophageal coins may be missed (this may be especially true in obese children).

Esophageal Foreign Body: Removal

In general, once an esophageal foreign body is detected, it should be removed promptly. This is especially true of sharp esophageal foreign bodies and disc batteries. Disc batteries may cause esophageal injury within a few hours that can lead to permanent sequelae and should be removed emergently. It has been noted that some impacted esophageal foreign bodies pass spontaneously, regardless of location. Spontaneous passage is most likely to occur when the object is lodged at the gastroesophageal junction. When evaluating an acute esophageal impaction (within a few hours of ingestion), it is reasonable to allow a period of less than 24 hours for spontaneous passage of round, noncorrosive foreign bodies (e.g., coins) in the asymptomatic patient, with no history of esophageal disease. Studies suggests a spontaneous passage rate for coins of nearly 30% in patients meeting these criteria with coins lodged at the GE junction more likely to pass than those at the thoracic inlet. This should be done only if good

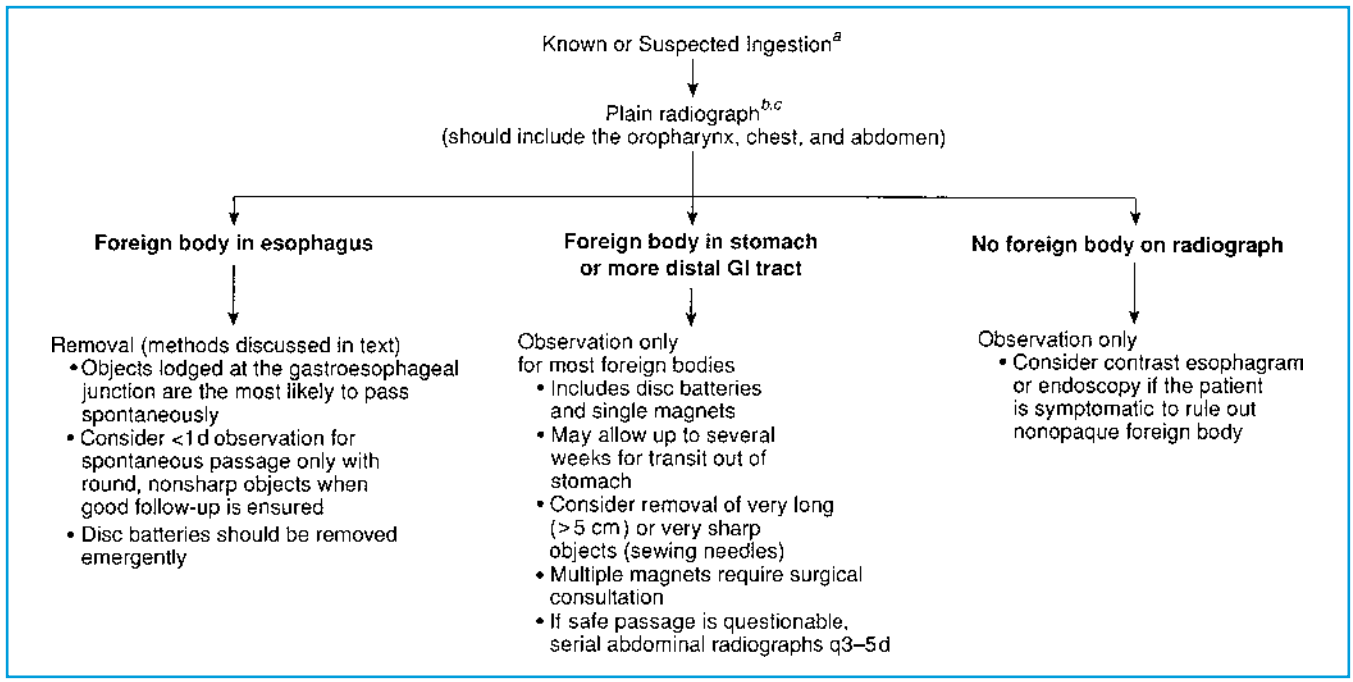

FIGURE 28.5 Management of ingested foreign body. GI, gastrointestinal.
[a]If the suspected foreign body is small (<1 cm), not sharp, and the patient is without symptoms, radiographs are not indicated. [b]In the patient with a known nonradiopaque foreign body with symptoms of an esophageal foreign body, go directly to esophagram or endoscopy. [c]In the patient with a prior history of esophageal surgery (e.g., TEF repair) or stricture, who presents with symptoms of an esophageal foreign body after eating (especially meats, including chicken and hot dogs), go directly to esophagram.

follow-up is available. Handheld metal detectors may have a role in following such patients with coin ingestions. Serious complications have not occurred from an esophageal coin that was impacted for less than a few days; however, the esophageal mucosa may grow around a coin after several days, which could hinder removal attempts.

Removal techniques for impacted esophageal foreign bodies vary regionally and depend on the duration of impaction, associated symptoms, and the nature of the foreign body. Traditional removal methods include rigid esophagoscopy under general anesthesia, and flexible endoscopy (with appropriate sedation). For coins and similar objects, other methods have been employed, including a balloon-tipped catheter under fluoroscopic guidance to extract or advance the coin, bougienage to advance the coin into the stomach, or a fluoroscopic-guided grasping endoscopic forceps covered by a soft rubber catheter. All these methods have a high success rate; provincial opinion and local referral patterns will determine removal options. Esophagoscopy under general anesthesia has been the method of choice for many years. This technique has proved to be safe and efficacious, and is applicable to all types of foreign bodies, allows for direct examination of the esophageal lumen, and can be used in patients with respiratory distress. The balloon-tipped catheter technique has been criticized because of lack of airway control, poor control of the foreign body during extraction, and inadequate visualization of the esophagus. Both Foley catheter and Bougie dilator methods, when used selectively on rounded foreign bodies of relatively short duration of impaction, have a high success rate with few complications at several institutions. These methods are less costly than esophagoscopy with general anesthesia. Use of a fluoroscopically guided endoscopic forceps covered with a soft rubber catheter reportedly takes only 1 minute. These alternative removal or advancement methods should be attempted only by clinicians familiar with the techniques and are generally recommended only for blunt esophageal foreign bodies that have been impacted for less than two days.

Use of medications (e.g., glucagon, diazepam) to reduce muscular tone, to enhance esophageal motility, or to relax the lower esophageal sphincter has been suggested to facilitate passage from the esophagus. Success with these methods is mostly anecdotal, and there is little data comparing the use of medications with spontaneous, non-medicated, passage rates. One study of impacted esophageal coins demonstrated similar passage rates when 1 mg intravenous glucagon was compared with placebo.

Stomach and Lower Gastrointestinal Tract

Most foreign bodies of the stomach and lower GI tract can be managed expectantly (Fig. 28.2). Management recommendations for sharp objects are varied but conservative—watchful waiting is usually safe. Sewing needles seem to have increased propensity for perforation, however, and should probably be removed. Long objects (greater than 5 cm) should also be removed from the stomach. If the long or very sharp object has passed out of the stomach at the time of evaluation and the safety of the remaining journey through the GI tract is questionable, serial abdominal radiographs every 3 to 5 days and serial examinations may be necessary to document continued uneventful passage. Most round objects (e.g., coins) will traverse the GI tract in 3 to 8 days without any complication. Some providers advocate parental examination of the stool for the foreign body, though in practice this may not be very useful. It is an unpleasant

task that is commonly, and understandably, abandoned. Furthermore, inability to retrieve the foreign body after 1 week or more of stool examination often heightens parental concern that some untoward complication has developed. Occasionally, some innocuous objects (e.g., quarter) remain in the stomach for a long duration. A prolonged time, up to a few weeks, can be allowed for passage of inert objects out of the stomach before surgical or endoscopic removal is necessary.

Disc Battery Ingestion

Disc batteries are used as a power source for many household items, ranging from watches, cameras, and calculators to hearing aids. Therefore, these intriguing, bite-size, "slippery when wet" batteries are often within reach of children. Most of these batteries fall into one of three varieties—a manganese dioxide system, a silver oxide system, or a mercuric oxide system. These systems may cause corrosive injury to the hollow viscera. Early case reports of disc battery ingestions emphasized serious hemorrhagic sequelae, so disc battery ingestion often raises the level of concern. However, subsequent large case series of ingested disc batteries have emphasized the benign nature of most ingestions once the battery is beyond the esophagus. A disc battery that reaches the stomach safely is likely to pass through the remainder of the GI tract without complication, and no operative or endoscopic intervention is indicated unless symptoms suggest a complication. Only sporadic cases of systemic absorption of battery contents have been suggested in the literature, and no serious toxicities have been reported. Disc batteries that lodge may establish a micro electrical current that rapidly injures tissues. Disc batteries that lodge in the esophagus should be removed emergently because of the potential to rapidly injure the esophagus.

Magnet Ingestions

Though most magnets that are ingested tend to be small and blunt, it is clear they pose a unique hazard to children. Single magnet ingestions can be treated as other GI ingestions but care must be taken by carefully comparing the size of the magnet to the x-ray image to insure that the magnet is in fact single. Multiple magnet ingestions pose a unique problem. If they connect in the stomach and travel as a single foreign body, there is generally little need for concern. If they traverse the GI tract separately they may magnetically attract each other across bowel wall. If the two magnets adhere then bowel wall is caught between them and this poses a risk of local ischemia with perforation, peritonitis, sepsis, or volvulus. Along with several case reports, 20 cases of multiple magnet ingestion resulting in serious complications were reported to the CDC between 2003 and 2006. These included 19 children requiring surgery and one death. Surgical consultation is recommended for all ingestions involving multiple magnets.

Respiratory Foreign Body

Lower Respiratory Tract: Diagnosis

A high clinical index of suspicion is necessary to diagnose foreign-body aspiration accurately and promptly. Symptoms seen in pediatric foreign-body ingestions are also present in other common diseases such as upper respiratory tract infection, bronchiolitis, pneumonia, and asthma. A few radiographic techniques serve as the most important diagnostic aids. Yet, when the clinical suspicion of foreign-body aspiration is high (good history for aspiration, and acute onset of symptoms and signs), the lack of confirmatory radiographic studies should not dissuade the clinician from pursuing bronchoscopy for diagnosis and treatment. In patients diagnosed early, as many as one-third have normal chest radiographs. The abnormal findings seen on a chest radiograph include air trapping, atelectasis, and consolidation. The more time that has elapsed since the aspiration event, the more likely the chest radiograph will be abnormal and the greater the percentage of patients who exhibit consolidation and atelectasis.

Inspiratory and expiratory films comparing the relative deflation of the two lungs may demonstrate unilateral air trapping indicative of a foreign body (Fig. 28.4). In some series, up to 60% to 80% of the foreign bodies demonstrated some radiographic abnormalities using inspiratory and expiratory chest radiographs. However the radiographic abnormalities may not be diagnostic of an aspirated foreign body. In the young or uncooperative child in whom obtaining an adequate expiratory film may be difficult, lateral decubitus chest radiographs (both obtained during inspiration) that compare the relative deflation of the dependent lung may be a useful adjunct. When available, chest fluoroscopy may be the preferred imaging technique. When positive, there is mediastinal shift during respiration or other evidence of focal air trapping; unfortunately, even this technique does not approach 100% sensitivity. More recently chest CT scan has been used to diagnose aspirated foreign bodies. This appears to be more reliable than either plain radiography or fluoroscopy with sensitivity of 90% or higher reported.

The approach to diagnosing foreign-body aspiration is outlined in Figure 28.6. In instances in which a respiratory foreign body is being considered, the patient should be kept on a nil per os (NPO) basis until the diagnosis is confirmed or the decision for bronchoscopy is made. The first step in the patient suspected of foreign-body aspiration is inspiratory and expiratory chest radiographs. If these studies are normal, the aspiration history is poor, the material uncommonly aspirated, and the patient has mild or no symptoms without focal findings on physical examination, then discharge with follow-up in a few days is usually adequate. If diagnosis is still unclear after plain films and there is a historical or clinical suspicion of aspiration, fluoroscopy may be obtained, looking for air trapping and evidence of mediastinal shift away from the foreign body. Alternatively a chest CT may be considered. In some instances, despite normal radiographic evaluation (including fluoroscopy), when there is a high clinical index of suspicion (choking history with typically aspirated foods—nuts, seeds, apples, carrots, popcorn), bronchoscopy is indicated to confirm the presence or absence of a pulmonary foreign object. In instances in which there is acute onset of focal physical findings (unilateral wheeze, decreased aeration) or a very convincing aspiration history, it is reasonable to proceed directly to bronchoscopy.

A history of aspirated foreign bodies should be sought in all cases of new-onset respiratory distress, wheezing, or cough, with special consideration to the high-risk children from 6 months to 4 years of age. History-taking should include questions about recent choking episodes, especially when eating nuts (peanuts), seeds, apples, and carrots. The differential diagnosis of foreign-body aspiration includes many common

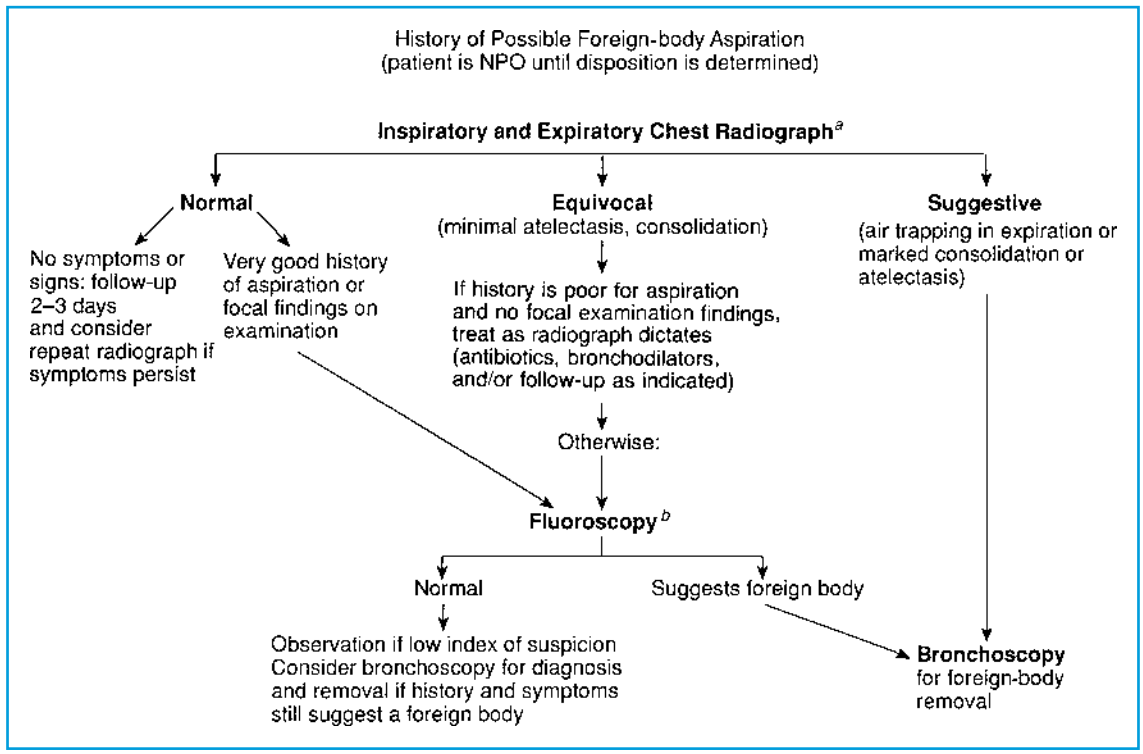

FIGURE 28.6 Guidelines for management of the child with suspected foreign-body aspiration. [a]This should include the oropharynx. Lateral decubitus chest radiographs or fluoroscopy may substitute in younger or uncooperative patients. [b]Fluoroscopy is not necessary if aspiration history is good or there is a new onset of focal symptom/sign complex (wheezing, decreased breath sounds, cough). Then the patient may go directly to bronchoscopy.

childhood diseases, including upper respiratory infection, bronchiolitis, viral and bacterial pneumonitis, and reactive airway disease; specific questioning concerning aspiration events should be explored.

Lower Respiratory Tract: Removal

Once a foreign body of the lower respiratory tract has been identified, bronchoscopic removal is performed under general anesthesia. This technique is successful in more than 98% of cases, and only rarely is a thoracotomy required. The procedure can often be performed on an outpatient surgery basis, although any preoperative or postoperative concerns about the patient's respiratory status mandate in-hospital observation after the procedure. Potential postoperative complications after removal of an aspirated foreign body include atelectasis, pneumonia, stridor, bronchospasm or laryngospasm, and retained foreign body.

CHAPTER 29 ■ GASTROINTESTINAL BLEEDING

STEPHEN J. TEACH, MD, MPH

Gastrointestinal (GI) bleeding is a relatively common problem in pediatrics. Over one 12-month study period at a large urban pediatric emergency department, complaints of rectal bleeding accounted for 0.3% of all visits. Most infants and children who arrive in the ED with what appears to be GI bleeding have an acute, self-limited GI hemorrhage and are hemodynamically stable. In such patients, three important questions must be asked: (i) Is the patient really bleeding? (ii) Is the blood coming from the GI tract? and (iii) Is there more than a trivial amount of blood? Children with only a few drops or flecks of blood in the vomit or stool should not be considered "GI bleeders" if their history and physical examinations are otherwise unremarkable. Caution must be taken, however, as small amounts of blood (whether in emesis or passed per rectum) may be the harbinger of more extensive enteral bleeding.

Likewise, caution must be taken to ensure the passed "blood" actually contains hemoglobin. Many substances ingested by children may simulate fresh or chemically altered blood. Red food coloring (as in some cereals, antibiotic and cough syrups, Jell-O®, and Kool-Aid®), as well as fruit juices and beets, may resemble blood if vomited or passed in the stool. Melena may be confused with dark or black stools due to iron supplementation, dark chocolate, bismuth, spinach, cranberries, blueberries, grapes, or licorice. In these cases, confirmation of the absence of blood with Gastroccult® (vomitus) or Hemoccult® (stool) tests will allay parental anxiety, as well as prevent unnecessary concern and testing. Gastroccult® is a specific and sensitive assay, stable in an acid environment and can detect as little as 300 mcg per dL of hemoglobin.

A careful search for other causes of presumed GI bleeding (recent epistaxis, dental work, menses, hematuria, buttock lesions, and pharyngitis) should be sought. In most cases of upper and lower GI bleeding, the source of the bleeding is inflamed mucosa (infection, allergy, drug induced, stress related, or idiopathic). The emergency physician must be vigilant in differentiating inflammatory conditions that are often self-limited from causes that may require emergent surgical or endoscopic intervention, such as ischemic bowel (intussusception, volvulus), structural abnormalities (Meckel's diverticulum, angiodysplasia), and portal hypertension (esophageal varices). Acute GI bleeding rarely represents a surgical emergency. In the previously noted study, only 4.2% of 95 patients required a blood transfusion or an operative intervention.

INITIAL ASSESSMENT

Because the presentation and differential diagnosis of GI bleeding are broad, a systematic approach to all patients is crucial and includes the following sequential steps:

1. Assessment of the severity of the bleeding and institution of appropriate resuscitative measures if the patient manifests hemorrhagic shock.
2. Establishment of the level of bleeding within the GI tract.
3. Narrowing of the differential diagnosis based on pertinent history, physical examination, and laboratory tests based on knowledge of age-related causes in upper and lower GI bleeding.
4. Evaluation and decision making.

Severity of Bleeding

Estimation of blood loss (a few drops, a spoonful, a cupful, or more) should be obtained initially. This can be extremely difficult and inaccurate. Hemoglobin and hematocrit are also unreliable estimates of acute blood loss because of the time required for hemodilution to occur after an acute hemorrhage. The estimated volume of blood loss should be correlated with the patient's clinical status. The presence of resting tachycardia, pallor, prolonged capillary refill time, and metabolic acidosis point to significant enteral blood loss. An orthostatic decrease in systolic blood pressure of 10 mm Hg or more, or an increase of 20 beats per minute in pulse, suggests a 10% to 20% loss of intravascular volume. Hypotension is a late finding in young children with hemorrhagic shock and demands immediate resuscitative measures.

Establishment of the Level of Bleeding

There are two general categories of GI bleeding: upper and lower. *Upper GI bleeding* refers to bleeding proximal to the ligament of Treitz. *Lower GI bleeding* is distal to the ligament. In most cases, the clinical findings along with nasogastric lavage will delineate the cause of bleeding within the GI tract. *Hematemesis,* defined as the vomiting of blood, can range from fresh and bright red to old and dark (due to the effect of gastric acidity) with the appearance of "coffee grounds." *Hematochezia*, the passage of bright red blood per rectum, suggests lower GI bleeding or upper GI bleeding with a very rapid enteral transit time. *Melena*, the passage of stool that is shiny, black, and sticky as a result of enzymatic or bacterial action on intraluminal blood, reflects bleeding from either the upper GI tract or the proximal small bowel. In general, the darker the blood in the stool, the higher it originates in the GI tract (or, alternatively, the longer it has resided in the GI tract). "Currant jelly" stools indicate vascular congestion and hyperemia of the colon with passage of abundant mucus from the colonic goblet cells, as seen with intussusception.

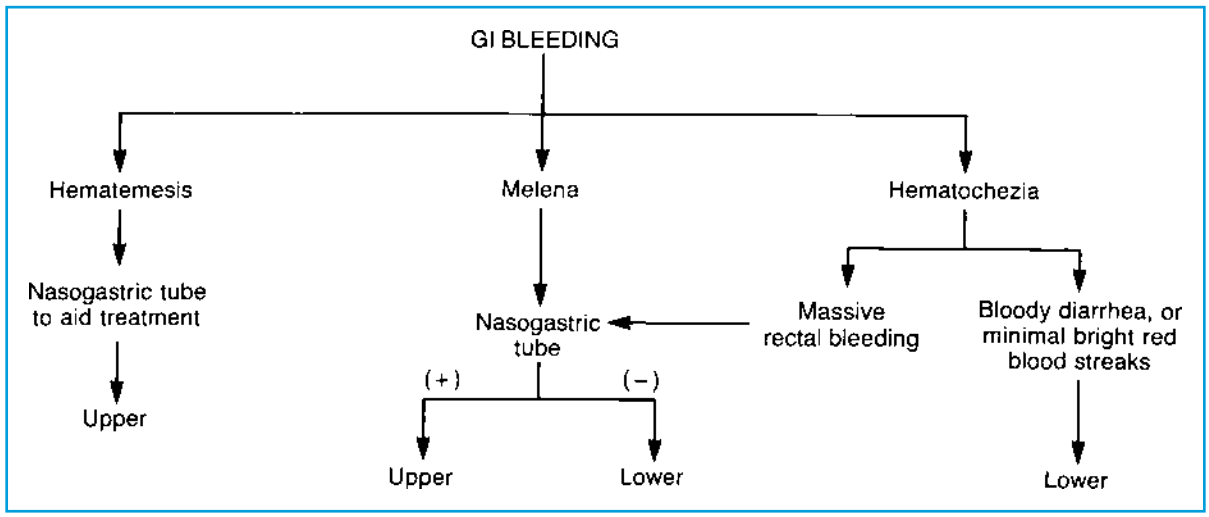

FIGURE 29.1 Establishing level of gastrointestinal (GI) bleeding.

Maroon-colored stools generally occur with a voluminous bleed anywhere proximal to the rectosigmoid area, such as seen with a Meckel's diverticulum.

All patients with a significant bleeding episode should have a nasogastric tube placed for a diagnostic saline lavage (Fig. 29.1). Presence of bilious material indicates an open gastric pylorus. In patients with hematemesis or melena, a positive examination of a nasogastric aspirate confirms an upper source of GI bleeding, whereas a negative result almost always excludes an active upper GI bleed. Occasionally, a postpyloric upper GI lesion, such as a duodenal ulcer, bleeds massively without reflux into the stomach, resulting in a negative aspirate. In such a case, an upper GI endoscopic study may be the best method to detect such a lesion. Patients with significant hematochezia or melena should likewise have a nasogastric tube placed. As noted above, because blood can exert a cathartic action, brisk bleeding from an upper GI lesion may induce rapid transit through the gut, thus preventing blood from becoming melanotic. In patients with hematochezia manifested as bloody diarrhea or minimally blood-streaked stools, a lower GI source should be investigated.

UPPER GASTROINTESTINAL BLEEDING

Differential Diagnosis

As seen in Table 29.1, there is considerable overlap between age groups and causes of upper GI bleeding. Mucosal lesions, including esophagitis, gastritis, peptic ulceration, and Mallory-Weiss tears, are the most common sources of GI bleeding in all age groups (see Table 29.2 and Chapter 89). Of all cases of upper GI bleeding in children, 95% are related to mucosal lesions and esophageal varices. Life-threatening causes of upper GI bleeding are listed in Table 29.3.

Hematemesis in a healthy newborn most likely results from swallowed maternal blood either at delivery or during breastfeeding (i.e., cracked nipples). The Apt test can differentiate neonatal from maternal hemoglobin based on the conversion of oxyhemoglobin to hematin when mixed with alkali. To perform the Apt test, the physician should mix one part bloody stool or vomitus with five parts water, centrifuge at 2,000 rpm

TABLE 29.1

ETIOLOGY OF UPPER GASTROINTESTINAL BLEEDING BASED ON AGE[a]

Neonatal period (<4 wk)	Infancy (<2 yr)	Preschool age (2–5 yr)	School age (>5 yr)
Swallowed maternal blood	Gastritis	Epistaxis	Gastritis
Hemorrhagic gastritis	Esophagitis	Gastritis	Mallory-Weiss tear
Peptic ulcer	Mallory-Weiss tear	Esophagitis	Peptic ulcer
Idiopathic	Peptic ulcer	Mallory-Weiss tear	Stress ulcer
Bleeding diathesis	Pyloric stenosis (<2 mo of age)	Toxic ingestion	Toxic ingestion
Esophagitis	Vascular malformation	Peptic ulcer	Esophagitis

for 2 minutes, and mix the supernatant with 1 mL of 1% sodium hydroxide for every 5 mL of supernatant. Fetal hemoglobin is more resistant to denaturing than adult hemoglobin and remains pink, whereas maternal hemoglobin becomes brown. Obtaining sufficient vomited blood to perform this test may be difficult.

In the breast-fed neonate with new onset of hematemesis and maternal history of cracked nipples, who is well-appearing and with normal examination, another approach is to allow the mother to nurse in the ED. Often, when the infant has been at the breast for a few moments and then is pulled away, an obvious significant degree of bleeding from the mother's nipple is apparent, providing considerable reassurance to both physicians and parents. As an alternative, a breast pump can be used.

Although rare, hemorrhagic disease of the newborn should be considered with prolongation of the prothrombin time. Failure to administer vitamin K in the immediate postpartum period is a critical risk factor for this disorder.

Significant and sometimes massive upper GI hemorrhage in a newborn infant may occur with no demonstrative anatomic lesion or only "hemorrhagic gastritis" at endoscopy. This is usually a single, self-limited event that is benign if treated with appropriate blood replacement and supportive measures. Pyloric stenosis may present with significant hematemesis, often preceded by significant non-bloody emesis.

Critically ill children of any age are at risk for developing stress-related peptic ulcer disease. Such ulcers occur with life-threatening illnesses, including shock, respiratory failure, hypoglycemia, dehydration, burns (Curling's ulcer), intracranial lesions or trauma (Cushing's ulcer), renal failure, and vasculitis. These ulcers may develop within minutes to hours after the initial insult and primarily result from ischemia. Hematemesis, hematochezia, melena, and/or perforation of a viscus may accompany stress-associated ulcers. Hematemesis secondary to gastroesophageal reflux and esophagitis is uncommon but should be considered in patients who are severely symptomatic with vomiting or aspiration. Hematemesis following the acute onset of vigorous vomiting or retching at any age suggests a Mallory-Weiss tear. These tears occur at the gastroesophageal junction due to a combination of mechanical factors (e.g., retching) and gastric acidity.

Idiopathic peptic ulcer disease is a common cause of GI bleeding in preschool and older children. Most preschool children with idiopathic ulcers develop GI bleeding (hematemesis or melena). Complications, including obstruction and perforation, may occur. Younger children have less characteristic symptoms, often localize abdominal pain poorly, and may have vomiting as a predominant symptom. Older children and adolescents describe epigastric pain in a pattern typical of adults. *Helicobacter pylori* infection has emerged as a leading cause of secondary gastritis, particularly in older children. Similar to adults, pediatric patients with evidence of *H. pylori* infection are treated with triple therapy of amoxicillin, clarithromycin, and a proton pump inhibitor; however, the current recommendations advocate for 10 to 14 days of treatment until the newer short courses (1 to 5 days) being used in adults have been tested in pediatric patients. Preparations of bismuth may be added to the regimen, and metronidazole may be substituted in patients with penicillin allergy. Note that bismuth subsalicylate can turn the stool a darker color, even black.

In older children, the possibility of bleeding esophageal varices must be considered in the differential diagnosis of upper GI bleeding. Although variceal bleeding is rare in infancy, esophageal and gastric varices associated with portal hypertension due to hepatic and vascular disorders are the most common causes of severe upper GI hemorrhage in older children. One-half to two-thirds of these children have an extrahepatic presinusoidal obstruction, often resulting from portal vein thrombosis, as the cause of portal hypertension. Omphalitis with or without a history of umbilical vein cannulation, dehydration, and a number of other factors may contribute. Other children with portal hypertension have hepatic parenchymal disorders such as neonatal hepatitis, congenital hepatic fibrosis, cystic fibrosis, or biliary cirrhosis associated with biliary atresia. Two-thirds of patients with portal hypertension develop bleeding before 5 years of age, and 85% do so by 10 years of age.

Evaluation and Decision: Upper Gastrointestinal Bleeding

History and Physical Examination

Pertinent historical elements to be sought include a history of umbilical catheterization or sepsis in the neonatal period, previous episodes of bleeding from the GI tract or other sites, and past hematologic disorders and liver disease. A family history of peptic ulcer disease can be found in up to 30% of patients with

idiopathic ulcers. The presence of prior epigastric pain may suggest more longstanding esophagogastritis or ulcer disease. Ingestions should be sought as a possible cause. These include theophylline, aspirin, iron, nonsteroidal antiinflammatory drugs (NSAIDs), alcohol, and steroids. Massive hemorrhage associated with right upper quadrant pain and jaundice in the post trauma patient indicates bleeding into the biliary tract (hemobilia).

The physical examination should include visualization of the posterior nose and pharynx to eliminate epistaxis as a source of bleeding. Signs of liver disease or portal hypertension may be subtle in children. Icterus, abdominal distension, prominent abdominal venous pattern, hepatosplenomegaly, cutaneous spider nevi, and ascites suggest liver disease and/or portal hypertension with esophageal varices. A rectal examination for the detection of melena, hematochezia, and occult blood is crucial in all cases of GI bleeding.

Laboratory Evaluation

Laboratory tests are not useful for identifying a precise cause of upper GI bleeding. Mucosal lesions are more likely than esophageal varices to be associated with prior occult bleeding. A low mean corpuscular volume and hypochromic, microcytic anemia suggest chronic mucosal bleeding. Initial low white blood cell and platelet counts may be seen in either hypersplenism from portal hypertension or sepsis with associated mucosal ulceration due to stress. Abnormal hepatic studies, including an elevation of serum bilirubin, transaminases, and prothrombin time, and a low serum albumin, are suggestive of esophageal varices. A blood urea nitrogen:creatinine ratio greater than 30 may indicate blood resorption and an upper GI source of bleeding.

Diagnostic Approach

If a significant upper GI bleed has occurred, and once hemodynamic stability is restored, identification of the specific age-related disorder is the next step (Table 29.1 and Fig. 29.2). If the bleeding is mild and self-limited or the gastric aspirate is negative, a minor mucosal lesion is likely. Although mucosal lesions such as esophagitis, gastritis, or peptic ulcer disease can present with severe bleeding, most often bleeding from mucosal lesions is self-limiting and will respond to conservative medical management. In patients with persistent or recurrent hemorrhage, emergent endoscopy may be necessary if the bleeding is considered life threatening (continued transfusion requirement, hemodynamic instability). In a small percentage of patients in whom bleeding is massive, making endoscopic visualization impossible, angiography or radionuclide studies (Technetium-sulfur colloid/Tc-labeled red blood cells) may be indicated. Treatment of specific mucosal conditions and esophageal varices is discussed in Chapter 89.

Eighty percent to 85% of upper GI bleeding stops spontaneously, regardless of the source, before or early in the hospital course. In stable patients who have stopped bleeding, double-contrast barium examination of the upper GI tract and endoscopy provide valuable and often complementary information. In this group of patients, endoscopy need not be performed on an emergent basis and may be done electively in the first 12 to 24 hours after admission. Elective endoscopy should be performed in patients who stop bleeding spontaneously but who have required transfusion and/or have a history of previously unexplained upper GI bleeding episodes.

TABLE 29.4

ETIOLOGY OF LOWER GASTROINTESTINAL BLEEDING BASED ON AGE[a]

Neonatal period	Infancy (1 mo–2 yr)	Preschool age (2–5 yr)	School age (>5 yr)
Well Infant			
Swallowed maternal blood	Anal fissure	Anal fissure	Infectious colitis
Infectious colitis	Infectious colitis	Infectious colitis	Polyps
Allergic colitis	Allergic colitis	Juvenile polyps	Inflammatory bowel disease
Hemorrhagic disease	Nonspecific colitis	Intussusception	Hemorrhoids
Duplication of bowel	Juvenile polyps	Henoch-Schönlein purpura	Meckel's diverticulum
Meckel's diverticulum	Intussusception	Meckel's diverticulum	Hemolytic uremic syndrome (HUS)
Sick Infant			
Infectious colitis	Meckel's diverticulum	HUS	Pseudomembranous colitis
Midgut volvulus	Duplication	Inflammatory bowel disease	Ischemic colitis
Hirschsprung's disease	HUS	Peptic ulcer	Peptic ulcer
Disseminated coagulopathy	Inflammatory bowel disease	Pseudomembranous enterocolitis	Angiodysplasia
Necrotizing enterocolitis	Pseudomembranous enterocolitis	Ischemic colitis	
Intussusception	Ischemic colitis	Angiodysplasia	
Congestive heart failure	Lymphonodular hyperplasia		

[a]In approximate order of frequency of occurrence.

LOWER GASTROINTESTINAL BLEEDING

Differential Diagnosis

Similar to upper GI bleeding, there is overlap among age groups in the etiology of lower GI bleeding (Table 29.4). The most common disorders by age group are listed in Table 29.5, and the life-threatening causes are listed in Table 29.6. Of note, many cases of lower GI bleeding resolve spontaneously without a specific diagnosis being established.

Neonatal Period (0 to 1 Month)

As is true for upper GI bleeding, a common cause of blood in the stool in well infants is the passage of maternal blood swallowed either at delivery or during breast-feeding from a fissured maternal breast. Although hemorrhagic disease of the newborn is uncommon after prophylactic administration of vitamin K at delivery, maternal drugs that cross the placenta, including aspirin, phenytoin, and phenobarbital, may interfere with clotting factors and cause hemorrhage. Infectious diarrhea can occur in very young infants, and stools may contain blood or mucus. Common bacterial pathogens in this age group include *Campylobacter jejuni* and *Salmonella*.

In ill-appearing neonates with lower GI bleeding, midgut volvulus, necrotizing enterocolitis, and Hirschsprung's disease should be considered (Table 29.4). Malrotation with midgut volvulus is most common during this period. Initially, bilious vomiting, abdominal distension, and pain are present. Melena is seen in 10% to 20% of patients and signifies vascular compromise. Of all cases of necrotizing enterocolitis, 10% occur in term infants. These patients can present with nonspecific signs of sepsis (temperature instability, apnea, and/or bradycardia) and with

Peptic ulcer

specific GI tract findings, such as abdominal distension, pain, and abdominal wall erythema. GI bleeding can be in the form of occult bleeding or grossly bloody stools. Hirschsprung's disease with enterocolitis may also present with GI bleeding in the neonatal period. Enterocolitis has recently been shown to occur in up to 25% of children with Hirschsprung's disease. The risk of enterocolitis remains high until about 6 months of age. The diagnosis should be considered in any newborn that does not pass meconium in the first 24 to 48 hours of life.

Infancy (1 Month to 2 Years)

In the first 2 years of life, anal fissures are among the most common cause of rectal bleeding and are usually associated with hard stools, constipation, or other trauma. Treatment with stool softeners and sitz baths will often resolve the problem spontaneously in most patients. Milk or soy allergic enterocolitis usually occurs during the first month of life, but it can occur later in infancy and occasionally in older children (depending on when exposure occurs). These infants can present with chronic diarrhea and failure to thrive, with stools containing blood or mucus, or less commonly, with fulminant colitis and shock. Milk-protein allergy responds (often slowly) to a change in formula from cow's milk or soy protein to an elemental formula (Nutramigen®, Alimentum®, Pregestimil®). Breast-fed infants whose mothers drink cow's milk may develop an allergic colitis that responds to removal of cow's milk from the mother's diet. Infectious enterocolitis as a cause of bloody diarrhea is common in all age groups. Bacterial causes (*Salmonella*, *Shigella*, *Campylobacter*, pathogenic *Escherichia coli,* and *Yersinia enterocolitica*) should be identified with stool cultures. In symptomatic infants and children, the presence of leukocytes in a stool smear may aid in preliminary diagnosis. Pseudomembranous colitis should be considered in any infant or child with bloody stools and a history of recent antibiotic therapy. "Nonspecific colitis" has been demonstrated to be a common cause of hematochezia in infants younger than 6 months of age. Although the cause of nonspecific colitis is unknown, it may represent a variation in the colonic response to viral invasion.

Meckel's diverticulum should be suspected in infants or young children who pass bright or dark red blood per rectum. Intermittent painless bleeding or massive GI hemorrhage can occur. Sixty percent of complications from Meckel's diverticulum (hemorrhage and intestinal obstruction) occur in patients younger than 2 years of age.

Idiopathic intussusception may occur in infancy, with 80% occurring before 2 years of age. In children older than 3 years, a lead point (polyp, Meckel's diverticulum, or hypertrophied lymphoid patch) is more often found than in younger children. Paroxysmal pain may be associated with occult blood, hematochezia, or "currant jelly stools" (formed by the combination of fresh blood with mucus elaborated by the colonic wall). Lethargy alone (without pain) has been increasingly recognized as a presenting symptom of intussusception in young children.

Lymphonodular hyperplasia is an uncommon cause of rectal bleeding in this age group and may cause mild, painless hematochezia. The nodular lymphoid response is self-limited and does not require any specific therapy. Intestinal duplications are also an uncommon cause of lower GI bleeding and, when diagnosed, are usually found in children younger than 2 years of age. Duplications can be found anywhere in the GI tract but are most common in the distal ileum. These usually present with obstruction and lower GI bleeding.

Preschool Period (2 to 5 Years)

The two most common conditions to cause bleeding in children 2 to 5 years of age are juvenile polyps and infectious enterocolitis. Most polyps in childhood are inflammatory without significant malignant potential and are often multiple. Between 30% and 40% are palpable on rectal examination. Like a Meckel's diverticulum, polyps may be seen with painless rectal bleeding in this age group. Significant bleeding is unusual. Infectious causes of colitis are similar to those discussed in younger age groups. Hematochezia is often a manifestation of systemic disease in infancy and throughout childhood. Hemolytic uremic syndrome (HUS) is the most prevalent of these conditions reported in infants and children up to 3 years of age. Bloody diarrhea due to *E. coli* O157:H7 may precede the development of renal and hematologic abnormalities in HUS. GI manifestations of Henoch-Schönlein purpura (HSP) occur in 50% of patients and include colicky abdominal pain, melena, and bloody diarrhea. These symptoms precede the characteristic rash in 20% of patients. GI complications among patients with HSP include hemorrhage (5%), intussusception (3%), and rarely, intestinal perforation.

Angiodysplasia is a rare cause of GI bleeding but can be associated with massive hemorrhage. Vascular lesions of the GI tract probably have a congenital basis. Several recognized syndromes, including Rendu-Osler-Weber syndrome and Turner's syndrome, may be associated with intestinal telangiectasia.

School Age through Adolescence Period

For the most part, the diagnostic considerations relevant to the preschool child apply to school-age and adolescent children with the addition of inflammatory bowel disease, which is rare before the age of 10 years. Rectal bleeding is a common presentation of both ulcerative colitis and Crohn's disease. Massive lower GI bleeding occurs in 2% to 5% of children with Crohn's disease. Toxic megacolon is a life-threatening presentation of both ulcerative colitis and Crohn's disease.

Evaluation and Decision: Lower Gastrointestinal Bleeding

History and Physical Examination

Symptoms of an acute abdominal process with bowel obstruction, including abdominal pain, distension, and vomiting, should be elicited. A history of bloody diarrhea may indicate infectious or allergic colitis, intussusception, or HUS. Extraintestinal manifestations of inflammatory bowel disease, including weight loss, anorexia, and arthralgias, may be predominant symptoms in school-age children. The dietary history may suggest features of milk or soy protein intolerance. Firm stool streaked with red blood characterizes anal fissures or lower colonic polyps. A detailed family history (bleeding diathesis, familial polyposis) and drug history (NSAIDs, salicylates, iron) or antibiotics (pseudomembranous colitis) are important in patients with lower GI bleeding. A history of constipation in a young infant with acute onset of bloody diarrhea suggests enterocolitis associated with Hirschsprung's disease.

Physical examination to detect abdominal obstruction (abdominal tenderness, distension, palpable mass, peritoneal signs, hyperactive (early) or hypoactive (late) bowel sounds) is the most urgent task of the evaluating physician. Careful separation of the buttocks with eversion of the anal mucosa may reveal a fissure. Prominent or multiple perianal skin tags may raise suspicion of Crohn's disease. Rectal polyps may be palpable on rectal examination. Cutaneous lesions may provide important diagnostic clues in patients with GI bleeding. Eczema may be associated with milk allergy, whereas erythema nodosum is the most common skin manifestation of inflammatory bowel disease. Mucocutaneous pigmentation (Peutz-Jegher syndrome) and cutaneous or subcutaneous tumors (Gardner's syndrome) indicate intestinal polyposis.

Diagnostic Approach

Rectal bleeding presents in all pediatric age groups (Table 29.4 and Fig. 29.3). The causes of lower GI bleeding vary significantly with age, and are often transient and benign. Occasionally, lower GI bleeding reflects a life-threatening pathologic condition, and establishment of a specific diagnosis becomes urgent.

The priority of the emergency physician in evaluating the patient with lower GI bleeding is to identify lower tract bleeding associated with intestinal obstruction and with other causes of large volume bleeding such as a Meckel's diverticulum. Intussusception and a late presentation of midgut volvulus secondary to malrotation are the major types of intestinal obstruction associated with lower GI hemorrhage. All causes of abdominal obstruction (e.g., adhesions, incarcerated hernia, and appendicitis) eventually result in bleeding if diagnosis is delayed and vascular compromise occurs.

Severe lower GI bleeding leading to hemodynamic instability or requiring transfusion is rare in pediatrics, and gastric lavage is essential in these cases to rule out a possible upper GI tract source. Meckel's diverticulum is the most common cause of severe lower GI bleeding in all age groups. Following Meckel's diverticulum, Crohn's disease and arteriovenous malformation are prominent causes of massive lower GI bleeding in adolescents.

The urgency and extent of evaluation of patients with lower GI bleeding will depend on the amount of bleeding, the patient's age, and associated physical findings. In a healthy infant with a few streaks of blood in the stool and a normal examination, a limited evaluation and observation are reasonable. If more significant hematochezia is found and if a nasogastric aspirate is negative, then significant pathology must be sought. Flat and upright abdominal radiographs should be performed if an obstructive process (e.g., intussusception, volvulus) is suspected by history or physical examination. The absence of radiographic findings should not, however, deter the physician from pursuing further diagnostic evaluation. An upper GI examination can often define the level of small-bowel obstruction. Ultrasound has been increasingly used to identify etiologies of obstruction. An air or barium enema examination may be diagnostic and therapeutic in children with intussusception.

If obstruction is not considered likely, the decision to perform contrast enema examination or colonoscopy will depend on the diagnosis suspected. Air-contrast barium enema can also be extremely valuable in the detection of polyps or inflammatory bowel disease. Indications for colonoscopy include severe bleeding, moderate but persistent bleeding with a negative double-contrast barium enema, or a lesion of unknown nature seen on barium enema. If undefined bleeding persists, radionuclide studies or angiography should be considered. A technetium scan may detect ectopic gastric mucosa as seen in Meckel's diverticulum, whereas angiography will help identify

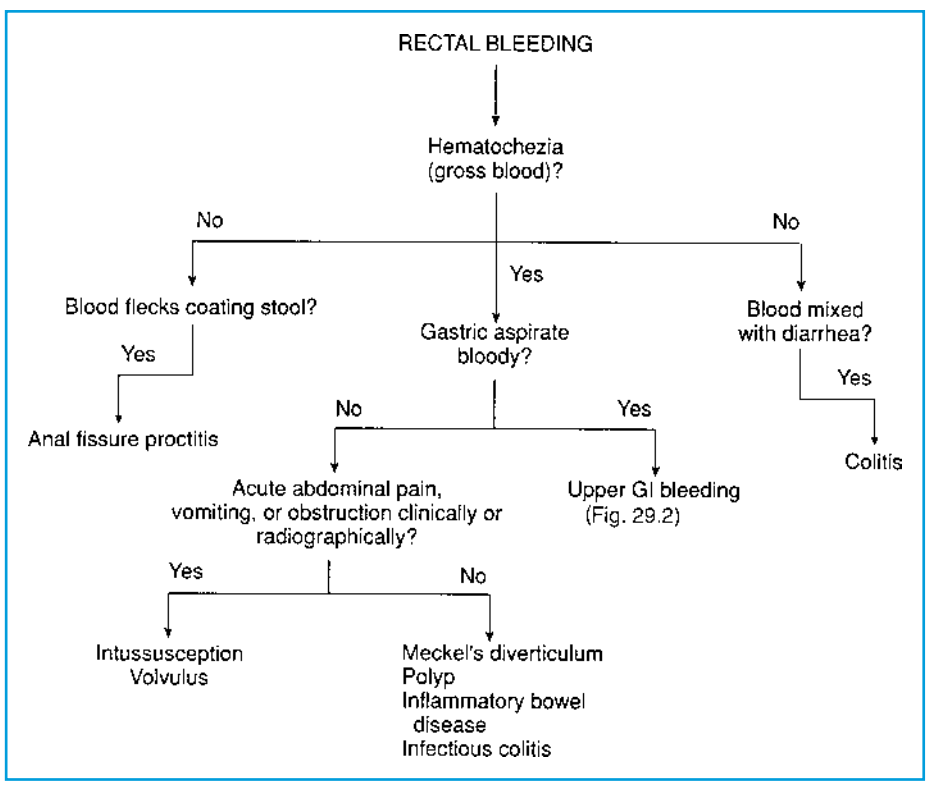

FIGURE 29.3 Diagnostic approach to lower gastrointestinal (GI) bleeding.

bleeding vascular malformations in the GI tract. Ongoing, undiagnosed GI hemorrhage accounts for fewer than 10% of cases in infants and children. Exploratory laparotomy may be necessary and lifesaving in these circumstances.

SUMMARY

Management of acute GI bleeding often requires a team approach, including the emergency physician, surgeon, and gastroenterologist. The foremost goals of ED evaluation of patients with GI bleeding are establishment of hemodynamic stability and determination of level of bleeding. Patients with nontrivial upper GI bleeding should generally be admitted for observation and further evaluation. If an acute abdominal process is suspected, surgical consultation and diagnostic workup should be instituted. If rectal bleeding is mild and self-limited and the history and physical are unremarkable, further investigation with the primary care provider or a gastroenterologist is recommended.

CHAPTER 30 ■ GROIN MASSES

DEENA BERKOWITZ, MD, MPH, AND BRUCE L. KLEIN, MD

Children occasionally present to the emergency department (ED) with an inguinal mass. It may be noticed during a diaper change, or the older child may bring it to the parent's attention; sometimes an adolescent arrives alone seeking help. There are many different causes, ranging from inconsequential to serious (Table 30.1). One generally can ascertain the correct diagnosis based on the age and gender of the child, the location of the mass, how painful it is, how rapidly it has evolved, and whether there are any associated symptoms or signs (Fig. 30.1). Lymph node enlargement and retractile, undescended, ectopic, and traumatically dislocated testes are discussed in this section. Hernia and hydrocele (as well as scrotal masses) are addressed in Chapters 57 and 121.

DIFFERENTIAL DIAGNOSIS

Lymphadenopathy and Lymphadenitis

There are two groups of inguinal nodes: superficial and deep. The superficial ones can be subdivided into a horizontal group that runs parallel to the inguinal ligament and a vertical group located lateral to it. The horizontal group drains lymph from (i) the skin of the lower abdominal wall, perineum, and gluteal region; (ii) the skin of the penis and scrotum; (iii) the mucosa of the vagina; and (iv) the lower anal canal. The vertical group drains lymph from (i) the gluteal region, (ii) the penis and deep structures of the scrotum, (iii) the anterior and lateral areas of the thigh and leg, and (iv) the middle and medial portions of the foot. The deep inguinal nodes, which lie beneath the fascia lata medial to the femoral vein, drain (i) all the superficial nodes, (ii) the clitoris or glans of the penis, (iii) the medial areas of the thigh and leg, and (iv) the lateral portion of the foot.

A healthy child can have a few small nodes normally. Normal inguinal nodes are less than 1.5 cm long, and they tend to be oval, firm, slightly moveable, and nontender. If the nodes are enlarged (especially unilaterally) or tender, erythematous, or suppurating, further evaluation is necessary (see Chapter 43).

Inguinal adenopathy—nodes that are enlarged but nontender—is often part of a more generalized lymphadenopathy. The list of causes of generalized lymphadenopathy is extensive and includes collagen vascular diseases (e.g., juvenile rheumatoid arthritis, serum sickness), immunologic disorders (e.g., chronic granulomatous disease), metabolic diseases (e.g., Gaucher's disease, Niemann-Pick disease), and certain hemolytic anemias. Inguinal nodes may be enlarged because of malignancy (e.g., acute lymphocytic leukemia), but this is rarely the sole presentation of a malignant tumor. Of note, some local tumors, such as testicular tumors, metastasize to the inguinal nodes. Although many infections, particularly viral ones (e.g., human immunodeficiency virus, Epstein-Barr virus), produce inguinal adenopathy, these also usually cause generalized lymphadenopathy as well as hepatosplenomegaly and other abnormalities.

Inflammation or infection of the gluteal region, perineum, genitalia, or ipsilateral lower extremity is the most common cause of isolated inguinal adenopathy or adenitis. These areas must be examined carefully. Chronic eczema, tinea cruris, or an innocuous inflammation (e.g., an insect bite, diaper rash) may produce lymphadenopathy. In such cases, treatment of the underlying condition suffices. If lymphadenitis—enlargement with tenderness, erythema, or suppuration—is detected, the node itself is probably infected. Group A β-hemolytic streptococcus, *Staphylococcus aureus*, or an enteric organism is the usual pathogen, depending on the site of the primary infection. A Gram stain and culture from the primary site or node aspirate helps identify the organism. Most children can be treated as outpatients with oral antibiotics (e.g., clindamycin or trimethoprim–sulfamethoxazole where MRSA is prevalent). Children with severe symptoms should be admitted and treated with intravenous antibiotics. Abscesses caused by these pathogens should be aspirated or incised and drained, unless they are already draining spontaneously (see Chapter 92).

Venereal diseases can result in inguinal adenopathy or adenitis in adolescents. Herpes simplex is a common cause of genital ulcerations and bilaterally enlarged, painful lymph nodes. Occasionally, enlarged lymph glands may precede the appearance of vesicles. Oral acyclovir initiated within the first six days of primary disease shortens the duration of symptoms and viral shedding by 3 to 5 days, but is somewhat less effective in recurrences. Topical acyclovir is not recommended. Symptomatic treatment of primary herpetic lesions does not affect the subsequent frequency or severity of recurrence.

The chancre of primary syphilis is painless and has a raised, indurated border and a clean surface. Bilateral (70%) or unilateral, nontender inguinal adenopathy is common. A positive rapid plasma reagin confirms the diagnosis, but this test is nonreactive in up to 30% of patients with primary syphilis. Recommended treatment for primary syphilis in adolescents is benzathine penicillin G, 2.4 million units, intramuscularly.

Chancroid is more common in developing countries than in the United States. It is caused by *Haemophilus ducreyi,* which is hard to isolate and requires selective media. Unlike syphilis, the chancroid ulcer is painful and nonindurated, and has serpiginous borders and a friable base covered with a gray or dirty yellow exudate. About one-half of patients develop painful adenitis, usually unilaterally. The node or nodes often suppurate and drain spontaneously, or require

needle aspiration or surgical incision. Recommended treatments for adolescents include azithromycin, 1 g, orally or ceftriaxone, 250 mg, intramuscularly.

Lymphogranuloma venereum, which occurs mostly in tropical and subtropical countries, is caused by *Chlamydia trachomatis*. The genital papule, vesicle, or ulcer is often missed because it is painless, inconspicuous, and transitory. One or more unilaterally enlarged, moderately tender, fluctuant nodes are characteristic. If left untreated, these nodes can drain and form fistulae. Three weeks of treatment with doxycycline or erythromycin is necessary, or longer until lesions have resolved.

Granuloma inguinale is caused by the gram-negative bacillus *Calymmatobacterium granulomatis*. Granuloma inguinale is rare in the United States but if untreated results in extensive subcutaneous granulomas (pseudobuboes), which mimic inguinal adenopathy. The initial, small red nodule or vesicle progresses to a painless red mass of granulomatous tissue, which ulcerates and coalesces. Both tetracycline and trimethoprim–sulfamethoxazole are reported to be effective.

An enlarged, tender inguinal node can be caused by plague, brucellosis, tularemia, or cat-scratch disease if the portal of entry for the infective organism is the lower extremity. *Yersinia pestis*, which causes plague, is typically transmitted by flea bites and is (extremely) rare in the United States; however, pneumonic plague has become of heightened concern in more recent years as a potential agent of bioterrorism (see Chapter 7). The buboes are firm and extremely tender. The overlying skin is often warm and edematous. Mortality can be as high as 80%. Streptomycin or gentamicin is the drug of choice for children in most cases.

Inguinal lymphadenopathy can be seen in ulcero-glandular tularemia when it is caused by an infected tick bite on the lower extremity. Like plague, pneumonic tularemia is considered a possible bioterrorism threat (see Chapter 7). Enlarged, tender, regional lymph nodes precede the appearance of a small papule (at the portal of entry) that later ulcerates. Streptomycin, gentamicin, or amikacin is recommended for children.

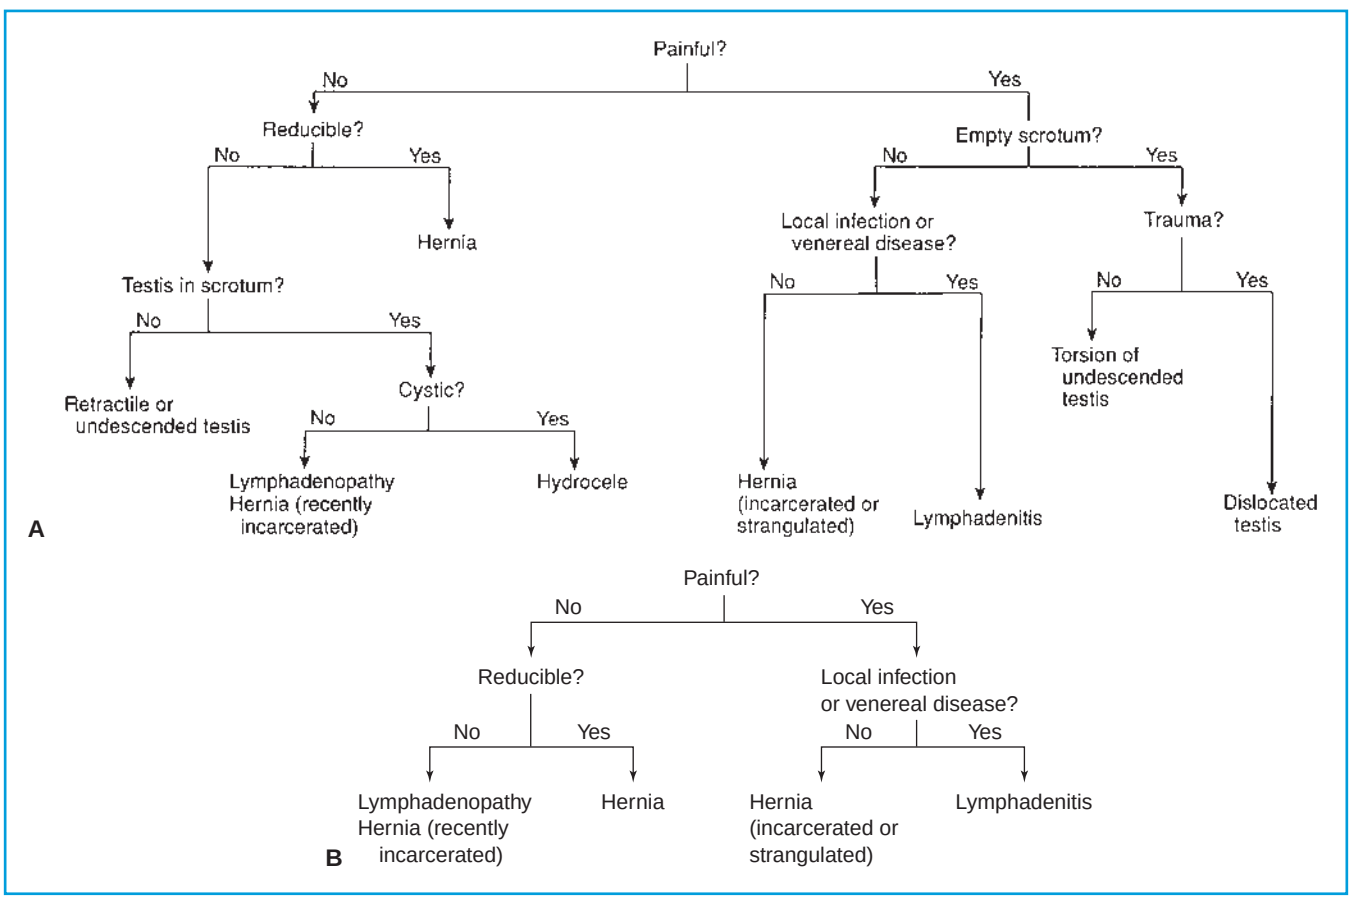

FIGURE 30.1 **A:** Groin masses in boys. **B:** Groin masses in girls.

Infection with *Bartonella henselae* (cat-scratch disease) results in regional lymphadenopathy that is usually red, indurated, and warm. Painful suppurative nodes can be treated with needle aspiration for relief of symptoms; incision and drainage should be avoided and surgical excision is unnecessary. Usually, the lymphadenopathy resolves spontaneously within 2 to 4 months. Antibiotic treatment for immunocompetent children with mild disease is of uncertain value (see Chapter 43).

Filariasis, which is found in the tropics, can produce adenopathy or adenitis associated with lower-extremity lymphedema and scrotal pathology. Diethylcarbamazine citrate (DEC) is the drug of choice for lymphatic filariasis.

Retractile, Undescended, Ectopic, and Traumatically Dislocated Testes

If the inguinal mass is firm, oval, and nontender and is associated with an empty scrotum, it probably is a retractile or undescended testis. A retractile testis, in contrast to a truly undescended one, is pulled into its abnormally high position by a hyperactive cremasteric reflex and can be "milked" back into the scrotum by the examiner. When the testicle is retractile, the scrotum appears fully developed. Although it may retract again, it will ultimately assume a normal position; therefore, no treatment is needed (see Chapter 124).

An undescended testicle occurs in 2% to 4% of term boys. As expected, its incidence correlates inversely with gestational age. For example, cryptorchidism is about ten times more common in boys born at 30 weeks' gestation, and practically all premature boys who weigh less than 900 g at birth are cryptorchid. The incidence falls to about 0.8% by 1 year of age. Because this is similar to the incidence in adult men, it seems that spontaneous descent rarely occurs after 6 months to 1 year of age. The testis can lodge anywhere along its natural line of descent—for example, intraabdominally, in the inguinal canal, or just outside the external inguinal ring. (An intraabdominal testicle is not palpable, and the scrotum appears underdeveloped.) Cryptorchidism is right-sided in about 50% of patients, left-sided in 20%, and bilateral in 30%. There is a right-sided predominance possibly because the right testicle descends later than the left one during embryologic development. Bilateral cryptorchidism occurs more often in premature boys and in conjunction with some anatomic, enzymatic, and chromosomal disorders that are diagnosed in the delivery suite or shortly thereafter. There is an increased incidence of cryptorchidism among family members.

The testis can also be located ectopically—for example, in a superficial pouch near the external ring or, less commonly, in the suprapubic, perineal, or femoral areas. It is important to note that an ectopic testis will never descend into the scrotum spontaneously.

If cryptorchidism is left untreated, various complications, including testicular hypotrophy, infertility, malignancy, injury related to trauma, torsion, and development of an inguinal hernia, can ensue. Regarding infertility, germ cell depletion increases after 15 months of age; other degenerative changes, such as Leydig cell atrophy, smaller seminiferous tubules, and peritubular fibrosis, also develop over time. These histological abnormalities are worse in testicles located more proximally. Interestingly, sperm counts are diminished in the normally descended testis, too, although not as markedly. The incidence of malignancy is increased four- to sevenfold compared with men who have normally descended testes. The malignancy is usually a seminoma or a nonseminomatous germ cell tumor, presenting later in life. If an undescended testicle is located in the inguinal region, it is more likely to be injured from trauma. Also, torsion occurs more often in cryptorchid testes. Finally, approximately 90% of undescended testicles are associated with a patent processus vaginalis, increasing the possibility that a hernia will develop.

Early referral to a urologist is warranted. Nowadays, laparoscopy is the preferred way to locate an impalpable testis. Although ultrasound, computed tomography scan, or magnetic resonance imaging scan sometimes yield positive findings, there are high false-negative rates with these studies. In no instance should a negative imaging study be interpreted as meaning the testis is not present. Orchiopexy (laparoscopic and/or surgical) is generally performed around 1 year of age, although many urologists recommend earlier treatment. During orchiopexy, the testis, spermatic cord, and vascular structures are mobilized and brought down into the scrotum, where the testis is either pexed or placed into a dartos pouch; in addition, the processus vaginalis is ligated if it is patent. (In some cases of cryptorchidism, the testis cannot be found during exploration or appears maldeveloped.) Although it was hoped that earlier orchiopexy would decrease the incidence of malignancy, this remains controversial. Because the testis can be palpated more easily when it is in the scrotal sac, orchiopexy should facilitate earlier diagnosis of a malignancy; however, this too has never been established. In certain cases, early orchiopexy may improve the chances for fertility.

Hormonal therapy (e.g., human chorionic gonadotropin) to promote testicular descent may benefit a few select cases. However, studies from the United States have demonstrated that it is not very effective, especially when retractile testes are excluded. (In fact, many pediatric urologists use it mainly to differentiate retractile from undescended testes.) Some clinicians report that it works better in infants than older boys. It is ineffective if the testis is located ectopically.

Finally, a traumatically dislocated testicle may be discovered in the groin. Testicular dislocation occurs primarily in the older adolescent and young adult but is rare even then. It usually follows major trauma—for example, a deceleration straddle injury in a motorcyclist. Often an associated injury, such as a pelvis or femur fracture, is found. Despite swelling, ecchymosis, and tenderness, the scrotum feels empty. As mentioned, sometimes the testis is palpated in an abnormal location, most often in the groin in the superficial pouch anterior to the external oblique aponeurosis. Occasionally, the testis can be manually reduced, but if this is unsuccessful, surgery is necessary (see Chapter 112).

EVALUATION AND DECISION

In evaluating a groin mass, one must consider the gender of the child, presence or absence of pain, location of the testis (in boys), response to attempted reduction, history of trauma, and findings of local infection.

Boys

In boys (Fig. 30.1A), pain often heralds a potentially emergent condition, including torsion of an undescended testis, an incarcerated or strangulated hernia, or a significant injury. One begins the evaluation by carefully palpating the scrotum. An empty scrotum points to a dislocated testis after trauma or spontaneous torsion of an undescended testis. In a boy with bilaterally descended testes, an isolated, painful groin mass may be an incarcerated or strangulated inguinal hernia. The finding of penile lesions, such as those of herpes or syphilis, or cutaneous inflammatory lesions, such as insect bites, eczema, or infected lacerations on the legs or lower abdomen, identifies the source of inguinal lymphadenitis.

Painless groin masses in boys are usually not urgent. If the mass is reducible, it is an inguinal hernia, which can be repaired electively. The absence of a testis in the scrotum on the side of the mass suggests a retractile or undescended testis. A retractile testis is more likely in the boy presenting with new-onset swelling; the diagnosis can be confirmed in most cases by "milking" the testis into the scrotum. When both testes are descended, a painless mass is likely to be either a hydrocele or an enlarged lymph node. One must keep in mind that a recently incarcerated hernia may be painless and is easily confused with a solitary, enlarged lymph node.

Girls

As for boys, one should first ascertain the presence or absence of pain. The highest priority in girls with painful masses (Fig. 30.1B) is to identify an incarcerated or strangulated hernia. Local lesions or signs of inflammation point to lymphadenitis.

Although hernias occur less often in girls than boys, they are still relatively common. The ability to reduce the mass with gentle pressure confirms this diagnosis. When a painless mass is irreducible, a recently incarcerated hernia (particularly involving an ovary) or an enlarged lymph node is the most likely cause.

CHAPTER 31 ■ HEARING LOSS

ROBERT J. VINCI, MD

Normal hearing is crucial for the proper development of speech and language, especially during early childhood development. Persistent hearing loss will distort a child's perception of expressive speech and language and may compromise the ability to attain normal language. Failure to recognize hearing impairment may lead to cognitive impairment and may negatively impact school performance, socialization, and emotional development. Acute hearing loss is of two main types: conductive and sensorineural. Several serious—even life-threatening—disorders can accompany acute hearing loss. Therefore, prompt clinical evaluation is mandated when hearing loss is suspected.

Hearing loss can occur as an isolated symptom or in association with auditory or central nervous system (CNS) dysfunction. The differential diagnosis of hearing loss includes congenital and acquired causes. It may be produced by the abnormal transmission of sound waves to the inner ear (conductive hearing loss) or by the defective processing of sound waves (sensorineural hearing loss) in the inner ear (Table 31.1). In young children, the possibility of acute hearing loss may be suspected by parents when the child does not respond to noise or to simple commands. Abnormal or delayed language development may be a sign of a more chronic process. Older children and adolescents may complain directly of hearing difficulty.

PATHOPHYSIOLOGY

An intricate series of properly aligned anatomic and physiologic connections is responsible for the precise functioning of the auditory system. The auricle or outer ear is designed to receive sensory transmission or "sound waves" from the child's environment. A patent external ear canal is required for the passage of sound waves to the tympanic membrane.

When sound reaches the tympanic membrane, vibrations of the membrane are transmitted and produce movement of the ossicles located within the middle ear. The vibrations of the ossicles produce fluid waves of the inner ear fluid within the cochlea. Here the specialized receptors in the form of hair cells in the spiral organ of Corti convert this mechanical energy to nerve impulses that are transmitted by the cochlear (acoustic) nerve, the auditory portion of the eighth cranial nerve to the brain. These nerve impulses are integrated by the brain and transformed into what we now perceive as sound. It is important to note that, anatomically, the acoustic apparatus is closely related to the vestibular system, which is concerned with the proprioceptive senses of posture and equilibrium. The three semicircular canals of the vestibular system are connected to the cochlear system; therefore, abnormalities in the inner ear may cause both auditory and vestibular symptoms.

DIFFERENTIAL DIAGNOSIS

Conductive Hearing Loss

In children, conductive hearing loss occurs when there is a decrease in the transmission of sound waves from the external environment to the cochlea or inner ear. Commonly, middle ear effusion (acute or chronic), impacted cerumen, foreign body of the external ear canal, infections of the external ear canal (otitis externa), and fixation or disruption of the middle ear ossicles may produce conductive hearing loss (Table 31.1). In children with chronic recurrent/otitis media (OM), a cholesteatoma—an epidermal inclusion cyst of the middle ear—may develop and cause a slowly progressive conductive hearing loss. Acute head injury, especially in association with a basilar skull fracture, may produce a conductive hearing loss secondary to hemotympanum, rupture of the tympanic membrane, or disruption of the inner ear ossicles. Especially in young children, perforation of the tympanic membrane can occur from self-inflicted injury from a cleaning device such as a cotton swab. Rarely, the conductive hearing loss may be secondary to malformations of the external or middle ears, such as malformations of the auricle, absence of the external ear canal, or atresia of the ossicular chain.

Congenital Sensorineural Hearing Loss

Approximately 1 of every 750 infants is born with congenital hearing loss. Diagnostic possibilities include genetic disorders, chromosomal abnormalities, metabolic and storage diseases, and abnormal development of the auditory apparatus (Table 31.1). Congenital hearing loss secondary to aplasia of the inner ear (Michel's aplasia) and abnormal cochlear development (Mondini's aplasia), or absence of parts of the cochlear apparatus (Scheibe's aplasia, Alexander's aplasia), are reported in children. Sensorineural hearing loss has been described in more than 70 syndromes, including Waardenburg syndrome (facial dysmorphism, white forelock), Jervell and Lange-Nielsen syndrome (prolonged Q-T syndrome), Usher's syndrome (retinitis pigmentosa and sensorineural hearing loss), and Alport's syndrome (nephritis, optic abnormalities, and hearing loss). The chromosomal disorders caused by trisomies (especially trisomies 13 to 15, 18, and 21) are associated with defects in hearing. Many of these patients are diagnosed because of anatomic features associated with each of these disorders,

TABLE 31.1

DIFFERENTIAL DIAGNOSIS OF HEARING LOSS

I. Conductive Hearing Loss
  A. Middle ear effusion
    1. Acute or chronic
  B. Impacted cerumen
  C. Foreign body of external ear canal
  D. Otitis Externa
  E. Ossicle dysfunction (fixation)
  F. Cholesteatoma
  G. Acute trauma
    1. Hemotympanum
    2. Rupture of the tympanic membrane
    3. Disruption of the inner ear ossicles
  H. Malformation of the auricle or external ear canal
  I. Atresia of the ossicle chain
II. Sensorineural Hearing Loss
  A. Congenital or neonatal
    1. Anatomic abnormalities
      a. Aplasia of the inner ear (Michel's aplasia)
      b. Abnormal cochlear development
        i. Mondini's aplasia
        ii. Scheibe's aplasia
        iii. Alexander's aplasia
    2. Syndromes (more than 70 described with hearing loss)
      a. Waardenburg syndrome
      b. Jervell and Lange-Nielsen syndrome (prolonged Q-T syndrome)
      c. Usher's syndrome
      d. Alport's syndrome

although the hearing loss that occurs may be present at birth or develop over time. Overall, one-third of patients with congenital hearing loss have associated clinical symptoms of a known syndrome. The remaining two-thirds of patients are classified as having nonsyndromic hearing loss. More recent advances in genetic testing have begun to elucidate gene abnormalities in patients with nonsyndromic hearing loss.

Acquired Sensorineural Hearing Loss

Although acquired sensorineural hearing loss occurs less commonly than congenital hearing loss, the absence of associated symptoms may make it a more difficult diagnosis. An array of clinical problems can produce sensorineural hearing loss during childhood.

Acute Infection

Hearing loss secondary to bacterial meningitis is the most common cause of acquired sensorineural hearing loss. Reported in 15% to 20% of patients with meningitis, the hearing loss is usually profound and often bilateral. The hearing loss associated with meningitis is organism specific and most commonly associated with *Streptococcus pneumoniae* (31%), but was also associated with infections caused by *Haemophilus influenzae* (9% to 18%) and *Neisseria meningitides* (10%), and can develop despite appropriate antimicrobial therapy. Since the mid-1990s, vaccine programs that have led to a decrease in the incidence of *H. influenza* and *S. pneumoniae* infections have been instrumental in decreasing the occurrence of this complication. For patients with acute bacterial meningitis, adjunctive therapy with dexamethasone may decrease the inflammation in the subarachnoid space and lessens neurologic sequelae such as hearing loss. To be most effective, the dexamethasone therapy should be given to the patient before or with the initial administration of antibiotics. All children who have had bacterial meningitis should have a complete hearing evaluation as part of their follow-up from their acute hospitalization.

Congenital infection caused by cytomegalovirus (CMV) is the most common intrauterine infection that produces sensorineural hearing loss. Congenital infection from rubella, syphilis, toxoplasmosis, and perinatally acquired herpes simplex infections are also associated with acquired sensorineural hearing loss. The hearing loss associated with these infections may occur in infants with no other manifestations of congenital infection and may not develop until early childhood. Thus, many experts advocate for universal newborn hearing screening and regular monitoring of children with known congenital infections or high-risk infants such as neonatal intensive care unit graduates.

Viral infections of the labyrinth (also called viral cochleitis) secondary to mumps, parainfluenzae, adenovirus, herpes simplex, CMV, and rubeola have been described and confirmed by serologic studies. Labyrinthitis usually has symptoms related to inflammation of the inner ear and involvement of the vestibular apparatus, and patients may complain of vomiting, tinnitus, and vertigo.

Vascular Insufficiency

Sudden hearing loss secondary to vascular insufficiency has been described in the pediatric patient. Vascular insufficiency may compromise blood flow to the cochlea, producing a

hypoxic insult to the sensitive nerve cells in the organ of Corti. Once injured, these nerve cells may not regenerate and profound sensorineural hearing loss can develop. In children, sickle cell disease, long-standing diabetes mellitus, and hyperviscosity states associated with polycythemia can compromise cochlear blood flow and produce sudden hearing loss.

Perilymphatic Fistula

Anatomic defects in the bony or membranous enclosure that normally surrounds the perilymphatic space can produce a perilymphatic fistula. These defects may produce an anomalous communication between the middle and inner ear compartment and should be considered in the differential diagnosis of the pediatric patient with acute sensorineural hearing loss. A perilymphatic fistula can occur at any age. The sudden ingress of air into the inner ear is believed to produce the symptom complex of hearing loss, tinnitus, vertigo, dizziness, and nystagmus. Antecedent trauma usually underlies the development of a fistula. This is especially true in any patient who has a recent history of vigorous exercise or changes in barometric pressure associated with airplane travel or scuba diving. Although unilateral hearing loss is most common, bilateral hearing deficits have been described. Occasionally, a perilymphatic fistula will develop in a child with previously abnormal hearing. Therefore, this diagnosis needs to be considered in any patient who has sudden onset of hearing loss, fluctuation in hearing, or complaints of progressive hearing loss, regardless of baseline hearing function. Patients with a perilymphatic fistula generally have a normal otoscopic examination. If a tympanogram is performed, middle ear effusion is usually absent. Emergent referral to an otolaryngologist is warranted because surgery may be required for closure of the anatomic defect.

Head Trauma

Both the vestibular and cochlear nerves can be injured with fractures of the temporal bone. Assessment of audiologic function should be considered in any child with major head trauma; computed tomography (CT) scan may be required to diagnose these injuries.

Acoustic Trauma

Immediate, severe, and permanent hearing loss can follow even a short period of exposure to sound greater than 140 dB. Exposure to sounds in the 80- to 100-dB range can produce hearing loss with chronic exposure and is most commonly diagnosed in adolescents. Rock concerts, stereo headphones, machinery, and explosive devices are capable of producing sound at the intensity required to produce this condition.

Chronic/Recurrent Otitis Media

A history of chronic/recurrent OM may predispose patients to the development of sensorineural hearing loss. This hearing loss is believed to be related to inflammatory changes in the inner ear produced by the diapedesis of toxins through the round window membrane. Such involvement of the inner ear has been confirmed pathologically by the presence of labyrinthitis in patients with acute OM. Because middle ear effusions produce a conductive hearing loss, the clinician must be aware of the possibility of OM producing a mixed picture.

Functional Hearing Loss

Functional hearing loss may occur in patients who have a psychological component to their presentation. Most commonly occurring during adolescence, functional hearing loss should be considered in patients who present with other manifestations of psychiatric illness. Often, these patients will have a normal physical examination and inconsistent findings with bedside hearing tests. Formal audiologic testing will be normal in these patients and mental health referral is indicated to elucidate the cause of this apparent hearing loss.

Miscellaneous

Acoustic neuroma, CNS tumors, and leukemic infiltrates are also associated with sensorineural hearing loss. Other considerations in pediatric patients include Kawasaki disease, hypothyroidism, lightning injury, hyperlipidemia, and hyperbilirubinemia, or the use of ototoxic drugs in the neonatal period. Finally, some children will have no demonstrable cause for their hearing loss.

EVALUATION AND DECISION

Any complaint of hearing loss requires prompt evaluation. Common causes of acute hearing loss are listed in Table 31.2. Life-threatening causes of acute hearing loss are rare in pediatric patients (Table 31.3). The initial step in evaluation is to confirm the presence of acute hearing loss (Fig. 31.1). Although sophisticated hearing tests are best performed by an audiologist, the emergency physician should attempt bedside testing of gross hearing function. In young children, behavioral responses to loud stimuli can be assessed. Without attracting visual attention, an auditory stimulus (e.g., vigorous hand clapping or ringing a bell) can be presented to the child. Eye blinking or turning toward the stimulus represents a positive response and suggests some degree of intact hearing. In older children or adolescents, hearing can be assessed by asking the patient if he or she hears a low-intensity sound such as a soft whisper or fingers rubbing together. Because hearing dysfunction can be subtle and can occur over the entire range of auditory frequencies, these bedside tests may underestimate the degree of hearing impairment. Therefore, an abnormal test should be considered a confirmation of hearing impairment; a

TABLE 31.2

COMMON CAUSES OF ACUTE HEARING LOSS

negative test needs to be interpreted in the context of the chief complaint of the patient. If the history remains strongly suggestive of hearing loss, the physician should assume some degree of hearing loss despite the results of bedside testing and formal audiology follow-up is required.

Critical elements of the medical history should include the onset of the hearing loss and the duration of symptoms. Family history of hearing loss may suggest the diagnosis of a genetic disorder with delayed presentation of hearing loss. A history of birth asphyxia, prematurity, hyperbilirubinemia, or maternal infection points to a neonatal cause. A more recent history of head trauma or barotrauma (e.g., scuba diving) may suggest the diagnosis of perilymphatic fistula. Fever and otalgia suggest a diagnosis of acute OM. Associated neurologic symptoms such as tinnitus, vertigo, and dizziness suggest inner ear disease or CNS involvement. Headache can be a marker for tumor of the CNS or extension of middle ear infection (Fig. 31.1).

TABLE 31.3

LIFE-THREATENING CAUSES OF ACUTE HEARING LOSS

Acute head injury
Brain tumor
Leukemic infiltrate
Vascular insufficiency

On physical examination, the presence of fever may suggest an infection such as OM or viral labyrinthitis. A detailed otoscopic examination to detect the presence of a middle ear effusion, impacted cerumen or evidence of an external ear infection, perforated tympanic membrane, foreign body, or other abnormality of the tympanic membrane is a priority. Tympanometry can be used to supplement the physical examination, especially if the otoscopic examination suggests the presence of middle ear disease. Because of the intricate relationship between the cranial nerves, a careful neurologic examination is required. Within the petrous bone, the cochlear nerve is closely related to the seventh cranial nerve and the vestibular branch of the eighth cranial nerve. An ipsilateral facial nerve palsy in a patient with hearing impairment suggests an intracranial process. Vestibular function should be tested looking for the presence of nystagmus at rest and with directed gaze. Patients with vestibular dysfunction often fall to one side with Romberg testing or have difficulty with rapid alternating movements or finger-to-nose testing.

Once hearing loss is established, the next step in the emergency department (ED) is to differentiate conductive from sensorineural hearing loss with the use of tuning fork tests (Fig. 31.1). Conductive hearing loss can be confirmed by the Weber test. In the Weber test, a vibrating, 512-Hz tuning fork is placed in the midline of the patient's forehead. Patients with hearing loss will report that the vibrations of the tuning fork lateralize to the side with the conductive hearing loss

(vibrations are felt better in the bad ear) or away from the side with the sensorineural hearing loss (vibrations are felt better in the good ear). For the Rinne test, the vibrating tuning fork is placed against the mastoid process. When the patient signals that the vibration has ceased, the tuning fork is placed adjacent to that ear to determine whether the patient can hear the sound of the still-vibrating tuning fork. Patients with conductive hearing loss will not be able to hear the tuning fork. This is a negative Rinne test (bone conduction greater than air conduction). Sensorineural hearing loss shows up as a positive Rinne test (air conduction greater than bone conduction). Finally, a test by confrontation is performed by placing a tuning fork at a point equidistant from both ears. Regardless of the type of hearing loss, the patient will report the sound to be higher on the side with normal hearing.

Laboratory evaluation is seldom necessary in the ED; when needed, it should focus on a diagnosis that may be contemplated after obtaining a detailed history and physical examination. Complete blood cell (CBC) count and peripheral blood smear, renal function tests, serologic tests for syphilis, TORCH titers, and bacteriologic cultures should be performed only if the history and physical suggest an associated diagnosis. Thyroid function tests, lipid profile, and serum calcium levels should be individualized in the context of clinical findings. Referral for genetic testing may be indicated for children with congenital sensorineural hearing loss.

In children with the clinical suspicion of intracranial pathology, a radiologic evaluation assists in the diagnosis. Patients with known or suspected congenital malformation of the middle and inner ears should be evaluated with a CT scan because bony detail is essential for diagnosis. Inner ear abnormalities have been demonstrated in 8% to 20% of patients with sensorineural hearing loss. A CT scan should also be performed in patients with suspected fracture of the temporal bone. Magnetic resonance imaging is indicated for the accurate diagnosis of an acoustic neuroma or for any patient with suspected retrocochlear pathology. With the addition of paramagnetic contrast, high-resolution scanning, and thin-section techniques, excellent detail of the internal auditory canal can be achieved.

Most children with decreased hearing in the ED have a conductive hearing loss. If impacted cerumen is seen on examination, it must be removed because it may be the cause of the decreased hearing and prevents further otoscopic evaluation. Children whose hearing improves after disimpaction and who have a normal otoscopic examination need no further treatment. Patients without impacted cerumen and those who fail to improve after removal of cerumen may have a foreign body in the ear canal. Only large objects that completely obstruct the external auditory canal should impair hearing; thus, this diagnosis is easily established during otoscopic examination. Foreign bodies may be removed either by grasping the object with alligator forceps or by placing a right angle instrument behind the object and then gently withdrawing the instrument and pulling the foreign body with it. Care must be taken to avoid irrigation of an ear canal if the foreign material consists of vegetable matter that could expand from the irrigation. Finally, irrigation is contraindicated with known or suspected perforations of the tympanic membrane.

The next step in the evaluation is a careful examination of the tympanic membrane, including pneumatic otoscopy. Many patients will show evidence of a middle ear effusion, the most common cause of hearing loss seen in the ED. Rarely, a cholesteatoma may be seen through the translucent tympanic membrane. Sensorineural hearing loss is seen less often in the ED. Most children with sensorineural hearing loss have congenital problems that are diagnosed during the course of routine care, although occasional cases will be brought to the attention of the emergency physician. Among the acquired causes, those that must be diagnosed urgently include CNS tumors, vascular accidents, and perilymphatic fistula. In cases of acquired sensorineural hearing loss, a history of trauma should be sought. Direct blows to the head may cause temporal bone fractures or a perilymphatic fistula, and sudden changes in pressure may injure the cochlea. If there is no preceding trauma, a careful neurologic examination should be performed, looking for evidence of CNS tumors. A CT scan is indicated if these lesions are suspected. The most common cause of acquired sensorineural hearing loss seen in children in the ED without a history of trauma is viral labyrinthitis. These patients usually have associated tinnitus, vertigo, and vomiting but no focal neurologic abnormalities. Most of the remaining causes of hearing loss are idiopathic. Vascular insufficiency merits consideration in children with sickle cell anemia, diabetes mellitus, and collagen vascular disease. If the cause of the hearing loss remains uncertain, otolaryngologic consult and evaluation should be considered.

CHAPTER 32 ■ PATIENTS WITH HEART MURMURS

BENJAMIN K. SILVERMAN, MD

A cardiac murmur is a noise created by the turbulence of blood flow, under varying pressures, through chambers and vessels and across valves that are of unequal sizes and shapes. The murmur itself is not an abnormality. Most murmurs, in fact, are sounds created by normal turbulence and, therefore, are best referred to as "normal" or "flow" rather than the less appropriate adjectives, "innocent" or "functional" (Table 32.1). Some loud murmurs are created by clinically inconsequential defects (e.g., small ventricular septal defects), whereas other, barely discernible, murmurs may be associated with far more serious defects or illnesses, such as acute myocarditis (which has a murmur only in rare patients with severe dilatation causing valvular insufficiency) or transposition of the great vessels. A host of cardiac and several extracardiac conditions can be associated with heart murmurs (Table 32.2).

In a "first encounter" examination of a child, the emergency physician will often hear a murmur and then must determine how to fit this finding into the sometimes complicated evaluation of the patient's current illness. Is the murmur an incidental finding of no relevance? Is it suggestive of heart disease? If so, are there cardiac-related symptoms? Is it related to life-threatening illness, not necessarily of cardiac origin?

Certain priorities prevail that should precede the further definition of the murmur per se. It is not important to pinpoint a primary cardiac lesion immediately, but it is essential to determine whether the patient is in cardiac decompensation, whether life is at risk, and whether there is an incipient need for evaluation by a cardiologist or cardiac surgeon.

The ultimate goal of this chapter is to provide criteria for determining whether a patient's murmur is associated with life-threatening illness of cardiac or extracardiac origin, and whether the patient needs cardiac consultation now, or eventually, or not at all.

DIFFERENTIAL DIAGNOSIS

History

Unless the patient is in extremis, a careful, focused history is always the starting place. For the patient in whom a murmur is heard, in addition to usual history related to the present complaint, relevant questions might include the following:

- If the patient is an infant, were ultrasound aberrations found during pregnancy?
- Has the murmur been known to have been present? If so, since when? Has it been evaluated at any previous examination? If so, what were the findings and conclusion? Has there been cardiac surgery?
- Was there an antecedent illness before discovery of the murmur? Sore throat? Viral infection? Apparent respiratory infection?
- Are there or have there been associated signs or symptoms? Feeding problems? Weight gain or loss? Difficult breathing? Cyanosis? Edema? Hypertension? Chest pain? Joint symptoms? Congenital defects?
- Does the child tire easily (during feedings in infants)? How far can he or she walk? Does the child squat after walking? Climb stairs? Have cyanotic "spells"?

Examination

The examination should consist of as complete a physical as possible under the prevailing circumstances.

Murmur Characteristics

Most physicians cannot dissect a murmur in intricate detail with the precision of a cardiologist. Therefore, although the characteristics are briefly defined here, the subsequent course of this chapter makes only minimal use of them. More detailed descriptions of murmur characteristics are given in the references at the end of this chapter.

- *Timing and duration:* Is the murmur systolic (between the first and second heart sounds) or diastolic (between the second and first sounds)? Early, mid, late, or throughout systole (holosystolic)? Beginning in systole and persisting into diastole (continuous)?
- *Intensity (loudness):* Usually graded from barely discernible (grade I) to accompanied by a palpable thrill (grade IV) to audible without making contact with the chest (grade VI).
- *Shape:* Terms such as *diamond-shaped, plateau, crescendo,* and *decrescendo* are more easily understood when learned in conjunction with a phonocardiogram; interpreting them by ear requires training and persistent practice.
- *Quality: Musical, blowing, rumbling, wood-sawing, harsh, vibratory, twang, soft, rough, grating,* and *click* are among the subjective terms used.
- *Frequency (pitch):* Described qualitatively as low, medium, or high.
- *Location and transmission:* Location is the point of maximum intensity (upper, lower, or mid left or right sternal margin; apex; midclavicular or axillary line; at which rib interspace?). Transmission refers to the areas of maximal spread of the sound (to the back, to the neck, axilla, throughout entire precordium).

TABLE 32.1

CHARACTERISTICS USUALLY ASSOCIATED WITH A "NORMAL" MURMUR

Timing: midsystole
Intensity: grades I through III
Location of maximal intensity: midsternal border
Radiation: possibly faintly to the precordium and neck, but rarely the back
Quality: "twangy" or "vibratory"
Heart sounds: readily definable, including splitting of S_2

Precordial Examination

The remainder of the precordial examination should be completed; inspect for left- or right-sided chest bulge, palpate for thrills and clicks and points of maximal impulse, and listen carefully for the heart sounds and adventitial sounds. The physician must interpret the first and second sound for intensity and splitting. The third and fourth sounds, opening snaps, clicks, rubs, and some unusual rhythms may be confused for murmurs at times and should be kept in mind as possible confounding factors.

Associated Signs and Symptoms

Vital Signs. Normal ranges of vital signs for age are listed in Appendix D at the end of this book.

- *Heart rate and rhythm:* Check the heart rate, and listen and palpate for rhythm disturbances (see Chapters 74 and 84). The normally rapid rate of the infant makes evaluation of the murmur even more difficult. Palpate the brachial and femoral artery pulsations.
- *Blood pressure:* Ascertain that a proper-size cuff is used. Lower-extremity pressures are normally measured 10 to 40 mm Hg higher than upper pressures.
- *Respirations:* Count the rate and observe for retraction, asymmetry, and hypoexpansion.
- *Body temperature:* Infants with heart murmurs are subject, of course, to the multiple causes of elevated body temperature as any other child. Particularly, though, infective endocarditis must be thought of in any child with heart disease and fever. Children with acute episodes of acquired entities, such as rheumatic fever and myocarditis, will probably be febrile. Hypothermia may be associated with cardiac shock.

TABLE 32.2

CONDITIONS THAT MAY BE ASSOCIATED WITH PRESENCE OF A CARDIAC MURMUR[a]

I. Infancy
  A. Cardiac
    1. Noncyanotic
      a. Normal murmur ("innocent" murmur)
      b. Congenital defects
        (1) Patent ductus arteriosus
        (2) Atrial septal defect
        (3) Ventricular septal defect
        (4) Aortic stenosis
        (5) Coarctation of aorta
        (6) Pulmonary stenosis
        (7) Partial anomalous pulmonary venous drainage
      c. Myocarditis
      d. Primary myocardial disease
    2. Cyanotic
      a. Congenital defects
        (1) Tetralogy of Fallot
        (2) Transposition of the great vessels
        (3) Truncus arteriosus
        (4) Pulmonary atresia
        (5) Severe pulmonary stenosis with patent foramen
        (6) Tricuspid atresia
        (7) Ebstein's anomaly
        (8) Total anomalous pulmonary venous drainage
        (9) Atrioventricular canal defect
        (10) Hypoplastic left heart
        (11) Primary Pulmonary Hypertension
      3. Congestive cardiac failure
        a. Secondary to any of the previous, as well as noncardiac causes listed as follows
  B. Extracardiac
    1. Severe anemia
    2. Arteriovenous malformation
    3. Pulmonary insufficiency (including infection, hypoperfusion, pulmonary arterial hypertension)
    4. Hyperpyrexia
II. Older Child
  A. Cardiac
    1. Normal murmur
    2. Congenital defect (same list as for infancy—both cyanotic and noncyanotic)
    3. Mitral valve prolapse
    4. Myocarditis (viral, collagen, toxic, endocrine, genetic)
    5. Acute rheumatic fever
    6. Healed rheumatic carditis
    7. Subacute bacterial endocarditis
    8. Congestive cardiac failure (associated with any of previous or following noncardiac diseases)
  B. Extracardiac
    1. Severe anemia
    2. Arteriovenous malformation
    3. Pulmonary insufficiency (with incidental murmur)
    4. Thyrotoxicosis
    5. Hyperpyrexia

[a]It should be kept in mind that *any* pediatric problem may be coincidentally associated with the presence of a normal cardiac murmur or with one of the other conditions in this table. The algorithms and chapter text are constructed to help sort out the significance of the murmur in the context of patient management.

Pulse Oximetry. Pulse oximetry is used to evaluate the presence and degree of oxygen desaturation and is sometimes referred to as "the fifth vital sign."

Color. Central cyanosis (see Chapters 15 and 98) is diffuse and is best differentiated from peripheral cyanosis by involvement of the tongue. Central cyanosis due to cardiac lesion may be differentiated from cyanosis due to pulmonary disease by the hyperoxia test—exposing the child to 100% oxygen while monitoring with pulse oximetry. Those with pulmonary disease may improve their oximetry reading while those with cardiac lesions probably will not. If accompanied by clubbing of the distal fingers in the older child, cyanosis is probably chronic and persistent. Severe pallor related to marked anemia may be associated with high-output cardiac failure.

Signs Associated with Cardiac Failure. Additional signs that may be associated with cardiac failure are listed as follows (also see Chapter 84):

- *Edema:* More likely to be dependent and pitting in cardiac disease. In the preambulant child, dependent edema may be appreciated best along the back, rather than the lower extremities, and also may be prominent in the periorbital area.
- *Neck veins:* Check for distended jugular veins in the neck of the patient who is lying flat or propped at a 45-degree angle.
- *Respiratory effort:* Look for tachypnea, grunting, difficult breathing (particularly subcostal retractions), and for the patient more comfortable when resting in an upright position. Listen to the lung fields for crackles and wheeze, usually symmetric in a patient in cardiac failure.
- *Organ enlargement:* Palpate for a soft, engorged liver (particularly the left lobe, which becomes palpable early in right-sided congestive heart failure). Check for splenomegaly.

Remaining Examination. Also look for the following signs:

- *Skin:* Look for non-blanching petechiae on the surface of the skin, in the conjunctivae, and under the fingernails. Also search for erythema marginatum and subcutaneous nodules. Look for thoracotomy scars.
- *Joints:* Check for tenderness, redness, heat, and swelling (see Chapter 56).
- *Neurologic:* Examine for cranial nerve malfunction? Paresis? Papilledema?
- *Nutritional evaluation:* Are the child's height and weight within a reasonable percentile compatible with the parents'? Is the weight percentile significantly less or greater than that for height?

Ancillary Diagnostic Aids

None of the following need to be used routinely, but most should be obtainable and interpretable for the emergency department (ED) setting. They should be ordered selectively if clinical assessment of the child does not allow a satisfactory conclusion regarding the significance of the murmur.

Electrocardiography. A full 14-lead electrocardiogram (EKG), using age- and size-appropriate electrodes, should be readily obtainable for screening and evaluation purposes. The emergency physician should have a working knowledge of the criteria for determining normality, which will vary with the age group of the child (see Chapter 84 and Appendix D). A lead II rhythm strip can be used for monitoring the patient in distress or with possible abnormal rhythm.

Echocardiography. Echocardiography allows definitive diagnosis for many congenital cardiac lesions, determination of the severity of cardiac failure, differentiation of myocarditis from pericardial effusion, evaluation of intrathoracic pressure phenomena (tamponade, effusion, tumors), and discovery of coronary artery malpositions or coronary dilatation, as in Kawasaki Disease.

Echocardiography has replaced cardiac catheterization in preoperative diagnosis of most, but not all, lesions. Because it is somewhat expensive and is so technician dependent, the procedure is of optimal value in conjunction with cardiology consultation. The cardiologist can guide the technician as to optimal methodology.

Procedures such as angiocardiography, electrophysiologic mapping, and cardiac flow determinations, although they may prove essential for eventual diagnosis, require cardiac consultation and should not be part of the evaluation in the ED.

Chest Radiograph. Films should be taken in both posteroanterior (PA) and lateral views. The physician should look for gross cardiac enlargement in the PA views, which may be determined in older children by a transverse diameter greater than 50% of the width of the thoracic cage. In infants, the diameter normally may be considerably wider than that ratio. Thymic shadows, scoliosis, rib abnormalities, and less than full inspiration may be confounding factors. The lung fields should be evaluated for infiltrates and for increased or diminished pulmonary vascular flow. Rib notching may be present secondary to long-standing coarctation of the aorta.

Blood Studies. Screening tests that might be of ancillary value under specific circumstances include a complete blood cell count, sedimentation rate and/or C-reactive protein, arterial blood gas measurements, co-oximetry, blood culture, antistreptolysin titer, sickle cell screening, troponin, and brain natriuretic protein (bnp) and anti-nuclear antibody.

EVALUATION AND DECISION

Neonates and older infants usually have differing clinical presentations than older children. Therefore, for the purposes of our first encounter evaluation, we divide murmur patients by two age groups: from birth to 3 years of age (Figs. 32.1A and 32.1B) and older than 3 years of age (Figs. 32.2A to 32.2C). Table 32.2 lists conditions that may be associated with cardiac murmurs.

Infants Younger Than 3 Years of Age with Cardiac Murmur

Neonates or infants younger than 3 years of age in whom a murmur is heard require extremely careful assessment. The

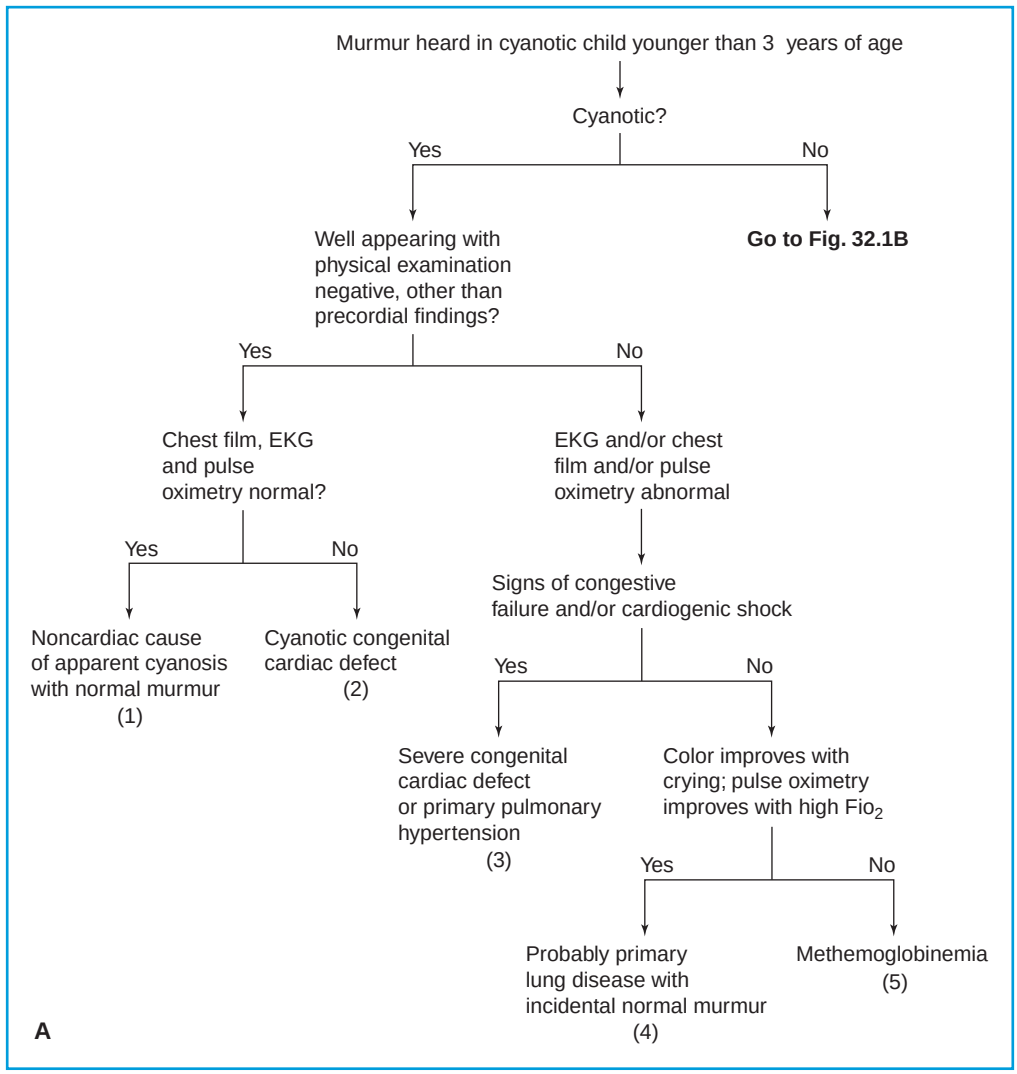

FIGURE 32.1A Assessment of a cyanotic infant younger than 3 years of age in whom a murmur is heard. (Numbers in parentheses refer to specific citations in text.) EKG, electrocardiogram.

lead point in the evaluation is the presence or absence of cyanosis, preferably confirmed by pulse oximetry.

Infants Younger Than 3 Years of Age Who Are Cyanotic

Any baby who has a murmur and appears cyanotic (Fig. 32.1A) should have a thorough physical examination, as well as a pulse oximetry determination, an EKG, chest film, and possibly arterial gases and echocardiography.

If the physical examination is normal, except for the cyanosis and the murmur, and the EKG, film, and pulse oximetry are normal, the infant probably has a normal murmur and a noncardiac cause of only apparent cyanosis (peripheral acrocyanosis, polycythemia, methemoglobinemia) [Fig. 32.1A (1)]. If still in doubt, echocardiography may be supportive.

A cyanotic infant who appears well, but who has an abnormal EKG and chest film and has diminished arterial saturation by oximetry or blood gas evaluation, probably has cyanotic heart disease; however, he or she is not likely to get into early trouble [Fig. 32.1A (2)]. This could include tetralogy of Fallot, transposition of the great vessels with single ventricle, truncus arteriosus, Ebstein's anomaly, tricuspid atresia with patent foramen ovale, anomalous pulmonary venous drainage, or moderately severe pulmonary stenosis with right-to-left shunting through an atrial or ventricular septal defect or a patent ductus. These babies should be referred for early echocardiogram and discussed with a cardiologist. Neonates should be admitted for evaluation and possible treatment in the hospital, but well-appearing children more than 4 weeks old should have early cardiac consultation but do not necessarily need to be admitted.

If the cyanotic infant appears acutely ill, a chest radiograph and/or the EKG will likely be abnormal. If the findings

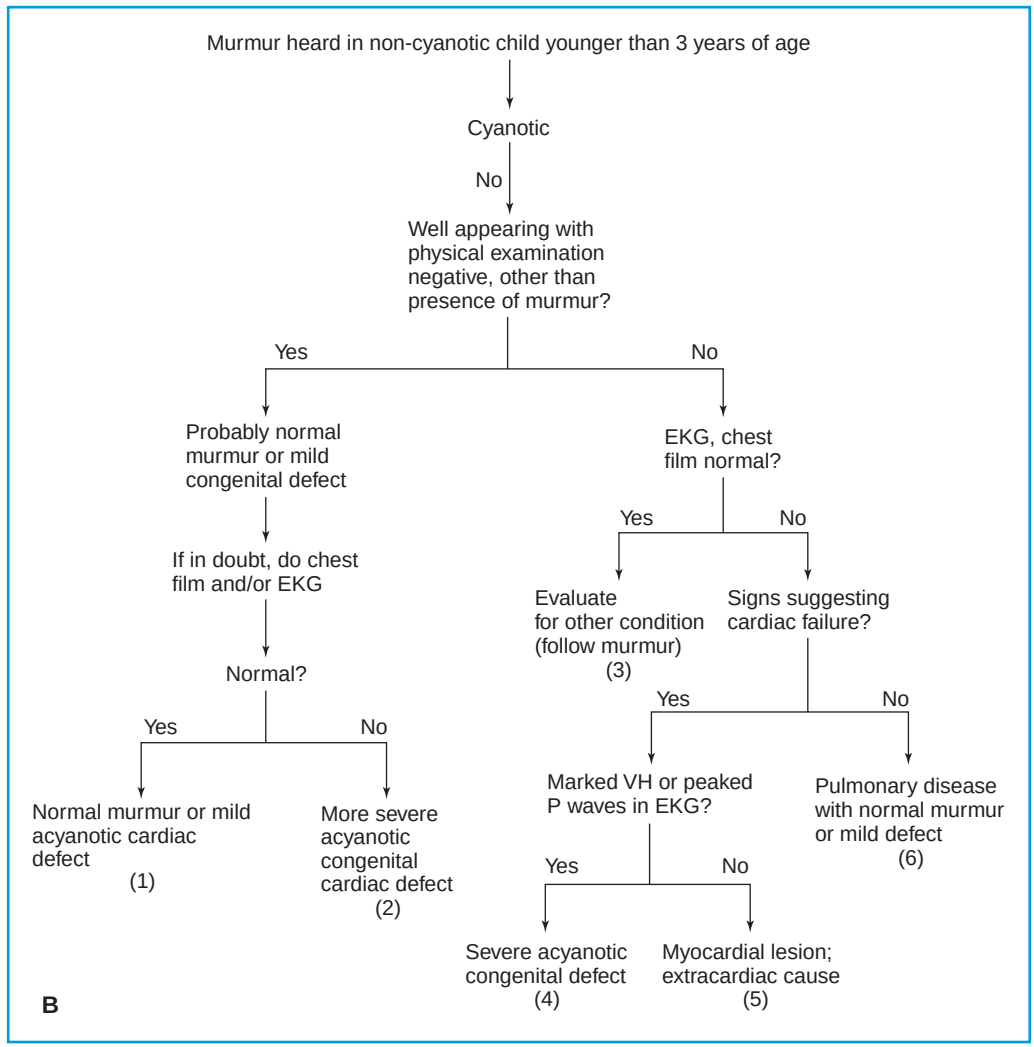

FIGURE 32.1B Assessment of a noncyanotic infant younger than 3 years of age in whom a murmur is heard. (Numbers in parentheses refer to specific citations in text.) EKG, electrocardiogram; VH, ventricular hypertrophy.

on examination suggest congestive heart failure (CHF) and/or cardiogenic shock, the baby probably has severe cyanotic congenital heart disease or an extremely severe acyanotic defect with the cyanosis related to poor perfusion and failure [Fig. 32.1A (3)].

Defects in the neonate could include hypoplastic left heart, extreme aortic or pulmonary stenosis, severe coarctation of the aorta, pulmonary atresia with intact ventricular septum, and tricuspid atresia with closed foramen (Table 32.3). Survival of patients with these severe lesions is dependent on maintaining patency of the ductus arteriosus. Early infusion therapy with prostaglandin E1 (Alprostadil) under carefully controlled monitoring should be considered (see Chapter 84). Interventional cardiac catheterization by experienced cardiologists provides an alternative approach to abetting right-to-left flow.

In the sick cyanotic neonate with respiratory distress, the possibility of primary pulmonary hypertension also should be considered. This might be defined by differential cyanosis—less in the upper body than in the lower. Urgent admission to a neonatal unit, for possible treatment with either inhaled NO or extracorporeal membrane oxygenation (ECMO), is essential [Fig. 32.1A (3)].

In the somewhat older infant, other considerations include Ebstein's anomaly, large arteriovenous malformation, atrioventricular canal defect, large ventricular septal defect, and total anomalous pulmonary venous drainage. These babies should be admitted to the hospital or transferred to a center for diagnostic cardiac workup and therapy.

TABLE 32.3

LIFE-THREATENING CARDIAC LESIONS IN THE LLL AND/OR DEEPLY CYANOTIC NEONATE

Hypoplastic left heart Extreme coarctation of the aorta Critical aortic stenosis Critical pulmonary stenosis Pulmonary atresia with intact ventricular septum Tricuspid atresia with closed foramen
For the deeply cyanotic and/or ill-appearing neonate, emergency cardiac consultation should be requested and consideration given to immediate infusion therapy with prostaglandin E1 to ensure patency of the ductus arteriosus.

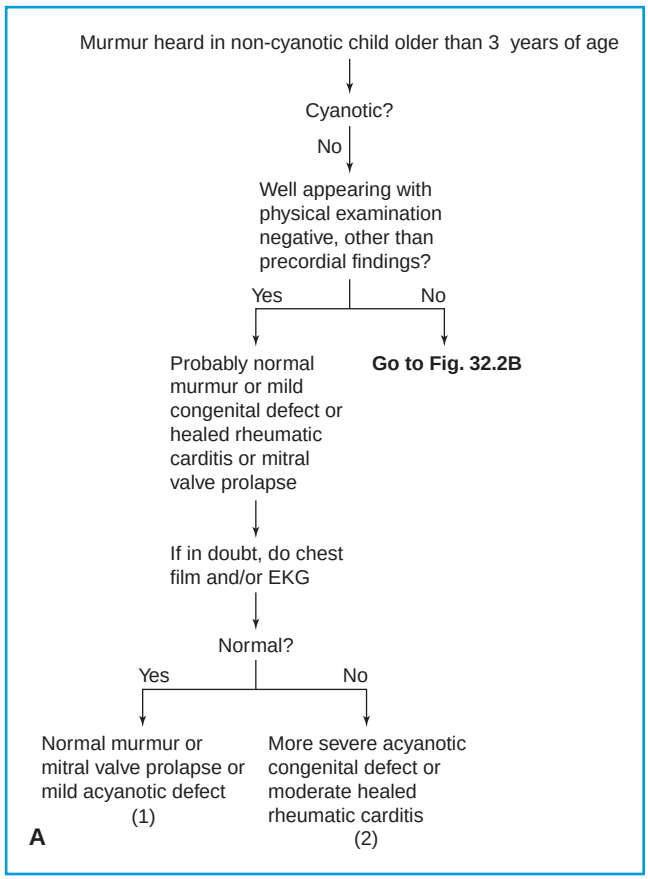

FIGURE 32.2A Assessment of a noncyanotic, well-appearing child 3 years of age and older in whom a murmur is heard. (Numbers in parentheses refer to specific citations in text.) EKG, electrocardiogram.

If the evaluation of the sick cyanotic baby does not suggest CHF or shock and the saturation improves somewhat with crying and in oxygen, the baby probably has primary lung disease caused by infection, hypoperfusion, or pulmonary arteriolar hypertension [Fig. 32.1A (4)]. These babies should be admitted for further evaluation and therapy and the murmur followed closely during therapy. If the saturation by oximetry of an infant without cardiac disease does not improve with oxygen, the patient may have methemoglobinemia [Fig. 32.1A (5)], either on a congenital basis or secondary to gastroenteritis. Co-oximetry studies of blood gases should be performed (see Chapter 87).

Infants Younger Than 3 Years of Age Who Are Not Cyanotic

Infants younger than 3 years who are not cyanotic (Fig. 32.1B) should be evaluated carefully, looking for the abnormalities as outlined previously under the "Examination" section.

If the baby has a negative physical examination, except for the murmur, and appears well [Fig. 32.1B (1)], the murmur may represent a congenital cardiac defect that is physiologically insignificant at the time (small patent ductus, atrial or ventricular septal defect, mild aortic or pulmonary stenosis, partial anomalous pulmonary venous drainage) or a normal murmur. These children can be followed by the primary care physician or referred to a cardiologist. If doubt exists about the infant's status because of the intensity or transmission of the murmur, an EKG and chest film, and possibly echocardiography, should be ordered; if normal, they confirm the previous impression. Peripheral pulmonary stenosis, related to angulation of the distal pulmonary arteries, is a common cause of normal murmurs in neonates; this murmur transmits well to the back, may be quite loud, but in time, will not be discernible.

If the EKG suggests abnormal atrial or ventricular hypertrophy and the chest film shows cardiac enlargement or abnormal pulmonary vasculature, a more significant degree of the same acyanotic defects, or possibly an acyanotic (or "silent") Tetralogy of Fallot, is likely. Nonemergent referral to a cardiologist is warranted [Fig. 32.1B (2)].

If the acyanotic baby with a murmur appears ill, an EKG and a chest film are obtained. If these are normal, the murmur is most likely inconsequential, and the baby should be evaluated for an underlying medical or surgical illness related to the presenting complaints at this visit [Fig. 32.1B (3)]. It is important to think also of noncardiac conditions causing high flow, such as severe anemia or hyperpyrexia, as causes of the murmur.

If the infant has signs suggesting cardiac failure, EKG findings of marked ventricular hypertrophy, and/or abnormally shaped P waves, it might be indicative of a severe acyanotic congenital cardiac defect (large ventricular septal defect, large patent ductus, severe aortic or pulmonary stenosis) [Fig. 32.1B (4)]. Urgent cardiac consultation should be obtained. In the neonate, consideration should be given to indomethacin or an accepted alternative therapy for closure of the ductus arteriosus to lessen the left-to-right shunting.

A baby in failure with only T-wave and/or ST-segment changes on EKG may have viral myocarditis, primary myocardial disease, anomalous origin of the left coronary artery, or an extracardiac problem that causes high cardiac output (severe anemia, large arteriovenous malformation). Some of these babies, although not cyanotic on the basis of their underlying lesion, may show a degree of diminished saturation on pulse oximetry because of the hypoperfusion related to cardiac failure. All such babies need admission or transfer to a tertiary pediatric center for emergency evaluation and treatment [Fig. 32.1B (5)].

If the chest film and/or EKG is not normal and the baby appears ill but does not have signs that suggest CHF, a primary pulmonary disease should be considered, with the murmur being either a normal one or representing a milder acyanotic defect [Fig. 32.1B (6)]. Admission for further evaluation and therapy is appropriate.

Children 3 Years and Older with Cardiac Murmur

The assessment and disposition of an older child in whom a murmur is discovered is somewhat less of a challenge to the emergency physician. The child is more cooperative and generally more interactive than the infant, and as a result, the sometimes subtle evaluation of the child's state of well-being is less uncertain. The heart rate normally is slower, allowing easier dissection of the murmur.

By the time children who live in geographic areas in which modern medical care is available reach 3 years of age, most

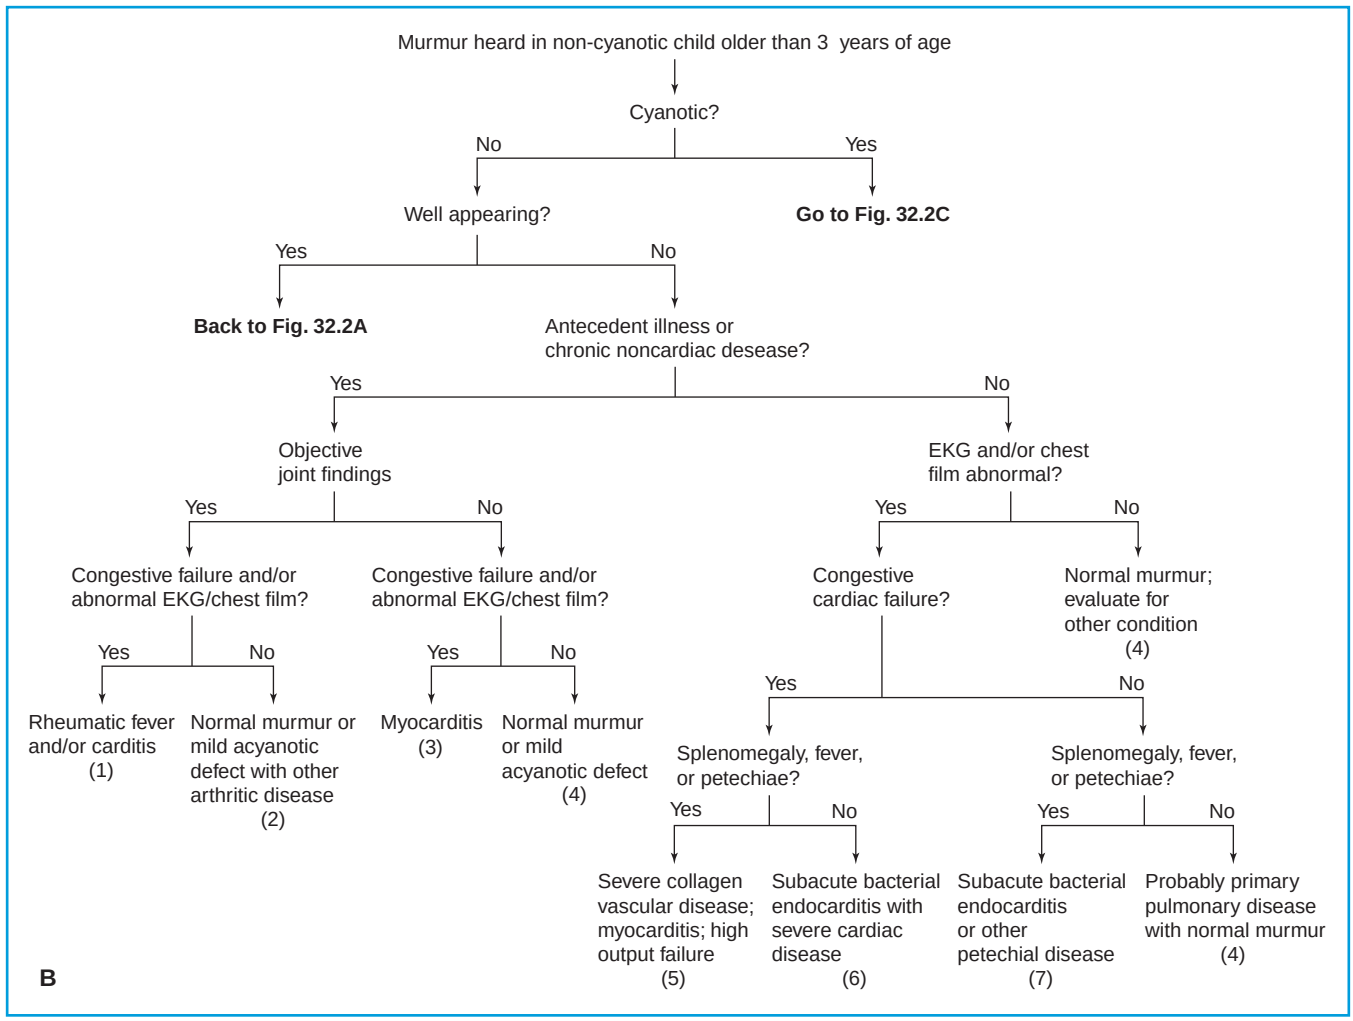

FIGURE 32.2B Assessment of a noncyanotic, sick child 3 years or older in whom a murmur is heard. (Numbers in parentheses refer to specific citations in text.) EKG, electrocardiogram.

congenital lesions have been discovered and many have been surgically repaired. Acquired cardiac and noncardiac illnesses, therefore, play a more prominent role in assessment. Still, some congenital lesions have gone unrecognized, some do not require surgery, and others that require surgery have not had access because of inadequate insurance or other economic or social reasons.

Normal murmurs are by far the most common ones discovered at a first encounter with an older child. Table 32.1 describes the characteristics generally associated with a normal murmur. If the examining physician is satisfied that the murmur is a normal one and the child has no other symptoms referable to the cardiovascular system, cardiac consultation and further workup is not necessary or advisable. Still, it is often difficult to distinguish a normal murmur from the murmur of relatively benign intracardiac lesions as small atrial or ventricular defects or mild aortic or pulmonic stenosis. The management guidelines outlined in this chapter obviate the need for the emergency physician to be concerned about such a differential. For the purposes of the ED evaluation, it is important to determine only whether the patient is in difficulty or needs further early evaluation. In these age groups also, the presence or absence of cyanosis is a significant finding.

Children 3 Years of Age and Older Who Are Not Cyanotic

The acyanotic child with a murmur who seems essentially well [Fig. 32.2A (1)] and has a negative physical examination other than the precordial finding most likely has a normal murmur but may have a mild acyanotic congenital defect, a healed rheumatic carditis, or a mitral valve prolapse. The femoral artery pulsations should always be palpated for the possibility of coarctation of the distal aorta. In mitral valve prolapse, a midsystolic "click" is a more constant finding than the murmur that follows the click. These children should be followed by the primary care physician. If in doubt because of the intensity or transmission of the murmur, an EKG and chest film, and possibly echocardiography, should be ordered. If these are

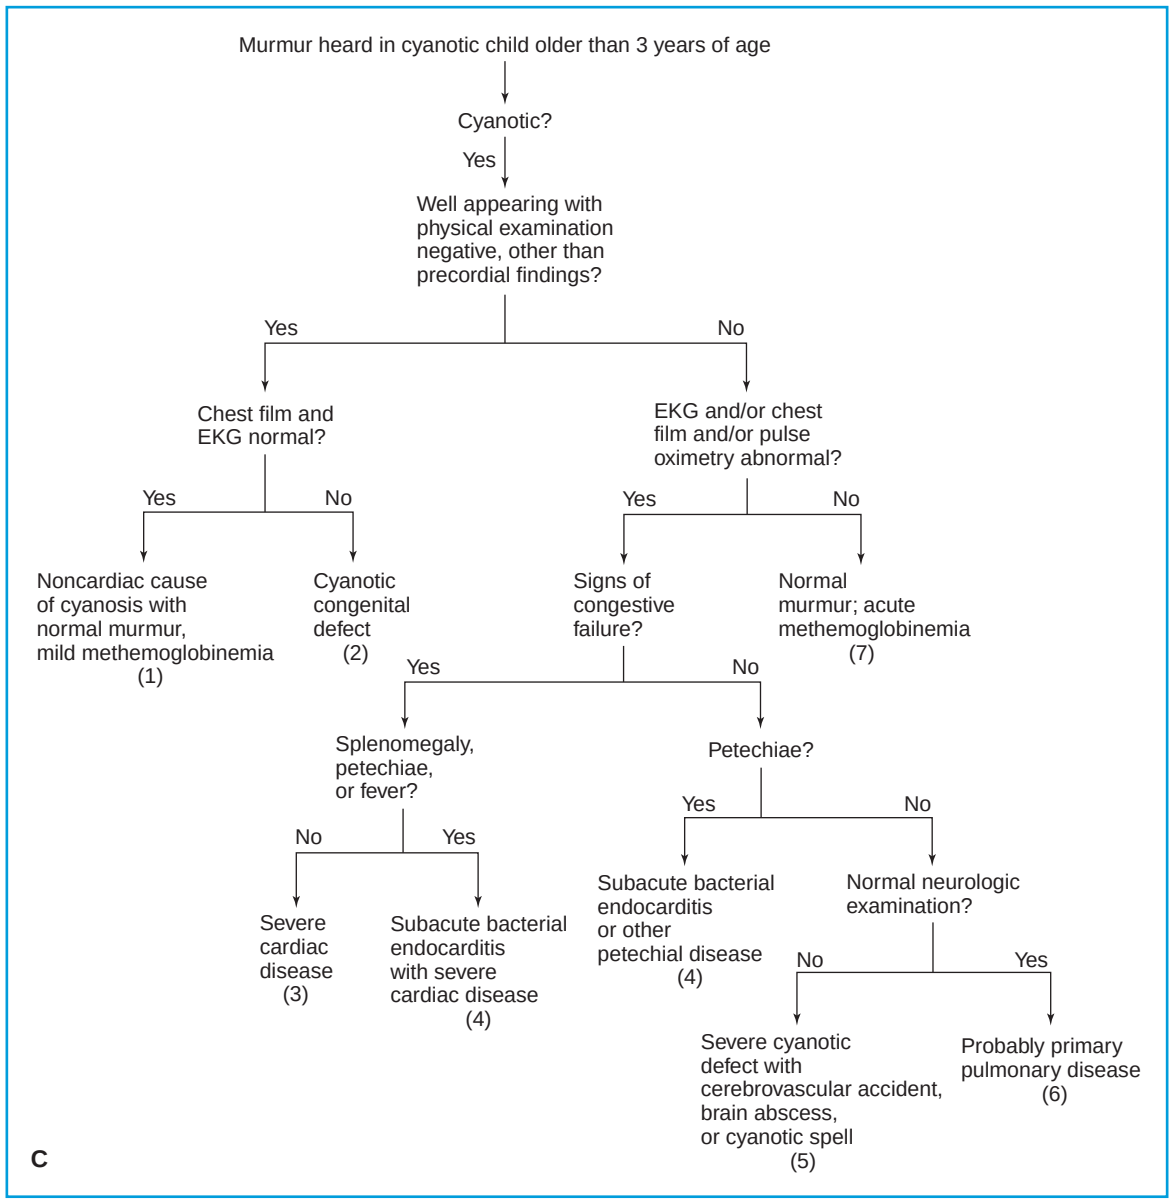

FIGURE 32.2C Assessment of a cyanotic child 3 years of age or older. (Numbers in parentheses refer to specific citations in text.) EKG, electrocardiogram.

normal, one has further assurance that primary care follow-up is all that is necessary. If these are abnormal, there is concern about the possibility of a more severe acyanotic defect or moderately severe healed rheumatic carditis [Fig. 32.2A (2)]. Referral should be made to a cardiologist on a nonemergency basis for further differentiation.

In evaluating the acyanotic child who appears acutely ill and has a murmur [Fig. 32.2B (1)], a careful history should be taken regarding prior or recent antecedent illness, including a significant sore throat or "viral" illness. If there is such a history, the possibility of swollen, red, and tender joints should be sought. If these are present, the child is febrile, and an EKG is abnormal, the child should be hospitalized to be evaluated for the possibility of acute rheumatic fever (see Chapter 84). In contrast, the acyanotic ill child with objective joint findings but a normal EKG is more likely to have a normal murmur with a concurrent arthritic-like illness, such as septic or reactive arthritis, juvenile rheumatoid arthritis, or Henoch-Schönlein purpura (HSP) [Fig. 32.2B (2)]. These children need diagnostic evaluation of their acute illness and follow-up of the murmur.

The ill-appearing acyanotic child who has a murmur and a history of known chronic or recent antecedent illness, but has no objective joint findings, should have an EKG, a chest film, and echocardiography. If the EKG shows ST-segment and T-wave abnormality and if the heart is enlarged, the patient probably has myocarditis or pericarditis, with the murmur resulting from turbulence created by ventricular dilation or compression and atrioventricular valve insufficiency [Fig. 32.2B (3)]. The cause

could be viral, collagen vascular, toxic, or endocrine (see Chapters 84, 86, 101). A brain natriuretic peptide (bnp) might be of value in confirming disturbance of cardiac musculature. The echocardiograph may be diagnostic. These children must be admitted for evaluation and therapy.

If the EKG and chest x-ray are normal in the acyanotic ill-appearing child, these children probably have a normal murmur, or a mild, acyanotic heart defect, but with a concurrent, unrelated illness [Fig. 32.2B (4)].

The ill-appearing acyanotic child who has a murmur but no chronic or recent antecedent illness and who shows signs of CHF may have severe acyanotic congenital heart disease, myocarditis, or high-output failure secondary to severe anemia, large arteriovenous malformation, or thyrotoxicosis [Fig. 32.2B (5)].

Regardless of whether in congestive failure, the ill-appearing infant with a murmur and fever should be examined carefully for splenomegaly and petechiae on the skin surface, on the conjunctivae, and under the nail beds. If these are found, although the murmur could represent the entire list of cardiac diseases, the important immediate concern is that of infectious endocarditis [Fig. 32.2B (5, 6)]. The child should be admitted for evaluation, cardiac consultation, and echocardiography (see Chapter 84).

If the patient with a murmur and petechiae is not showing signs of failure, the murmur may be normal or represent a mild acyanotic defect. In addition to infectious endocarditis, consideration must then be given to other conditions manifested with petechiae, such as meningococcemia, idiopathic thrombocytopenic purpura (ITP), rickettsial infection, hemolytic uremic syndrome, or HSP [Fig. 32.2B (7)]. Blood cultures and other appropriate labs should be drawn, appropriate emergency treatment initiated, and the child admitted for further evaluation and treatment.

If the acyanotic ill-appearing child with a murmur is not in failure, has no splenomegaly or petechiae, and has a normal EKG, the murmur is most likely normal or associated with the high cardiac output of hyperpyrexia or anemia [Fig. 32.2B (4)]. These children should be evaluated for their underlying condition.

Children 3 Years and Older Who Are Cyanotic

As with infants, cyanotic older children (Fig. 32.2C) with murmurs should have an EKG, chest film, pulse oximetry, and possibly an arterial blood gas after a careful history and complete physical examination. If these are normal, except for the cyanosis and murmur, the child probably has a noncardiac cause of the cyanosis (polycythemia, methemoglobinemia) [Fig. 32.2C (1)]. The murmur may be normal or associated with a coincidental acyanotic congenital defect. The primary condition should be investigated. If uncertainty exists about a noncardiac etiology once the studies are obtained, an echocardiogram should her performed.

The cyanotic child who is well appearing but has abnormal EKG, chest film, echocardiography, and pulse oximetry has cyanotic heart disease that possibly could be improved surgically [Fig. 32.2C (2)]. The child should be referred to a cardiologist on a nonemergent basis for further evaluation, including echocardiography.

If the cyanotic child appears acutely ill and has signs of CHF, severe cardiac disease is present [Fig. 32.2C (3)]. The causes could include a decompensating congenital cyanotic cardiac defect, in which case the cyanosis would be intense (Table 32.2), or cardiac failure secondary to acquired disease, in which the cyanosis is related to hypoperfusion and is usually less intense. These children need to be admitted for therapy and evaluation.

Regardless of whether there are signs of congestive failure in the cyanotic child with a murmur, if there is fever, splenomegaly, and/or petechiae on the skin, on the conjunctivae, or under the nail beds, blood cultures should be drawn for the likelihood of infective endocarditis [Fig. 32.2C (4)]. If the child is not in failure and petechiae are found, infective endocarditis is still a possibility, but other noncardiac causes of petechial presentations must be considered (meningococcemia, Valsalva maneuvers, HUS, ITP, HSP). Blood cultures and other appropriate labs should be drawn and the child admitted.

A careful neurologic examination should be part of the evaluation of every ill child with cyanotic heart disease. If findings are abnormal, consideration has to be given to the complications of hypoxemic "spells," cerebrovascular accident ("stroke"), or, if febrile, brain abscess [Fig. 32.2C (5)].

If the ill cyanotic child with a murmur and abnormal chest film shows significant improvement of oxygen saturation with supplemental oxygen, the child most likely has primary pulmonary disease. The EKG abnormality, if there is one, would most likely consist of tall, pointed P waves and evidence of right ventricular hypertrophy [Fig. 32.2C (6)]. The murmur would most likely be related to tricuspid regurgitation secondary to the high right ventricular pressure. These children need admission for evaluation and therapy.

In the cyanotic child with a murmur who has a normal EKG and chest film, abnormal pulse oximetry, but normal arterial Po_2, the possibility of acute toxin-induced methemoglobinemia must be considered, with the murmur being normal or representing a mild acyanotic defect. Co-oximetry should be ordered [Fig. 32.2C (1, 7)].

SUMMARY

This chapter provides clinical guidelines for the initial assessment and disposition of infants and children in whom a murmur is discovered during a first visit. Although diagnostic pathways have been suggested, it has also been shown that definitive diagnosis of the underlying cardiac defect is not the primary aim of ED evaluation; careful assessment of the patient and safe disposition are required at first encounter. The emphasis, in other words, is on the patient and less so on the murmur.

CHAPTER 33 ■ HEMATURIA

ERICA L. LIEBELT, MD, FACMT

Hematuria, the presence of red blood cells (RBCs) in the urine, is a common presenting complaint in the emergency department (ED). The required evaluation for hematuria (either gross or microscopic) in the ED and its urgency is dictated by the patient's history and clinical presentation. Recent literature has demonstrated that gross hematuria in children and adolescents most often has a benign cause (hypercalciuria without nephrolithiasis or no apparent etiology) and long-term prognosis is good. Disease processes manifested by gross hematuria accompanied by other symptoms (e.g., acute onset of edema, headache, and hypertension), or with a history of trauma, are the context in which hematuria requires urgent/emergent evaluation in the ED. Microscopic hematuria [(more than 5 RBCs/high-power field (HPF)] may be accompanied by other signs and symptoms or may be completely asymptomatic; it can usually be evaluated in the outpatient setting. In addition, there is evidence to suggest that asymptomatic microscopic hematuria (more than 5 RBCs/HPF) in children is rarely indicative of serious illness and may warrant only a limited or even no diagnostic evaluation.

Red or brown urine does not always indicate hematuria. Several foods, substances, and drugs may color the urine; therefore, it is important to document the presence of blood in the urine. Reagent strips (based on the peroxidase reaction with hemoglobin) can be used as the initial screening test for hematuria. Heme-positive reagent strips must be confirmed by microscopic examination for the presence of RBCs because both hemoglobinuria and myoglobinuria can cause a positive reaction in the absence of RBCs. The presence of 5 to 10 or more RBCs per HPF is abnormal and warrants further workup. The evaluation of a child with hematuria must take into consideration the clinical presentation, patient and family histories, physical examination, and complete urinalysis so that a logical, orderly, and cost-effective approach can be undertaken.

PATHOPHYSIOLOGY

RBCs can be added to the urine at any point along the urinary tract—from the glomerulus through the tubule or through the collecting system, the ureter, the bladder, or the urethra. The pathophysiology of hematuria can be explained by categorizing it as either glomerular or nonglomerular. Immune-mediated inflammatory damage to the glomerular filtration surface, as seen in postinfectious nephritis, causes disruption of the glomerular basement membrane with subsequent leakage of RBCs and protein. Glomerular bleeding that results in gross hematuria may be brown, smoky, or cola- or tea-colored as a result of the acidic urine changing the hemoglobin to hematin. RBCs may become enmeshed in the protein matrix to form RBC casts, a sensitive indicator of glomerular hematuria. The renal papillae are sites of nonglomerular bleeding that are susceptible to microthrombi and anoxia in patients with sickle cell disease or trait. Inflammation of the tubules and interstitium caused by antibiotics can result in hematuria, proteinuria, and eosinophiluria. Nonsteroidal agents can produce hematuria from both tubulointerstitial nephritis and inhibition of prostaglandin synthesis. Grossly bloody urine that is bright red or pink with or without clots is more likely to be originating from the lower urinary tract, usually the bladder or urethra. Hematuria from trauma to the kidney or bladder is caused by contusions, hematomas, or lacerations anywhere along the tract. Increased vascularity from infection or chemical irritation can lead to leakage of RBCs into the urine. Exercise-related hematuria results from ischemic injury as well as direct trauma. Benign familial hematuria, a principal cause of asymptomatic hematuria, is caused by leakage of RBCs through a thin glomerular basement membrane and rarely comes to the attention of the emergency physician except as an incidental finding.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of hematuria is vast and can be categorized on the basis of whether the cause of bleeding is disease restricted to the urinary system or secondary to a systemic process (Table 33.1). The most common causes of hematuria (Table 33.2) are urinary tract infection (UTI; either cystitis or pyelonephritis), hypercalciuria without nephrolithiasis, acute poststreptococcal glomerulonephritis, and trauma; the latter two also being the most common of the potentially life-threatening causes. Other potentially serious causes of hematuria (Table 33.3) include hematologic disorders, renal stones with obstruction, tumors, and hemolytic uremic syndrome (HUS). Other glomerular causes of hematuria that are primary renal diseases include nonstreptococcal postinfectious glomerulonephritides, membranous glomerulonephritis, immunoglobulin A (IgA) nephropathy, and Alport syndrome (hereditary nephritis). Hematuria as a manifestation of a systemic condition is most commonly seen in children with vasculitides such as Henoch-Schönlein purpura, systemic lupus erythematosus (SLE), and polyarteritis nodosa.

Extraglomerular causes of hematuria include congenital anomalies such as diverticula of the urethra and bladder; hemangiomas in the bladder; cysts of the kidneys, as in polycystic or multicystic kidney; and obstruction of the ureteropelvic junction. In addition to congenital anomalies, renal vein thrombosis secondary to a coagulation disorder or to the placement of

TABLE 33.1

PRINCIPAL CAUSES OF HEMATURIA IN CHILDREN

Urinary tract
Extraglomerular
- Trauma
- Urinary tract infection (cystitis, pyelonephritis)
- Hemorrhagic cystitis (bacterial, viral, drugs)
- Stones
- Hypercalciuria
- Interstitial nephritis
- Polycystic kidney disease
- Renal vein thrombosis
- Papillary necrosis
- Wilms' tumor
- Posterior urethral valves
- Hydronephrosis
- Ureteropelvic junction obstruction
- Urethritis
- Urethral diverticula
- Urethral prolapse
- Foreign body
- Hemangiomas

Glomerular
- Acute poststreptococcal glomerulonephritis
- Other postinfectious glomerulonephritis
- IgA nephropathy
- Alport syndrome (hereditary nephritis)
- Exercise
- Familial benign hematuria
- Other chronic nephritides (membranoproliferative, membranous)
- Nutcracker syndrome (compression of the left renal vein)

Systemic
Coagulation disorders—hemophilia, platelet disorders
Sickle cell disease or trait
Anticoagulant therapy
Drugs—aspirin, nonsteroidal antiinflammatory drugs, phenacetin, penicillins, cephalosporins, cyclophosphamide
Leukemia
Serum sickness
Henoch-Schönlein purpura
Hemolytic uremic syndrome
Systemic lupus erythematosus
Polyarteritis nodosa
Subacute bacterial endocarditis
Shunt nephritis
Tuberculosis
Hepatitis

TABLE 33.2

COMMON CAUSES OF HEMATURIA

- Urinary tract infection—cystitis, pyelonephritis
- Trauma (kidney, bladder, urethra)
- Acute poststreptococcal glomerulonephritis
- Sickle cell disease or trait
- Hypercalciuria without nephrolithiasis
- Benign hematuria
- Urethritis
- No defined etiology

TABLE 33.3

LIFE-THREATENING CAUSES OF HEMATURIA

- Trauma (kidney, bladder, spleen)
- Acute glomerulonephritis
- Hemolytic uremic syndrome
- Renal stones with obstruction
- Tumor
- Hematologic disorders
- Toxin/xenobiotic

an umbilical catheter is a cause of hematuria in the neonate. Wilms' tumor is a common childhood solid tumor associated with hematuria in 12% to 25% of the cases. Nephrolithiasis should be considered if there is a family history or a predisposing condition such as recurrent infection, bladder dysfunction (seen in myelomeningocele), or chronic diuretic therapy (as seen in infants with bronchopulmonary dysplasia). Hypercalciuria and cystinuria are metabolic diseases that also predispose patients to renal stones and hematuria. Finally, urethral prolapse, seen most commonly in girls 2 to 4 years of age, may present with vaginal bleeding that can contaminate a collected urine specimen and be misinterpreted as hematuria.

EVALUATION AND DECISION

The initial evaluation of hematuria must begin with the confirmation of blood in the urine. Further investigation of the cause and treatment includes detailed patient and family histories, careful physical examination, and microscopic urinalysis (which lends information to probable causes and helps determine the site of bleeding within the urinary tract system). A specific diagnosis may or may not be made in the ED, and the patient may require further diagnostic testing. The most important role for the emergency physician in evaluating a child with hematuria is to identify serious, treatable, and progressive conditions such as trauma, nephritis associated with hypertension, bleeding disorders, and infection.

Blood in the urine may come from sources outside the urinary tract. Vaginal hemorrhage in the female secondary to infection, foreign body, or trauma (sometimes secondary to abuse) may contaminate the urine. In addition, parents may report finding blood in the urine when, in fact, a rectal fissure has caused a small hemorrhage, producing a mixture of blood and urine in the diaper or underwear. In prepubertal girls, urethral prolapse may present with vaginal bleeding, which may be confused with hematuria.

Urine dipsticks yielding positive result for blood require microscopic examination of the urine. Hemoglobinuria from hemolysis and myoglobinuria from rhabdomyolysis will cause a positive dipstick reaction for blood and an absence of RBCs on urine microscopic examination. Many dyes, drugs, and pigments will change the urine color to pink, red, brown, or black but will not yield a positive dipstick test result for blood. A partial list includes beets, blackberries, urates, aniline dyes, bile pigments, porphyrin, diphenylhydantoin, phenazopyridine (Pyridium), rifampin, deferoxamine, phenolphthalein, ibuprofen, methyldopa, chloroquine, homogentisic acid, and *Serratia marcescens* infection. False-positive dip reactions may be seen from certain cleaners, such as those containing hypochlorite and iodine, or other strong oxidizers.

The history taking for infants and neonates with hematuria should include questions about umbilical vessel catheters (renal venous or arterial thrombosis), passage of clots on voiding (hemorrhagic disorders), abdominal swelling or palpable mass (tumor, polycystic disease, ureteropelvic junction obstruction, posterior urethral valves), and significant birth asphyxia (corticomedullary necrosis). Urate crystals are commonly seen in the newborn/neonatal period as pink/salmon-colored spotting on the diaper. In the absence of other symptoms, no further evaluation is needed when the history and observation are suggestive of this etiology. Dysuria or urinary frequency in children and adolescents suggests cystitis, whereas flank, abdominal, or back pain suggests trauma, genitourinary infection, or stones as the cause. Sore throat, upper respiratory tract infection, or pyoderma (preceding or appearing concurrently with the onset of hematuria) points to acute postinfectious glomerulonephritis, streptococci being the most common bacterial cause. A history of gross hematuria with a concomitant viral upper respiratory tract or gastrointestinal tract infection may also suggest IgA nephropathy. Hematuria associated with systemic disorders may be uncovered by eliciting a history of skin rashes and arthralgia or arthritis as seen in Henoch-Schönlein purpura and SLE. Both sickle cell anemia and sickle cell trait are associated with chronic, asymptomatic gross hematuria. Finally, a history of drug use, especially the use of nonsteroidal antiinflammatory drugs, penicillins, and cephalosporins, may point to interstitial nephritis as the cause. Antibiotic-associated tubulointerstitial nephritis is associated with high-dose, long-term antibiotic therapy and is characterized clinically by fever, rash, eosinophilia with pyuria, eosinophiluria, hematuria, proteinuria, and nonoliguric renal failure. Family history of renal stones, deafness, nephritis, renal anomalies, or hematologic disease may suggest a diagnosis in the child such as Alport syndrome (hereditary nephritis), sickle cell anemia, or hemophilia.

Physical examination of a child with hematuria should always include a blood pressure measurement. Hypertension may accompany glomerulonephritis, obstructive uropathy, Wilms' tumor, polycystic kidney, or vascular disease. Periorbital edema and facial swelling may be the first physical sign of nephritis. Urethral prolapse presents as a doughnut-shaped mass at the site of the urethral meatus, which is usually hyperemic and friable with scant bloody drainage.

Bruising of the abdomen, flank, or back should raise suspicion of trauma, including child abuse, as a cause of hematuria. Tenderness of the flank or lower abdomen may signal pyelonephritis, obstructed kidney, or lower urinary tract infection. Flank or abdominal masses suggest Wilms' tumor or hydronephrosis, hydroureter, or polycystic kidney. Petechial or purpuric lesions on the skin and arthritis may accompany hematuria seen in vasculitic syndromes such as Henoch-Schönlein purpura, HUS, and SLE. The "nutcracker syndrome," or compression of the left renal vein, may present with hematuria, left-flank pain, and abdominal or groin pain. Pallor may be a sign of anemia from chronic renal insufficiency, HUS, hemoglobinopathy, leukemia, or tumors.

A careful, detailed urinalysis plays an essential role in the evaluation of the child with hematuria. Several clues in the urinalysis can help localize the site of hematuria. RBC casts, cellular casts, tubular cells, tea-colored or smoky-brown urine, and proteinuria 2+ or more by a dipstick test all point to glomerular bleeding. In addition, the presence of dysmorphic RBCs and/or acanthocytes (ring-formed RBCs with one or more protrusions of different shapes and sizes) as well as the measurement of the mean volume of urine erythrocytes using a Coulter counter have been used as markers of glomerular bleeding (erythrocyte volume less than 50 m^3). In contrast, nonglomerular bleeding is suggested by red or pink urine, blood clots, no proteinuria (or less than 2+ in the absence of gross hematuria), and normal morphology of erythrocytes. Calcium oxalate crystals may be seen in the urine of patients with renal stones. Suspicion for disease processes that may cause eosinophiluria requires examination of the urine with Hansel's stain to specifically delineate eosinophils. Interpretation of catheterized urinary specimens must take into account that the catheterization itself might produce a small amount of trauma and cause a small number of RBCs ($n = 0$ to 10).

Other blood studies may be useful in selected cases and include a complete blood cell (CBC) count, prothrombin time (PT), partial thromboplastin time (PTT), erythrocyte sedimentation rate (ESR), blood urea nitrogen (BUN), serum creatinine, complement levels (C3 and C4), and streptococcal serologies (antistreptolysin O, anti-DNase-B, and antihyaluronidase titers). The history and physical examination should direct the emergency physician to those additional tests that are needed, if any. Most patients, other than those with isolated microscopic hematuria or lower urinary tract infection, will require at least a CBC count as part of their evaluation.

A clinical algorithm for evaluating hematuria in the ED is shown in Figure 33.1. The first step is to confirm the presence of true hematuria. If a traumatic cause for the hematuria is suspected on the basis of history or physical findings, emergent evaluation for serious anatomic lesions must be initiated. Parenchymal contusions, lacerations, renal transections, and pedicle disruptions are possible injuries. Hematuria is the cardinal marker of renal injury, with the severity paralleling the magnitude of the injury (except for renal pedicle injuries, which may have no associated hematuria). Hematuria may also signal traumatic injury to adjacent organs such as the spleen. The rationale and hence decision to pursue radiologic evaluation in children with blunt renal trauma and microscopic hematuria has changed in the last several years on the basis of emerging clinical evidence that it is usually not warranted. There is both adult and pediatric evidence that patients presenting with blunt trauma, microscopic hematuria, or no associated injuries, and clinically who are hemodynamically stable, do not require radiologic evaluation because significant renal injuries are unlikely. The presence of gross hematuria or significant microscopic hematuria (more than 50 RBCs/HPF) in the context of significant mechanisms of injury necessitates emergent imaging (see Chapter 112). Hematuria disproportionate to the injury may indicate a congenital renal anomaly or tumor.

If there is no history of trauma, then coagulopathies should be considered as the cause. However, the medical history alone usually will point to this cause because the sudden occurrence of isolated hematuria in a previously healthy child is unlikely with either a congenital or an acquired bleeding disorder. Hematuria in a child known to have hemophilia or a related disorder often requires minimal investigation and is managed in accordance with standard protocols. If an acquired coagulopathy is suspected, a CBC count with platelet count, PT, and PTT is warranted.

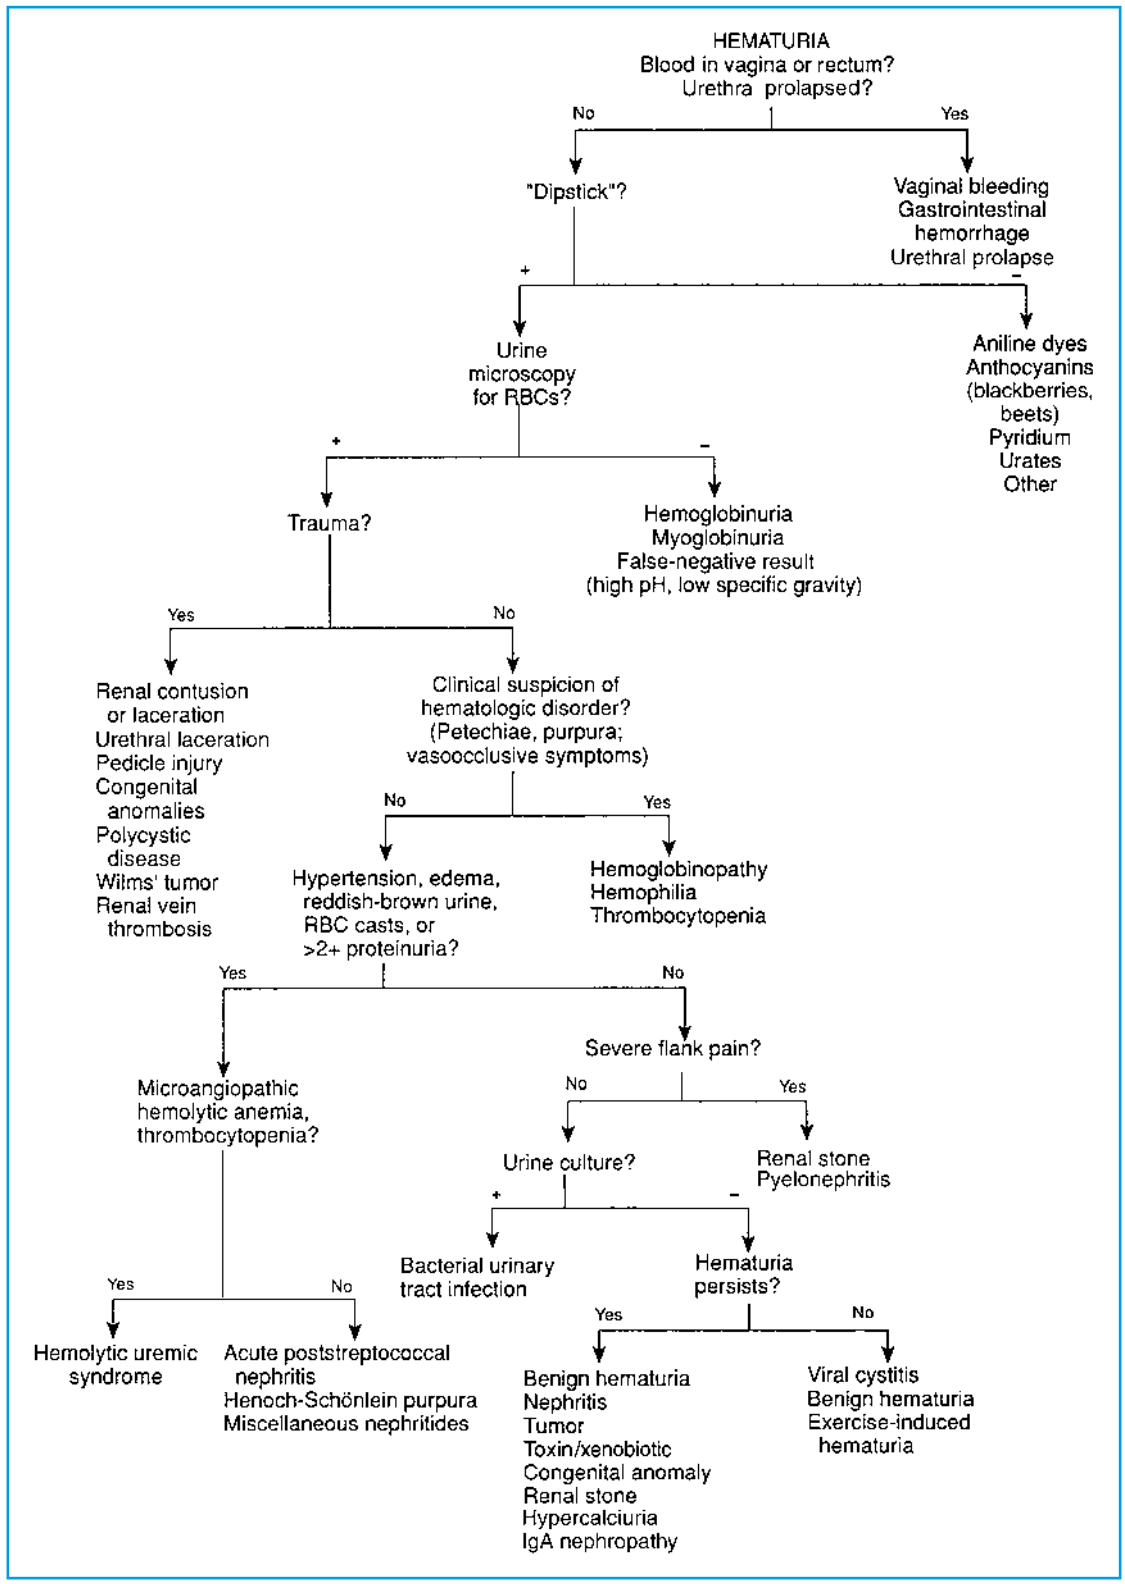

FIGURE 33.1 Approach to hematuria in the emergency department.

If trauma and coagulopathies are considered unlikely, identifying the site of bleeding as either glomerular or nonglomerular (based on urinalysis and other signs or symptoms) can direct further evaluation and diagnosis. Acute glomerulonephritis characterized by hypertension, edema, RBC casts, proteinuria, and tea-colored urine most often follows a streptococcal infection and merits serious consideration in the ED because it may cause significant hypertension and pulmonary edema requiring immediate intervention. HUS is a serious disorder that may present with glomerular-induced hematuria and proteinuria as well as a characteristic microangiopathic hemolytic anemia, thrombocytopenia, and renal failure. Laboratory studies useful in children suspected of having nephritis include a CBC count, ESR, BUN, serum creatinine, complement levels, and antistreptococcal antibodies. Other nephritides may be associated with vasculitis (Henoch-Schönlein purpura, SLE, periarteritis nodosa, Wegener's granulomatosis) and may require further diagnostic evaluation before a specific diagnosis is made (see Chapter 100).

Most children without a history of trauma who are evaluated for gross and/or microscopic hematuria in the ED have a UTI. The infection may be either in the upper tract (e.g., pyelonephritis, characterized by fever, chills, flank pain, vomiting, and dysuria) or in the lower tract (e.g., cystitis, characterized by dysuria, frequency, and occasionally, abdominal pain, and fever). The cause of a UTI is either bacterial or viral. Acute hemorrhagic cystitis is often associated with adenovirus. The findings of pyuria and bacteriuria on urinalysis suggest an infectious cause, although their absence does not exclude either pyelonephritis or cystitis; thus, a urine culture is essential if no other cause has been uncovered. If the clinical suspicion is high for a bacterial UTI, presumptive antimicrobial treatment should be initiated (see Chapter 92).

Severe flank pain radiating to the groin is characteristic of renal colic from calculi, which may present with either gross or microscopic hematuria. Stones may occur in children with metabolic abnormalities or stasis secondary to obstruction and in premature infants taking furosemide, especially those with bronchopulmonary dysplasia. Topiramate (Topamax®), a newer anticonvulsant and mood-stabilizing drug, is also associated with an increased risk of nephrolithiasis. Crystals may be seen on urinalysis; further investigation with intravenous pyelography, renal ultrasound, or spiral computed tomography usually confirms stones if a plain abdominal radiograph does not reveal the presence of radiopaque material. Hypercalciuria is an important cause of hematuria in children and may be idiopathic or secondary to another disease and can lead to nephrocalcinosis (see Chapter 100).

Hematuria that persists after the previously mentioned causes have been ruled out or deemed unlikely on the basis of history and physical examination usually does not require further evaluation in the ED and should be pursued by the primary health care provider, possibly in collaboration with a pediatric nephrologist. These additional causes are listed in Figure 33.1 and Table 33.1 and may require more extensive imaging and interventions such as renal biopsy, metabolic studies, or serial urinalyses (benign hematuria, exercise-induced hematuria).

CHAPTER 34 ■ HYPERTENSION

ERIKA CONSTANTINE, MD

Until recently, the incidence of hypertension in the pediatric population, cited at 1% to 3%, had been relatively low. Recent trends in childhood obesity, however, appear to be linked to the observation of an overall increase in blood pressure values seen in the pediatric population. The Fourth Report on High Blood Pressure in Children and Adolescents, a national consensus statement published in 2004, suggests that a child with three or more blood pressure measurements above the 95th percentile for age, height, and gender should be considered hypertensive. *Stage 1 hypertension* is defined as blood pressure values that range from the 95th percentile to 5 mmHg above the 99th percentile. Those with blood pressure measurements of 5 mmHg or more above the 99th percentile are considered to have stage 2 hypertension (Table 34.1). We can expand the definition of hypertension to include two additional terms. *Hypertensive emergency* describes an elevated blood pressure level associated with the evidence of secondary organ damage such as hypertensive encephalopathy or acute left ventricular failure. *Hypertensive urgency* is a less severely elevated blood pressure level that may be potentially harmful but is without the evidence of end-organ damage or dysfunction. Hypertensive urgencies ordinarily develop over days to weeks, whereas hypertensive emergencies generally develop over hours.

Appropriate blood pressure cuff size is essential for accurate measurement of blood pressure levels. Standard blood pressure nomograms in children are based on auscultatory measurements of blood pressure levels using the right arm supported at the level of the heart. The inflatable rubber bladder should be long enough to completely encircle the circumference of the arm (overlap is acceptable). Bladder width should be approximately 40% of arm circumference at a point halfway between the acromion and the olecranon. A narrow cuff can produce falsely elevated readings. Likewise, a cuff that is too broad may produce readings that are falsely low.

For ease of comparison with standard blood pressure nomograms, auscultation remains the recommended method for blood pressure determination in children. Current guidelines recommend that the disappearance of Korotkoff sounds (the fifth Korotkoff sound) should be used to define diastolic blood pressure in children, adolescents, and adults. In the emergency department (ED) setting, however, sphygmomanometer readings are sometimes difficult to perform, particularly in neonates and very young children. In such cases, an oscillometric device, which measures the mean arterial pressure and calculates systolic and diastolic blood pressure values, may be used. Because blood pressure calculations by this method may vary widely from device to device, any abnormal reading should be repeated by auscultation.

In the ED setting, where children are often stressed or agitated by an unfamiliar environment or underlying illness, abnormally high blood pressure readings are not uncommon. These measurements should be repeated after a brief period of quiet rest. If second and third blood pressure measurements remain elevated, careful evaluation and treatment of the child's high blood pressure levels should be undertaken.

PATHOPHYSIOLOGY/ DIFFERENTIAL DIAGNOSIS

Blood pressure is determined by both cardiac output and peripheral vascular resistance. Alterations in heart rate, stroke volume, or peripheral vascular resistance will ultimately cause a change in blood pressure levels. Several factors, including disruptions in the renin-angiotensin system, volume overload or sympathetic stimulation by tumors, drugs, or other processes, may contribute to the development of hypertension.

Hypertension may be either primary or secondary in nature. Primary, or essential, hypertension is a condition in which no underlying disease can be identified. Particularly in the pediatric population, this is generally considered to be a diagnosis of exclusion and is rarely the cause of hypertensive urgencies or emergencies. The increasing frequency of primary hypertension in the pediatric population is believed to be largely attributable to the increasing body mass index, sedentary lifestyle, and high-salt and high-caloric diets of today's children. Secondary hypertension is usually the result of an underlying pathologic process, such as a cardiovascular, renal, endocrine, toxic, or central nervous system disturbance.

The differential diagnosis of hypertension changes with the age of a child, with younger children being more likely to have a discernable cause for their hypertension (Table 34.2). In newborn infants, for example, the most common causes of hypertension are renal artery thrombosis or stenosis, congenital renal malformations, and coarctation of the aorta. In children younger than 6 years, renal artery stenosis, renal parenchymal diseases, and coarctation of the aorta are the most common causes. Between 6 and 10 years of age, renal parenchymal disease is the leading cause of hypertension. After 10 years of age, essential hypertension becomes the leading cause of pediatric hypertension (Table 34.3). In adolescent girls, oral contraceptive pills may be a cause of hypertension, and in all age groups, drug- or toxin-induced hypertension should be considered.

EVALUATION AND DECISION

All children with a persistently elevated blood pressure level in the ED require a brief but thorough history and physical examination, with emphasis on detecting an underlying cause

TABLE 34.3

COMMON CAUSES OF HYPERTENSION

Age group	Cause
Newborn infants	Renal artery thrombosis, renal artery stenosis, congenital renal malformations, coarctation of the aorta, bronchopulmonary dysplasia
Infancy–6 yr	Renal parenchymal diseases,[a] coarctation of the aorta, renal artery stenosis
6–10 yr	Renal parenchymal diseases, renal artery stenosis, essential hypertension (including obesity)
Adolescence	Essential hypertension (including obesity), renal parenchymal diseases

[a]Includes renal structural and inflammatory lesions and tumors.
Adapted from the Task Force on Blood Pressure Control in Children. Report of the second task force on blood pressure control in children—1987. *Pediatrics* 1987;79:1–25.

for hypertension and eliciting signs and symptoms of end-organ damage resulting from the hypertensive process. In the absence of any concerning findings in the history or physical examination, the child with mild or moderate hypertension should be referred for follow-up with his or her primary care physician. Although it is appropriate to initiate the process of patient education in the ED regarding weight loss, dietary salt reduction, and exercise, a definitive diagnosis of hypertension should not be offered until the child has had repeated measurements of his or her blood pressure on several occasions.

The workup of a child with severe hypertension requires careful evaluation for the presence of clinical findings that may represent either the primary cause of the elevated blood pressure or the secondary systemic effects of hypertension. Relevant history includes frequent urinary tract infections, unexplained fevers, hematuria, dysuria, frequency, and edema—all suggestive of possible renal disease. A history of umbilical artery catheterization as a neonate may indicate the risk of renal artery stenosis or thrombosis. Ingestion of prescription, over-the-counter, or illicit drugs, or rapid withdrawal of some blood pressure medications used for chronic hypertension, may support the diagnosis of drug-induced hypertension. Alternatively, a history of sweating, flushing, palpitations, fever, and weight loss may indicate a pheochromocytoma.

Physical examination should concentrate on identifying potentially involved organ systems, paying particular attention to cardiovascular, renal, and central nervous systems. The cardiac examination should inspect for the evidence of congestive heart failure (CHF) and pulmonary edema. Absent or decreased femoral pulses are suggestive of aortic coarctation. Abdominal examination may reveal the presence of a bruit or renal mass such as Wilms' tumor, implicating a renovascular cause for the hypertension. Peripheral edema may suggest volume overload from renal failure. Neurologic evaluation should include observation for sensorimotor symmetry and appropriate cerebellar function. Funduscopic examination for hypertensive changes such as hemorrhages, infarcts, and disc edema should be conducted, in addition to testing the pupillary light reflex and visual acuity.

Initial investigations for severe hypertension in the ED should be limited to the most basic of tests. Blood studies including a complete blood cell count, electrolytes, blood urea nitrogen, serum creatinine, and urinalysis are usually warranted. In addition, a urine culture should be obtained in all girls and in boys with known renal pathologic conditions. A chest radiograph and an echocardiogram may help evaluate the extent damage from hypertension and may help detect the presence of CHF. If there are concerning findings on the initial cardiovascular examination, an echocardiogram may also be warranted. Although several additional studies exist for the evaluation of hypertension, these are rarely part of the routine ED assessment.

When the cause of hypertension is not readily apparent, a systematic approach to evaluation is indicated (Fig. 34.1). Because underlying renal disease is among the more common causes of hypertension in children, assessing for renal pathology based on historical elements, physical examination, and an initial urinalysis is often a good starting point. If this assessment is unrevealing, attention should be directed to the cardiovascular system, as coarctation of the aorta is most likely to manifest in a toddler or an older child with previously undiagnosed hypertension. When a careful evaluation of the renal and cardiovascular systems is not revealing, a detailed neurologic assessment is in order because any condition accompanied by increased intracranial pressure may elevate the systemic blood pressure. The history and signs of head trauma are usually obvious but may be occult when injuries in young children are not witnessed or are intentionally inflicted. Specific questioning about the ingestion of illicit drugs or other medications and a toxicologic screen are an appropriate next step if renal, cardiovascular, and neurologic causes are ruled out. Finally, although the endocrine disorders are relatively rare, a careful history and directed physical examination may identify temperature sensitivity, a goiter or abdominal striae suggestive of hyperthyroidism, or Cushing's syndrome. Intermittent headaches and flushing occur with pheochromocytoma, and elevated circulating catecholamines are responsible for hypertension seen in neuroblastoma. A negative evaluation for an underlying cause of hypertension in the ED is compatible with, but not sufficient for, the diagnosis of essential hypertension. Follow-up is always indicated.

MANAGEMENT (SEE CHAPTER 100)

There is little consistency in the literature as to when treatment of hypertension should be initiated, particularly in the ED setting. Acuteness of the rise in blood pressure levels, the presence of symptoms, preexisting medical problems, and the extent of end-organ damage are all factors to be considered (Fig. 34.2). According to the Fourth Report, immediate evaluation and treatment should be undertaken for patients with symptomatic stage 2 hypertension. However, some authors suggest that severe hypertension, even if asymptomatic, warrants acute treatment. In the end, the decision to treat a patient acutely in the ED setting will be based on a blood

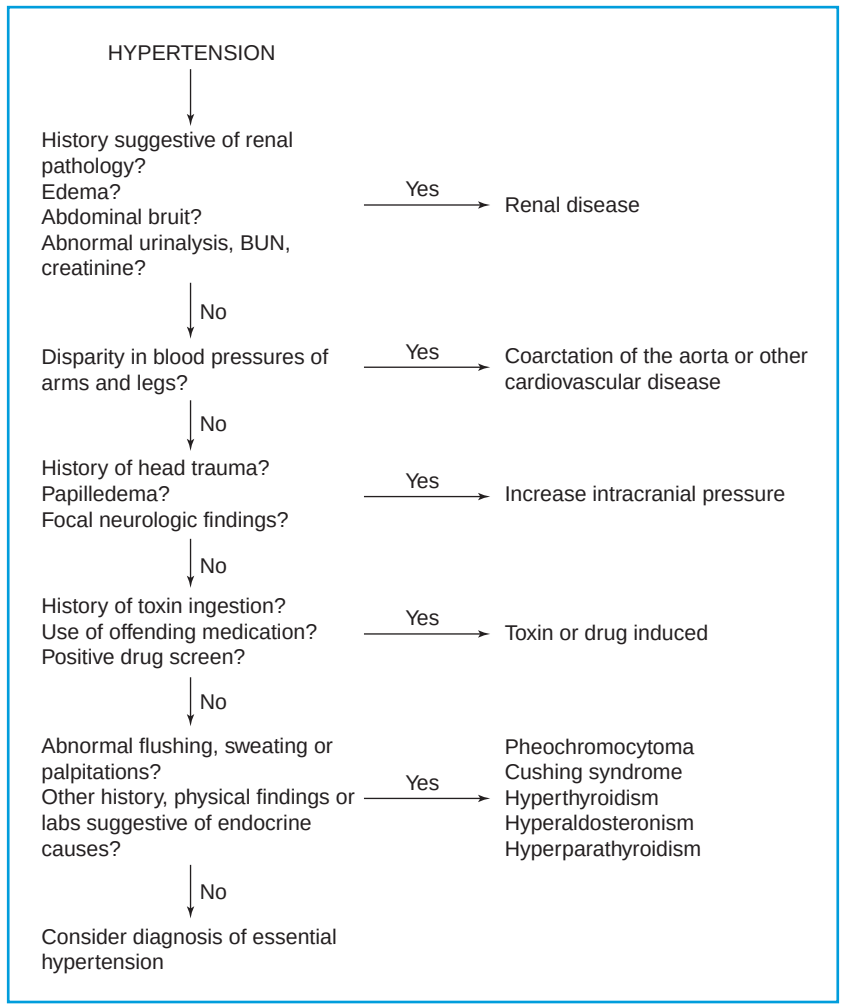

FIGURE 34.1 Diagnostic approach to the most common causes of acute, persistent hypertension in a previously healthy child. CHF, congestive heart failure.

pressure measurement that the clinician feels is imminently dangerous to the patient.

For children with severe hypertension, treatment must be rapid and, at the same time, cautious. There is a compelling reason for a conservative approach. Under normal conditions, autoregulation maintains a constant cerebral perfusion pressure, dilating cerebral vasculature when blood pressure falls and constricting cerebral vasculature when blood pressure level rises. Particularly in chronic hypertension, the range of pressures over which autoregulation occurs shifts upward to protect the brain from excessive perfusion. As such, cerebral vasculature may no longer be able to maintain perfusion pressure at lower ranges of blood pressure values. Too rapid a decrease in blood pressure levels can result in dangerous underperfusion and cerebral ischemia. Although there is no consensus on how slowly blood pressure levels should be lowered, a good rule of thumb is to reduce blood pressure levels by no more than 25% in the first 6 to 8 hours. Thereafter, the goal of therapy should be to normalize the blood pressure levels over a period of 3 to 4 days.

In addition to treating the elevation in blood pressure levels, the child with complications of hypertension may also require treatment of the specific complications. Careful attention should be paid to managing the child's airway, breathing, and circulation. The child with seizures or CHF often requires the standard treatment of these problems in addition to antihypertensive therapy. However, when other complications are believed to be secondary to severe hypertension, treatment of the hypertension should take precedence.

SPECIFIC THERAPY

For the treatment of hypertensive emergencies, it is recommended that an intravenous antihypertensive formulation be used because of its more predictable pharmacokinetic profile and ease of titration. Hypertensive urgencies may be managed using either intravenous or oral antihypertensive agents.

The choice of drugs (Table 34.4) depends on the severity of the patient's hypertension, the patient's current medications,

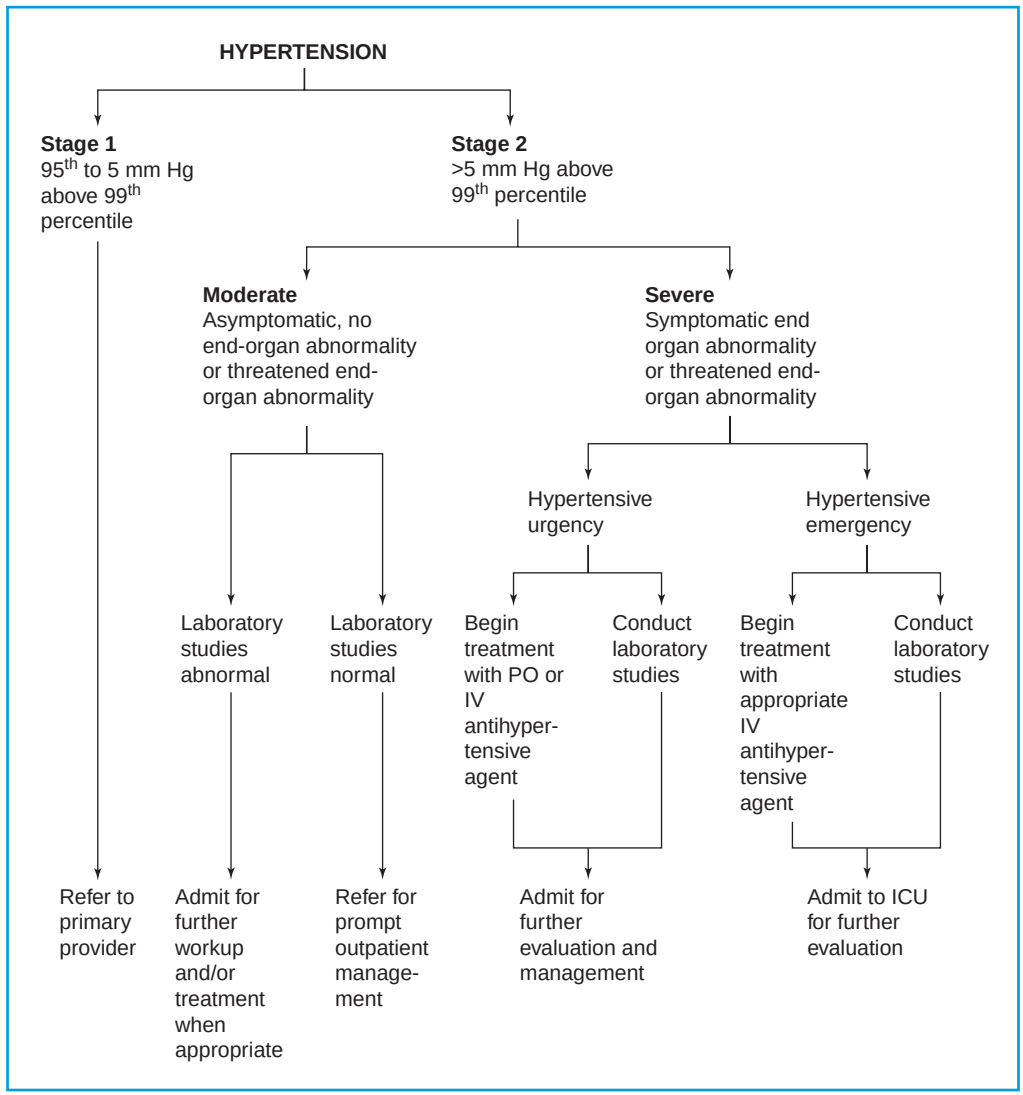

FIGURE 34.2 Approach to the initial emergency department triage and stabilization of the persistently hypertensive child. ICU, intensive care unit.

underlying medical conditions, the suspected cause of the hypertension, and the organs involved. Ideal medications for the treatment of hypertensive emergencies have a rapid onset of action and short half-life, allowing for the easy titration necessary for controlled blood pressure reduction. It is difficult to recommend one particular type of antihypertensive agent over another, as the choice of agent is so often multifactorial. However, the most commonly used agents for hypertensive emergencies include nicardipine, labetalol, and sodium nitroprusside. Hypertension caused by a catecholamine-secreting tumor (pheochromocytoma) might best be controlled with an α-blocking agent such as phentolamine. Elevated blood pressure levels secondary to high renin states may respond best to an angiotensin-converting enzyme inhibitor such as enalaprilat. However, if hypertension is associated with an intracerebral bleed, medications that cause an increase in cerebral blood flow, such as nicardipine and hydralazine, are best avoided.

Intravenous Antihypertensive Medications

Labetalol

Labetalol is a combined α_1- and β-adrenergic blocking agent. As such, it has the ability to reduce peripheral vascular resistance with little to no effect on heart rate or cardiac output. It has a rapid onset of action (usually 5 to 10 minutes) and a plasma half-life of 3 to 5 hours when given intravenously. Because of its duration of action, labetalol can be more difficult to titrate to effect than other agents and therefore is not routinely used as a continuous infusion.

Dosing recommendations for labetalol use in hypertensive emergencies vary widely. The drug may be administered by intermittent bolus dosing, or by a bolus dose followed by a continuous infusion (See Table 34.4). Recommendations for bolus dosing are 0.2 to 1 mg per kg and for infusion 0.25 to

TABLE 34.4

MOST COMMONLY USED ANTIHYPERTENSIVE AGENTS FOR THE TREATMENT OF HYPERTENSIVE URGENCIES AND EMERGENCIES IN CHILDREN[a,b]

Drug	Class	Route	Dose	Onset of action	Duration of action	Side effects/comments[c]
Labetalol	α_1- and β-Blocker	IV	Bolus dosing: 0.2–1 mg/kg (max 40 mg/dose) Infusion: 0.25–3 mg/kg/hr IV	5–10 min	2–4 hr	Contraindicated in asthma, heart failure, heart block, pheochromocytoma, cocaine toxicity; may mask symptoms of hypoglycemia
Nicardipine	Calcium channel blocker	IV	1–3 μg/kg/min	2–5 min	30–60 min	Risk of phlebitis at infusion site Reflex tachycardia May cause increased ICP
Sodium nitroprusside[d]	Direct vasodilator	IV	0.3–8 μg/kg/min	Seconds	During infusion only	Risk of cyanide/thiocyanate toxicity May cause transient hypotension
Hydralazine[d]	Direct vasodilator	IV/IM	0.2–0.6 mg/kg/dose (max 20 mg)	10–30 min	4–12 hr	Commonly used in pregnancy May cause headaches, tachycardia, increased ICP, fluid retention
Esmolol	β_1-Blocker	IV	100–500 μg/kg/min	Seconds	10–20 min	May cause profound bradycardia Metabolism independent of hepatic or renal processes
Phentolamine[d]	α-Blocker	IV	0.05–0.1 mg/kg/dose (max 5 mg)	Seconds	15–30 min	Useful for catecholamine-induced hypertensive crisis
Fenoldopam[d]	Dopamine receptor agonist	IV	0.2–0.8 μg/kg/min	5–15 min	1–4 hr	Limited experience in children
Nifedipine	Calcium channel blocker	PO	0.25–0.5 mg/kg/dose (max 10 mg)	20–30 min	6 hr	Precipitous decrease in MAP associated with doses > 0.25 mg/kg/dose Difficult to administer in exact doses May cause dizziness, flushing, rebound hypertension
Isradipine	Calcium channel blocker	PO	0.05–0.1 mg/kg/dose (max 5 mg)	30 min–2 hr	12 hr	Limited experience with pediatric use
Clonidine[d]	α_2-Receptor agonist	PO	0.05–0.1 mg/dose, may be repeated up to 0.8 mg of total dose	15–30 min	6–8 hr	Dry mouth, drowsiness
Minoxidil[d]	Direct vasodilator	PO	0.1–0.2 mg/kg/dose (max 10 mg)	Within 1 hr	8–12 hr	Potent vasodilator Hirsutism, fluid retention, primarily seen with long-term use

IV, intravenous; ICP, intracranial pressure; IM, intramuscular; PO, by mouth; MAP, mean arterial pressure.
[a]Because several of these medications have not been extensively tested in children, existing pharmacokinetic data are frequently based on studies in adults.
[b]Dosing recommendations vary by source.

[d]Indicates drugs with Food and Drug Administration–approved pediatric labeling for use in hypertension.

3 mg per kg per hour. Because of its more potent β-blocking effects, it should be used neither in patients with asthma, heart block, or CHF nor for the treatment of hypertension in patients with pheochromocytoma or sympathomimetic drug overdose (e.g., cocaine; see Chapter 102), due to its potential to cause unopposed alpha effects.

Nicardipine

Nicardipine is a dihydropyridine calcium channel blocker that prevents vascular smooth muscle contraction by blocking the movement of calcium across the cell. This results in a reduction in peripheral vascular resistance without compromising cardiac output. Its onset of action within 1 to 2 minutes of administration and short elimination half-life make it relatively easy to titrate. Nicardipine is the preferred agent for the treatment of hypertensive emergencies at many institutions because of its safety profile, ability to produce a relatively rapid effect, and low risk for causing hypotension. Recommended dosing is 1 to 3 μg per kg per minute by continuous infusion. Excessive reductions in blood pressure levels, though uncommon, can be reversed by the administration of calcium. Because it elevates intracranial pressure, nicardipine should be avoided in patients with increased intracranial pressure. Reflex tachycardia that is usually not clinically significant and phlebitis at the site of administration are known adverse effects of the drug.

Sodium Nitroprusside

Nitroprusside is a powerful vasodilator, affecting both arteriolar and venous smooth muscle cells. Its onset of action is almost immediate, and its duration of action is extremely short, allowing for easy titration of the drug to the desired blood pressure level. Because of its venous dilatory effects, nitroprusside reduces preload and often improves cardiac output if CHF is present. It may also increase intracerebral pressure, though some note that a rise in cerebral blood flow is offset by a concomitant drop in systemic pressure. Nitroprusside is metabolized to thiocyanate, and cyanide is an intermediary in its metabolism. Consequently, cyanide and thiocyanate toxicity must be considered a risk of its use, particularly for infusions lasting more than 24 to 48 hours. Such toxicity is also compounded by liver or renal impairment, as both organ systems are involved in the metabolism of sodium nitroprusside. In cases of renal or liver impairment, and for infusions lasting more than 24 hours, thiocyanate levels should be monitored daily. Because of this toxicity and its propensity to cause more episodes of transient hypotension than other agents, some institutions use only sodium nitroprusside as a second-line agent.

Nitroprusside is given as an intravenous infusion, starting at a dosage of 0.3 to 0.5 μg per kg per minute and increasing as needed to 8 μg per kg per minute. The patient should be kept in the recumbent position because of the frequency of orthostatic hypotension. The degree of drop in blood pressure levels is dose related; thus, the infusion should be started at the low end of the dosage range and titrated to achieve the desired blood pressure levels. The average dosage required for the control of hypertension is approximately 3 μg per kg per minute. Because nitroprusside has an extremely short half-life, blood pressure returns to pretreatment levels within 1 to 10 minutes of the cessation of the infusion.

Hydralazine

Hydralazine is an arteriolar vasodilator that can be given intravenously, intramuscularly, and orally, but onset of action is faster, in the order of 10 to 30 minutes, when administered intravenously. Its relative safety and efficacy, combined with extensive clinical experience, make it among the most commonly used agents for hypertension associated with pregnancy. Known side effects include reflex tachycardia, fluid retention, facial flushing, and increased intracranial pressure. These adverse effects and the availability of more potent, faster acting agents have largely replaced its use in the ED setting for nonpregnant patients. Hydralazine is given at a dose of 0.2 to 0.6 mg per kg intravenously or intramuscularly, or at a dose of 0.25 mg per kg orally to a maximum of 25 mg.

Esmolol

Esmolol is a selective β_1-blocker that has traditionally been used for the treatment of early postoperative hypertension following repair of congenital heart disease. Primary effects are at the level of the heart and kidneys. It has an onset of action of approximately 60 seconds and a duration of action of 10 to 20 minutes. It is usually administered by continuous infusion after an initial bolus dose. A single pediatric trial found esmolol to be effective for use after coarctation of the aorta repair by administering an initial bolus of 125 to 500 μg per kg followed by an infusion of 125 to 500 μg per kg per minute. Metabolism is independent of both hepatic and renal processes, making a good choice for use in patients with multiorgan failure. Although reported use in hypertensive children outside of the postoperative setting is limited, the drug certainly has potential for use in the ED setting.

Phentolamine

Phentolamine is an α-adrenergic receptor antagonist that is particularly useful in the treatment of hypertension associated with catecholamine-induced hypertensive crises, as seen with pheochromocytoma or sympathomimetic toxicity. Effectiveness has not been shown to be consistent for other types of hypertensive crises. Dosing recommendations vary widely. Some recommend 0.05 to 0.1 mg per kg per dose intravenously to a maximum of 5 mg, and others recommend a pediatric dose of 1 mg administered intravenously or intramuscularly, repeated as needed to achieve appropriate blood pressure control.

Enalaprilat

Enalaprilat is an angiotensin-converting enzyme inhibitor that can be useful in high renin states. It is contraindicated for use in patients with bilateral renal artery stenosis. Because of the high incidence of renovascular disease in the pediatric population, and limited pediatric experience with its use, caution must be exercised before using this agent for the treatment of severe hypertension in the ED. It should be administered at a

dose of 0.05 to 0.1 mg per kg intravenously up to a maximum of 1.25 mg.

Oral Antihypertensive Medications

Nifedipine

Short-acting nifedipine is a calcium channel blocker that works by decreasing peripheral vascular resistance. Its use in children remains controversial, owing to the serious hypotensive side effects of the drug experienced in adults. However, similar exaggerated effects have not been clearly demonstrated in children.

Although traditionally administered sublingually, more recent reports suggest more predictable absorption when the capsule is bitten and swallowed. Nifedipine is administered at a dose of 0.25 to 0.5 mg per kg up to a maximum of 10 mg. Onset of action is within 20 to 30 minutes; duration of action is approximately 6 hours. Precipitous decreases in mean arterial pressure (>25%) have been associated with doses exceeding 0.25 mg per kg. There are also isolated case reports of rebound hypertension causing adverse neurologic events after the use of short-acting nifedipine in children with hypertensive encephalopathy. Because of the difficulties in titrating to effect and its slower onset of action, the use of nifedipine should be limited to hypertensive urgencies only. Facial flushing and increased cerebral blood flow are other side effects of nifedipine administration.

Isradipine

A second-generation dihydropyridine calcium channel blocker, isradipine has received more recent attention for use in children with severe hypertension. Onset of action is usually 30 minutes to 2 hours, with a half-life of 3 to 8 hours. It has selective action on vascular smooth muscle, which allows it to be used in children with compromised myocardial function. At present, only anecdotal experience with its use for severe elevations in blood pressure levels in children exists. Dosing ranges from 0.05 to 0.1 mg per kg per dose to a maximum of 5 mg, given 2 to 4 times daily.

Clonidine

Clonidine is an α_2-adrenergic agonist that works by reducing cerebral sympathetic output. Its onset of action is 15 to 30 minutes following administration. It is recommended by some for the management of hypertensive urgencies, although most studies have evaluated its use as a treatment of chronic primary hypertension. The drug has been approved by the Food and Drug Administration for use in children older than 12 years. Side effects include somnolence and dry mouth.

Minoxidil

Minoxidil is a direct vasodilator that exerts its effect on the potassium channels of smooth muscle cells causing hyperpolarization and eventual relaxation of arterioles. Venous vessels are not affected. This has been shown to be effective particularly in children with chronic hypertension experiencing acute elevations. It is recommended for occasional use in hypertensive urgencies.

Newer Agents

Fenoldopam

Fenoldopam is a selective dopamine agonist causing vasodilation of the renal, coronary, cerebral, and splanchnic vasculature, resulting in a decrease in mean arterial pressure. The use of fenoldopam in pediatric patients has increased in recent years. Case reports have demonstrated success with its use for controlled hypotension during spinal instrumentation and in the intensive care setting when conventional therapy was unsuccessful. More recently, a clinical dose-ranging study of the use of fenoldopam in children showed that although fenoldopam resulted in a decrease in blood pressure levels, this decrease was less than that observed in adults.

In adults, peak effects of fenoldopam have been observed in 5 to 15 minutes, with steady-state serum levels achieved in 30 to 60 minutes. Infusion rates of 0.2 to 0.8 μg per kg per minute are recommended for use in children. Side effects include reflex tachycardia, increased intracranial pressure, and increased intraocular pressure. Although pediatric experience with fenoldopam is limited, it appears to be a reasonable alternative to other more conventional therapies.

Clevidipine

Clevidipine is a recently developed, ultra-short-acting dihydropyridine calcium channel antagonist with high specificity for vascular smooth muscle. Its half-life is only a few minutes, making it relatively easy to titrate when administered as a continuous infusion. Its decreased tendency to cause tachycardia when compared with sodium nitroprusside and more rapid offset of action when compared with nicardipine make it a strong contender for the management of severe elevations in blood pressure levels in the ED. Clevidipine has not yet been approved for use in pediatric patients and no dosing recommendations in children exist as of yet, although pediatric trials are expected to begin in the next few years.

SUMMARY

It is not unusual that a child presenting to the ED will have an elevation in blood pressure levels. In many such cases, the blood pressure level will normalize with rest or acclimation to the environment. Occasionally, however, the elevation in blood pressure levels will be sustained. In children with asymptomatic mild hypertension and no target organ involvement, the emergency physician must ensure adequate follow-up. Moderate or severe hypertension that affects or threatens to affect end organs, in contrast, requires evaluation and initiation of treatment in the ED (Fig. 34.2). In severe or life-threatening cases, blood pressure reduction will often need to be instituted before the cause of the hypertension is known.

CHAPTER 35 ■ IMMOBILE ARM

SARA A. SCHUTZMAN, MD

An infant or child brought for the evaluation of an "immobile arm" is not moving the limb because of pain or weakness. The evaluation is often a challenge because most of these children are preverbal; therefore, the history is second or third hand if available at all, patients are unable to report symptoms or pain location, and the physical examination is often difficult because of children's fear of strangers. These children can be considered as having an upper-extremity equivalent of "limp." By using historical information, physical findings, selective radiologic studies, and laboratory tests, children with this complaint can be diagnosed and managed.

DIFFERENTIAL DIAGNOSIS

Table 35.1 lists most conditions that cause decreased use of the arm. Trauma is by far the most common cause of decreased arm movement in children (Table 35.2). Any injury from the clavicle to the fingertips can cause arm pain in children and can lead to diminished use of the limb. These injuries range from a serious (fracture or dislocation with neurovascular compromise; Table 35.3) to a simple contusion. Most young children with diminished arm use will have a radial head subluxation ("nursemaid's elbow"), fracture, or soft-tissue injury. Although one can often elicit a history of trauma, the diagnosis must be considered even in its absence because of unwitnessed events in preverbal children or, less commonly, intentional injuries inflicted by caregivers who are not forthcoming. With musculoskeletal injuries, the child may have an obvious abnormality, such as a deformity or contusion, or more subtle findings of localized tenderness or decreased arm movement. Children with hemophilia may have hemarthrosis or hematoma with minimal trauma. Radiographs are useful for demonstrating most fractures or dislocations but may appear normal with Salter-Harris type I fractures and nursemaid's elbow, as well as with contusions and other minor soft-tissue injuries (see also Chapter 114).

Although much less common than trauma, infection may also cause decreased use of an arm. There may be a history of fever, and onset of arm disuse is often less abrupt than with trauma. The infection can be located at any point from the shoulder to finger and may be superficial (e.g., cellulitis, paronychia) or deep. Arthritis and osteomyelitis frequently have associated localized swelling, warmth, and tenderness; infected joints usually have limited, painful range of motion. With more severe infections, the child may be febrile and appear ill (especially if bacteremic). Laboratory findings may include elevated white blood cell count, elevated sedimentation rate (ESR), or elevated C-reactive protein (CRP) level, and blood culture results may yield the offending agent. Acutely, radiographs often are nondiagnostic; if arthritis or osteomyelitis is suspected, ultrasound, bone scintigraphy, or magnetic resonance imaging (MRI) should be considered (depending on the clinical scenario), with arthrocentesis or subperiosteal/bone aspiration as indicated (see Chapters 92 and 125). Congenital syphilis, although unusual, may present as pseudoparalysis in infants due to metaphysitis, periostitis, osteochondritis, or pathologic fracture, with bony changes evident on the radiograph.

Other inflammatory causes of arm pain include noninfectious arthritis and myositis. In addition to a swollen, tender joint, children with arthritis caused by postinfectious, Lyme, and rheumatologic diseases may have multiple joint involvement, rash, fever, adenopathy, heart murmur, hematuria, or bloody stools. If the examination suggests an inflammatory arthritis but cannot exclude a septic process, then arthrocentesis is necessary for definitive diagnosis.

Tumors are a rare cause of diminished arm use. The tumors can be benign or malignant and of bone, cartilage, or muscle, or they may represent neoplastic infiltration of bone marrow (e.g., leukemia, neuroblastoma). Tumors are usually less acute in onset; cardinal symptoms may include pain and, perhaps, increasing mass or joint swelling, although the lesions may be asymptomatic. Occasionally, tumors lead to a pathologic fracture. Systemic complaints, including fever, malaise, and weight loss, may be present. Physical examination may reveal localized tenderness, joint swelling, or a mass of the soft tissue or bone. With leukemia or neuroblastoma, fever, abdominal mass, hepatosplenomegaly, or pathologic adenopathy may also be found. Plain radiographs are of obvious importance; lesion location and radiologic appearance (density and peripheral margin) can be diagnostically significant. Complete blood cell count (CBC) and ESR are helpful in screening for possible infection or bone marrow neoplasm (see Chapter 97).

Children with neurologic abnormalities will have diminished use of an arm because of weakness, with or without pain. An isolated monoplegia may be caused by a radiculopathy, plexopathy, or neuropathy that results from compression, inflammation, or injury. Trauma, particularly traction on the arm, is a common mechanism that leads to neurologic abnormalities (e.g., brachial plexus injury from birth); however, nontraumatic conditions may have an abrupt onset with no apparent antecedent illness. The child will have diminished arm movement, weakness, and may even experience pain; unlike the previously discussed causes of arm disuse, however, the pain (if present) is usually not reproducible with palpation and is not accompanied by swelling or redness. Reflexes may be diminished or absent. It is important to identify any associated neurologic abnormalities because facial or leg weakness may be subtle but would point to a lesion in the central nervous system.

Miscellaneous
Reflex sympathetic dystrophy

Children with hemoglobinopathies (most commonly sickle cell disease) may present with decreased arm use because of vasoocclusive crisis, causing ischemia or infarction of bone marrow with acute bone pain. Long bones are commonly affected; however, young children frequently have involvement of the small bones of the hands and feet (dactylitis). Usually, no precipitating events are identified. The child experiences pain with localized tenderness and swelling of the involved areas; there may be associated warmth and erythema. Acutely,

  Nursemaid's elbow
  Fracture
  Soft-tissue injury

there are no bony abnormalities on radiographs. Because the "hand-foot syndrome" may be the first clinical manifestation of sickle cell disease, all children at risk for sickle cell disease with limb pain or swelling (or fever) must be screened for hemoglobinopathy if not tested previously. It is also particularly important to consider septic arthritis and osteomyelitis in children with sickle cell disease, as they are susceptible to infection, and the clinical findings may overlap with bone infarction, particularly if fever and leukocytosis are present (see Chapter 91).

Several other much less common processes can cause decreased upper-limb use. These include avascular necrosis of the humeral head or capitellum in otherwise healthy children and reflex sympathetic dystrophy.

EVALUATION AND DECISION

The evaluation of the child who has diminished arm movement consists of a complete history and a thorough physical examination, with radiologic studies and laboratory tests when indicated. On the basis of these findings, appropriate management can be undertaken.

A history of any trauma should be ascertained. Details of the event may provide clues to the type of injury incurred; a fall onto an outstretched hand may cause a wrist, forearm, or elbow injury, whereas a sudden arm pull by a caregiver can cause dislocation or subluxation of the radial head ("nursemaid's elbow"). Of note is that some children with radial head subluxation may have a mechanism of injury other than a pull. If an immediate causative traumatic event is not elicited, the duration, course, and pattern of diminished arm use should be clarified. Fever, malaise, rash, or weight loss may give clues to a systemic illness. If the patient is an infant, it should be determined whether the arm disuse was from birth: a difficult delivery may lead to clavicular fractures or brachial plexus injuries. It should be remembered that infants do not always mount a

TABLE 35.3

LIFE- AND LIMB-THREATENING CAUSES OF DIMINISHED ARM USE

Septic arthritis/osteomyelitis
Leukemia/other malignancy
Fracture with neurovascular compromise

febrile response to infection and may have only nonspecific symptoms of diminished feeding, increased sleeping, lethargy, or irritability. General medical history should include any history of inflammatory process, hemophilia, or sickle cell disease.

After a careful history, a physical examination should be performed. Fever should be noted and may be indicative of infection or, less likely, inflammatory or neoplastic process. Observation and inspection, sometimes from a distance of several paces, can provide information that might otherwise be unobtainable because many children cry when approached or touched by a stranger. The position of the arm should be noted. A child with nursemaid's elbow often holds the arm pronated and slightly flexed with obvious diminished movement, although often without apparent discomfort; a child with neurologic abnormality may hold the arm limply at the side of the body. Close inspection for areas of deformity, redness, swelling, or bruising should be done. Observation of the child's reach and grasp for an interesting object can provide information about the active range of motion and neurologic function. The clinician should palpate from clavicle to fingertips to identify areas of warmth, swelling, or tenderness (often best accomplished in the younger child while he or she is being distracted). Joints should be assessed for warmth, swelling, tenderness, and range of motion; however, if a history of trauma is present, manipulation can be deferred until an acute fracture has been excluded. Neurovascular integrity of the arm should be assessed carefully. A thorough general examination for rash, other joint abnormalities, hepatosplenomegaly, adenopathy, abnormal mass, and neurologic status should be performed, particularly for children without an obvious injury.

Plain radiographs are one of the most useful studies for evaluating children with diminished arm use. They may reveal a fracture or dislocation, joint effusion, or lytic bone lesion. If a discrete area of tenderness is identified, radiographs of that location, including the joint above and below, should be obtained. If the focus of pain is not apparent, it may be necessary to obtain radiographs of the entire limb from clavicle and shoulder to fingers.

A CBC may help in the diagnosis of infection, inflammation, malignancy, or hemoglobinopathy. Although nonspecific, an ESR or CRP levels may be useful in differentiating inflammatory or infectious processes from other causes.

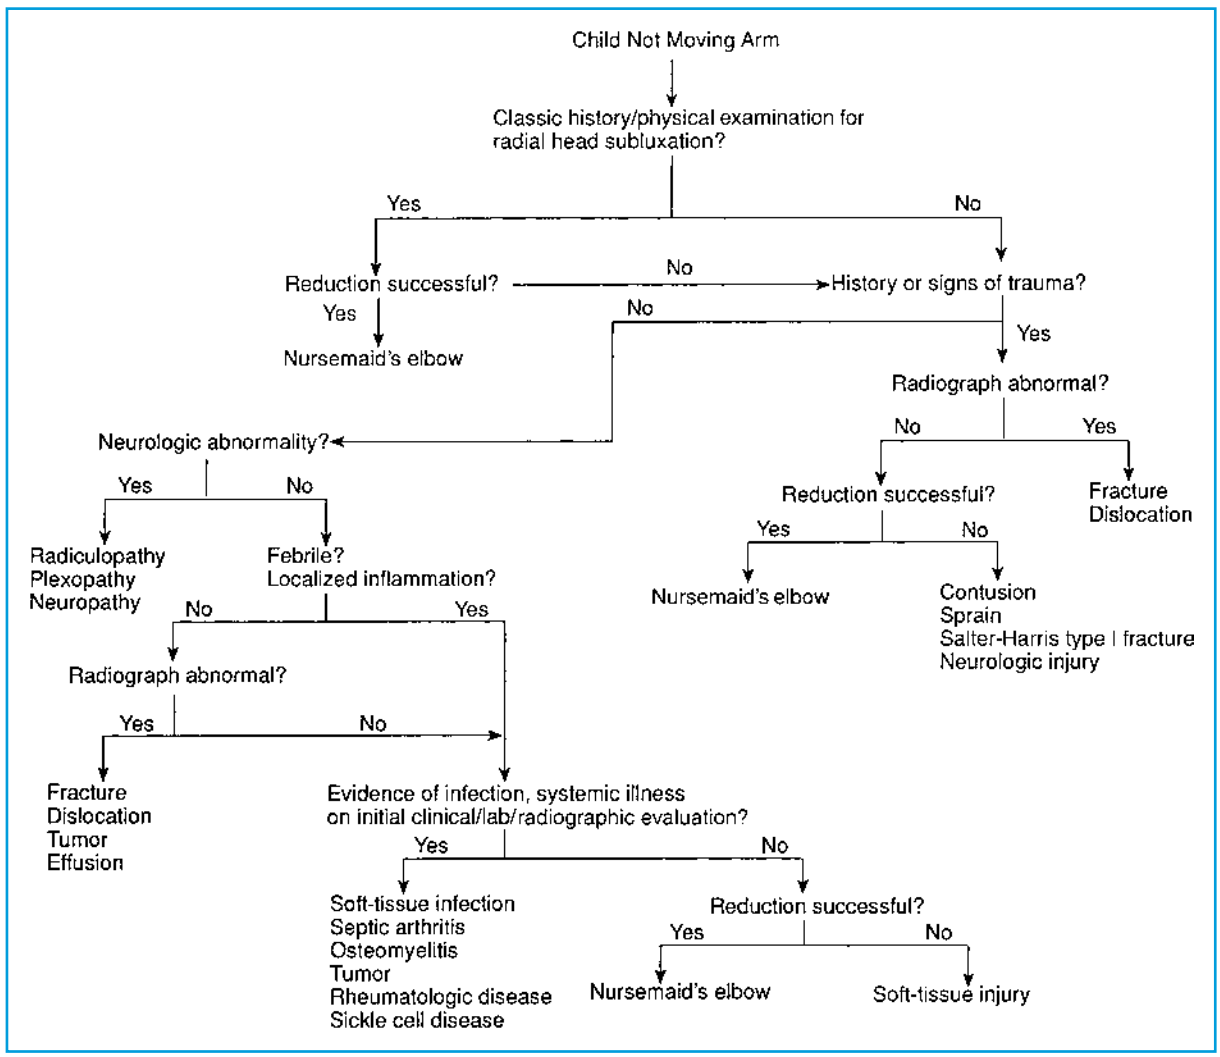

FIGURE 35.1 Approach to the child with diminished arm use.

Other tests helpful in selected cases include blood culture (if an infectious process is suspected), hemoglobin electrophoresis (if sickle cell disease is a possibility), bone scan, or MRI (for osteomyelitis, septic arthritis, aseptic necrosis). Arthrocentesis is imperative if septic arthritis is a possibility, and if osteomyelitis is suspected, evaluation and treatment should proceed urgently.

When a child is brought for the evaluation of diminished arm use, the physician should first determine whether this resulted from a specific traumatic event (Fig. 35.1). If the history is classic for radial head subluxation, the patient is holding the arm pronated and slightly flexed, and there is no localized tenderness or swelling, then the physician may attempt reduction. If the child does not regain full use of the arm quickly, as in all other cases of trauma, radiographs should be obtained. In many cases, the radiographic studies provide the diagnosis (e.g., fracture, dislocation). Normal radiographs in the setting of acute trauma usually imply soft-tissue injury and the patient should be treated symptomatically with close follow-up, provided that neurovascular integrity is established. If radiographs appear normal but the child has reproducible tenderness localized to the epiphyseal plate, then the patient should be presumptively treated for a Salter-Harris type I fracture. Occasionally, a child with a nursemaid's elbow may have an atypical history (e.g., "fell onto arm"); if radiographs exclude a fracture but the patient is holding the arm in a characteristic position, an attempt at reduction should be performed.

Children with neurologic abnormalities should be evaluated urgently to localize the site and cause of the impairment; the appropriate subspecialist (neurologist, neurosurgeon) should be involved.

If the child has no clear history of trauma but is afebrile with no obvious localized findings of infection, the limb should be evaluated radiographically. Abnormalities revealed might include fracture, dislocation, tumor, or effusion. If radiographs are normal in these children, one could consider obtaining a CBC count, ESR, CRP, and blood culture tests, or hemoglobin electrophoresis to evaluate for occult infectious or inflammatory processes.

Children who are febrile, have signs of localized inflammation (e.g., warm, swollen joint), or have evidence of systemic illness should have a CBC and ESR, CRP, and blood culture tests in addition to radiographs. On the basis of specific findings, further evaluation might include arthrocentesis, bone scan, MRI, or rheumatologic tests. When the initial history, physical examination, laboratory tests, and radiographs localize with the site and etiology of the pathology, the physician can begin specific management.

Some children with no history of trauma in whom a thorough initial evaluation is unrevealing will have a nursemaid's elbow. Therefore, an attempt at reduction is warranted in selected cases. Children with persistently diminished arm movement who are afebrile and nontoxic, with no localized findings, normal neurovascular function, and normal laboratory tests, likely have an occult soft-tissue injury and can be managed as outpatients. A few of these children may have indolent pathologic processes or occult fractures; therefore, close follow-up must be ensured. These patients should be reevaluated every few days until normal arm use is regained or until evidence of a pathologic process develops. If arm disuse persists, a more extensive evaluation to diagnose or exclude occult fracture, infection, tumor, or inflammatory process is in order.

CHAPTER 36 ■ INJURY—ANKLE

ANGELA C. ANDERSON, MD, FAAP

Approximately 26% of sports-related injuries in school-aged children involve the ankle. Young children with ankle injuries may complain of pain anywhere from their mid-calf to their toes because it is often difficult for children to localize pain. Conversely, pathology in the lower leg and foot can cause referred pain to the ankle.

The ankle joint is composed of three bones: the tibia, the fibula, and the talus. The bony prominence of the distal fibula constitutes the lateral malleolus, whereas the prominence of the distal tibia forms the medial malleolus. The physes are located one to two fingerbreadths above the distal ends of the tibia and the fibula.

The ankle ligaments are attached to the physes. The distal fibular physis is the most commonly injured growth plate in the lower extremities. It is second only to the distal radius in the incidence of physeal injuries.

Growth plates and bones are weaker than ligaments. Consequently, ankle trauma in preadolescent children is much more likely to cause fractures of the physis and the adjacent epiphysis and/or metaphysis than do ligamentous injuries or sprains.

DIFFERENTIAL DIAGNOSIS

A number of traumatic injuries may cause ankle pain (Table 36.1). Although trauma is the most common cause of ankle pain in children, infectious, rheumatologic, inflammatory, neoplastic, and hematologic abnormalities also should be considered (Table 36.2) because trauma may occasionally merely exacerbate pain in children with underlying conditions. Again, keep in mind that a complaint of ankle pain may result from a lesion anywhere between the knee and the toe, particularly in preverbal children. The most common injuries vary according to age (Table 36.3).

Ankle Fractures

Fractures of the ankle account for 5.5% of all fractures in pediatrics. The system used to classify ankle fractures in children differs from the one used in adults because of the presence of growth plates and the possible implications of physeal injuries. The Salter-Harris classification is most commonly applied, as described in Chapter 114.

Inversion ankle injuries in preadolescents most commonly cause a Salter-Harris type I fracture of the distal fibula (Fig. 36.1). Clinically, the patient presents with swelling about the lateral malleolus and tenderness at the distal fibular physis. Fractures confined to the physes may not be visible on radiographs. Consequently, routine radiographs may appear normal despite the presence of a fracture.

In severe inversion injuries, the distal fibular fracture described previously may be accompanied by a fracture of the medial malleolus (Fig. 36.2). This medial malleolus fracture is usually a Salter-Harris type III or IV fracture of the distal tibia. These patients will have tenderness at the medial malleolus and the distal fibular physis.

Fractures resulting from eversion of the ankle are usually a combination of a Salter-Harris type II 2 fracture of the lateral tibia and a transverse fracture of the fibula (Fig. 36.3). The fibular fracture is relatively high (4 to 7 cm above the fibular physis). Therefore, it is important to examine the full length of the fibula in patients with ankle injuries.

Direct axial compression of the ankle is uncommon but can cause a Salter-Harris type V injury to the distal tibia.

External rotation injuries are responsible for lesions known as transitional fractures. Transitional fractures occur during adolescence when closure of the growth plates is beginning. Closure of the distal tibial physis starts at the center of the bone and then spreads medially, posteriorly, and finally laterally. The distal tibial physis closes before the distal fibular physis.

As skeletal maturity (and physeal closure) progresses, the relative strengths of various parts of the tibia change. As a result, the same mechanism of injury may cause very different fracture patterns, depending on the age of the patient. The juvenile Tillaux fracture and the triplane fractures are examples of transitional fractures.

In the juvenile Tillaux fracture, a fragment of bone is torn off the lateral border of the tibia by the anterior tibiofibular ligament (Fig. 36.4). It is a Salter-Harris type III injury of the distal tibia. This fracture is seen almost exclusively in patients between the ages of 12 and 14 years. This is because the closure of the medial aspect of the distal tibial physis begins around 12 to 14 years of age, whereas the lateral aspect remains open and therefore less stable for approximately another 18 months. The greater the skeletal maturity of the patient, the more lateral the epiphyseal fracture line occurs.

Diagnosis of these fractures may be difficult because routine radiographs may not show the fracture line well. If displacement is minimal, the only radiographic sign may be a slight widening of the lateral tibial physis or a faint vertical fracture line through the epiphysis on anteroposterior (AP) or oblique views. In some cases, the only finding may be local tenderness in the area of the lateral tibial physis. Multiple oblique views, computed tomography (CT), or tomography may be needed to adequately delineate the extent of the fracture.

Growth arrest and angular deformity are rare because these fractures occur at the time of physeal closure. However, ankle

joint arthritis may complicate the long-term outcome if the diagnosis is missed or if reduction is inadequate.

Triplanar fractures are characterized by a fracture line that runs in three planes: coronal, sagittal, and transverse. They are a combination of a juvenile Tillaux fracture and a Salter-Harris type II fracture of the distal tibia. Two types of triplane fractures have been described. The first is a three-fragment fracture (Fig. 36.5). The first fragment is the same as the one found in the juvenile Tillaux fracture—a fragment of the epiphysis torn off the anterolateral quadrant of the tibia. The

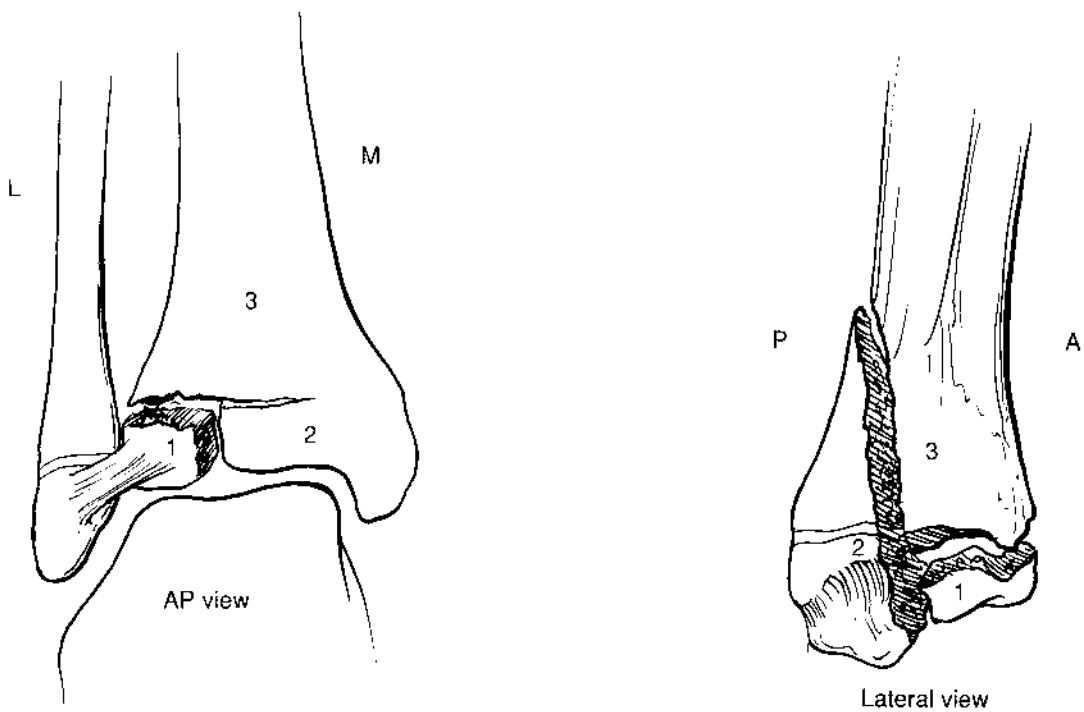

FIGURE 36.5 Anteroposterior and lateral views of three-fragment triplanar fracture. L, lateral; M, medial; P, posterior; A, anterior.

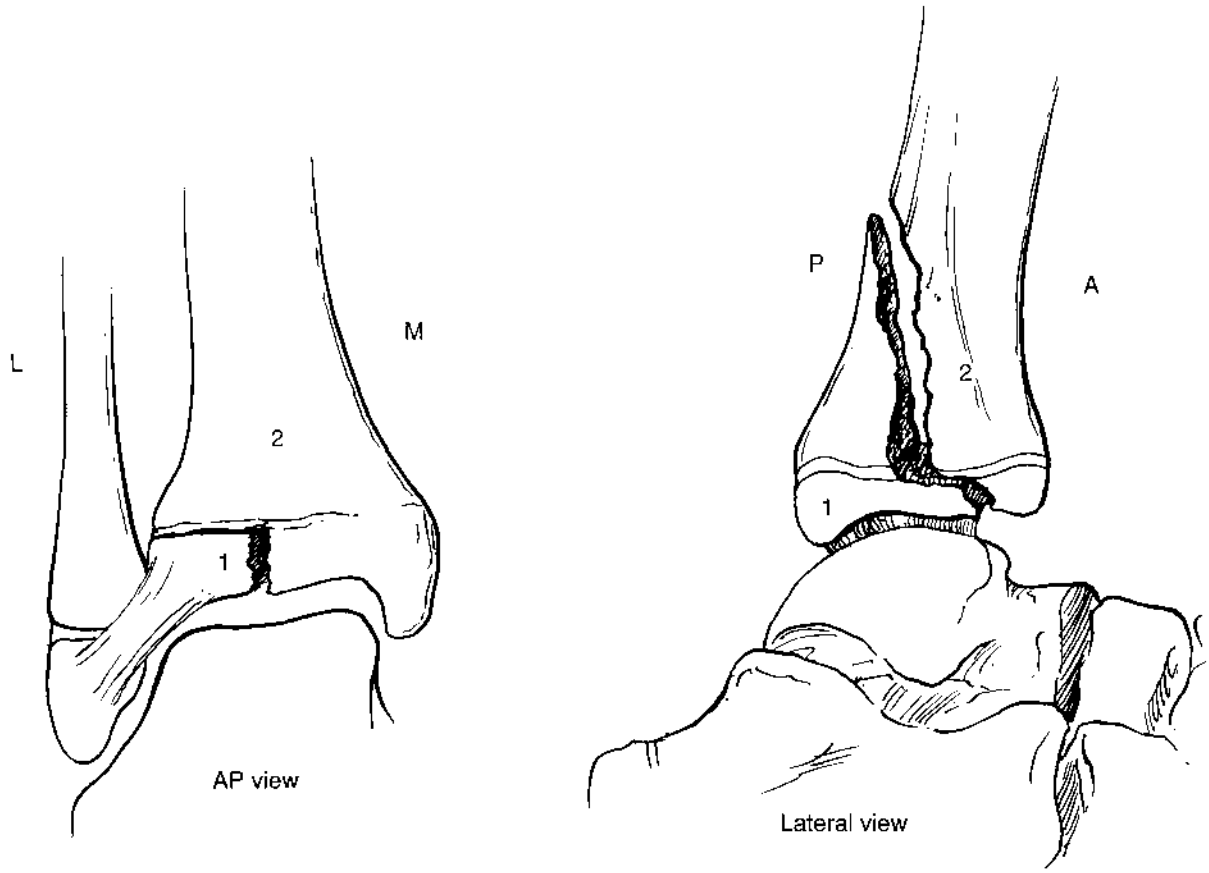

FIGURE 36.6 Anteroposterior and lateral views of two-fragment triplanar fracture. L, lateral; M, medial; P, posterior; A, anterior.

second fragment is the remaining medial part of the epiphysis, which is attached to a posterior spike of the metaphyseal bone. The third fragment is the tibial shaft.

A two-fragment fracture has also been described. The first fragment is again the lateral tibial epiphysis, but it is attached to a posterior spike of the metaphyseal bone. The second fragment is the remaining medial epiphysis and is attached to the tibial shaft (Fig. 36.6).

On a radiograph, triplanar fractures have the appearance of a Salter-Harris type III fracture on the AP view and a Salter-Harris type II fracture on the lateral view. If only the AP view is obtained, it may be difficult to distinguish these fractures from the juvenile Tillaux fracture. The key to diagnosis is the posterior metaphyseal spike seen on the lateral film.

Ankle Sprains

Ankle sprains in children or preadolescents are less common than fractures because the ligaments in this age group are much stronger than growth plates or even bone. If a ligamentous injury occurs in a child with an open growth plate, an associated avulsion fracture is almost always present. However, once skeletal maturity is reached, ankle sprains become the most common of sports injuries.

Inversion injuries cause 85% of ankle sprains. The most commonly injured structures are the lateral ligaments. Three lateral ligaments support the ankle joint: the anterior talofibular (ATFL), the calcaneofibular (CFL), and the posterior talofibular (PTFL) (Fig. 36.7). The ATFL is the weakest and most commonly injured of the three. The CFL is intermediate in strength and is rarely injured without an associated tear of the ATFL. The PTFL is the strongest and least injured of the lateral ligaments. Because its fibers run horizontally, only extreme dorsiflexion will stress this ligament. The peroneus brevis tendon also traverses the lateral aspect of the ankle joint and can be injured by inversion stress. It inserts at the base of the fifth metatarsal.

Eversion injuries account for 15% of ankle sprains. The deltoid ligament, which supports the medial aspect of the ankle, is most commonly affected by this mechanism (Fig. 36.8). It is composed of deep and superficial fibers. Eversion may also cause disruption of the tibiofibular syndesmosis, which connects the distal tibia and the fibula.

Classification of Ankle Sprains

There are many systems of classification for ankle sprains. Table 36.4 provides guidelines that can be used in grading injuries to the lateral ligaments.

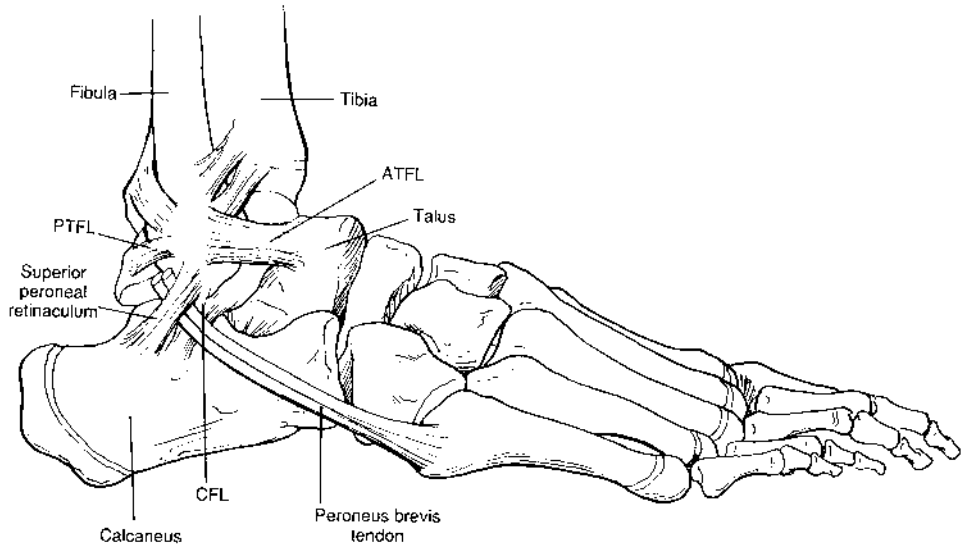

FIGURE 36.7 Lateral view of the ankle. ATFL, anterior talofibular ligament; PTFL, posterior talofibular ligament; CFL, calcaneofibular ligament.

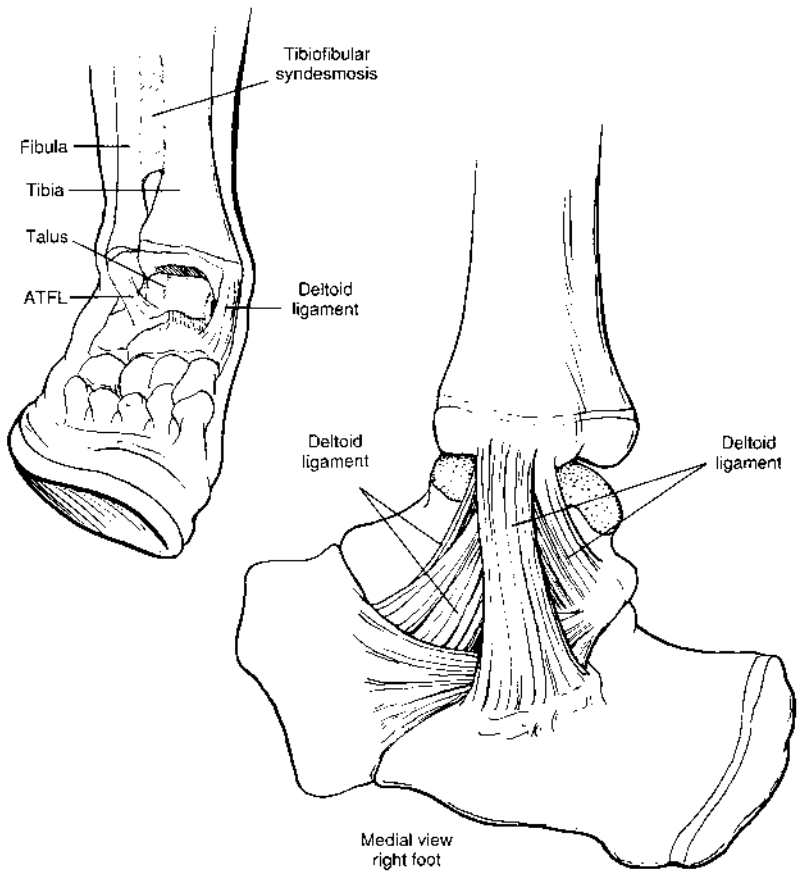

FIGURE 36.8 Ankle eversion injury. ATFL, anterior talofibular ligament.

TABLE 36.4

CLASSIFICATION OF ANKLE SPRAINS

	Grade I: Mild sprain	Grade II: Moderate sprain	Grade III: Severe sprain
Ligament injury	Minor	Near complete tear	Complete rupture
Swelling	Mild	Moderate	Severe
Tenderness	Mild, local	Moderate, diffuse	Marked
Functional loss	Minimal	Ambulates with difficulty	Inability to bear weight

Injuries Associated with Ankle Sprains

Approximately 7% of ankle sprains are accompanied by osteochondral fractures of the talus. The medial dome is more commonly fractured than the lateral dome. Avulsions of the peroneus brevis tendon from the base of the fifth metatarsal have been observed in up to 14% of patients with ankle ligament ruptures. If this injury occurs in children younger than 15 years, the avulsed fragment is usually an apophysis and is considered a Salter-Harris type I injury. In older patients, the displaced portion represents a bony fragment and is known as a Jones fracture.

EVALUATION AND DECISION

History

Trying to obtain a reliable history in ankle injuries can be very unsatisfying. It is a rare occasion when the patient says: "I sustained an inversion injury while playing basketball!" More commonly, the description is: "I twisted it and it hurts." Nevertheless, the mechanism of injury, if obtainable, can provide a clue to the diagnosis. Other questions include the following: (i) When did the injury occur? (ii) Did swelling occur immediately or gradually? (iii) Is there a history of any previous injury to that limb? and (iv) Does the patient have a history of any other medical problems—osseous, neurologic, or muscular disease?

A history of fever, rash, or other joint involvement, in combination with a history of minimal or no trauma, suggests nontraumatic diagnoses such as septic joint, arthritis, or collagen-vascular disease.

Physical Examination

General Inspection

Look for obvious deformities, open wounds, loss of anatomic landmarks, local swelling, and ecchymosis. If an obvious deformity is present, keep manipulation of the extremity to a minimum and assess neurovascular status promptly. Any break in the skin may communicate with the joint space or constitute an open fracture. The need for antibiotic coverage must be evaluated immediately.

Neurovascular Evaluation

Palpate the dorsalis pedis and posterior tibial arteries. Note skin temperature, color, and capillary refill. The absence of pulses or the presence of pallor requires immediate attention. A Doppler device may help identify pulses.

Vascular compromise is usually caused by a posterior dislocation. Traction reduction of the deformity should be attempted as rapidly as is feasible by performing the following steps: (i) sedate the patient; (ii) apply longitudinal traction to the foot; (iii) if relocation is not accomplished in step ii, apply longitudinal traction and pull the foot in a posterior to anterior direction; and (iv) immobilize the ankle and obtain radiographs. If the vascular status has not been compromised, continue with the examination and evaluate the nerves that cross the ankle. Test soft touch and pain sensation of the foot.

Bony Palpation

Trace all three bones of the ankle joint (the tibia, the fibula, and the talus), searching for areas of point tenderness. It is very important to palpate the distal tibial and fibular physes because fractures in these areas may not be evident on radiographs. Any tenderness found along a physis should be considered a Salter-Harris type I fracture at the least, even if radiographic studies are negative. Also keep in mind that the only clue to a juvenile Tillaux fracture may be tenderness at the lateral tibial physis. Remember to palpate the fibula proximal to the ankle joint. External rotation and triplanar injuries may be associated with high fibular fractures.

Finally, examine the foot. This should include palpation of the dome of the talus. This is performed most easily with the foot in plantar flexion. Palpate the base of the fifth metatarsal. Tenderness here suggests an avulsion of the peroneus brevis tendon.

Once one area of point tenderness is found, continue to examine the entire joint. A single injury may cause many abnormalities.

Ligament Palpation

Palpate for tenderness along all three lateral ligaments, remembering that each one arises from the distal fibula. The ATFL can be further tested by inverting and plantar flexing the foot. This will increase pain if injury to this ligament is present. More than 4 cm of swelling in an area of lateral ligament tenderness is highly suggestive of significant ligament injury.

Examine the superficial fibers of deltoid ligament on the medial aspect of the joint. The deep fibers are intraarticular and nonpalpable; therefore, rupture may be present without much medial tenderness. Isolated injuries to the deltoid ligament are rare because of the great strength of this ligament. If the deltoid ligament has been damaged, the tibiofibular syndesmosis is usually disrupted along with it.

Injuries to the tibiofibular syndesmosis may be explored by (i) squeezing the midshafts of the tibia and the fibula together, (ii) dorsiflexing and then externally rotating the foot while holding the tibia and the fibula stable, or (iii) forcefully dorsiflexing the ankle with the patient supine. Exacerbation of pain with these maneuvers suggests syndesmotic disruption.

Stability Testing

An attempt should be made to assess the stability of the ankle joint. However, stability testing in the immediate postinjury period may be limited significantly by pain, swelling, and/or muscle spasm. Several maneuvers are useful, but they are generally not performed if an ankle fracture is present.

- *Anterior Drawer Test*—The anterior talofibular ligament is the only structure that prevents forward subluxation of the talus. The anterior drawer test is performed to assess the anterior stability of the ankle joint and the integrity of the ATFL (Fig. 36.9). The test result is positive if the foot can be pulled forward by more than 4 mm or if there is a significant difference in the degree of anterior movement in the injured ankle compared with the normal ankle.

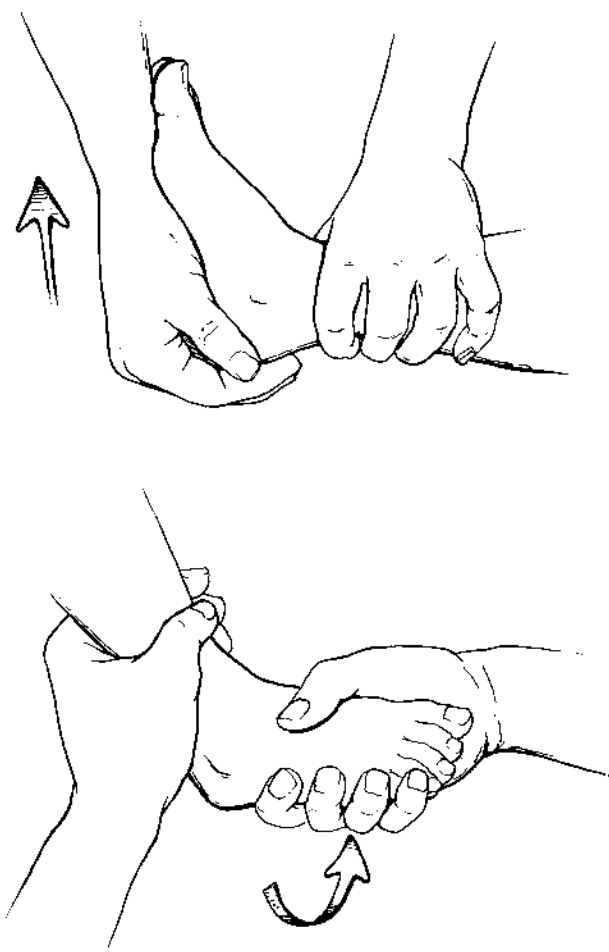

FIGURE 36.9 (**Top**) The anterior drawer test is performed by placing the patient's heel in the palm of the examiner's hand with the ankle at a 90-degree angle to the long axis of the leg. The examiner gently, but firmly, moves the heel and foot forward *(arrow)*. (**Bottom**) In the talar tilt maneuver, the heel is firmly adducted *(arrow)* and assessed for increased laxity or instability compared with the noninjured side.

- *Talar Tilt Test*—This test is used to examine the lateral stability of the ankle joint. It is performed by firmly adducting the heel, looking for increased laxity compared with the noninjured joint (Fig. 36.9). Both the anterior talofibular and calcaneofibular ligaments must be torn to cause gross lateral ankle instability.

Radiographic Imaging

The Ottawa ankle rules (OARs) were developed to help clinically predict radiographically evident ankle fractures in adults. OARs maintain that ankle radiographs are required only if the patient has pain near the malleoli and one or both of the following: (i) inability to bear weight immediately following the injury and in the emergency department (four steps) and (ii) bone tenderness at the posterior edge or tip of either malleolus. These rules were 100% sensitive in detecting clinically significant fractures in patients older than 18 years; application of these rules allowed for a 28% reduction in the number of radiographs ordered. A more recent study suggests that OARs were 100% sensitive in detecting ankle fractures 3 mm or more in width in children older than 2 years; however, patients with Salter-Harris type I fractures were not included as positive outcomes. One study that investigated OARs in children and included Salter-Harris type I fractures as abnormal determined that OARs had a sensitivity of only 80% if applied to children younger than 15 years. All studies utter warnings regarding the use of OARs to predict ankle fractures in very young children.

Radiographic evaluation of the ankle should include at least three views: AP, lateral, and mortise. If tenderness of the proximal fibula is noted, full-length views of the fibula are essential. Tenderness at the base of the fifth metatarsal mandates visualization of this area on the lateral film. If radiographic findings are questionable, consider obtaining comparison views of the noninjured ankle. The practice of *routinely* obtaining comparison views has not been studied and it is unknown if doing so would change clinical practice or patient outcome.

Note areas of soft-tissue swelling. This may be the only clue to a Salter-Harris type I fracture of the distal fibula. Stress radiographs to evaluate growth plate injuries are rarely necessary and may cause further damage. The value of stress radiographs to assess ligament damage is also questionable. Severe pain and muscle spasms frequently prohibit stress maneuvers. Arthrography may be more helpful but is seldom indicated in the acute care setting. This method uses the location of extravasated contrast material in the ankle joint to identify ligamentous ruptures.

CT scan of the ankle is often necessary to fully evaluate triplane fractures. Magnetic resonance imaging (MRI) may be useful in evaluating patients in whom one has a high clinical suspicion of injury despite normal radiographs. MRI may also delineate suspected tendon and ligament injuries in selected circumstances.

Approach

The approach (Fig. 36.10) to the evaluation and diagnosis of traumatic ankle injuries relies primarily on physical findings

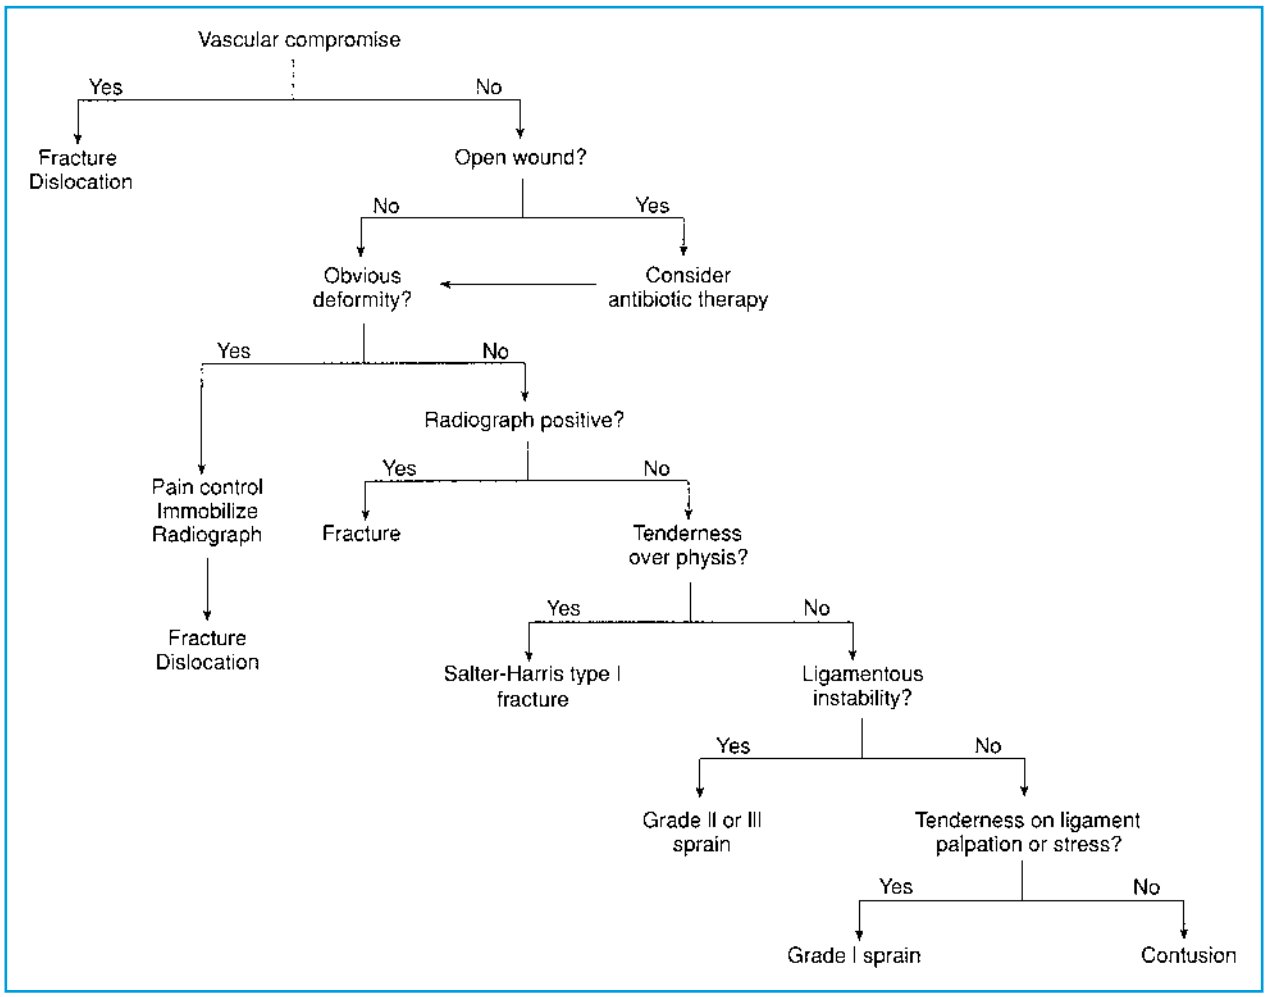

FIGURE 36.10 Evaluation and diagnosis of traumatic ankle injuries.

and the results of radiographic evaluation. Initially, pulses and sensation are assessed. Loss of pulses and/or sensation suggests a fracture/dislocation and the need for a rapid reduction; when available without delay, orthopedic consultation is advisable. After immobilization to prevent further compromise and the provision of analgesia, a radiograph should be obtained immediately. If neurovascular status is adequate and the general inspection reveals no obvious abnormalities, proceed with the rest of the physical examination as described previously.

Next, examine the area for open wounds. If present, fashion a sterile saline dressing and immobilize the extremity before obtaining a radiograph. Consider in addition the administration of intravenous antibiotic therapy and tetanus prophylaxis.

If radiographic studies indicate a fracture or dislocation, provide treatment of the specific injury (see Chapter 114). Administer analgesia as needed.

If no fracture is evident on the radiograph, but tenderness is elicited over a physis, the diagnosis of a Salter-Harris I injury can be made and appropriate immobilization is performed (see Chapter 114). One study demonstrated that approximately 18% of children with tenderness at the distal fibular physis and normal radiographs will develop new periosteal bone formation, thus implying the presence of an occult fracture. A negative radiographic result in the absence of bony tenderness suggests the diagnosis of contusion or ligamentous injury. The diagnosis of a grade II or III sprain is rendered to the patient with joint instability. If the ankle is stable, but pain is elicited with ligamentous stress or palpation, a grade I sprain is diagnosed.

TREATMENT

Fractures

Fracture reduction is usually accomplished by reversing the mechanism of injury. Closed reduction and a short leg cast are usually adequate for Salter-Harris type I and II fractures of the distal tibia and the fibula (see Chapter 114). Some displacement can be accepted in younger patients because of their ability to remodel. Two studies have suggested that children with nondisplaced Salter-Harris type I fractures my benefit from even more conservative therapy; those treated with crutches, a 5-day period of non–weight bearing, and the use of a removable ankle brace (e.g., an air-stirrup ankle brace or an elastic bandage) were able to return to normal activity sooner than those in whom short leg

casts were used. Patients in these studies advanced their activities as tolerated. Salter-Harris type III and IV injuries involve the articular surface and are therefore less stable. They require anatomic realignment, frequently by open reduction. A long leg cast is commonly applied in any rotational injury.

Sprains

A common approach to the treatment of ankle sprains is described by the "RICE" (rest, ice, compression, elevation) mnemonic. It should be initiated within 36 hours of the injury.

- *Rest*—The patient is allowed to ambulate/exercise only if the activity does not cause pain or swelling during or within 24 hours. Otherwise, crutches and lightweight bearing are recommended until ambulation without pain is possible.
- *Ice*—Apply ice directly to the ankle for 20 minutes, every 2 hours if possible, for the first 48 hours postinjury.
- *Compression*—The object of compression is to keep (and/or push) fluid out of the area of the ankle joint. This can be accomplished using an elastic bandage starting at the foot and wrapping proximally toward the ankle. For additional compression, any bulky padding can be applied to the malleoli and then secured with an elastic wrap. The combined application of an elastic wrap covered with an air-stirrup ankle brace may allow for an earlier return to normal function than either device used alone.
- *Elevation*—To help decrease or prevent swelling, elevate the ankle as often as possible.

Splinting

If swelling or pain is severe, apply a stirrup and/or posterior splint to the ankle (see Procedures 12.14a–c). Air splints can also be used; they allow dorsiflexion and plantar flexion while maintaining medial and lateral stability.

Rehabilitation

Early rehabilitation shortens the period of disability considerably. Plantar flexion and dorsiflexion exercises are initiated as soon as possible, followed by toe raises and inversion/eversion exercises.

Orthopedic Referral

Absolute indications for orthopedic referral include (i) obvious deformity with growth plate involvement, (ii) neurovascular compromise, (iii) suspected syndesmotic injury, (iv) a grade III sprain, and (v) locking of the ankle.

CHAPTER 37 ■ INJURY—HEAD

SARA A. SCHUTZMAN, MD

PEDIATRIC HEAD TRAUMA

Head injuries in children are common, accounting for more than 600,000 emergency department (ED) visits per year in the United States. Although the majority of these injuries are minor, head trauma causes significant pediatric morbidity and mortality. Trauma is the leading cause of death in children older than 1 year, and traumatic brain injury is the leading cause of death and disability caused by trauma in children, resulting in approximately 3,000 deaths annually.

The most common mechanism of injury for pediatric head trauma is falls, followed by motor vehicle and pedestrian accidents and bicycle injuries; the majority of fatal injuries occur secondary to motor vehicle-related accidents. The mechanism of head injury varies with age; younger children are more likely to suffer falls or abuse, whereas older children are often injured in sporting or motor vehicle accidents (in addition to falls).

Many of the serious neurologic complications of head injury are evident soon after the traumatic event; however, some life-threatening injuries can appear initially as minor head trauma. To manage head injuries best, the physician must approach the child in a systematic manner to address all injuries (global resuscitation is the first priority of cerebral resuscitation), identify and treat any neurologic complications, and prevent ongoing cerebral insult.

PATHOPHYSIOLOGY

Neurologic injury following head trauma is related to the unique physiology and pathophysiology of the brain and the intracranial environment. The brain is a semisolid structure bathed in cerebrospinal fluid (CSF) and covered by the fine inner pia-arachnoid membrane and the outer thick fibrous layer of dura, all of which are encased in the skull, which is covered by the five-layered structure of the scalp. After infancy (when the skull sutures fuse), the cranial vault becomes a stiff and poorly compliant structure housing the brain. Because the intracranial volume is relatively fixed, any change in the volume of one of the intracranial components (blood, brain, and CSF) must occur at the expense of the others; if the other components do not decrease proportionally, intracranial pressure (ICP) will increase.

Brain injury occurs in two phases: primary and secondary. The primary injury is the mechanical damage sustained at the time of trauma and can be caused by direct impact of the brain against the internal calvarial structures, by bone or foreign bodies projected into the brain, and by shear forces delivered to the white matter tracts. Secondary brain injury is further neuronal damage sustained after the traumatic event to cells not initially injured. This results from numerous causes, including hypoxia, hypoperfusion, and metabolic derangements, and may also result from sequelae of the primary injury (e.g., cerebral edema, expanding intracranial mass) or be caused by extracranial injuries (e.g., hypotension from excessive blood loss, hypoxia from pulmonary contusion). The clinician's goal is to identify and treat any complications of primary brain injury in order to limit further neuronal damage by secondary brain injury.

One of the most common causes of secondary brain injury is cerebral ischemia resulting from impaired perfusion. Cerebral perfusion pressure is the difference between the mean arterial pressure of blood flowing to the brain and the ICP. In the healthy child, blood flow to the brain is maintained at a constant rate over a wide range of systemic blood pressures by means of autoregulatory changes in the cerebrovascular resistance so that the brain does not suffer ischemia or excessive blood flow during periods of relative hypo- or hypertension, respectively. With severe injuries, this autoregulatory control may be lost and the cerebral blood flow can become directly dependent on the cerebral perfusion pressure; with low mean arterial pressure or increased ICP, there will be inadequate blood flow and cerebral ischemia results. In addition to potential for causing decreased cerebral perfusion, increased ICP, if left unchecked, can lead to brain herniation and compression. This may be caused by a number of posttraumatic conditions, including cerebral edema and expanding intracranial mass.

Clinical symptoms of increased ICP or herniation include headache, vomiting, irritability, lethargy, visual disturbance, gait abnormalities, and weakness. Signs include depressed level of consciousness, abnormal vital signs (bradycardia, hypertension, respiratory irregularity), cranial nerve palsies, hemiparesis, and decerebrate posturing. The classic findings in transtentorial herniation are headache, decreasing level of consciousness followed by ipsilateral pupillary dilatation (cranial nerve III palsy), and contralateral hemiparesis or posturing. If the process continues unchecked, dilatation of the opposite pupil, alteration in respirations, and ultimately, bradycardia and arrest ensue. For a more detailed description of the anatomy, pathophysiology, and treatment of specific head injuries, please see Chapter 105.

DIFFERENTIAL DIAGNOSIS

Head trauma may cause injuries of the scalp, skull, and intracranial contents. Although each is discussed here separately, the clinician must remember that these injuries may occur alone or in combination, and all potential injuries must be considered when dealing with one.

Scalp

The scalp consists of five layers of soft tissue that cover the skull; contusions and lacerations of this structure are common results of head trauma. The outermost layers of the scalp are skin and the subcutaneous tissue; edema and hemorrhage here may produce a mobile swelling. The third layer, the galea aponeurotica, is a strong membranous sheet that connects the frontal and occipital bellies of the occipitofrontalis muscle. The remaining two layers deep to the galea are the loose areolar tissue and pericranium. Subgaleal hematomas may result from more forceful blows as vessels in the fourth layer bleed and dissect the galea from the periostium, or they may be signs of an underlying skull fracture. In subperiostial hematomas, or cephalohematomas, the swelling is localized to the underlying cranial bone and most frequently occurs with birth trauma. Scalp lacerations may occur with or without underlying contusions or fractures and they often require suturing. Given the high vascularity of the scalp, these injuries can result in significant blood loss if not recognized and treated appropriately.

Skull

Skull fractures occurring in the calvarium, or bony skullcap, include frontal, parietal, temporal, and occipital fractures and may be linear, diastatic, depressed, comminuted, or compound. Fractures in the base of the skull are termed *basilar*. Most simple fractures require no intervention but are important in that they are a marker of significant impact to the head and are associated with up to a 20-fold increased risk of intracranial injury (ICI).

Linear fractures account for 75% to 90% of skull fractures in children and often manifest with localized swelling and tenderness. Diastatic fractures are traumatic separations of cranial bones at a suture site or fractures that are widely split. A depressed skull fracture is present when the inner table of the skull is displaced by more than the thickness of the entire bone. These may be palpable and are diagnosed with tangential skull radiographs (SRs) or computed tomography (CT) scans. Compound fractures are those that communicate with lacerations.

Basilar skull fractures may be difficult to detect on routine SR or CT; however, their location produces clinical signs that lead to the diagnosis. Fractures of the petrous portion of the temporal bone may cause hemotympanum, hemorrhagic or CSF otorrhea, or Battle's sign (bleeding into mastoid air cells with postauricular swelling and ecchymosis). Fracture of the anterior skull base may cause a dural laceration with subsequent drainage of CSF into paranasal sinuses and rhinorrhea. Anterior venous sinus drainage may cause blood leakage into the periorbital tissues (raccoon's eyes). Given the location of basilar skull fractures, associated cranial nerve palsies may occur. There is a high incidence of associated ICI in children with basilar skull fracture, even in those with a Glasgow Coma Scale (GCS) score of 15 and normal neurologic examination results.

Intracranial Injury

Insults to intracranial contents include functional derangements without demonstrable lesions on CT scan (concussion, posttraumatic seizures), hemorrhage [cerebral contusion, epidural hematoma (EDH), subdural hematoma, subarachnoid hemorrhage, and intracerebral hemorrhage], and acute brain swelling. Rarely, penetrating brain injuries occur in children. ICIs may also be classified as focal (e.g., contusions, hematomas, lacerations) or diffuse (e.g., diffuse axonal injury, diffuse brain swelling). Focal injuries are usually apparent on the initial CT scan, even if clinically asymptomatic. Diffuse injuries, in contrast, may not demonstrate striking abnormalities on early CT imaging, even if the patient manifests significant alteration in neurologic function.

Concussion

Concussion is the most minor brain injury and is characterized by posttraumatic alteration in mental status that may or may not involve loss of consciousness (LOC). No consistent associated pathologic lesion in the brain has been identified. The child may have a depressed level of consciousness, pallor, vomiting, amnesia, and confusion; however, the clinical picture usually normalizes within several hours without specific therapy.

Posttraumatic Seizure

Posttraumatic seizures can be divided temporally into immediate, early, and late, and they occur in 5% to 10% of children hospitalized for head trauma.

Immediate seizures occur within seconds of the trauma and may represent traumatic depolarization of the cortex. They usually are generalized and rarely recur.

Early seizures occur within 1 week of the trauma (the majority within 24 hours). Skull fractures, intracranial hemorrhage, and focal signs are associated with increased risk of early posttraumatic seizures; therefore, an early seizure should prompt investigation of these possibilities.

Late seizures occur more than 1 week after the traumatic event and may be attributed to scarring associated with local vascular compromise, distortion, and mechanical irritation of the brain. These seizures are more likely to occur in children with severe head injuries, dural lacerations, and intracranial hemorrhages. A substantial number of patients will have subsequent seizures.

Cerebral Contusion

Cerebral contusion is a bruising or crushing of brain and often results from blunt head trauma. The site of contusion may be a "coup" lesion, with the injured cerebral cortex directly beneath the site of impact (with or without skull fracture), or a "contrecoup" lesion, with damage opposite the site of impact; the contusion is demonstrable by CT scan. Children with cerebral contusion may have had LOC (not imperative), may show a depressed level of consciousness or symptoms of vomiting or headache, and may have focal neurologic signs or seizures.

Epidural Hematoma

Epidural hematoma (EDH) is a collection of blood between the skull and the dura. An overlying fracture is present in 60% to 80% of cases, and, depending on the location and vascular structure involved, the hemorrhage may be of arterial or venous origin; injury to the middle meningeal artery is frequently responsible for temporal EDH. The classic pattern of a "lucid interval" between initial LOC and subsequent neurologic

deterioration occurs only in a minority of children with EDH; furthermore, patients may occasionally develop EDH after relatively "minor" trauma with no history of LOC. Although many children present with marked lethargy, focal neurologic signs, or a clinical pattern consistent with temporal lobe herniation as the hematoma expands, some children may be alert with a nonfocal neurologic examination and may have symptoms only of headache or persistent vomiting; nevertheless, rapid deterioration can ensue.

Subdural Hematoma

Subdural hematomas (SDHs) occur as a result of bleeding between the dura and the arachnoid membranes covering the brain parenchyma. They may result from direct trauma or from shaking injuries and are due to tearing of the cortical bridging veins or due to bleeding from the cortex itself. SDHs may be bilateral, and frequently, there is an associated underlying brain injury. Skull fractures occur in only a minority of cases. Children with SDHs often have seizures, may present with evidence of acutely elevated ICP, or may have more nonspecific signs of vomiting, irritability, or low-grade fever. Physical examination often reveals an irritable or lethargic child, with a bulging fontanel in infants, who may or may not have neurologic abnormalities. CT scan commonly demonstrates crescent-shaped subdural collections.

Intracerebral Hematoma

Posttraumatic intracerebral hematomas are unusual in children. Blood within the parenchyma is usually the result of severe focal injury or penetrating trauma, usually manifests with severe neurologic compromise, and often portends a poor prognosis.

Subarachnoid Hemorrhage

Subarachnoid hemorrhage may occur following head trauma (including shaking injuries in infants) and may cause headache, neck stiffness, and lethargy in the child.

Diffuse Axonal Injury

Diffuse axonal injury is characterized by injury to the white matter tracts of the brain and is one of the most common causes of prolonged posttraumatic coma in children. The initial CT scan may be normal or may demonstrate multiple petechial hemorrhages in the deep white matter and central structures. The degree of microscopic injury is usually greater than that seen on diagnostic imaging, accounting for clinical symptoms that may be disproportionate to CT scan findings.

Diffuse Brain Swelling

Diffuse brain swelling occurs frequently in children with severe head trauma. It appears to be a reactive phenomenon that occurs within hours of the traumatic event and is likely a final common manifestation of brain injury caused by a variety of pathophysiologic processes. The major effect of this swelling is potential for significant elevation of ICP. These children have a depressed level of consciousness and may have focal neurologic signs or symptoms of herniation.

Penetrating Injuries

Penetrating head injuries are uncommon in children and may be caused by bullets, teeth (e.g., dog bites), or other objects (e.g., dart, pencil, pellet) penetrating the skull. These injuries have obvious potential for extensive damage to the brain and intracranial vessels.

EVALUATION AND DECISION

The clinical spectrum of head injury in children varies from a small contusion of the scalp with no neurologic sequelae to severe ICI that causes death. The general approach is essentially the same as with any child who presents with trauma, paying particular attention to potential CNS damage. Following the ABCs (airway, breathing, and circulation) of resuscitation, the physician must systematically evaluate and stabilize the child with head trauma. The goals of management are to identify complications of the head trauma and to prevent secondary brain injury. Because some complications of head trauma may not manifest immediately, the assessment period includes the initial evaluation in the ED and a more extended observation period, either in the hospital or as an outpatient, as clinically indicated. Specific therapy will vary based on specific diagnosis in each case and may include supportive care and possible neurosurgical intervention. Although complications are more common in children with severe head injury, they also occur in children with apparently minor head trauma; thus, all patients merit some degree of scrutiny.

The immediate management of the child varies with the degree of compromise. A brief initial assessment is performed to determine immediate stability. In the older child, verbal response to a question often establishes the adequacy of the airway, ventilation, and cognitive function. If the child is unconscious or has unstable vital signs, immediate resuscitation is initiated to ensure a patent airway (with cervical spine immobilization), effective ventilation, and adequate tissue perfusion (see Chapter 1); efforts to decrease possible increased ICP may be indicated, depending on the degree of neurologic compromise (see Chapter 105). The child with airway and hemodynamic stability and with only mild to moderate depression of mental status can undergo a more timely evaluation to identify subtle or occult abnormalities.

CLINICAL ASSESSMENT

History

The history should be obtained from the patient (if age and level of consciousness permit) and from any witnesses to determine the nature and severity of the impact and the prehospital course. Specifics of the traumatic event should include how, when, and where the trauma occurred, as well as details such as height of a fall, type of impact surface, and type and velocity of striking objects. Occurrence of LOC as well as duration should be determined. If the event was unwitnessed and the patient is amnestic, the clinician should assume that LOC occurred. Occurrence of seizure activity (including details of time of onset posttrauma, duration, and focality) and the child's level of alertness since the injury should be noted, as well as presence of vomiting, irritability, ataxia, and abnormal behavior—all signs of possible brain injury. Vomiting after a head injury is not uncommon;

however, persistence for more than several hours may signal intracranial abnormalities. If the child is verbal, he or she should be questioned about the presence of headache or neck pain, amnesia, weakness, visual disturbances, or paresthesias. In many cases, elicited symptoms may be the only evidence of underlying CNS injury. In infants, symptoms of ICI may be subtle or absent; therefore, the clinician should pay particular attention to any alteration in behavior in this age group. Progression or resolution of any symptoms, neurologic signs, and level of consciousness since the traumatic episode must be defined clearly. One should also inquire about previous medical history and factors predisposing to head trauma (e.g., seizure disorder, gait disturbance, bleeding diathesis, alcohol abuse, or illicit drug use). When there are discrepancies in the history, when the history does not fit the physical findings, or when there is a skull fracture or ICI in a young child without a history of significant trauma, one should suspect nonaccidental injury.

Physical Examination

After a primary survey with appropriate resuscitation, a thorough physical examination should be performed, with special emphasis on the vital signs, head and neck, and neurologic examination. Bradycardia may be a sign of increased ICP; it is of particular concern when associated with hypertension, abnormal breathing pattern, depressed level of consciousness, or neurologic abnormality. Bradycardia may also be seen with spinal cord injuries caused by unopposed parasympathetic tone; in this case, it is often associated with hypotension, flaccidity, a sensory level, and absent deep tendon reflexes. Tachycardia may reflect hypovolemia (especially if associated with hypotension), hypoxia, or anxiety. Isolated head injuries rarely cause hypovolemia (except in infants with large subgaleal or intracranial hematomas); therefore, hypotension should alert the clinician to a possible extracranial or spinal cord injury.

The head should be inspected and palpated carefully for scalp swelling, lacerations, irregularities of the underlying bony structure, and fontanel fullness (in infants). Signs of basilar skull fracture (periorbital or postauricular hemorrhage in the absence of direct trauma, hemotympanum, CSF otorrhea, or rhinorrhea) and retinal abnormalities (hemorrhage or papilledema) should be noted. All children with depressed mental status or neck pain should have cervical spine immobilization maintained at least until its integrity has been confirmed radiographically; one should note cervical abrasions, deformity, or tenderness—findings that may indicate underlying cervical spine injuries.

Neurologic examination encompasses assessment of the child's mental status, as well as cranial nerve, motor, sensory, cerebellar, and reflex functions. Serial examinations are important in the child with head trauma to document improvement or deterioration. The GCS is a convenient way to quantify the level of consciousness and monitor neurologic progression. The GCS rates patient performance in three areas: eye opening, verbal ability, and motor ability. It also assesses the level of alertness, mentation, and major CNS pathways (Table 37.1); an individual's score may range from a low of 3 to a high of 15. The score has been modified for more age-appropriate behaviors in infants (Table 37.2). Although ICIs are more common in a child with a low GCS score, even a child with a GCS score of 15 may harbor potentially life-threatening complications of head trauma (e.g., EDH), especially if neurologic abnormalities are present. Further evaluation of mental status includes assessing orientation and memory. Subtle signs (irritability and high-pitched cry) may be indicative of underlying abnormalities in infants.

TABLE 37.1

Cranial nerve function is assessed by checking for facial symmetry, corneal reflexes, presence of a gag reflex, full extraocular movements, pupillary size, and pupillary reactivity. In the comatose patient or in the child with possible neck injury who is uncooperative, lateral gaze may be tested by caloric stimulation of the vestibular apparatus (but not the "doll's eye" maneuver) once tympanic membrane integrity has been established.

Examination of the motor system to evaluate both CNS and spinal cord function varies with age and level of consciousness. The alert patient should have individual muscle groups tested and gait evaluated. The child with a depressed level of consciousness may have motor responses elicited by noxious stimuli (e.g., sternal rub, nail bed pressure). Deep tendon reflexes and Babinski response should also be evaluated. Obviously, a complete physical examination with attention to possible thoracic, abdominal, pelvic, and extremity injuries should be performed.

Radiographic Investigation

Complications of head trauma may be identified with radiographic studies, which include plain radiographs of the skull and cervical spine and CT scan of the head; specific studies are indicated based on the child's history and physical findings. Although MRI is an additional imaging modality for the cranial contents, limited availability and prolonged study time limit its utility for evaluation of acute trauma at this time. All children with significant head trauma should be evaluated for associated cervical spine injuries. This evaluation will be clinical, with or without radiographic studies, based on the specific circumstances (see Chapter 106).

CT provides excellent images of the intracranial contents, and therefore, is the diagnostic modality of choice when intracranial pathology is suspected. CT imaging, however, has disadvantages, including exposure to ionizing radiation and the possible requirement for pharmacologic sedation, especially in younger patients. Ideally, CT imaging should be used selectively for patients at higher risk for ICI, limiting potentially unnecessary studies for those who are at low risk. Identifying clinical predictors for traumatic brain injury that have both high sensitivity and specificity, however, has been a challenging, and thus far, incompletely accomplished task.

Clear risk factors for possible ICI, for which CT imaging should be obtained, include history of penetrating trauma, altered level of consciousness, focal neurologic abnormalities, and signs of skull fracture. Other factors concerning for possible ICI include seizure, persistent vomiting, progressive or severe headache, loss of consciousness (particularly if more than brief or associated with other symptoms), and a predisposing condition for ICIs (e.g., coagulopathy). Mechanisms of injury that are either very significant or high-impact focal force (e.g., golf club to temporal area) are also more concerning for possible complications. Additional indicators for possible ICI in children younger than 2 years include bulging fontanel, irritability/behavioral change, and suspicion of abuse.

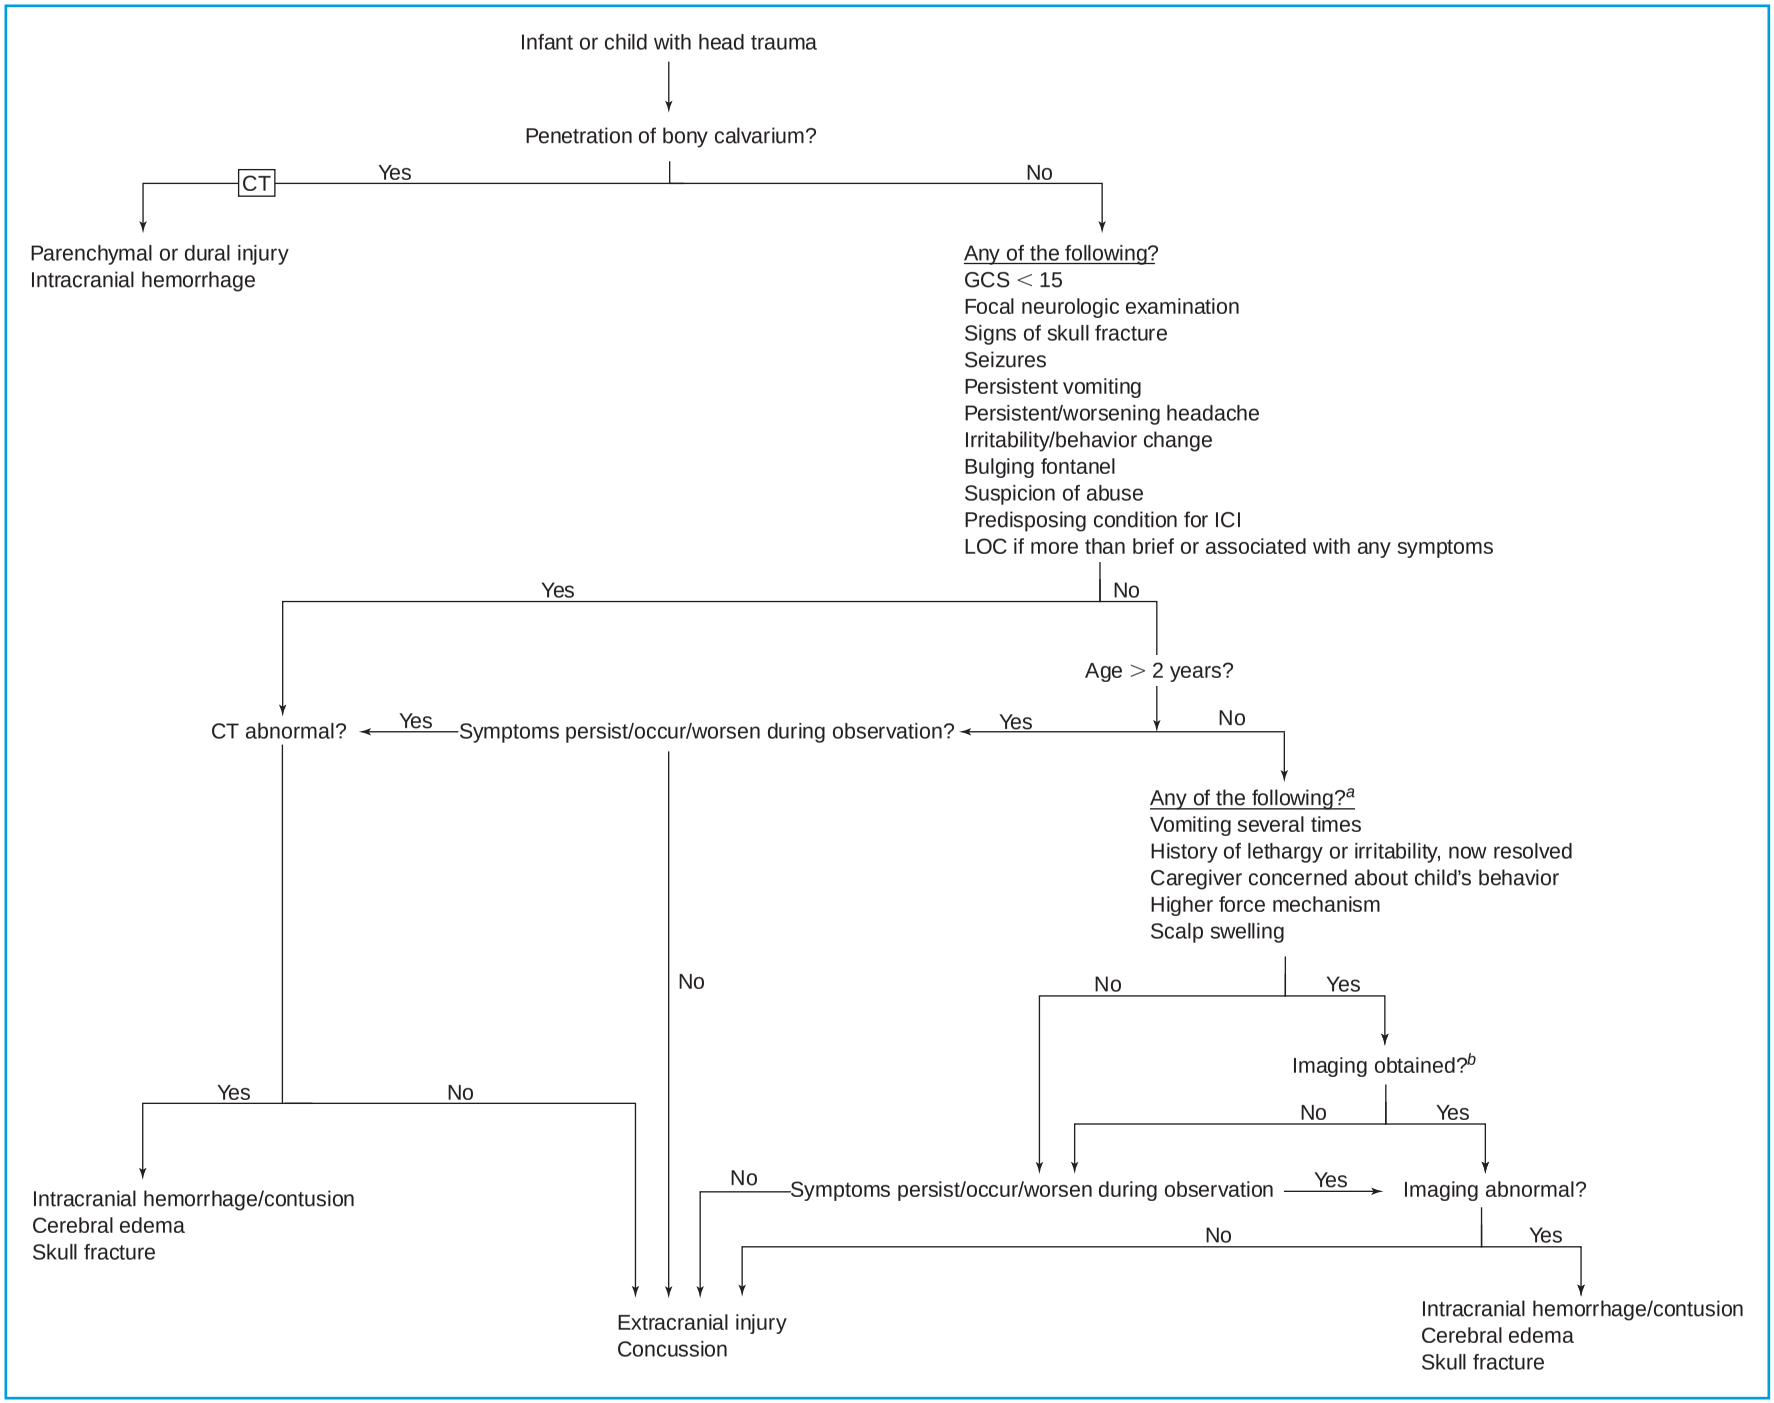
Children younger than 24 months are more challenging to assess because they cannot report symptoms, have a limited behavioral repertoire, are at higher risk for abuse, and are often minimally symptomatic with ICI (up to one-half of infants with ICI have no symptoms of brain injury). Most of those with ICI and no symptoms, however, have an associated skull fracture, which is typically associated with overlying scalp swelling. Swelling more concerning for underlying fracture is that in younger infants, larger in size, and in nonfrontal location. Published guidelines have divided children younger than 2 years into those at high, intermediate, and low risk for ICI (Table 37.3). Those at high risk should have CT imaging, those at low risk require no imaging, and those at intermediate risk should have imaging or observation, based on the clinical scenario, need for sedation, availability of CT or radiographs, and expertise in image interpretation. The younger the age, the more difficult to assess and the higher the incidence of ICIs (and particularly of occult or asymptomatic ICIs); although this is a continuum, the clinician should have a very low threshold for obtaining a CT scan for infants younger than 3 months with trauma, unless trivial, even without symptomatology. In all cases, the patient's condition must be stabilized before transfer to the neuroradiologic suite; the patient should be monitored appropriately and accompanied by a health-care professional with medication and equipment necessary for resuscitation.

TABLE 37.3

RISK FACTORS FOR ICI IN CHILDREN YOUNGER THAN 2 YEARS

High risk
Depressed mental status
Focal neurologic examination
Signs of skull fracture
Seizure
Irritability
Bulging fontanel
Persistent/progressive vomiting
Loss of consciousness >1 min
Suspicion of abuse
Underlying condition predisposing to ICI
Intermediate risk
Few episodes vomiting
Brief LOC
History of lethargy/irritability, now resolved (more concerning if behavioral change was prolonged)
Caretakers concerned about child's current behavior
Nonacute skull fracture
Higher force mechanism/fall onto harder surface
Hematoma, particularly if larger, nonfrontal in location, or in younger child
Unwitnessed trauma with possibility of significant mechanism
Vague or no history of trauma, but child with signs or symptoms of head trauma
Low risk
Low energy mechanism
No signs or symptoms
More than 2 h since injury
Older age more reassuring

ICI, intracranial injury; LOC, loss of consciousness.



Infant or child with head trauma
Penetration of bony calvarium?
CT
Yes
No
Parenchymal or dural injury
Intracranial hemorrhage
Any of the following?
GCS < 15
Focal neurologic examination
Signs of skull fracture
Seizures
Persistent vomiting
Persistent/worsening headache
Irritability/behavior change
Bulging fontanel
Suspicion of abuse
Predisposing condition for ICI
LOC if more than brief or associated with any symptoms
Yes
No
Age > 2 years?
CT abnormal?
Yes
Symptoms persist/occur/worsen during observation?
Yes
No
Any of the following?a
Vomiting several times
History of lethargy or irritability, now resolved
Caregiver concerned about child's behavior
Higher force mechanism
Scalp swelling
No
Yes
Imaging obtained?b
No
Yes
Yes
No
Intracranial hemorrhage/contusion
Cerebral edema
Skull fracture
No
Symptoms persist/occur/worsen during observation
Yes
Imaging abnormal?
No
Yes
Extracranial injury
Concussion
Intracranial hemorrhage/contusion
Cerebral edema
Skull fracture

Over the years, one of the most controversial issues in the management of head trauma has been use of SRs. Since SRs give no direct information about ICI, their use has appropriately dwindled. However, SRs are useful for demonstrating skull fractures (one of the best predictors for ICI in infants and young children) and have the advantages of delivering lower doses of ionizing radiation, being more universally available, less costly, and not requiring sedation. Certainly, any child for whom there is significant concern for ICI should undergo CT imaging; however, there may still be a very small role for SRs in certain select circumstances when immediate CT is not warranted, yet significant chance of fracture exists to justify the test. Data suggest that a substantial number of children younger than 12 to 24 months with ICI are minimally symptomatic, but most of these asymptomatic children have an associated skull fracture. One possible approach to imaging would be to use SRs as a screening tool in infants and young children with scalp findings (but not an obvious fracture) who do not have other features concerning for ICI. Scalp findings more highly associated with fracture in young children include hematomas that are larger in size, nonfrontal in location, and found in younger infants and children. Those with fractures identified on SRs would need to have CT scans performed because they are at increased risk for associated ICI. Other indications for SRs would include a question of depressed fracture or penetrating trauma, possibility of a foreign body, and as part of a skeletal survey. When considering the use of SRs, the clinician should take into account the experience of the physician/radiologist interpreting the radiographs; SRs of young children can be very challenging to interpret, and the utility of the study depends on an accurate reading.

Approach

The goals of management are to define specific anatomic lesions (e.g., skull fracture and ICI) and to prevent secondary brain injury, while limiting unnecessary cranial irradiation. Pediatricians and emergency physicians will be the initial clinicians to evaluate and manage most children with head trauma. Neurosurgical consultation should be considered for all children with penetrating trauma, abnormal mental status or neurologic examination, skull fractures, and intracranial complications. The urgency of neurosurgical involvement varies with the acuity of the patient's clinical condition.

One approach (Fig. 37.1) to diagnosing complications of head trauma involves determining whether a penetrating injury has occurred. If so, brain or vascular injury is likely and emergent CT scanning and neurosurgical consultation are mandated in addition to stabilization.

If the head injury has resulted from blunt trauma, it must be determined whether an ICI is likely. Suggestive historical features and physical findings include a GCS score less than 15, focal neurologic abnormality, signs of a skull fracture, history of seizure, persistent vomiting, persistent/progressive or severe headache, or underlying condition that predisposes to ICI (e.g., coagulopathy). An additional factor may be LOC, especially if longer than momentary or associated with other complaints. In infants, irritability, significant behavior change, bulging fontanel, and suspicion of abuse are also concerning for possible ICI. If any of these findings are present, in addition to supportive therapy, CT scan and possible neurosurgical consultation are indicated. Abnormalities on CT might include intracranial hemorrhage or contusion, diffuse cerebral swelling, or skull fracture; if the CT scan is normal, then concussion or extracranial injury has likely occurred.

If these findings are not present, then the child will be alert with a nonfocal neurologic examination. The drowsy child who quickly became alert, the one with a history of momentary LOC who is alert with a nonfocal examination, the patient with mild headache or one to two episodes of vomiting, may show no evidence of intracranial complications, yet the child may have had more than a trivial head injury. In the event these patients do not undergo a CT scan, they should be observed in the ED for at least 4 to 6 hours after the injury for signs and symptoms of complications. These would include neurologic abnormalities, mental status depression, persistent vomiting, or increasingly severe headache. A CT scan should be obtained if these signs or symptoms develop. As previously stated, discrete abnormalities may be identified on CT scan, but if the scan is normal, then the child has suffered a concussion or extracranial injury.

For children younger than 2 years, presence of vomiting several times, history of lethargy or irritability reported that has since resolved, caregiver's concern about the child's behavior, a higher force mechanism, and presence of a scalp swelling indicate that more than a trivial injury may have occurred and either imaging or observation for symptoms is indicated. The incidence of complications (fracture and/or ICI) is higher with hematomas that are larger, nonfrontal in location, and present in younger patients. CT is the appropriate imaging modality for any child with symptoms. SRs may be an alternative for the asymptomatic infant with isolated scalp swelling. Decision for CT versus SR imaging for the asymptomatic infant with scalp swelling should be based on the clinical scenario, availability for CT/SR, need for sedation, and expertise in image interpretation. If SRs demonstrate a fracture, then CT scan is indicated to evaluate for ICI. If imaging is not performed, then the child should be observed for a period of time in the ED for onset of symptoms. These would include neurologic abnormalities, lethargy/depressed mental status, persistent vomiting, and

FIGURE 37.1 Approach to the child with head trauma. CT, computed tomography; GCS, Glasgow Coma Scale; ICI, intracranial injury; LOC, loss of consciousness. [a]Children in this group who have had more than trivial head trauma and who should have imaging or observation, as appropriate; the decision will be based on the specific clinical scenario. Patients who are younger, those with a history of more intense/prolonged symptoms, and those with swelling that is larger in size or nonfrontal in location are at greater risk for complications. [b]CT is the appropriate modality for symptomatic patients; skull radiographs may be considered as an alternative to CT for asymptomatic patients with hematoma. The decision for CT/skull radiographs should be based on clinical scenario, availability of CT, need for sedation, expertise in imaging interpretation; if skull radiograph demonstrates fracture, CT is indicated to evaluate for ICI.

TABLE 37.4

CRITERIA FOR DISCHARGE WITH HOME OBSERVATION

Traumatic force not life threatening
Glasgow Coma Scale score of 15
Nonfocal neurologic examination
No significant symptoms
No history of prolonged loss of consciousness (or normal CT if it did occur)
No intracranial abnormalities on CT (if obtained)
Reliable caregivers who are able to return, if necessary
No suspicion of abuse or neglect

CT, computed tomography.

irritability. A CT scan should be obtained if signs or symptoms develop. As previously stated, discrete abnormalities may be identified on CT scan, but if imaging is normal, then the child has likely suffered a concussion or extracranial injury.

The remaining children who sustained impact of minimal force, had no LOC, and are alert and asymptomatic with normal examinations likely have only minor head trauma with or without extracranial injuries, including contusions and lacerations. Home observation is appropriate management for the majority of these patients. Rarely, intracranial complications develop in these children, causing symptoms hours after the traumatic event; therefore, the caregiver should be given a printed list of signs and symptoms indicative of increased ICP with instructions to check the child at regular intervals and to return to the ED if symptoms occur. Postconcussive counseling (especially with regard to return to sports), when indicated, should also be given. The caregivers must be reliable and able to return with the child if necessary, and there must be no suspicion of abuse or neglect—otherwise admission for observation in the hospital should be considered (Table 37.4).

CHAPTER 38 ■ INJURY—KNEE

MARC N. BASKIN, MD

Acute pain or injury to the knee is a common complaint in the emergency department (ED). Many injuries are minor and require only limited therapy; others, however, require consultation with an orthopedist, either in the ED or as outpatients after pain and inflammation subside. The emergency physician can provide appropriate therapy or determine the need for consultation, based on a comprehensive history, physical examination, and an appropriate radiographic evaluation.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of acute and chronic knee injuries is summarized in Table 38.1. The pertinent anatomy is illustrated in Figures 38.1 and 38.2.

Acute Injuries

Fractures

Fractures of the distal femoral epiphysis are classified by the Salter-Harris pattern (see Chapter 114) and by the displacement of the epiphysis (usually lateral or medial). The injury usually follows significant trauma (e.g., being struck by a car and the knee hyperextended or being hit during contact sports from the lateral side with the foot fixed by cleats). The patient has severe pain, refuses to bear weight, and has extensive soft-tissue swelling and possibly deformity. Distal neurovascular status should be assessed because compromise of the popliteal artery occurs in 1% of cases and peroneal nerve injury occurs in 3% of cases. Radiographs are usually diagnostic but may be normal if the injury is a nondisplaced Salter-Harris type I fracture. Stress views should be considered in this situation if the physis is tender or a large effusion is present.

Fractures of the proximal tibial epiphysis are rarer than those of the distal femoral epiphysis but are more likely to involve vascular compromise because of the proximity of the popliteal artery to the posterior aspect of the tibial epiphysis. The patient has severe pain, limited range of motion (ROM), and commonly, a hemarthrosis. If displaced, the knee will be deformed. Distal neurovascular status should be assessed. Usually, radiographs are diagnostic but may be normal if the injury is a nondisplaced Salter-Harris type I fracture. Lateral and anteroposterior (AP) stress views may be necessary.

Acute traumatic avulsion of the tibial tuberosity is caused by acute stress on the knee's extensor mechanism. The quadriceps muscle group extends the knee by way of the patellar ligament. The patellar ligament inserts on the tibial tuberosity and may avulse it during sudden acceleration (e.g., beginning a jump) or deceleration (e.g., landing after a jump). The patient will have tenderness and swelling over the tibial tubercle and is unable to extend the knee fully. The patella may be displaced superiorly. A lateral radiograph is diagnostic.

Fractures of the patella are rare in children younger than 6 years because the child's patella is surrounded by cartilage, protecting it from direct trauma. Avulsion fractures can occur. A medial avulsion fracture suggests that the mechanism was a patellar dislocation that spontaneously reduced. The patient's knee will be swollen, the patella tender. A radiograph is diagnostic although a bipartite patella may be confused with an acute fracture. The curved radiolucent line associated with a bipartite patella is usually in the superior lateral quadrant, a rare area for a fracture, and should not be associated with the soft-tissue swelling and effusion seen with a fracture.

Osteochondral fractures are fractures of articular cartilage and underlying bone not associated with ligamentous attachments. These fractures often involve the femoral condyles or the patella. Occasionally, a patient sustains a direct blow to the knee, but, more commonly, the knee is injured during a twisting injury or the patella is dislocated. The patient has severe pain, has immediate swelling, and holds the knee partially flexed. Knee radiographs need to include an intercondylar view because the fragment may be in the intercondylar notch. Osteochondral fractures can be missed because only the small ossified portion of the osteochondral fragment is radiopaque. Magnetic resonance imaging may be necessary.

Analogous to an adolescent who ruptures the anterior cruciate ligament (ACL), patients 6 to 16 years old may sustain avulsion fractures of the tibial spine at the point where the ACL inserts. The tibial spine is incompletely ossified and may avulse before the ligament ruptures. The patient may have a hemarthrosis and will be unable to bear weight. If the patient tolerates an examination, the Lachman test (Fig. 38.3) may be positive because the injury is similar mechanically to an ACL tear. AP, lateral, and intercondylar or tunnel-view radiographs will show the avulsed fragment. The visible ossified fragment may be small because the tibial spine is mostly radiolucent cartilage.

Dislocations

In a child, the knee joint itself rarely dislocates; usually, the distal femoral or proximal tibial epiphysis separates first. Dislocation occurs more frequently when the growth plates have closed and usually with trauma that involves significant force, such as a motor vehicle crash or contact sports. The knee appears obviously deformed with the tibia or femoral condyles abnormally prominent in an anterior or posterior dislocation, respectively. Disruption of the popliteal artery may occur with the dislocation, and the resulting hypoperfusion may be limb threatening. Posterior tibial and dorsalis pedis

TABLE 38.1

DIFFERENTIAL DIAGNOSIS OF THE INJURED KNEE

Acute injuries
- Fractures
  - Distal femoral epiphysis[a]
  - Proximal tibial epiphysis[a]
  - Tibial tubercle avulsion
  - Patella
  - Tibial spine avulsion
  - Osteochondral fractures
- Soft-tissue injuries
  - Collateral ligament sprain or rupture
  - Anterior cruciate ligament sprain or rupture
  - Posterior cruciate ligament sprain or rupture
  - Meniscal tears
  - Quadriceps tendon rupture
  - Patellar tendon rupture
  - Hamstring strain[b]
- Posttraumatic infections
  - Septic arthritis[a]
  - Osteomyelitis[a]
  - Cellulitis
  - Septic prepatellar bursitis
- Dislocations and subluxations
  - Patellar[b]
  - Knee joint[a]

Subacute injuries
- Osgood-Schlatter's disease[b]
- Patellofemoral pain syndrome[b]
- Patellar tendon tendinitis (jumper's knee)
- Prepatellar bursitis
- Osteochondritis dissecans
- Baker's cyst
- Iliotibial band friction syndrome

Other
- Pathologic fractures[a]
- Hip disease
  - Slipped capital femoral epiphysis
  - Aseptic necrosis of the femoral head

[a]Life- or limb-threatening causes of the injured knee.
[b]Common causes of the injured knee.

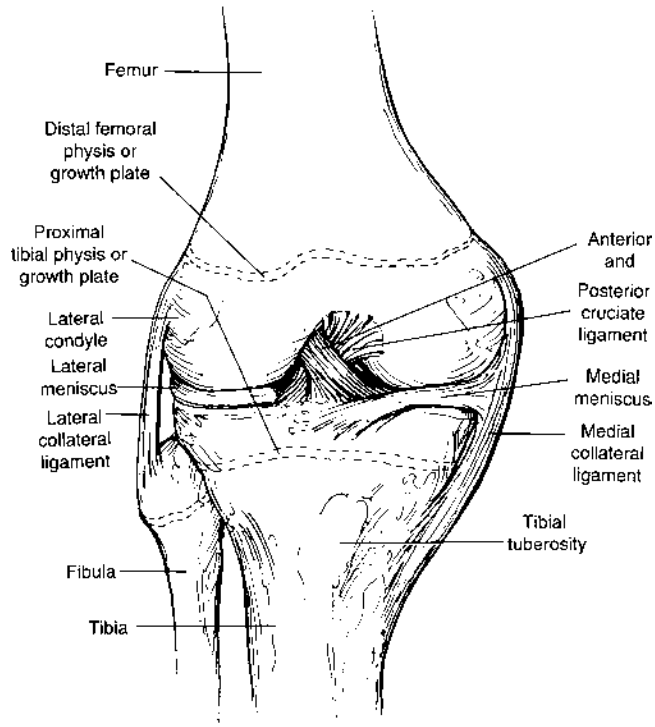

FIGURE 38.1 Anatomy of the knee—anterior view (patella removed).

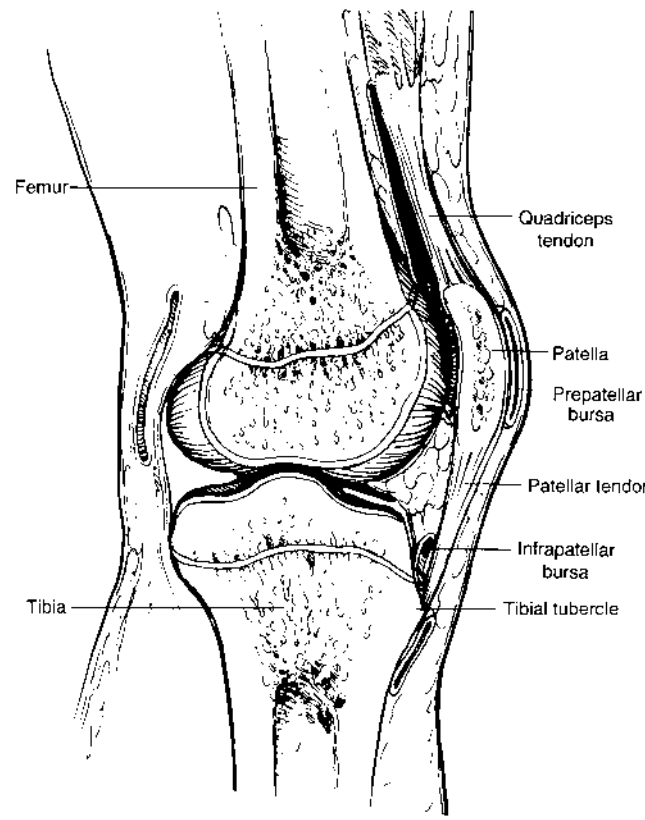

FIGURE 38.2 Anatomy of the knee—sagittal section.

pulses and peroneal nerve function (sensation between the great and second toe and ankle dorsiflexion) must be documented. Radiographs will confirm the diagnosis.

Patellar dislocation occurs as the quadriceps muscles pull along the patellar tendon to extend the knee. If the vastus medialis fibers do not keep the patella in the intercondylar groove, the patella may dislocate laterally. This often recurrent injury rarely occurs from direct force but happens more often during dancing or gymnastics. The patient may feel a ripping or popping sensation. The patient complains of intense pain and holds the knee flexed. The patella is displaced laterally, and the diagnosis is usually made based on history and examination. The dislocation may be reduced before radiographs are taken. Radiographs should be obtained to rule out an associated avulsion fracture of the patella.

If the history is consistent with dislocation but the patient is no longer in pain and has a normal examination results, he or

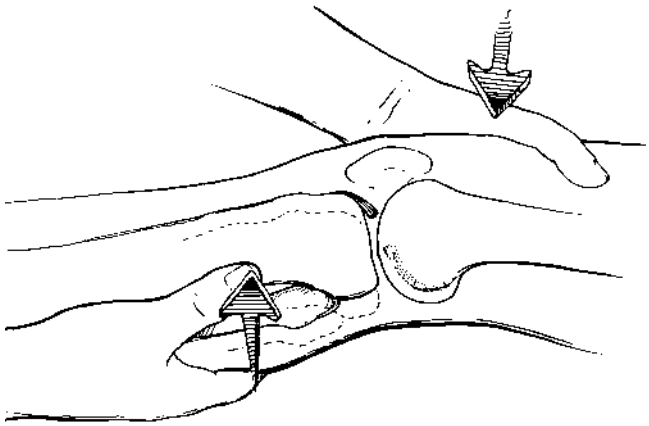

FIGURE 38.3 Testing for anterior cruciate ligament injury with the Lachman test. Flex the knee 20 to 30 degrees, support the thigh with one hand, and grasp the calf with the other hand. Move the tibia forward on the femur. Observe the tibial tubercle for movement and feel for excessive forward movement of the tibia in relation to the femur.

she may have subluxated the patella. A high-riding or laterally displaced patella may be observed. The quadriceps or Q angle formed by a line drawn from the anterior-superior iliac spine to the midpatella and one drawn from the midpatella to the tibial tubercle can be measured. When the angle is above 20 degrees, the extensor mechanism may sublux the patella laterally. The patellar apprehension test is performed by gently attempting to move the patella laterally. If the patient becomes apprehensive or grabs the examiner's hand, this suggests that he or she has subluxated the patella. Radiographs should be obtained to look for an associated osteochondral fracture.

Soft-Tissue Injuries

Medial collateral ligament (MCL) or lateral collateral ligament (LCL) injuries are rare when the epiphysis is open because the involved ligaments are stronger than the growth plate. The LCL inserts on the fibular head proximal to the physis, and the MCL inserts on the tibia distal to the physis. In older patients, the MCL may be damaged by a blow to the lateral side of the knee during contact sports or stress during a skiing accident, when the athlete "catches an edge" and falls forward with the leg rotated externally. Severe collateral ligament injury may be associated with ACL or meniscal damage. On examination, the knee may be swollen only minimally but will be tender over the involved ligament. The knee should then be tested for lateral laxity in full extension (associated with more severe injuries) and in 30 degrees of flexion (associated with less severe injuries), as shown in Figure 38.4. Orthopedic referral may be indicated if the examination reveals lateral or medial laxity.

ACL injuries occur in many scenarios, but usually involve rotational forces on a fixed foot. The patient often reports the sensation of a "pop." The joint usually swells rapidly as a result of hemarthrosis and has a marked decrease in ROM. The Lachman test (Fig. 38.3) is sensitive (0.7 to 0.9) in detecting ACL injuries but may be falsely negative soon after the injury, when the knee is swollen and painful. Examining the uninjured knee can be helpful for comparison. Arthroscopy or magnetic resonance imaging is often needed for definitive diagnosis. ACL

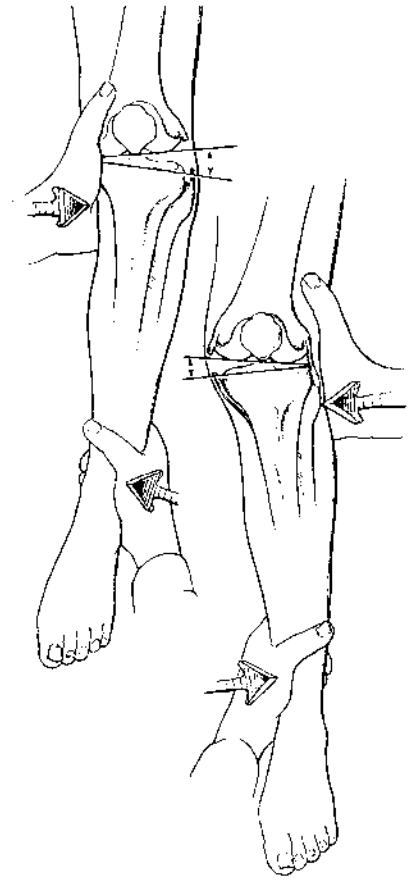

FIGURE 38.4 Testing for collateral ligament injury. Test the knee in full extension and in 30 degrees of flexion. To test for medial collateral ligament injury, hold and apply force to the medial side of the ankle with one hand and apply pressure over the fibular head with the other hand. To test for lateral collateral ligament injury, hold and apply force to the lateral side of the ankle with one hand and apply pressure just below the medial side of the knee with the other hand. If the knee "opens up" laterally or medially more than the uninjured knee, the collateral ligament is injured.

injuries are rare before adolescence because in a child, the ACL's insertion point, the tibial spine, is incompletely ossified. Therefore, the same force that would produce an ACL injury in an adolescent will cause an avulsion fracture of the tibial spine in a child. Radiographs may detect an epiphyseal fracture, tibial spine fracture, or an avulsed bone fragment due to an MCL or LCL injury.

Posterior cruciate ligament injuries are extremely rare and usually result from direct force on the tibial tubercle, pushing the tibia posteriorly on the femur. The posterior drawer sign will be present in most cases (Fig. 38.5).

The menisci are tough fibrocartilage pads that help distribute the body's weight over the femoral and tibial condyles. They can be injured when the knee is twisted during weight bearing. The patient, usually older than 12 years, may report a popping sensation and the feeling of the knee "giving out." More chronically, the patient may report that the knee suddenly refuses to extend fully, "locking up," and then suddenly "unlocking." Joint-line tenderness is frequently present (sensitivity 0.7 to 0.8, specificity 0.2) but must be differentiated from the tenderness associated with collateral ligament injuries. An

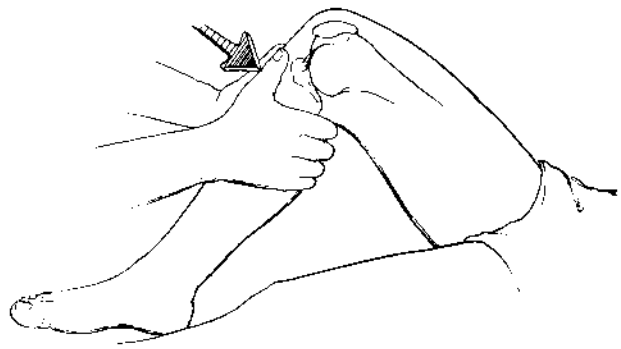

FIGURE 38.5 Testing for posterior cruciate ligament injury with the posterior drawer test. With the patient supine and the knee flexed to 90 degrees, sit on the patient's foot to stabilize it. Attempt to force the tibia posteriorly. Posterior movement greater on the injured side than on the uninjured side is abnormal and suggests a posterior cruciate ligament injury.

effusion is commonly detected. Acutely, the injury may be difficult to diagnose because the patient has significantly reduced ROM, making the classic McMurray's sign difficult to elicit (Fig. 38.6). The Apley compression test (Fig. 38.7) requires less knee movement and may be easier for the patient to tolerate.

FIGURE 38.7 Testing for meniscal injury with the Apley compression test. With the patient prone and the knee flexed to 90 degrees, apply pressure to the heel while the tibia is rotated. If this produces pain that resolves when the tibia is distracted from the femur while rotated, a meniscal injury should be suspected.

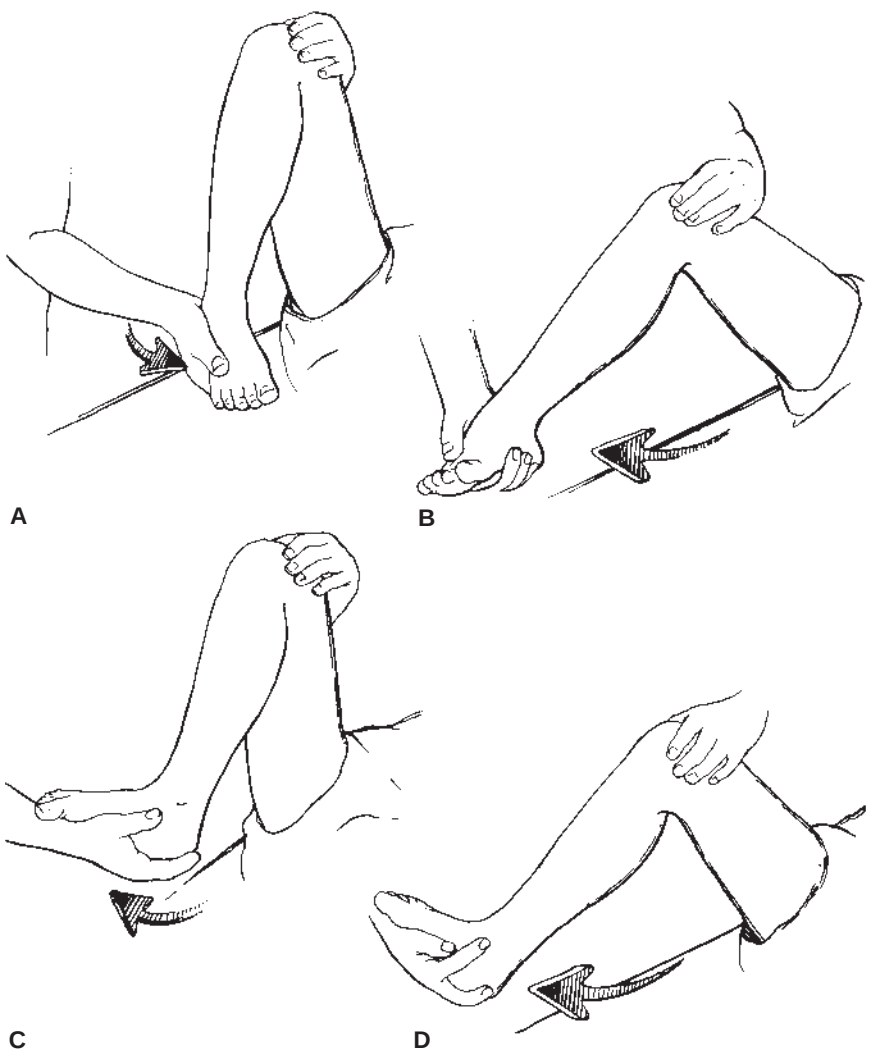

FIGURE 38.6 A–D: Testing for meniscal injury with the McMurray test. Grasp the patient's foot with one hand and place the other hand over the joint lines, push on the lateral side to apply a valgus force. Fully flex and extend the knee while alternately internally and externally rotating the tibia. The injured meniscus may be felt as a click or snapping sensation as the knee is manipulated.

Radiographs are generally obtained to evaluate for other causes of the pain. A subluxating patella, ACL injury, or osteochondral fracture may also cause a popping sensation, and the patellofemoral pain syndrome (PFPS) may be associated with "giving way" of the knee.

The quadriceps or patellar tendon can rupture acutely, especially in an older athlete who jumps or falls a great distance. The patient will not be able to actively extend the knee, the area over the rupture may be tender, and the patella may be positioned abnormally. A hemarthrosis may be present, and radiographs may show the abnormally positioned patella.

The three hamstring muscles (semitendinosus, semimembranosus, and biceps femoris) flex the knee and may be strained in young athletes. The semitendinosus and semimembranosus run along the medial popliteal space, and the biceps femoris tendon runs laterally. The patient may describe an acute pain or even a pop in the back of the thigh or may present subacutely with posterior thigh and popliteal knee pain when the hamstrings are strained by repetitive use. Palpation of the tendons is painful.

Posttraumatic Infection

Although not considered injuries, acute infections may present after a vague history of trauma. Physical findings of acute infection are present. The most common disorders are septic arthritis, osteomyelitis, cellulitis, and septic prepatellar bursitis.

Subacute Injuries

Many subacute knee problems manifest acutely in the ED. Osgood-Schlatter's disease of the tibial tubercle may lead to similar symptoms as a traumatic avulsion of the tubercle; however, with Osgood-Schlatter's disease, the symptoms have been noted for days or weeks. The symptoms of Osgood-Schlatter's disease are exacerbated by squatting or jumping, but they do not cause the same disability as an acute avulsion. The disease is usually seen in patients between 11 and 15 years of age. It may be caused by recurrent contractions of the patellar tendon during knee extension, traumatizing the tendon's insertion on the tibial tubercle during the child's growth spurt. The patients have localized tenderness and occasional swelling over the tibial tubercle. The patient will refuse to extend the knee against force (e.g., perform a deep-knee bend) and have difficulty going up or down stairs, although they may have a normal gait on a level surface. To eliminate the possibility of a neoplasm, the physician should always obtain radiographs. In Osgood-Schlatter's disease, the radiographs will either be normal or show irregularity of the tubercle.

PFPS or chondromalacia patella may be caused by misalignment of the extensor mechanism of the knee. The patella transmits the force of the quadriceps muscles to the patellar tendon to extend the knee. The vastus lateralis, vastus intermedius, and rectus femoris pull the patella slightly laterally and need to be balanced perfectly by the vastus medialis to keep the patella tracking across the articular cartilage correctly. Some of these patients have chondromalacia patella, with softening of the cartilage. The patient with PFPS has patellar pain with running and especially while going down inclines or stairs. The patient may also have the sensation of the knee giving out when descending, although an actual fall does not usually occur. The patient may describe pain when sitting for a prolonged time with the knee flexed at 90 degrees (e.g., in class). The pain disappears once the patient is ambulatory. On examination, the patient may have the medially displaced patella, an increased Q angle, tenderness of the articular surface of the patella, and a positive patellar stress test. This test is performed with the patient in the supine position with the knee fully extended. The patient is asked to relax the quadriceps so that the physician can move the patella. With the patella pulled inferiorly, the physician should gently press down on it and ask the patient to tighten the quadriceps. (A younger patient should be asked to "push the knee into the examination table.") This will move the patella superiorly as the physician continues to press down. A patient with PFPS will have acute pain with this maneuver. Radiographs are normal.

Patellar tendon tendinitis, or "jumper's knee," occurs in patients during their growth spurt, especially those involved in jumping (knee extension) sports. The knee is tender on the inferior pole of the patella and the adjacent patellar tendon, but not on the tibial tubercle; radiographs are generally normal.

Prepatellar bursitis occurs after acute or chronic trauma to this bursa, which overlies the patella. The patient will have swelling over the anterior aspect of the knee, especially over the patella. A septic bursitis may need to be ruled out by needle aspiration.

Osteochondritis dissecans is the separation of a small portion of the femoral condyle with the overlying cartilage. The patient is usually an adolescent with a 1- to 4-week history of nonspecific knee pain. The physical examination may be normal, or the femoral condyle may be tender with the knee flexed. Because AP and lateral radiographs may not show the lesion, a tunnel or intercondylar view should be obtained.

Iliotibial band syndrome usually occurs in older runners who complain of pain over the lateral femoral condyle. The iliotibial band moves in an anterior or posterior direction across the lateral femoral condyle as the knee flexes and extends. This repetitive movement may cause the pain. When examined, the patient is tender over the lateral femoral epicondyle, palpable 2 cm above the joint line. Radiographs are normal.

The Baker's cyst is a herniation of the synovium of the knee joint or a separate synovial cyst located in the popliteal fossa. The patient complains of popliteal pain and swelling only if the cyst enlarges. The sac can be palpated in the posterior medial aspect of the popliteal space and may be transilluminated. For the most part, radiographs will be normal or show soft-tissue swelling.

In any patient with knee pain, with or without a history of trauma and benign (e.g., osteochondroma and nonossifying fibroma) and malignant tumors (e.g., osteosarcoma or Ewing's sarcoma), the various causes of monoarticular arthritis (see Chapter 56) and hip disease that may present with knee pain (e.g., slipped capital femoral epiphysis or aseptic necrosis of the femoral head) must be considered.

EVALUATION AND DECISION

Four points are critical in the patient's history: (i) the activity and forces that led to the injury (e.g., direction of the force, whether the foot was fixed); (ii) the initial location of the pain; (iii) any

sensations or noises (e.g., "locking," "pops," or "tears"); and (iv) the timing of any swelling.

The possibility of abuse in young children must always be considered, especially if the injury is unexplained, the history is implausible, or the delay in seeking of medical care was unreasonable.

Most severe injuries (e.g., ACL, collateral ligament, or meniscal injuries) occur when the patient is involved in high-velocity weight-bearing activities, especially running and making sharp cuts or being subjected to direct valgus or varus stress.

Lower-velocity injuries usually result in only patellar dislocation or subluxation. Direct trauma to the front of the knee may cause posterior cruciate ligament injuries or patellar fractures, whereas lateral to medial (valgus) forces may cause collateral or cruciate ligament damage or fractures. Distinct popping noises or tearing sensations are reported in ACL injuries and patellar subluxation. Locking of the knee often may be reported in meniscal injuries but not immediately after the injury. Although the knee may "hurt all over" when seen in the ED, the patient may be able to localize the initial pain. Meniscal or collateral ligament injuries cause pain on the lateral or medial aspect of the knee, whereas ACL injuries hurt just inferior to the patella, and Osgood-Schlatter's disease is painful a few centimeters inferior to the patella over the tibial tubercle. Swelling within 2 hours strongly suggests hemarthrosis and an associated ACL injury, meniscal injury, or osteochondral fracture. Swelling after 4 to 12 hours is more likely to be an isolated effusion without an associated fracture or ligamentous injury.

In subacute injuries, ask about hip or groin pain because the hip and knee share sensory nerves. Legg-Calve-Perthes disease or a slipped capital femoral epiphysis may cause anterior thigh or knee pain. Inquire about changes in physical activities or footwear. Patellar pain and the sensation of the knee giving way without actually falling when going down stairs or inclines suggest PFPS (i.e., chondromalacia patella). Exacerbation doing deep-knee bends suggests Osgood-Schlatter's disease or patellar tendonitis.

Examination of the patient should include walking and standing to check for medially deviated "squinting" patellae. Inspect and palpate the knee in two positions, sitting relaxed with the knees at 90 degrees and supine. When sitting, the knees are inspected for swelling, bony changes (e.g., swelling and tenderness over the tibial tubercle in Osgood-Schlatter's disease), joint-line tenderness (meniscal injuries), and quadriceps atrophy.

With the patient supine, repeat inspection and palpation over the joint line, collateral ligaments, patella, proximal fibula, tibial tuberosity, and popliteal space. If the knee appears swollen, check for an effusion. Normally, synovial fluid coats the patellar surface but does not separate the patella and femur. When fluid separates the two bones, a sharp pat on the patella results in the sensation of a tap as the two bones meet. If the joint contains a large amount of fluid, the patella will not touch the femur but will feel as if it is sitting on a cushion. Document the ROM of the knee.

The physician should test for collateral and cruciate ligament damage, meniscal injuries, patellar subluxation, and PFPS, using the appropriate maneuvers (Table 38.2).

Distal pulses, the posterior tibial, and the dorsalis pedis should be palpated, and the peroneal nerve function should be assessed. The deep peroneal nerve enervates the ankle dorsiflexors. The extensor hallucis longus can be tested by opposing dorsiflexion of the great toe. The deep peroneal nerve supplies sensation to the web space between the great and second toes.

TABLE 38.2

SUMMARY OF DIAGNOSTIC MANEUVERS FOR THE INJURED KNEE

Maneuver	Diagnosis
Collateral laxity test (Fig. 38.4)	Collateral ligament injury
Lachman test (Fig. 38.3)	Anterior cruciate ligament injury
Posterior drawer test (Fig. 38.5)	Posterior cruciate ligament injury
McMurray test (Fig. 38.6)	Meniscal injury
Apley compression test (Fig. 38.7)	Meniscal injury
Patellar apprehension test	Patellar subluxation
Patellar stress test	Patellofemoral pain syndrome

Patients with knee symptoms should have a careful hip examination because patients with aseptic necrosis of the femoral head or a slipped capital femoral epiphysis may present with anterior thigh or knee pain.

All patients with acute knee injuries should have AP and lateral radiographs, and if indicated, a patellar (or skyline view) radiograph should be taken. If the injury is more chronic, an intercondylar or tunnel view should also be taken to evaluate for osteochondritis dissecans.

The Ottawa Knee Rules have demonstrated 100% sensitivity for knee fractures in large, prospective, multicentered adult trials. Studies in children are more limited but they also demonstrated a sensitivity of 100% (95% confidence interval = 95% to 100%) in a study involving 750 children of whom 70 had fractures. According to the OKR, radiographs are required of children only if the patient has any of the following finding: (i) isolated tenderness of the patella, (ii) tenderness of the head of the fibula, (iii) inability to flex to 90 degrees, (iv) inability to bear weight both immediately and in the ED (4 steps) regardless of limping.

Figure 38.8 summarizes an approach to the child with an acutely injured knee. If the initial evaluation suggests vascular compromise, traction and reduction of the knee should be attempted and an emergency orthopedics consultation should be obtained. If the patella is obviously dislocated, it may be reduced before obtaining radiographs. Postreduction radiographs and a careful examination for physeal tenderness then can exclude the diagnosis of a fracture. If the patient's knee is too painful or swollen to allow a complete examination, or if the patient has a hemarthrosis, ligament or meniscal damage should be suspected. The patient should be instructed to use cruches and remain completely non–weight bearing until medical or surgical follow-up or until the patient improves.

If the patient tolerates an examination, a series of maneuvers may suggest collateral ligament injury, cruciate ligament

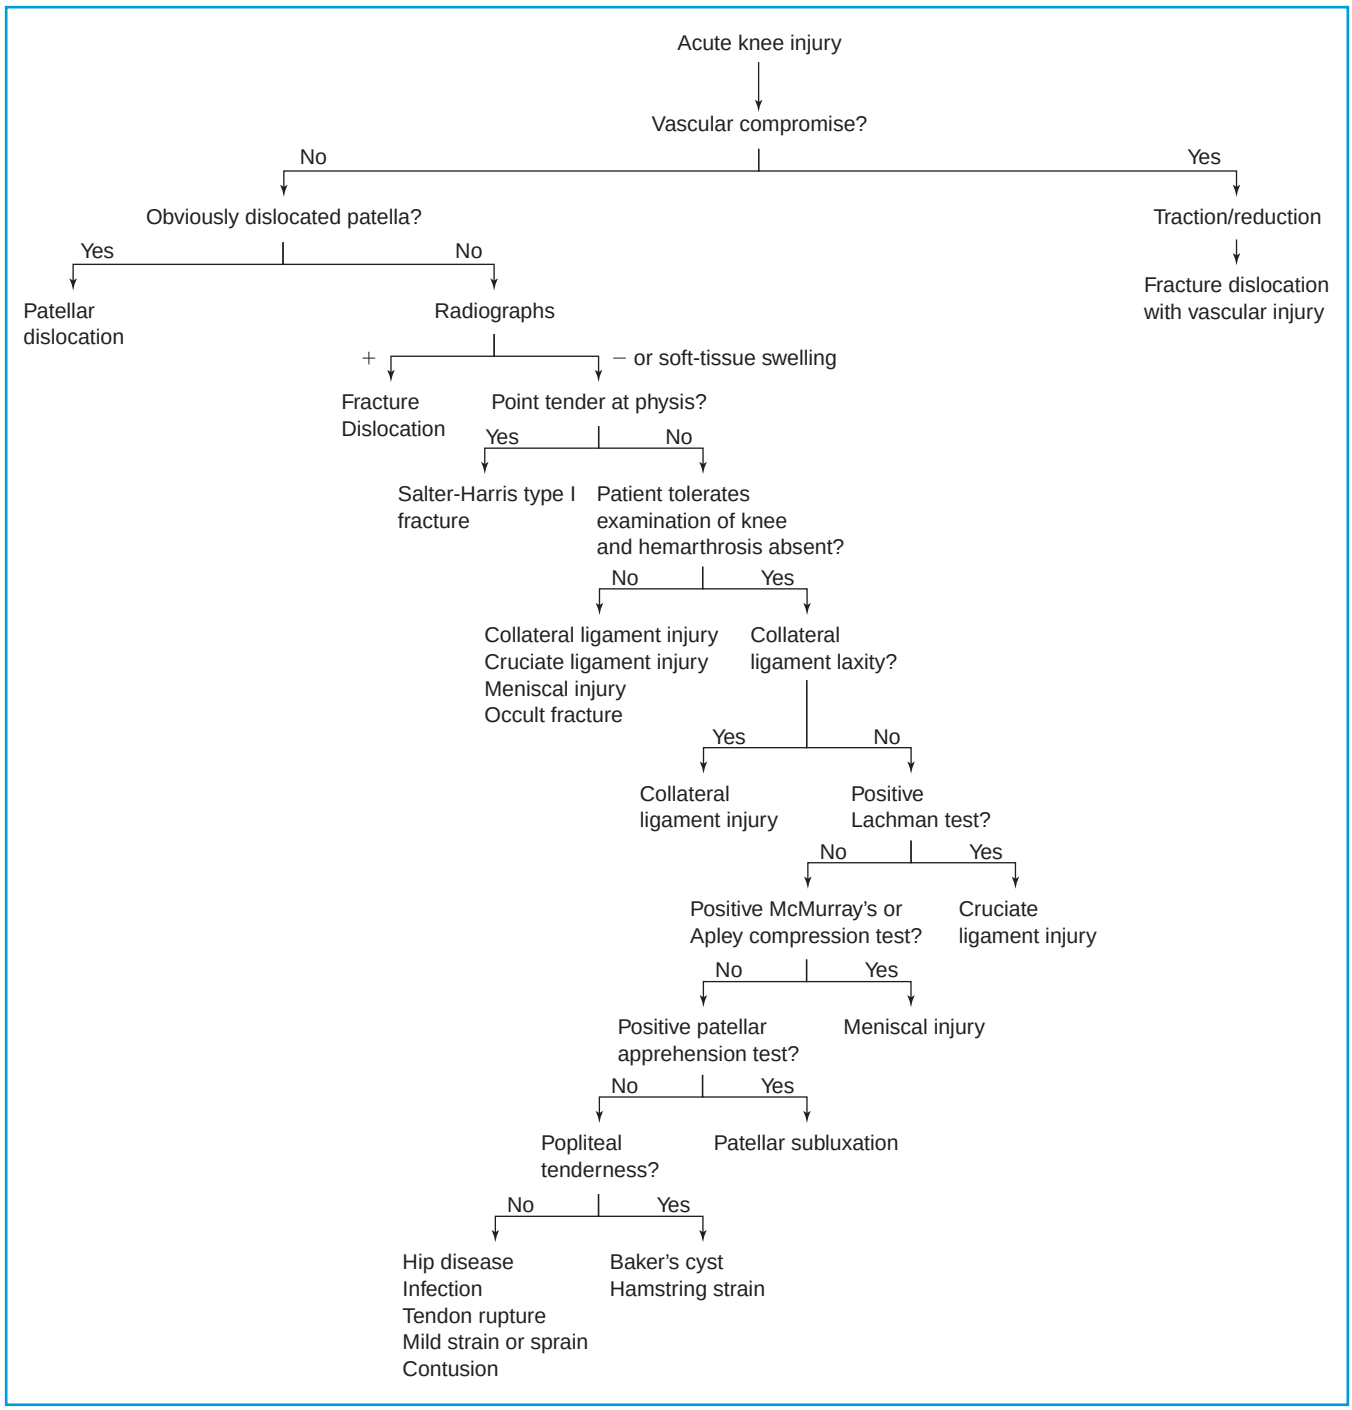

FIGURE 38.8 Approach to the patient with an acute knee injury.

injury, meniscal injury, or patellar subluxation as the diagnosis. (Table 38.2 summarizes the diagnostic maneuvers for the knee.) Next, an assessment for popliteal tenderness, to exclude a Baker's cyst or hamstring strain, is performed. Finally, if no signs of infection or hip disease exist, the patient may have a tendon rupture, mild ligament sprain, or bone contusion.

Often, a patient may come to the ED with a history of trauma and knee pain that has been present for more than 1 or 2 days (Fig. 38.9). In addition to the standard AP, lateral, and patellar views, a tunnel or intercondylar view should be taken to exclude a fracture, tumor, and osteochondritis dissecans. If the initial knee and hip examinations do not suggest a diagnosis and no signs of infection exist, the diagnostic maneuvers in Table 38.2 should be completed. The patient may have an old collateral ligament, cruciate ligament, or meniscal injury and may require an orthopedic referral.

CHAPTER 39 ■ INJURY—SHOULDER

MARC N. BASKIN, MD

This chapter focuses on the diagnosis of the child with an acutely injured shoulder. For the preverbal child with a possible shoulder injury presenting with an immobile arm, see Chapter 35. Children have different etiologies for their shoulder injuries than do adults because of their open growth plates, and young patients may be more difficult to examine because of anxiety and limited verbal skills. Figure 39.1 shows the important bony anatomy.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis depends primarily on exactly where the patient has pain and the type of trauma. In this chapter, injuries are described anatomically, from the sternoclavicular joint to the humeral shaft (Tables 39.1 and 39.2).

Physeal (growth plate) fractures of the medial clavicle can be caused by direct trauma to the medial clavicle or by indirect trauma that forces the shoulder medially and separates the growth plate. This injury mimics the sternoclavicular dislocations seen in skeletally mature patients. In patients younger than 22 to 25 years, injury to the sternoclavicular joint causes physeal fractures because the epiphysis of the medial clavicle begins to ossify between 13 and 19 years of age and fuses between 22 and 25 years of age. Once fused, a similar injury will cause sternoclavicular joint dislocations. Most separations are anterior, and the patient has swelling and tenderness over the sternoclavicular joint. Anteroposterior (AP) and superiorly projected lordotic radiographs comparing both clavicles may not visualize the lesion. Computed tomography (CT) is usually necessary to delineate the lesion. If the dislocation is posterior, the aorta or trachea may be injured. The child may remain asymptomatic or may complain of dysphagia or difficulty breathing. If the growth plate and ligaments are not disrupted by the injury, a simple sprain has occurred.

The clavicle is a commonly fractured bone in children, most often in the middle or lateral third of the bone. The clavicle is subject to any medially directed force on the upper limb (e.g., a fall on an outstretched hand) but is commonly fractured by a direct blow. Although subclavian vessels and the brachial plexus are just beneath the clavicle, they are rarely injured because the subclavius muscle is interposed between the bone and vessels, and the thick periosteum of the clavicle rarely splinters. A neonate's birthing injury or an infant's greenstick fracture of the clavicle may go unnoticed until the focal swelling of the developing callus is noted. In the older child, the arm droops down and forward and the head may be tilted toward the affected side because of sternocleidomastoid muscle spasm. Localized swelling, tenderness, and crepitations may be noted. A radiograph will confirm the diagnosis. Rarely, a radiograph obtained because of clavicular trauma will show a congenital pseudarthrosis or false joint of the clavicle.

Osteolysis of the distal clavicle with resorption of the bone may develop after minor injuries to the clavicle. Patients experience chronic pain and mild swelling 2 to 3 weeks after the initial injury. Radiographs are diagnostic.

Acromioclavicular (AC) joint injuries usually cause physeal fractures of the distal clavicle in patients younger than 14 years. Older children may sprain the AC joint (shoulder separations). Either injury is most often caused by a direct blow to the shoulder. The child will have pain with any motion of the shoulder and tenderness over the AC joint. Grade I and II injuries are nondisplaced. Grade III and IV injuries are displaced 25% to 100%, and Grade V injuries are more than 100% displaced. Bilateral "stress view" radiographs of the AC joint may be obtained to compare the separation on the normal and affected sides. Cosmetic deformities and degenerative changes of the distal clavicle may complicate these injuries, even with appropriate therapy.

Scapula fractures are rare in pediatrics and usually occur only after major direct trauma, such as a motor vehicle accident or a fall from a height. The child will have tenderness over the scapula. The patient often sustains other more life-threatening injuries (e.g., head injuries, rib fractures, or pneumothoraces).

Shoulder or glenohumeral joint dislocations are rare in children younger than 12 years. These injuries become common in adolescence as the skeleton matures. The glenohumeral joint is shallow, allowing a wide range of motion but increasing the risk of dislocation. The patient is injured when an already abducted and externally rotated arm is forcibly extended posteriorly (e.g., blocking in football or missing a slam dunk and striking the rim during basketball). This action leverages the humeral head out of the glenoid fossa. The trauma can damage the axillary nerve or fracture the humeral head. More than 95% of all dislocations are anterior, and less than 5% are posterior. The patient will be in severe pain, supporting the affected arm internally rotated and slightly abducted (i.e., the patient cannot bring the elbow to his or her side). The shoulder contour is sharp, unlike the smooth contour of the opposite shoulder, and the acromion is prominent (Fig. 39.2). Sensation over the lateral deltoid muscle (axillary nerve distribution), lateral proximal forearm (musculocutaneous nerve distribution), and distal pulses should be documented. Radiographs should always be obtained because a humeral head or even a clavicular fracture may mimic a shoulder dislocation. An AP, transcapular lateral (Neer's), and an axillary view will show the position of the dislocation and the presence of any fractures.

If the patient has a history consistent with dislocation but has more range of motion than expected and the radiograph is

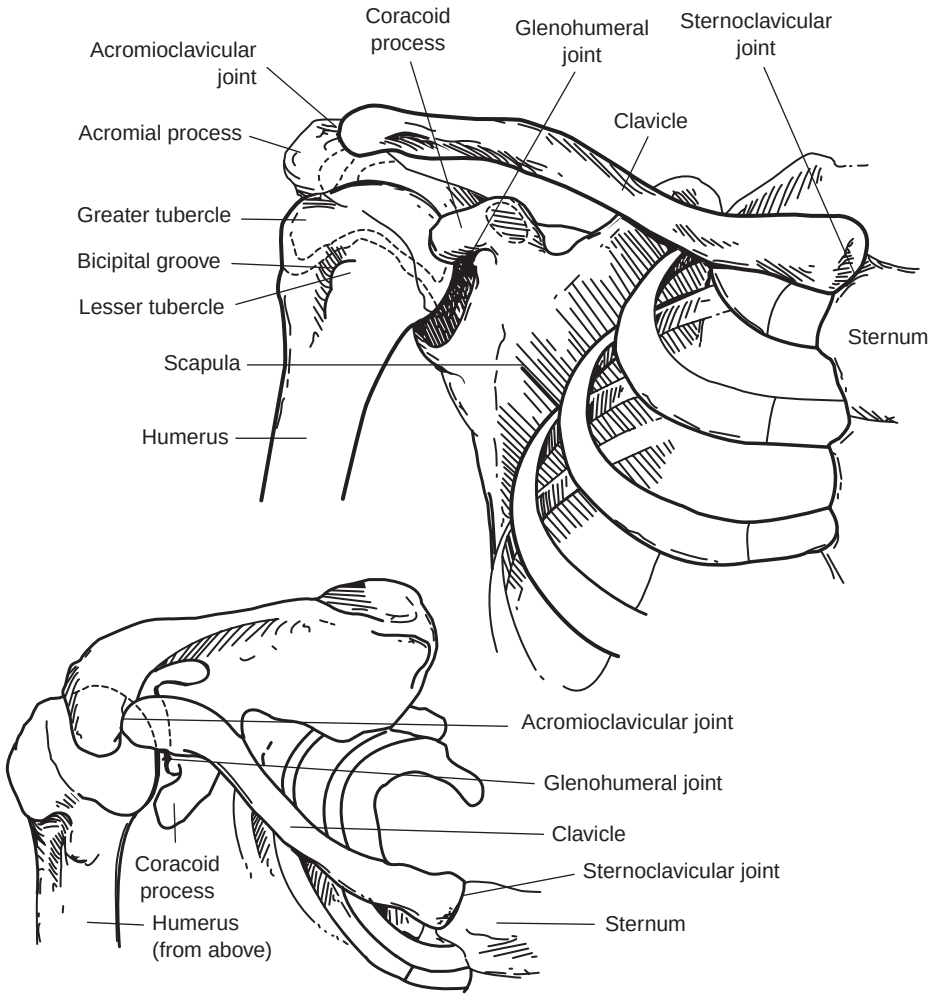

FIGURE 39.1 Anatomy of the shoulder.

FIGURE 39.2 An older adolescent patient with left anterior glenohumeral joint dislocation. Notice the sharp contour of the shoulder, the fullness below the glenoid fossa, and the prominent acromion.

normal, the patient may have spontaneously reduced a dislocated shoulder or subluxated the glenohumeral joint and only sprained the ligaments overlying the glenoid fossa. An apprehension test may confirm the diagnosis (Fig. 39.3).

Actual tears of the rotator cuff are uncommon before 21 years of age. However, if the rotator cuff muscles are damaged or weak, the humeral head is displaced upward during overhead motion and may impinge the tendon of the supraspinatus muscle as it runs below the acromion. Impingement symptoms usually occur with repetitive overhead motions (e.g., throwing a ball). The pain is poorly localized or most notable over the deltoid area. Pain with passive full forward flexion may be suggestive. The Hawkins' test (Fig. 39.4) and Yocum's test may elicit pain suggestive of rotator cuff injury. For the Yocum's test, have the patient place the hand of the painful side on the opposite shoulder. The examiner should then raise the elbow without raising the affected shoulder. Pain during this maneuver is suggestive of rotator cuff injury. Of the rotator cuff muscles, the most commonly weakened is the supraspinatus. This can be tested by putting the arm in about 90 degrees of abduction and 30 degrees of forward flexion with the shoulder internally rotated, that is, thumbs down or "empty the

[a]Potentially life-threatening conditions.

can" position. Push down on the arm as the patient resists. Pain without weakness is consistent with rotator cuff injury. Pain with significant weakness suggests possible tendon tear. Plain radiographs are usually normal, and a magnetic resonance imaging may be necessary.

Fracture separations of the proximal humeral epiphysis occur until the patient's epiphysis closes because the ligamentous attachments are stronger than the growth plate. The epiphysis closes between 16 and 18 years of age in males and about 1 year earlier in females. The injury occurs because of direct or indirect trauma, such as an attempt to break a fall with a hand. The patient usually has mild swelling and local tenderness. AP and lateral radiographs confirm the diagnosis, although they are

TABLE 39.2

COMMON CAUSES OF THE INJURED SHOULDER

- Clavicle fracture
- Glenohumeral joint
  - Dislocation (shoulder dislocation)
  - Subluxation
- Humerus
  - Fracture of proximal humeral physis

FIGURE 39.3 The apprehension test to evaluate for shoulder subluxation. The patient's shoulder should be abducted passively and rotated externally. If this elicits apprehension or pain, the test is positive. If not, the examiner then should apply anteriorly directed pressure to the posterior aspect of the humeral head. If this elicits pain, then the test also is positive and the patient's shoulder may have subluxed or the patient may have instability of the glenohumeral joint.

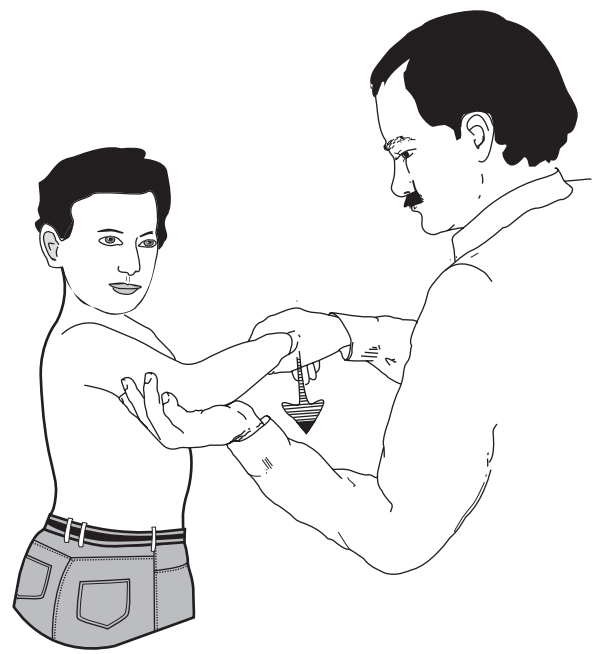

FIGURE 39.4 The Hawkins' test to evaluate for impingement of the supraspinatus tendon. The patient's arm should be held in internal rotation and 90 degrees of forward flexion. Internally rotatate the shoulder further by gently pushing the forearm downward while supporting the elbow. This brings the humeral head up against the acromion. Pain especially localized below the acromion suggests impingement.

less reliable in infants and young children because the epiphysis is mainly cartilaginous. Even in older patients, slight widening of the epiphysis may be difficult to appreciate, and comparison views of the uninjured side may be useful.

Stress fractures of the proximal humeral epiphysis, or "Little League shoulder," are caused by repetitive internal rotation of an abducted, externally rotated shoulder during the throwing motion. The child, usually 11 to 16 years of age, has diffuse shoulder pain that worsens after throwing. The proximal humerus may be tender and radiographs may show widening of the proximal humeral epiphysis. Radiographs of the contralateral humerus may be helpful.

Transverse or comminuted fractures of the humeral shaft may occur from direct trauma, whereas spiral fractures usually occur from indirect trauma (e.g., a fall on a hand). If the history is implausible, inconsistent from one caregiver to another, or the patient is younger than 2 years, the possibility of nonaccidental trauma must be considered. The patient will have obvious pain, tenderness, and local deformity. Care must be taken not to miss an associated neurovascular injury because the radial nerve runs along the humeral shaft. Radial nerve damage results in weakness of wrist extension and anesthesia of the skin between the first and second metacarpals. Radiographs help rule out a pathologic fracture (e.g., through a unicameral bone cyst or tumor).

In older patients, shoulder pain may be due to tendonitis of the tendon of the long head of the biceps. This tendon is palpable as it runs through the bicipital groove just anterior and medial to the greater humeral tuberosity. The patient often has chronic pain and tenderness over the bicipital groove.

A painful shoulder or fracture that follows minimal trauma may be caused by a benign or malignant tumor or by nonneoplastic bone lesions. Osteochondromas (exostoses) are outgrowths of benign cartilage from the bone adjacent to the epiphysis and present with a mass adjacent to a joint. The nonossifying fibromas (called "fibrous cortical defects" if smaller than 0.5 cm) are common asymptomatic lesions that may lead to pathologic fractures.

The malignant chondroblastoma is a rare tumor, but its most common location is the proximal humerus. The patient often has joint pain from an effusion associated with this tumor. Osteogenic sarcomas and Ewing's sarcoma are more common but involve the humerus in only 10% of cases.

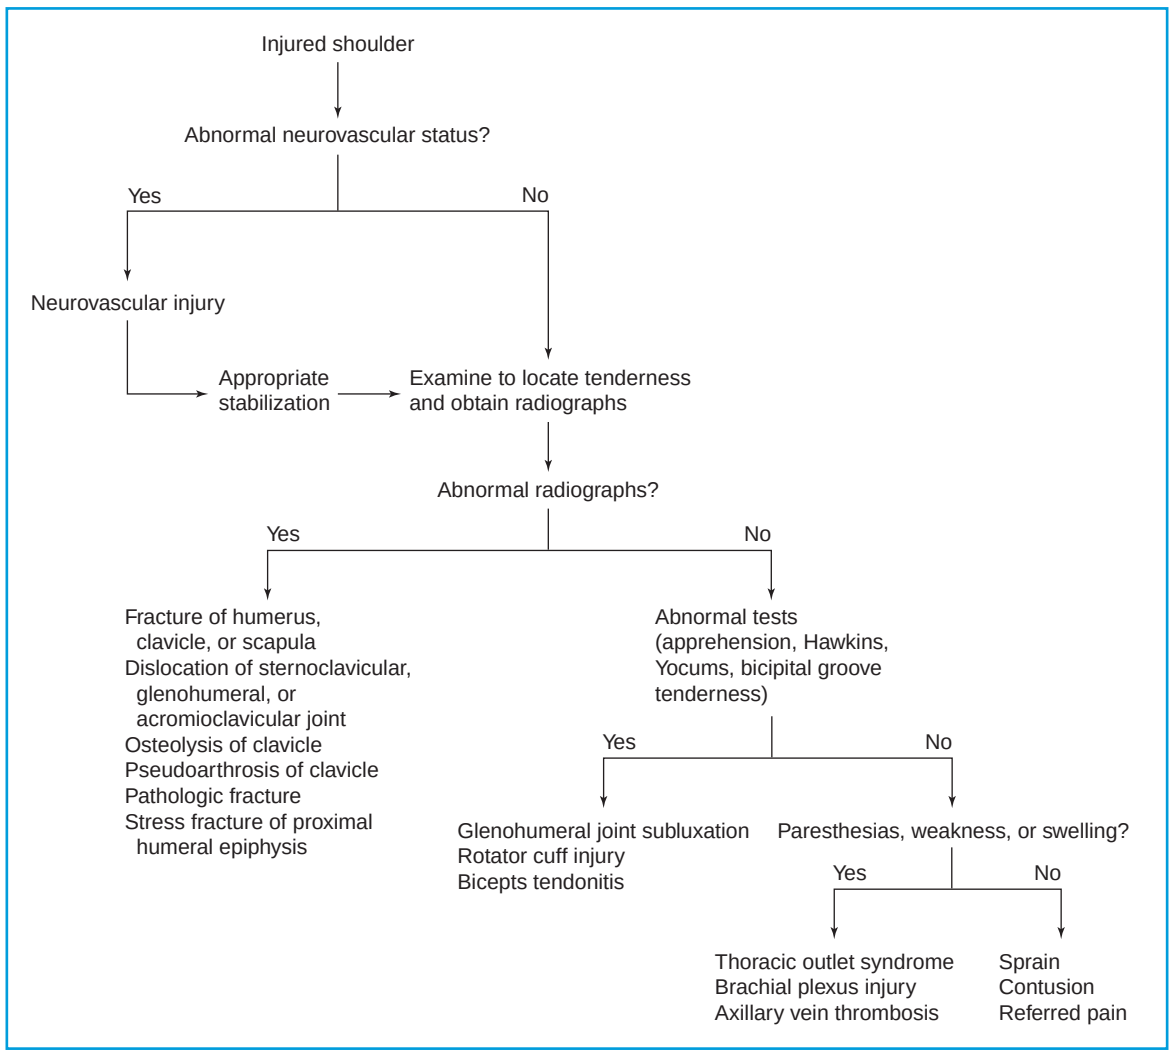

FIGURE 39.5 Approach to the patient with an injured shoulder.

Unicameral and aneurysmal bone cysts are asymptomatic until the bone fractures, but they are not neoplastic lesions. Unicameral or "simple bone" cysts are benign fluid-filled cavities most commonly localized to the proximal humerus.

Shoulder pain may also be referred from the neck (e.g., cervical disc herniation), myocardium, or diaphragm (e.g., a splenic hematoma) after trauma to those areas.

Thoracic outlet syndrome, with compression of the lower roots of the brachial plexus (C8 to T1) may present as shoulder pain. The numbness and paresthesias most commonly follow the dermatome of the ulnar nerve. The symptoms may be induced (Roo's test) by having the patient rapidly open and close their hands for 3 minutes with the arm abducted 90 degrees and the shoulder externally rotated. The test is considered positive if it induces the patient's pain and paresthesias. A chest radiograph may demonstrate a cervical rib. Thoracic outlet symptoms may also be caused by axillary vein thrombosis, most commonly in a pitcher. The patient may have nonspecific arm pain and swelling but may also have dyspnea and chest pain if the thrombus is embolizing. Swelling and discoloration due to venous congestion may be present. Ultrasonography is diagnostic.

Acute brachial plexus injuries ("pinched nerves" or "stingers") are common in high-impact sports. Most commonly, the shoulder is forcefully depressed and the head and neck tilted to the opposite side, stretching the brachial plexus. The patient has immediate arm weakness or paralysis and paresthesias or numbness along a cervical dermatome, most commonly C5 and C6. Less commonly, C8 to T1 can be injured when the arm is forcefully abducted, for example, falling and grabbing a tree branch. The symptoms may resolve prior to the emergency department evaluation. Cervical spine injuries must be excluded.

EVALUATION AND DECISION

Initially, the patient's neurovascular status is assessed and fracture stabilization provided, if necessary (Fig. 39.5).

For an isolated shoulder injury, ask the patient to localize the pain as specifically as possible and determine the mechanism of injury. Determine whether the trauma was direct or indirect and ascertain what position the shoulder was in when the injury occurred. If the pain is chronic, determine the position or motion that most exacerbates the pain (e.g., throwing a ball). Ask the patient about any distal paresthesias, associated pain, and trauma (e.g., neck, chest, abdomen). Always consider the possibility of abuse in young children, especially if the injury is unexplained, the history is implausible, or inconsistent between caregivers, or the seeking of medical care was delayed unreasonably.

Observe the patient without clothes over the shoulder for positioning of the arm, swelling, deformity, or any asymmetry. Ask the patient to point with one finger to the most painful area. This observation period before the formal physical examination is especially important in a young, anxious child and helps prioritize the rest of the evaluation.

If the child seems anxious, examine the uninjured side first. Carefully palpate the entire shoulder from sternoclavicular joint to the shaft of the humerus. Swelling and tenderness at the sternoclavicular joint suggests a physeal separation or dislocation at this site. The clavicle is covered only by a thin platysma muscle, and a fracture is easily seen and palpated. Just lateral to the clavicle is the AC joint. Elevation of the clavicle above the acromion or tenderness of the articulation suggests AC joint dislocation (shoulder separation) or sprain. Just in front of the greater tuberosity of the humerus is the tendon of the long head of the biceps within the bicipital groove. Pressure may produce exquisite tenderness in this area, so palpation should be gentle; if uncertainty about a finding of tenderness exists, a comparison with the examination of the uninjured side is helpful. Finally, the proximal humeral shaft and the scapula are palpated.

During the neurologic evaluation, it is important to test sensation over the deltoid muscle (to assess axillary nerve damage after shoulder dislocation) and over the lateral proximal forearm (to assess musculocutaneous nerve damage).

Next, examine the patient's active and passive range of motion (Fig. 39.6), checking for abduction, adduction, forward flexion, backward extension, internal rotation, and external rotation. Internal and external rotation can be observed easily in a child by asking the patient to touch behind the neck (external rotation) and lower back to the inferior tip of the opposite scapula (internal rotation).

Once the pain has been localized, appropriate radiographs should be obtained. When indicated, additional specific tests may be performed: the apprehension test for shoulder subluxation and laxity (Fig. 39.3), Hawkins' (Fig. 39.4) and Yocum's tests for rotator cuff injury, and Roo's test for thoracic outlet syndrome.

If the patient has nonspecific pain with numbness, paresthesias, weakness, or diffuse swelling, a brachial plexus injury or thoracic outlet syndrome should be considered.

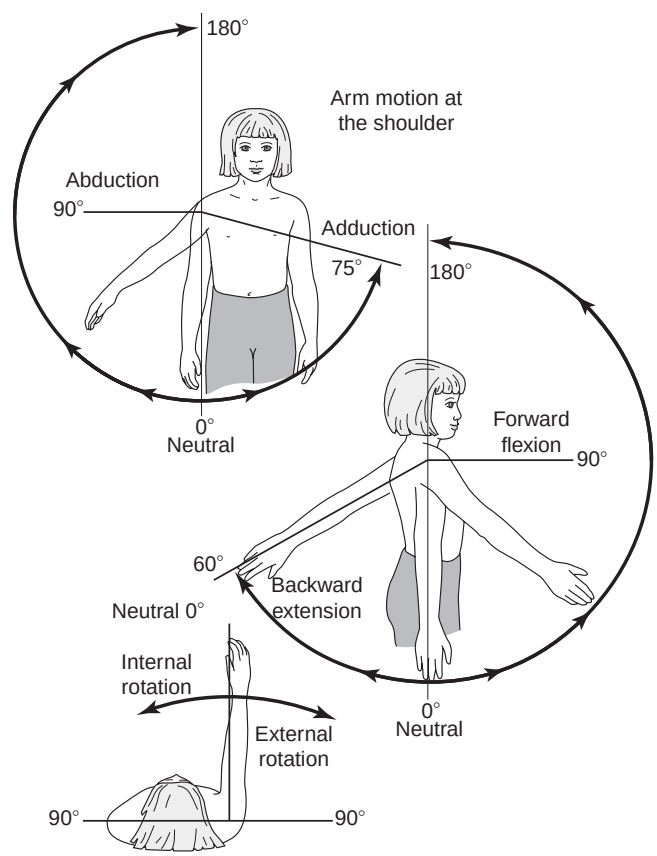

FIGURE 39.6 Range of motion of the shoulder joint.

Patients with normal radiographs and negative maneuvers are most likely to have sprains or contusions, but occasionally, they may be experiencing referred pain.

CHAPTER 40 ■ JAUNDICE—UNCONJUGATED HYPERBILIRUBINEMIA

KENNETH D. MANDL, MD, MPH

Jaundice—a yellowish discoloration of the skin, tissues, and bodily fluids—indicates an increased production or impaired excretion of bilirubin, leading to hyperbilirubinemia. Both physiologic and pathologic etiologies may give rise to unconjugated (or indirect) hyperbilirubinemia. To distinguish between them, the clinician must consider the patient's age, the rate of increase and peak level of serum bilirubin, and the historical features of the case. Prompt evaluation and therapy for unconjugated hyperbilirubinemia are particularly important for infants younger than 1 week. If bilirubin levels rise too high, these young infants risk developing neurodevelopmental deficits and kernicterus.

PATHOPHYSIOLOGY

Bilirubin is formed from the degradation of hemoglobin and other heme-containing proteins. Heme protoporphyrin becomes oxidized, producing biliverdin, which is then reduced to form bilirubin. In the blood, bilirubin is bound to albumin. The liver uptakes bilirubin for conjugation by a glucuronyl transferase and then excretes the conjugated form into bile. The net balance of its entry into and removal from the circulation determines serum bilirubin concentration. In the newborn infant, multiple factors contribute to hyperbilirubinemia, including increased red blood cell (RBC) volume and decreased red blood cell survival, as well as impaired plasma binding, liver uptake, conjugation, and excretion of bilirubin.

Older children and adults normally have serum bilirubin concentrations below 1 mg per dL and appear jaundiced when the bilirubin level rises above 2 mg per dL. Newborn infants become visibly jaundiced when their serum bilirubin concentration is above 5 mg per dL. In conjugated, or direct, hyperbilirubinemia, the conjugated (or direct reacting) portion of the serum bilirubin exceeds 2.0 mg per dL and is more than 15% to 30% of the total. Otherwise, the hyperbilirubinemia is unconjugated, or indirect (see Chapter 41).

In neonates, severe hyperbilirubinemia (levels greater than 25 to 30 mg per dL), especially when present with hemolysis or other significant illness, may be associated with neurotoxicity, encephalopathy, or kernicterus. Kernicterus is a rare but devastating neurologic disorder, with characteristic yellow staining in the basal ganglia and other brain regions. Kernicterus is found almost exclusively in breastfed infants. Of note, one more recent report found that, in a large, managed care organization, serum bilirubin levels over 30 mg per dL occurred in about 1 per 10,000 neonates and were generally not accompanied by acute neurotoxicity or chronic neurological sequelae.

DIFFERENTIAL DIAGNOSIS

The most common causes of unconjugated hyperbilirubinemia for patients beyond the neonatal period are hemolytic processes resulting in overproduction of bilirubin (Table 40.1). Extravascular blood in a concealed hemorrhage may be metabolized into supraphysiologic concentrations of bilirubin. Enzyme deficiencies and other conditions that impair the hepatic uptake or conjugation of bilirubin can cause jaundice. Upper gastrointestinal (GI) obstruction generally causes conjugated hyperbilirubinemia but may occasionally be associated with an unconjugated hyperbilirubinemia. Jaundice may be associated with dehydration due to inadequate fluid intake—generally in breastfed infants during the first week of life. After the first week of life, jaundice may be associated with the components of the breast milk itself.

Excess Bilirubin Production

The numerous causes of hemolysis may be classified as intravascular or extravascular. Intravascular hemolysis may be further divided into intracorpuscular and extracorpuscular defects (Table 40.1). Inborn errors of metabolism, such as glucose-6-phosphate dehydrogenase (G6PD) deficiency, may result in destruction of RBCs. This disorder is common in African American and Asian children as well as in those of Mediterranean origin. Patients with G6PD deficiency who are exposed to oxidant stress (e.g., fava beans, sulfa drugs) may have acute rapid hemolysis. Neonates with G6PD deficiency have an increased risk of jaundice that is only partially attributable to hemolysis.

Hemoglobinopathies, including sickle cell disease, can result in hemolysis, as can the impairments in hemoglobin chain synthesis that occur in the thalassemias. Defects in the RBC membrane found in hereditary spherocytosis and hereditary elliptocytosis increase the fragility of the corpuscles. Extracorpuscular causes of RBC destruction include the autoimmune, microangiopathic, and drug-induced hemolytic anemias.

Hematomas, pulmonary hemorrhages, and other collections of extravasated blood undergo hemolysis and, if sufficiently large, can elevate serum levels of unconjugated bilirubin. Rarely, hemophilia in young infants can present as jaundice. Various hypersplenic states, including splenic sequestration crisis in sickle cell disease, may result in anemia with accompanying hemolysis and hyperbilirubinemia.

Inherited disorders of bilirubin metabolism
  Crigler-Najjar syndrome type I
  Galactosemia (early)
  Lucey-Driscoll syndrome

Infection

Jaundice may be evident in cases of serious infection. Bacterial endotoxins reduce bile flow and can cause hyperbilirubinemia. The neonate with jaundice, as well as poor feeding, lethargy, or fever, should be evaluated for sepsis and urinary tract infection. Sepsis is exceedingly rare among well-appearing jaundiced neonates who have no additional signs or symptoms, occurring at a rate considerably below 1%. However, young infants, particularly those older than 8 days with the new onset of jaundice, have an elevated risk of urinary tract infection. Malaria, caused by *Plasmodium* species, is endemic in tropical regions; in patients with malaria, a high degree of parasitemia may result in massive hemolysis presenting with jaundice.

Inherited Disorders of Bilirubin Metabolism

Gilbert's syndrome is a common cause of mild, intermittent, unconjugated hyperbilirubinemia that occurs in as much as 6% of the population. Patients with Gilbert's syndrome have a partial deficiency of glucuronyl transferase. They generally do not present until late childhood or early adolescence, when they may develop nonspecific abdominal pain, nausea, and mild jaundice during an intercurrent illness. Other liver function studies (including hepatic enzymes and measures of liver function including coagulation studies and ammonia level) are normal and there is no evidence of hemolysis or hepatosplenomegaly. The serum bilirubin rarely exceeds 5 mg per dL.

Crigler-Najjar syndrome is characterized by the absence or deficiency of the enzyme bilirubin glucuronyl transferase. Type I, the more severe form, manifests soon after birth and is associated with high morbidity and mortality. Type II, the milder form, caused by an incomplete enzyme deficiency, typically presents in infancy or later in childhood but has been reported to first appear as late as adolescence. The type II form is generally treatable with phototherapy or phenobarbital.

Special Considerations in the Neonate

Physiologic Neonatal Hyperbilirubinemia. Circulating indirect bilirubin is normally conjugated by the liver to direct bilirubin, which is water soluble and excreted with bile acids. Newborns are deficient in the enzyme responsible for this conjugation, and most newborns develop a mild hyperbilirubinemia with approximately 60% manifesting clinical signs of physiologic jaundice. Physiologic jaundice peaks between 3 and 5 days of life in the term infant and requires no treatment. Because at high levels bilirubin may be associated with neurotoxic effects, careful attention should be paid to distinguishing physiologic from nonphysiologic jaundice.

Nonphysiologic Neonatal Hyperbilirubinemia. One percent to 2% of newborns require readmission within the first week of life, and up to 85% of these readmissions are for nonphysiologic neonatal hyperbilirubinemia. Jaundice in the term newborn is nonphysiologic if it is conjugated or appears within the first 24 hours of life. Other indications that jaundice may not be physiologic are a peak serum total bilirubin concentration of 17 mg per dL or higher in the breastfed infant and 15 mg per dL or higher in the formula-fed infant. Also, infants with a persistence of jaundice beyond the first week of life, or whose serum bilirubin level increases more than 5 mg per dL per day, should be followed closely for nonphysiologic jaundice. Risk factors for nonphysiologic neonatal hyperbilirubinemia include the history of a sibling with hyperbilirubinemia, breast-feeding, lower gestational age, maternal diabetes, bruising (from birth trauma), and Asian race. Dehydrated neonates may develop unconjugated hyperbilirubinemia.

Breast-feeding and Jaundice. Breastfed newborns develop a greater degree of hyperbilirubinemia more often than do

formula-fed newborns. During the first week of life, breastfed infants are at risk of inadequate intake of fluid and if dehydrated, may develop breast-feeding–associated jaundice. Breast milk jaundice, on the other hand, occurs in 1% of newborns, is associated with the breast milk itself and may be hormonally mediated or related to intestinal excretion and resorption of bile.

Hemolysis. Birth trauma, when associated with a cephalohematoma, extensive bruising, or swallowed maternal blood, can result in hyperbilirubinemia. Intracranial, pulmonary, or other concealed hemorrhage can also lead to extravascular hemolysis. Similarly, polycythemia, caused by delayed clamping of the cord or maternal-fetal or fetal-fetal transfusion (in multiple gestations), increases the RBC mass and causes jaundice in neonates.

Maternal-fetal blood group incompatibility is critical to recognize early. When maternal antibodies are produced against fetal red blood cell antigens, the neonate can develop a Coombs' positive isoimmune hemolytic anemia that incurs a higher risk of kernicterus than the risk in infants with nonhemolytic causes of jaundice. Fetal Rh and A and B blood group antigens are most commonly etiologic in the hemolysis syndrome, although dozens of antigens have been implicated. Rh-negative mothers may become sensitized to an Rh-positive fetus during pregnancy and mount an antibody response to a fetus during a subsequent pregnancy. Administration of Rho (D) immune globulin (RhoGAM) to Rh-negative mothers who have not yet developed anti-Rh antibodies can prevent Rh isoimmunization. ABO hemolytic disease of the newborn generally occurs in infants with A or B blood groups whose mothers have type O blood group. Maternal anti-A and anti-B antibodies are produced and can result in hemolysis with a positive direct Coombs' test.

Upper Gastrointestinal Obstruction. Pyloric stenosis, meconium ileus, Hirschsprung's disease, duodenal atresia, and other causes of upper GI obstruction may present with jaundice and clinical signs of obstruction. In neonates, obstruction can increase enterohepatic circulation or decrease the enzyme activity responsible for bilirubin uptake, resulting in unconjugated hyperbilirubinemia. In contrast, older children and adults with upper GI obstruction and jaundice generally have a conjugated hyperbilirubinemia.

Endocrine Disorders. Unconjugated hyperbilirubinemia may be the presenting sign of congenital hypothyroidism, preceding other manifestations by several weeks. The mechanism probably relates to reduced bile flow. Other signs that may be present include persistent poor feeding, prolonged jaundice, constipation, and hypotonia. Infants of diabetic mothers are also at increased risk of jaundice, with as many as 19% developing nonphysiologic hyperbilirubinemia.

Inherited Disorders of Bilirubin Metabolism. Very high, rapidly rising levels of bilirubin not responsive to phototherapy raise the concern for Crigler-Najjar syndrome type I or Lucey-Driscoll syndrome. Lucey-Driscoll syndrome is probably caused by an inhibition of glucuronyl transferase. Infants with galactosemia may exhibit an unconjugated hyperbilirubinemia during the first week of life. Older infants with galactosemia tend to have a conjugated hyperbilirubinemia. Infants with galactosemia usually also present with vomiting, failure to thrive, poor feeding, abdominal distension, and hypoglycemia.

Overproduction of bilirubin
Hemolysis
Maternal-fetal blood group incompatibility (ABO, Rh, other)
Cephalohematoma

EVALUATION AND DECISION

An approach to the patient with unconjugated hyperbilirubinemia is outlined in Figure 40.1. Hemolysis and Gilbert's syndrome are the most common causes of jaundice in the patient beyond the neonatal period (Table 40.2). During the neonatal period, physiologic jaundice and breast-feeding–related jaundice are the most likely causes. The differential diagnosis is broad, and evaluation should always begin with a detailed history and physical examination.

History

A general clinical history may help guide the workup. An infant who has been lethargic or apneic or a child who has been ill and febrile may require evaluation for serious bacterial infections (Table 40.3). A neonate with persistent or bilious emesis may have an upper GI obstruction.

The clinician should ascertain whether there are factors predisposing a patient to jaundice. One such factor is a family history of jaundice or anemia or a racial or ethnic origin associated with hemolytic anemias. African American race and Mediterranean ancestry are associated with G6PD deficiency. Additional causes of jaundice run in families or have racial predisposition. African American patients are much more likely to have sickle cell disease. Mediterranean and Asian children have higher incidence of thalassemia. East Asian neonates are more likely to develop nonphysiologic hyperbilirubinemia.

A history of drug ingestion may lead to the diagnosis of drug-induced hemolysis. Dietary history may identify an agent such as the fava bean that induces hemolysis in patients with G6PD deficiency. Residence in or travel to sub-Saharan Africa, Southeast Asia, or parts of Central and South America carries a risk of exposure to malaria.

Special Historical Considerations in the Neonate

For the newborn, timing of the onset of jaundice is critical. Most jaundice appearing before the first 24 hours of life is pathologic. Maternal blood type and Rho (D) immune globulin

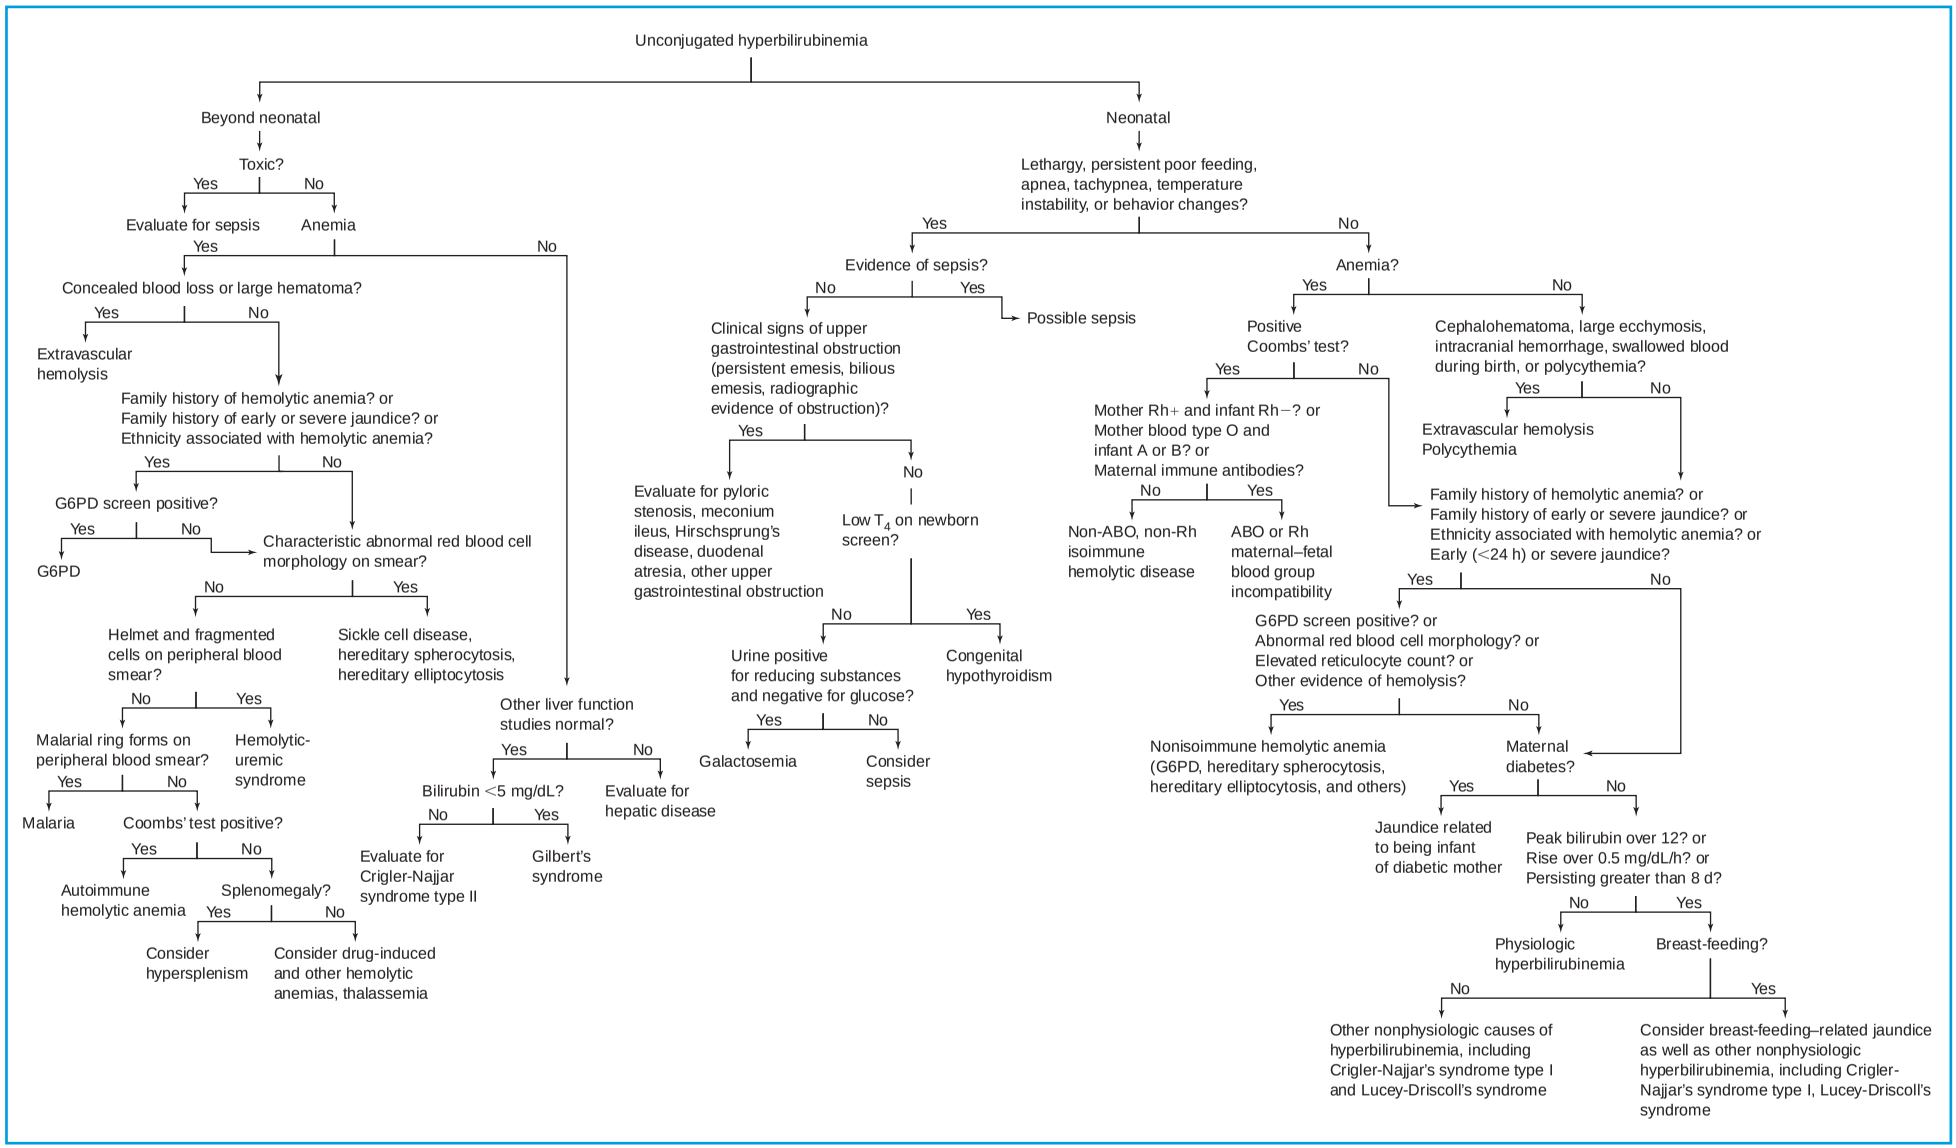

FIGURE 40.1 Evaluation of the pediatric patient with unconjugated hyperbilirubinemia. G6PD, glucose-6-phosphate dehydrogenase.

- Lucey-Driscoll syndrome

status should be ascertained to establish risk factors for isoimmune hemolytic anemia. Previous bilirubin levels and the results of Coombs' test should be reviewed. Feeding practices influence development of jaundice; a breastfed infant is at risk for breast-feeding–related jaundice, including jaundice resulting primarily from dehydration. Knowledge of weight gain or loss may help judge hydration status.

Physical Examination

The general appearance of the patient will help guide the clinician as to the likelihood of a serious underlying condition such as bacterial sepsis. In the neonate, poor feeding, lethargy, apnea, tachypnea, and temperature instability may accompany serious infections.

The sclera and skin should be examined closely under adequate light. In a patient with dark skin, palms and soles may be less pigmented and easier to assess for jaundice. Gentle pressure with one finger to blanch the skin facilitates inspection of skin color. In neonates, jaundice progresses in a cephalocaudad direction. Newborns with jaundice below the knees and on the palms have the highest levels of serum bilirubin. Pallor may indicate anemia from hemolysis or bleeding.

Presence of a cephalohematoma or large areas of ecchymosis may suggest extravascular hemolysis as the cause of hyperbilirubinemia. Hepatomegaly may indicate underlying liver dysfunction. Splenomegaly can indicate a hypersplenic state such as splenic sequestration in sickle cell disease. Splenomegaly may also be present in lupus, which is associated with an autoimmune hemolysis. In a neonate with jaundice and vomiting, an abdominal mass suggests upper GI obstruction.

Laboratory Testing

The serum bilirubin level should always be measured as visual inspection alone can be unreliable as a screen for significant neonatal hyperbilirubinemia. Transcutaneous measurements of bilirubin are correlated with serum bilirubin. However, transcutaneous measurements can be inaccurate and thus are best used as a screen with a low threshold to follow up with a serum measurement. Jaundiced patients beyond the neonatal period should be evaluated for anemia with a complete blood cell count and reticulocyte count. Those with evidence of anemia and/or hemolysis should have a peripheral blood smear examined microscopically. Characteristic abnormal morphology, such as sickle cells, spherocytes, or elliptocytes, may be identified. Helmet and fragmented cells are diagnostic of a microangiopathic hemolytic anemia, such as that occurring in hemolytic-uremic syndrome. Malarial ring forms may be apparent. Nucleated RBCs and Howell-Jolly bodies indicate a sustained hemolysis. Patients with anemia or hemolysis should also have a Coombs' test performed to look for evidence of autoimmune hemolysis. Testing for G6PD should be performed if the patient has risk factors or a consistent clinical presentation. Hemoglobin electrophoresis may be used to diagnose hemoglobinopathies, such as sickle cell disease and thalassemia. If hepatomegaly is present or if there is no evidence of anemia, liver function studies should be performed. Patients with no laboratory abnormalities other than serum unconjugated bilirubin below 5 mg per dL have Gilbert's syndrome, a benign condition.

Special Laboratory Considerations in the Neonate

In neonates, it may be important to determine the rate of rise of serum bilirubin with serial measurements. The clinician must know whether a newborn has a setup for maternal-fetal isoimmune anemia.

Therefore, either the mother's blood and Rh type and antibody status should be obtained or the infant's blood type should be determined and Coombs' test performed. A neonate with probable physiologic jaundice does not need to undergo an anemia or hemolysis workup if he or she has no family history of hemolytic disease, no maternal-fetal blood group incompatibility, and no physical stigmata of anemia.

If clinical signs of obstruction are present, the patient should undergo appropriate laboratory testing such as abdominal radiographs, ultrasound, or upper GI series with contrast. The neonate with fever or ill appearance should be evaluated for serious bacterial infection, with peripheral white blood cell count, urine analysis, and cerebrospinal fluid analysis, as well as blood, urine, and cerebrospinal fluid cultures. Results of the newborn screen for congenital hypothyroidism may be available. The newborn with symptoms of congenital hypothyroidism needs to have a determination of T_4 level. A newborn with poor feeding, vomiting, or failure to gain weight should be evaluated for galactosemia. If the newborn with galactosemia has already started feeds, the urine will contain reducing substances (Clinitest positive) but no glucose.

Approach

Beyond the Neonatal Period

In all children with jaundice, a total bilirubin level with fractionation and complete blood cell count should be performed. If a patient appears acutely ill, the physician should proceed with the appropriate evaluation and treatment for sepsis. Among well-appearing patients, the hematocrit determines the likely diagnostic possibilities and appropriate studies.

Anemia. Anemic children are suspect for having hemolytic processes, including autoimmune hemolytic anemia, hemoglobinopathies (e.g., thalassemia or sickle cell anemia), enzyme deficiencies (e.g., G6PD), red blood cell membrane defects (e.g., spherocytosis), hypersplenism, drug reactions, hemolytic-uremic syndrome, and malaria. Extravascular hemolysis and resultant jaundice occur occasionally in children with concealed blood loss or large hematomas. A family history of hemolytic anemia and severe jaundice, particularly among children of Mediterranean descent, suggests G6PD deficiency, whereas abnormal RBC morphology points to sickle cell anemia, hereditary spherocytosis, or heredity elliptocytosis. Additional clues on the peripheral smear include helmet and fragmented cells in hemolytic-uremic syndrome and ring forms in malaria.

A positive Coombs' test is seen with autoimmune hemolytic anemia. In patients with splenomegaly, hemolysis may lead to jaundice. Finally, drug reactions and unusual hemolytic anemias should be considered.

Normal Hematocrit. When unconjugated hyperbilirubinemia occurs without anemia, abnormal liver function studies (transaminases, prothrombin time, and partial thromboplastin time) differentiate hepatic disease from inherited disorders of bilirubin metabolism. Among these latter disorders, only Gilbert's syndrome, which produces a mild elevation in the serum bilirubin level, is at all common.

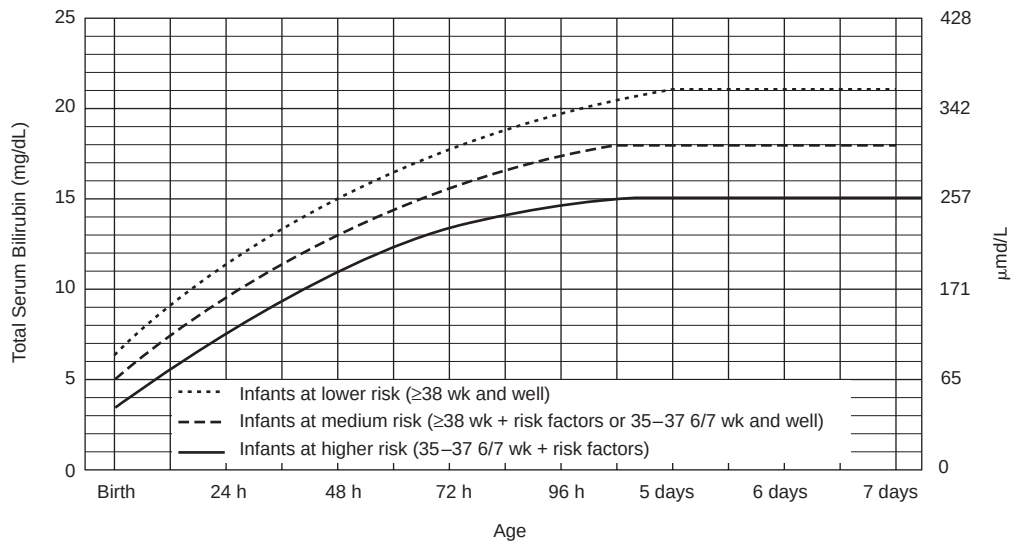
Neonatal Period

An ill appearance and/or fever suggest sepsis. Other disorders likely to cause lethargy include bowel obstruction, hypothyroidism, and inborn errors of metabolism, such as galactosemia. Among well-appearing neonates, the presence of anemia is important in the differential diagnosis.

Anemia. The foremost consideration in the infant with indirect hyperbilirubinemia and anemia is isoimmune hemolytic disease, caused by blood group incompatibility, because this disorder may lead to kernicterus. The diagnosis can be established by determining the blood group and Rh status of the maternal-infant dyad in combination with a Coombs' test in the infant. Other disorders that produce jaundice include enzymatic and structural disorders of the red blood cell (e.g., G6PD, hereditary spherocytosis) and the poorly understood occurrence of jaundice in infants of diabetic mothers.

Normal Hematocrit. In the absence of anemia, extravascular hemolysis is a common cause of jaundice in the newborn, with the breakdown of hemoglobin occurring in a cephalohematoma, in large ecchymosis, or from swallowed blood. In addition, polycythemic infants are prone to jaundice. Also, hemolysis of even small amounts of hemoglobin may markedly elevate the serum bilirubin level in the infant with an immature liver. Thus, the same disorders that are diagnosed in anemic infants may occur in the jaundiced neonate with a normal hematocrit.

Most infants with indirect hyperbilirubinemia will have a negative evaluation for the disorders previously listed. If the bilirubin level is below 12 mg per dL, rises slowly, and resolves before 8 days of age, one can diagnose physiologic hyperbilirubinemia without further laboratory studies. When these conditions are not met, the most likely cause for the jaundice is the



- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin.
- Risk factors = Isoimmune hemolytic disease. G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin < 3.0 g/dL (if measured)
- For well infants 35–37 6/7 wk can adjust TSB levels for intervention around the medium risk line. It is an option to intervene at lower TSB levels for infants closer to 35 wk and at higher TSB levels for those closer to 37 6/7 wk.
- It is an option to provide conventional phototherapy in hospital or at home at TSB levels 2–3 mg/dL (35–50 mgd/L) below those shown but home phototherapy should not be used in any infant with risk factors.

FIGURE 40.2 Guidelines for phototherapy in hospitalized infants of 35 or more weeks' gestation. The guidelines refer to the use of intensive phototherapy, which should be used when the TSB exceeds the line indicated for each category. Consultation with neonatology and/or hematology is recommended. TSB, total serum bilirubin measured in mg/dL. (From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics* 2004;114(1):297–316. Reprinted by permission).

hormonal impairment of bilirubin conjugation. Other possibilities, either alone or in combination with breast milk jaundice, include Crigler-Najjar and Lucey-Driscoll syndromes.

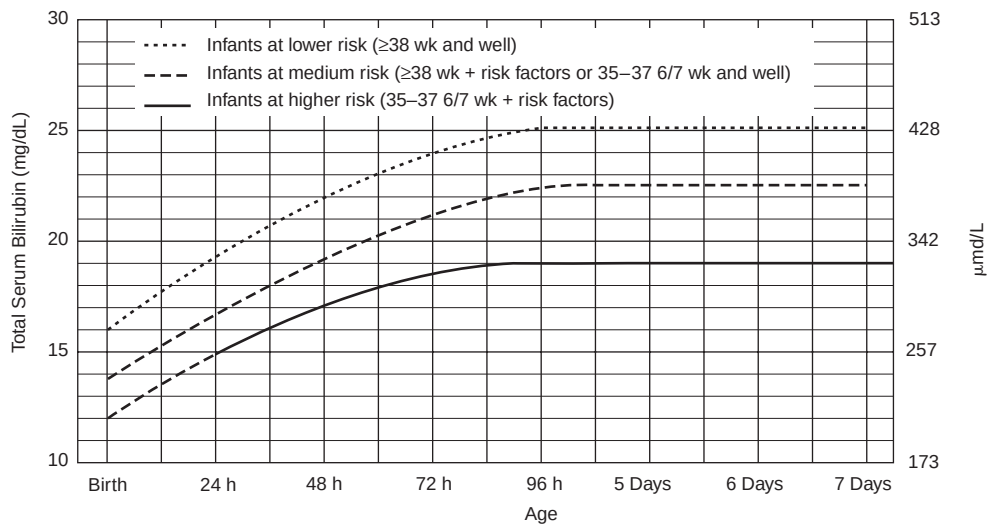
MANAGEMENT

For patients beyond the neonatal period, the management of hyperbilirubinemia is primarily directed at identification and treatment of the underlying cause. In some cases of severe hyperbilirubinemia, such as those caused by Crigler-Najjar syndrome type II, phototherapy or phenobarbital may be indicated. In contrast, newborns with jaundice require careful monitoring and, sometimes, specific therapies for hyperbilirubinemia because the neonatal central nervous system is susceptible to the toxic effects of bilirubin. The emergency physician may initiate the management of term newborn infants with jaundice and arrange hospitalization or subsequent follow-up after discharge. Infants discharged home from their birth hospitalization on the first or second day of life are at increased risk of readmission for hyperbilirubinemia. The management of premature infants with hyperbilirubinemia is highly specialized and not discussed here.

The goal of neonatal hyperbilirubinemia management is to prevent neurotoxicity, encephalopathy, and kernicterus. The jaundiced newborn needs to be kept well hydrated, and enteral feeding should be encouraged to promote bilirubin excretion. When bilirubin levels rise significantly, phototherapy and exchange transfusion may be indicated.

Phototherapy can be initiated with either an overhead bank of lights or a fiberoptic light source in a blanket. Phototherapy primarily promotes (i) photoisomerization of unconjugated bilirubin to a less toxic isomer, which is excreted in the bile and (ii) structural isomerization of bilirubin to lumirubin, which is excreted in the bile and urine.

Indications for phototherapy and exchange transfusion vary according to the age of neonate (see also Chapter 95 for further discussion). For the term neonate who develops jaundice and has no evidence of hemolysis, indications for phototherapy and exchange transfusion as recommended by the American Academy of Pediatrics in 2004 are shown in Figures 40.2 and 40.3. For the ease of understanding, these are summarized by age at 24-hour intervals in Table 40.4, although the action values by age in hours as depicted in the nomograms are the more definitive authority. When there is evidence of isoimmune



- The dashed lines for the first 24 h indicate uncertainty due to a wide range of clinical circumstances and a range of responses to phototherapy.
- Immediate exchange transfusion is recommended if infant shows signs of acute bilirubin encephalopathy (hypertonia, arching, retrocollis, opisthotonos, fever, high pitched cry) or if TSB is ≥5 mg/dL (85 μmol/L) above these lines.
- Risk factors—isoimmune hemolytic disease, (G6PD) deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis.
- Measure serum albumin and calculate B/A ratio (see legend).
- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin
- If infant is well and 35–37 6/7 wk (median risk) can individualize TSB levels for exchange based on actual gestational age.

FIGURE 40.3 Guidelines for exchange transfusion in infants 35 or more weeks' gestation. During birth hospitalization, exchange transfusion is recommended if the TSB rises to these levels despite intensive phototherapy. For readmitted infants, if the TSB level is above the exchange level, repeat TSB measurement every 2 to 3 hours and consider exchange if the TSB remains above the levels indicated after intensive phototherapy for 6 hours. Measurement of serum albumin allows calculation of a bilirubin/albumin (B/A) ratio, which may be used together but not in lieu of the TSB level as an additional factor in determining the need for exchange transfusion. The following risk catagories and B/A ratios (TSB mg per dL per Alb g per dL) would suggest consideration of exchange transfusion: infants older than 38 weeks (8.0); infants 35 to 37 6/7 weeks and well or older than 38 weeks with risk factors as noted above (7.2); infants 35 to 37 6/7 weeks and risk factors (6.8). Consultation with neonatology and/or hematology is recommended. TSB, total serum bilirubin measured in mg per dL. (From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics* 2004;114(1):297–316. Reprinted by permission.)

TABLE 40.4

MANAGEMENT OF HYPERBILIRUBINEMIA IN THE INFANT 35 WEEKS' OR MORE GESTATION

Risk category (wks' gestation)	Age (h)	Phototherapy (TSB mg/dL)	Exchange transfusion (TSB mg/dL)
Low risk	24	12	19
≥38 and well	48	15	22
	72	17.5	24
	96	20	25
	120	21	25
Medium risk	24	10	16.5
35–37 6/7 and well	48	13	19
≥38 and risk factors	72	15	21
	96	17	22.5
	120	18	22.5
High risk	24	8	15
35–37 6/7 and risk factors	48	11	17
	72	13	18.5
	96	14.5	19
	120	15	19

TSB, total serum bilirubin measured in mg/dL.
These guidelines apply only to neonates of gestational age equal to or greater than 35 weeks.
Note that the bilirubin values in this Table are **total bilirubin** values.
The low-risk patients are those who are healthy term neonates.
Medium-risk applies to those well infants of slightly shorter gestation or to term infants who meet additional risk criteria as noted here.
The high-risk patients would warrant initiation of phototherapy or exchange transfusion as defined in the table and include infants who are shorter gestation (less than 38 weeks) and have any of the following: isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, respiratory distress, temperature instability, sepsis, acidosis, or albumin level less than 3.0 g per dL.
Consult neonatology and/or hematology regarding possible need for exchange transfusion or alternative therapy if levels significantly exceed these numbers or if the bilirubin is predominately conjugated (direct).
Adapted from American Academy of Pediatrics Subcommittee on Hyperbilirubinemia. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics* 2004;114:297–316.

hemolysis, phototherapy should be started immediately and a neonatologist should be consulted regardless of bilirubin level.

During phototherapy, the baby should be undressed to maximize the exposed surface area of the skin. Intensive phototherapy with two banks of lights or two fiberoptic blankets will improve efficacy. When using overhead lights, the infant's eyes must be shielded and maintenance fluid requirements are increased. Phototherapy is relatively contraindicated in patients with conjugated hyperbilirubinemia because it can cause the "bronze baby syndrome."

When bilirubin levels are toxic, exchange transfusion may be necessary. Exchange transfusion is most commonly indicated in infants with hemolytic disease. Generally, fresh, irradiated, reconstituted whole blood is pushed in through an umbilical vein catheter while blood is pulled out through an umbilical artery catheter. Careful monitoring is necessary. Complications include electrolyte and acid-base disturbances, hemolysis, and infection.

For jaundiced, breastfed infants, the interruption or discontinuation of breast-feeding should be discouraged. Any of several management strategies, however, are accepted, such as following: (i) the infant may be observed while normal breast-feeding continues; (ii) if bilirubin levels are high (Table 40.4), the infant may continue to breast-feed while receiving phototherapy; (iii) breast-feeding may be supplemented with or without administration of phototherapy; and (iv) breast-feeding may be interrupted and formula may be substituted with or without administration of phototherapy.

CHAPTER 41 ■ JAUNDICE—CONJUGATED HYPERBILIRUBINEMIA

JONATHAN I. SINGER, MD

The presence of jaundice in a child can be a useful indicator of occult pathology. The finding of icterus should set in motion a careful diagnostic search to elucidate the cause. The ultimate goal, to identify precisely the cause of the clinical syndrome, may rest in some cases with the longitudinal caregiver. In all cases, however, the emergency physician at first visit must separate patients whose admission can be temporized from those who require urgent intervention and/or immediate hospitalization.

PATHOPHYSIOLOGY

Unconjugated bilirubin is largely a product of converted heme from senescent red blood cells. Unconjugated bilirubin is transported from extrahepatic reticuloendothelial cells to the liver, bound to albumin. Albumin is detached as the bilirubin gains entry into the hepatocyte. In the liver cell, bilirubin is conjugated with glucuronide by the action of uridine diphosphate glucuronyl transferase. The soluble conjugated diglucuronide then is secreted across the canalicular membrane into the bile. In the intestine, as a result of the activity of bacterial flora, bilirubin is converted to urobilinogen. A portion of urobilinogen is reabsorbed into the portal circulation and is taken up by the liver cells, only to be reexcreted into the bile. A small percentage of urobilinogen escapes into the systemic circulation and is excreted in the urine. The unabsorbed urobilinogen is excreted in the stool as fecal urobilinogen.

In hepatocellular disease, the damaged liver may be unable to excrete the conjugated bilirubin produced in normal amounts. Or, in the absence of hepatic damage, regurgitation into the plasma of conjugated bilirubin may result from functional cholestasis, disruption of the hepatic architecture, or extrahepatic biliary obstruction. In most instances of jaundice primarily related to hepatic disease, the plasma exhibits elevated concentrations of unconjugated and conjugated bilirubin. Overt mechanical obstruction of bile excretion leads to raised plasma levels of conjugated bilirubin, and only as secondary liver damage occurs do unconjugated bilirubin levels rise.

DIFFERENTIAL DIAGNOSIS

Conjugated hyperbilirubinemia is defined by a conjugated bilirubin level higher than 1 mg per dL if the total bilirubin is less than 5 mg per dL or the conjugated bilirubin level represents more than 20% of the total bilirubin if the total bilirubin is higher than 5 mg per dL. Conjugated hyperbilirubinemia, indicating cholestasis, is considered pathological. Cholestatic jaundice may be congenital or acquired. The differential diagnosis includes a variety of structural defects, infections, hepatotoxins, inborn errors of metabolism, and familial syndromes (Table 41.1).

Although only a few diseases commonly cause conjugated hyperbilirubinemia (Table 41.2), all are serious. In addition, several less common conditions are important considerations because they are life threatening (Table 41.3).

EVALUATION AND DECISION

It is convenient to divide the approach to patients with conjugated hyperbilirubinemia by age, focusing first on those younger than 8 weeks old and then on those who are older (Fig. 41.1). A majority of children who eventually develop life-threatening or chronic liver disease initially present in the first 2 months of life. Early physician recognition may lead to successful treatment and a more favorable prognosis.

Infants Younger than 8 Weeks

In the perinatal period, infants develop conjugated hyperbilirubinemia in response to a variety of conditions that may not be encountered in older patients. The increased sensitivity to insult is a result of different patterns of hepatic enzyme activity and liver immaturity with regard to bile formation. Many systemic or hepatic insults may produce perinatal cholestasis (Table 41.1). However, a small number of disorders account for the overwhelming majority of perinatal cholestasis. They include idiopathic neonatal hepatitis, biliary atresia, α_1-antitrypsin deficiency, cystic fibrosis, tyrosinemia, galactosemia, choledochal cyst, and perinatal infections. These disorders can be separated by the tempo of the presentation and the appearance of the infant.

The tempo of cholestasis is most abrupt with the infections acquired in utero and during the birthing process. Infected patients are more likely to present shortly after birth. Those who have congenital infections will have a low birth weight. They present with cholestatic jaundice, irritability, jitteriness, and/or seizures. On examination, microcephaly, hepatomegaly, splenomegaly, and petechiae may be seen with the perinatal TORCHS complex. These include perinatal infections from toxoplasmosis, other infections, rubella, cytomegalovirus (CMV), herpes simplex, and syphilis. Jaundice may be one of the first signs of bacteremia without apparent focus of infection or bacterial sepsis in the first few days of life. Hyperbilirubinemia may

TABLE 41.1

CAUSES OF CONJUGATED HYPERBILIRUBINEMIA IN INFANTS AND CHILDREN

First 8 wk of life
Hepatic disorders
- Biliary atresia
- Intrahepatic biliary hypoplasia
- Idiopathic neonatal cholestasis or neonatal hepatitis syndrome
- Ischemic hepatitis

Perinatal infections
- Toxoplasmosis
- Rubella
- Cytomegalovirus
- Varicella zoster
- Herpes simplex
- Coxsackievirus
- Human immunodeficiency virus
- Bacterial sepsis
- Listeriosis
- Syphilis
- Babesiosis
- Urinary tract infection

Metabolic disorder
- Galactosemia
- Galactokinase deficiency
- Hereditary fructose intolerance
- Hereditary tyrosinemia
- α_1-Antitrypsin deficiency
- Cystic fibrosis
- Hypothyroidism
- Hypopituitarism

Biliary tree disorders
- Spontaneous perforation of the bile duct
- Choledochal disorders
- Gallstones or biliary sludge

Childhood
Hepatic disorders
- Hepatotoxins (drugs, chemicals)
- Byler disease
- Dubin-Johnson syndrome
- Rotor syndrome

Infections
- Viral hepatitides (A through E)
- Epstein-Barr virus, Coxsackievirus, echovirus
- Liver abscess (usually anicteric)
- Myocarditis
- Urinary tract infection
- Suppurative cholangitis
- Peritonitis
- Pneumonia

Metabolic disorders
- Wolman disease
- Zellweger syndrome
- Glycogen storage (III, IV)
- Wilson's disease

Biliary tree disorders
- Choledocholithiasis
- Cholangitis
- Cholecystitis
- Choledochal cyst
- Pancreatic disease

Miscellaneous
- Abdominal crisis, sickle hemoglobinopathy
- Hepatorenal syndrome
- Kawasaki disease

TABLE 41.2

COMMON CAUSES OF CONJUGATED HYPERBILIRUBINEMIA

Infancy
- Idiopathic neonatal cholestasis
- Biliary atresia
- Perinatal infections (TORCHS)
- Sepsis/urinary tract infection

Childhood
- Viral hepatitis
- Hepatotoxins

TORCHS, toxoplasmosis, other (infections), rubella, cytomegalovirus, herpes (simplex), and syphilis.

occur antecedent to blood cultures becoming positive and may precede findings of anorexia, vomiting, abdominal distension, fever, hepatomegaly, or alterations in respiratory pattern or sensorium. The precise mechanism of jaundice that complicates bacteremia and sepsis is not completely understood. Jaundice may also be an early diagnostic sign of urinary tract infection in the neonatal period. An increase in the conjugated bilirubin fraction may be seen in patients who have afebrile, otherwise asymptomatic urinary tract infection.

The tempo of icterus is subacute with the other common causes of conjugated hyperbilirubinemia. The metabolic and hepatic disorders have variable symptoms at onset. However, the manifestations are far less acute than those seen in the infectious states. Infants with galactosemia, tyrosinemia, and fructose intolerance may appear ill in the emergency department due to metabolic derangement or secondary infection. However, they have had an antecedent history of failure to thrive, developmental delay, and inconstant jaundice. Unexplained fatality in the sibship or unexplained pulmonary, gastrointestinal, neurologic, or psychiatric disturbance in other family members may provoke diagnostic consideration (see Chapter 94).

The tempo of hepatic and biliary tree disorders is chronic. Those with biliary atresia have intermittent, mild conjugated hyperbilirubinemia during the first 6 to 8 weeks of life. They feed well and thrive. Their stools may be intermittently pigmented early on and become permanently without pigment only after 4 to 6 weeks. They have a benign appearance and

TABLE 41.3

LIFE-THREATENING CAUSES OF CONJUGATED HYPERBILIRUBINEMIA

Fulminant hepatic failure
Septicemia
Intraabdominal sepsis
- Pyogenic liver abscess
- Suppurative cholangitis
- Peritonitis

Abdominal crisis, sickle hemoglobinopathy
Hepatorenal syndrome

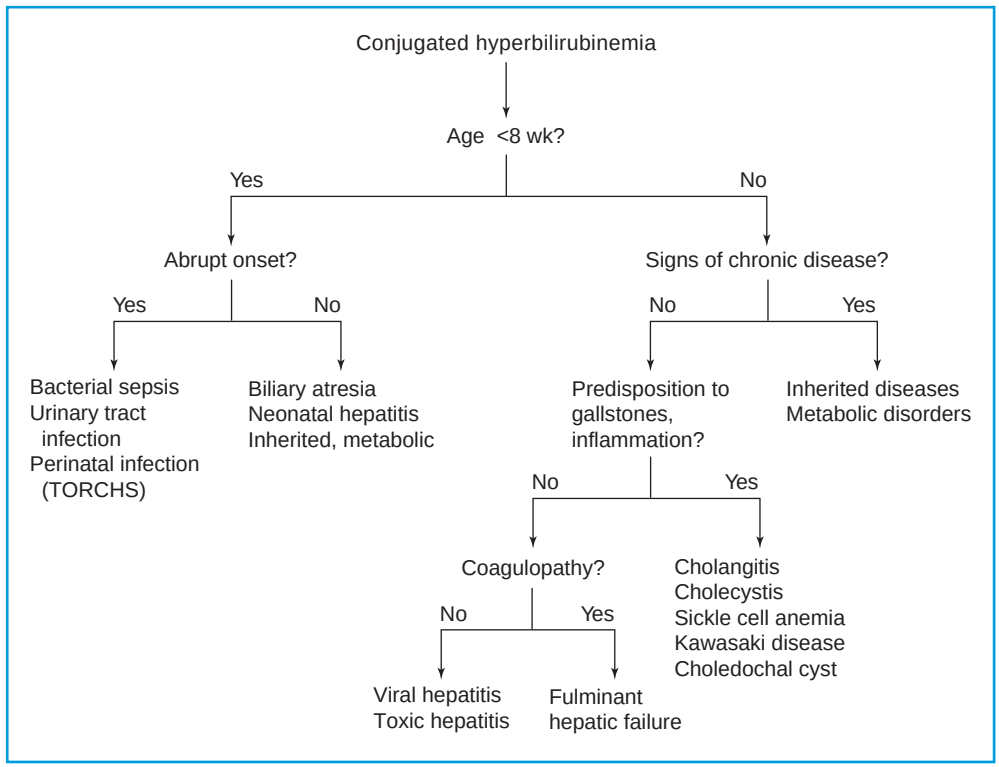

FIGURE 41.1 Approach to the patient with congenital hyperbilirubinemia. TORCHS, toxoplasmosis, other (infections), rubella, cytomegalovirus, herpes (simplex), and syphilis.

with the exception of jaundice and hepatomegaly seem otherwise well. Those patients without a precise anatomic, genetic, or infectious cause of cholestasis are considered to have idiopathic neonatal cholestasis or neonatal hepatitis syndrome. They have onset of their jaundice from 1 to 30 days, with a mean of 7 days. Initially, their stool color is normal, but the stools may become acholic after several weeks. The presence of acholic stools may make it difficult to differentiate between obstructive jaundice causing hepatocellular disease and that caused by obstruction of the biliary tree.

The priorities for the emergency physician are to diagnose medically treatable infections, identify metabolic disorders for which effective therapy is available, and detect extrahepatic obstructive lesions that are amenable to surgical correction. The evaluation begins with cultures of cerebrospinal fluid, blood, urine, and stool. Infants should also have complete blood cell and platelet counts, coagulation studies, hepatic enzymes (aspartate aminotransferase, alanine aminotransferase, and gamma-glutamyl transpeptidase), ammonia, albumin, total protein, alkaline phosphatase, electrolytes, blood urea nitrogen, creatinine, and blood sugar tests. Urine should be obtained for urinalysis and tested for reducing substances. A right upper quadrant ultrasound should be performed in order to identify anatomic abnormalities such as a choledochal cyst. If cystic fibrosis is suspected, schedule the patient for a sweat chloride iontophoresis or testing for common genetic variants in the cystic fibrosis transmembrane conductance regulator gene. Additional studies of blood and urine that they may find useful include α_1-antitrypsin, TORCHS and hepatitis B virus serology, serum amino acids, thyroid function tests, red blood cell galactose 1-phosphate uridyltransferase activity, and urine examination for cytomegalovirus.

Inpatient observation is appropriate in this age group because the diagnosis can rarely be established in the emergency department. Empiric therapy for sepsis or urinary infection is often warranted, pending culture results.

Children Older than 8 Weeks

In the evaluation of conjugated hyperbilirubinemia beyond infancy, it is necessary to know if there has been exposure to contagion or a potential for sexual or vertical transmission of infections such as hepatitis or human immunodeficiency virus. Other risk factors for hepatitis (e.g., needle sticks, hemodialysis, transplant, transfusion of blood products, or factor use) need to be evaluated. The physician should pursue possible exposure to industrial toxins or foods previously implicated in hepatic injury (e.g., carbon tetrachloride, yellow phosphorus, tannic acid, alcohol, mushrooms of the *Amanita* species). The emergency physician must inquire about use of acetaminophen, salicylates, nonsteroidal anti-inflammatory drugs, iron salts, erythromycin estolate, ceftriaxone, rifampin, nitrofurantoin, oxacillin, tetracycline, trimethoprim-sulfamethoxazole, ketoconazole, diphenylhydantoin, isoniazid, and chlorpromazine. The presence of prior episodes of jaundice, acholic stools, and/or abdominal pain may suggest an underlying disorder, predisposing the patient to obstruction of the biliary tree. Other historical points include the presence of fever, arthralgia, arthritis, conjunctivitis, rash, pruritus, vomiting,

diarrhea, weight loss, color of the urine, abnormal bruising or spontaneous bleeding, and changes in mental status.

An examination that focuses on ongoing physical signs of liver disease may result in greater accuracy in clinical evaluation of the older jaundiced patient. These signs include skin changes (spider angiomata, excoriations, palmar erythema) and peripheral edema. The abdominal examination should include observations of the venous pattern, presence of ascites, mass, or peritoneal irritation. There should be an estimation of liver size, contour, and tenderness, as well as an estimate of spleen size. The clinician should exclude cardiovascular dysfunctions such as hypoxemia, systemic venous congestion, and low cardiac output. Observations should be made of mental status and neuromuscular changes.

Patients with cystic fibrosis, α_1-antitrypsin deficiency, Wilson's disease, or inflammatory bowel disease tend to have symptoms that remit and relax. However, slow progression is the rule. Patients with α_1-antitrypsin deficiency may have onset of respiratory or hepatic complaints at any age. Similarly, infants who have failure to thrive from cystic fibrosis may develop obstruction at any age in the extrahepatic or intrahepatic ducts and, transiently or persistently, may exhibit jaundice. Patients with ulcerative colitis and Crohn's disease may become symptomatic intermittently with episodes of cholestasis. The degree of hepatic derangement and expression of neurologic abnormality is variable with Wilson's disease. Before the diagnosis is entertained, patients typically exhibit dysarthria, tremors, rigidity, or psychic disturbances. Rarely, younger patients without prodromal events have acute jaundice and hepatomegaly and progress to hepatic failure.

Biliary calculi and acute inflammation of the gallbladder are uncommon causes of conjugated hyperbilirubinemia in the pediatric population (Chapter 89). However, a subset of patients is predisposed to these complications. Cholelithiasis may complicate any of the hemolytic anemias, particularly in patients with sickle hemoglobinopathies. These patients have increased incidence of both liver and gallbladder disease. Liver or gallbladder dysfunction accounts for jaundice when more than 10% of an elevated bilirubin in a patient with sickle cell disease is conjugated. Cholecystitis may accompany a variety of acute focal infections, such as pneumonia or peritonitis, and may occur in the course of bacterial sepsis. In this event, shock and hyperpyrexia may divert the clinician from the deranged biliary system. In less severe cases, fever, nausea, vomiting, abdominal distension, and right upper quadrant pain are prominent features of cholecystitis. Right upper quadrant abdominal mass, pain, and jaundice constitute the classic triad in the diagnosis of choledochal cyst. The clinical recognition may be delayed until there is a complication, such as cholangitis. An acute, painful right upper quadrant mass associated with jaundice may also occur in the course of acute hydrops of the gallbladder from Kawasaki disease or systemic streptococcal infection.

In the previously healthy child, the most common cause of conjugated hyperbilirubinemia is acute hepatitis (Chapter 92). The illness may be abrupt in onset, with fever, urticaria, and arthralgia as primary manifestations. More often, the illness is insidious. Viral hepatitis is characterized by low-grade fever and gastrointestinal complaints such as anorexia, malaise, nausea, vomiting, and abdominal pain before the jaundice. Liver enlargement with hepatitis (A, B, C, and non-A, non-B, non-C), varicella, herpesvirus, Coxsackievirus, echovirus, Epstein-Barr virus, and adenovirus infection is inconstant. Hepatic tenderness is a more reliable finding. Rarely, ascites can accompany hepatitis virus infection. Splenomegaly is the rule with Epstein-Barr virus but is unusual with the other agents. On occasion, hepatitis may be associated with a distinctive erythematous papular eruption localized to the limbs (Gianotti-Crosti syndrome).

Toxic hepatitis, unlike viral hepatitis, does not have a prolonged prodrome. Acute nausea, vomiting, and malaise are followed in 1 to 2 days by alterations in mental status and deterioration of liver function. Most patients with toxic hepatitis will have an identifiable exogenous precipitant. Children with fulminant hepatic failure typically experience anorexia, nausea, vomiting, malaise, and fatigue—all symptoms indistinguishable from those expected with viral hepatitis. The patient's jaundice becomes more profound and vomiting becomes protracted. Hyperexcitability, mania, and subtle psychomotor abnormalities may be seen. Coagulopathy, ascites, and sudden decrease in liver size are often the prelude to the development of frank neuromuscular signs.

The objectives of the emergency physician are to render supportive care to those icteric patients with infectious and metabolic derangements and to identify those cases in which jaundice is caused by mechanical obstruction or hepatic failure. The impression based on a targeted history, physical examination, and clinical algorithms can be bolstered with the following laboratory examinations: complete blood cell count, platelet count, coagulation profile, prothrombin time, total and direct bilirubin, hepatic enzymes, alkaline phosphatase, electrolytes, blood urea nitrogen, and creatinine. Urinalysis, culture, and toxicologic screen should be considered. Chest and abdominal radiographs are indicated when there are pulmonary parenchymal complaints or significant abdominal findings. Other laboratory tests that are often available immediately and that may provide useful information in specific circumstances are serum ammonia, albumin, total protein, lipid profile, pH, and carbon dioxide. If available, abdominal sonography or computed tomography may be helpful occasionally. In no circumstance will results of several important blood and urine tests be of immediate use. Such studies, which are appropriate, include antinuclear antibody, α fetoprotein, and serum for bile acids, ceruloplasmin, protein electrophoretic pattern, polymerase chain reaction assays or serologic evidence of recent infection (e.g., Epstein-Barr virus, mycoplasmal or hepatitis profiles). Urinary analysis includes assessment of organic acids and copper. These investigations may be helpful, however, to the longitudinal caregiver who must maintain a vigilant watch over the jaundiced patient.

Children older than 8 weeks with conjugated hyperbilirubinemia should be admitted to the hospital at the time of their presentation in all cases in which life-threatening conditions may exist (Table 41.3). Inpatient treatment is also suggested when intravenous fluids are necessary to treat symptomatic hypoglycemia or electrolyte imbalance and when operative intervention may prove necessary. Icteric patients who have been diagnosed previously with confidence and who have exacerbation of their symptoms may require admission to reappraise their status. The physician may also be influenced to admit the patient when social factors or geographic barriers inhibit consistent observations. Admission is also indicated for

patients who require further diagnostic intervention, such as hepatobiliary scintigraphy, endoscopic retrograde cholangiopancreatography, or liver biopsy to arrive at a definitive diagnosis.

CHAPTER 42 ■ LIMP

SUSANNE KOST, MD, FAAP, FACEP

Limping is a common complaint in the pediatric acute care setting. A *limp* is defined as an alteration in the normal walking pattern for the child's age. The average child begins to walk between 12 and 18 months of age with a broad-based gait, gradually maturing into a normal (adult) gait pattern by the age of 3 years. Normal walking involves a complex integration of the nervous and musculoskeletal systems, yet it should appear smooth and effortless. A normal gait cycle can be divided into two phases: stance and swing. The stance phase, the time from the heel striking the ground to the toe leaving the ground, encompasses about 60% of the gait cycle. The swing phase involves a sequence of hip then knee flexion, followed by foot dorsiflexion and knee extension as the heel strikes the ground to begin the next cycle.

The causes of limping are numerous, ranging from trivial to life threatening, but most children who limp do so as a result of pain, weakness, or deformity. Pain results in an antalgic gait pattern with a shortened stance phase. The most common causes of a painful limp are trauma and infection. Neuromuscular disease may cause either spasticity (e.g., toe-walking) or weakness, which results in a steppage gait to compensate for weak ankle dorsiflexion. Ataxia may be interpreted by parents as a limp. The Trendelenburg gait, characterized by a pelvic tilt away from the affected hip, is common in congenital or acquired hip disorders. A vaulting gait may be seen in children with limb-length discrepancy or abnormal knee mobility. A stooped, shuffling gait is common in patients with pelvic or lower abdominal pain.

The evaluation of a child with a limp demands a thorough history and physical examination, using an age-based approach. Toddlers generally provide the greatest diagnostic challenge because a history of trauma may be unclear and the ability to describe or localize pain may be lacking. In all age groups, a detailed history of the circumstances surrounding the limp should be obtained, with focus on the issues of trauma, pain, and associated fever or systemic illness. The physical examination must be complete because limping may originate from abnormalities in any portion of the lower extremity, nervous system, abdomen, or genitourinary tract. The location of the pain may not represent the source of the pathology, for example, hip pain may be referred to the knee area. Laboratory and imaging studies should be tailored to the findings in the history and physical examination, keeping in mind an appropriate age-based differential diagnosis.

DIFFERENTIAL DIAGNOSIS

The extensive differential diagnosis of the child with a limp may be approached from several angles: disease category, location of pathology, or age of the child. Table 42.1 presents the differential diagnosis by disease category; Table 42.2 organizes the differential diagnosis by age and the location of pathology. The most common causes of limp are outlined in Table 42.3, and potentially life- or limb-threatening conditions are listed in Table 42.4. This section reviews the differential diagnosis within the framework of an algorithmic approach (Fig. 42.1).

The most common cause of limping in all ages is trauma, either acute or repetitive microtrauma (stress fractures). Older children who limp as a result of trauma can generally describe the mechanism of injury and localize pain well. The toddler and preschool age groups, with their limited verbal ability and cooperation skills, often provide a diagnostic challenge. A common type of injury in this population (often not witnessed) is the aptly named "toddler's fracture," a nondisplaced spiral fracture of the tibial shaft that occurs as a result of torsion of the foot relative to the tibia. Occult fractures of the bones in the foot also occur in young children. Initial plain radiographic findings may be subtle, or at times nonexistent, but will become apparent in 1 to 2 weeks. The advent of digital radiography has led to improved accuracy in the diagnosis of toddler's fracture. Bone scans will identify these lesions sooner. Another fracture often lacking initial radiographic confirmation is a Salter-Harris type I fracture, which presents as tenderness over a physis after trauma to a joint area. Stress fractures may also lack overt radiographic findings. Common sites for overuse injury include the tibial tubercle (Osgood-Schlatter's disease), the anterior tibia (shin splints), and the calcaneus at the insertion of the Achilles tendon (Sever's disease). More information on the subject of fractures is found in Chapter 114.

Trauma may also induce limping as a result of soft-tissue injury. Although young children are more likely to sustain fractures than sprains and strains, the latter can occur. Joint swelling and pain out of proportion to the history of injury raises the possibility of a hemarthrosis as the initial presentation of a bleeding disorder (see Chapter 91). Severe soft-tissue pain and swelling in the setting of a contusion or crush injury suggests compartment syndrome. With compartment syndrome, pain is exacerbated by passive extension of the affected part; pallor and pulselessness are late findings. Severe pain of an entire limb out of proportion to the history of injury suggests complex regional pain syndrome, formerly known as *reflex sympathetic dystrophy*. This entity is most common in young adolescent girls. It may be accompanied by mottling and coolness of the extremity, presumably as a result of abnormalities in the peripheral sympathetic nervous system.

A limp that is accompanied by a history of fever or recent systemic illness is likely to be infectious or inflammatory in origin. However, the absence of fever does not preclude the possibility of a bacterial bone or joint infection, and many infections

are preceded by a history of minor trauma. Septic arthritis is the most serious infectious cause of joint pain and limp. It is more common in younger children and typically presents with a warm, swollen joint (although swelling in the hip is very difficult to detect clinically). Exquisite pain with attempts to flex or extend the joint is characteristic of septic arthritis, and the degree of pain with motion serves as a helpful clinical sign in distinguishing bacterial joint infection from inflammatory conditions. A common diagnostic challenge is differentiating septic arthritis from transient (or toxic) synovitis in a young child with fever, limp, and pain localized to the hip. Transient synovitis, a postinfectious reactive arthritis, generally follows a milder course. It is usually preceded by a recent viral respiratory or gastrointestinal illness. Acute-phase reactants may be elevated in both conditions, although usually less so in synovitis. A unilateral joint effusion, which is better visualized with ultrasound than plain films, may be present in both. Bilateral effusions are more suggestive of an inflammatory synovitis. Doppler ultrasonography may reveal hyperemia of the femoral head in a septic hip, where increased flow would not be expected in synovitis. Orthopedic consultation for joint aspiration may be required for a definitive diagnosis because a septic hip is a surgical emergency requiring open drainage. Osteomyelitis is another potentially serious infectious cause of limp, although the presentation is typically more chronic than that of a septic joint. Osteomyelitis, which is also more common in younger children, presents with pain and occasionally warmth and swelling, usually over the metaphysis of a long bone. A reactive joint effusion may be present. Occasionally, osteomyelitis and septic arthritis will coexist. More detailed discussions of both septic joint and osteomyelitis are found in Chapters 92 and 125.

Rheumatic conditions that may result in limp are numerous; many are accompanied by systemic symptoms and characteristic skin rashes. Examples include Lyme disease, Henoch-Schönlein purpura, erythema multiforme, acute rheumatic fever, juvenile rheumatoid arthritis, and systemic lupus erythematosus. Occasionally, limping from arthralgia will precede the development of the arthritis and systemic involvement. An approach to the child with joint pain is found in Chapter 56, and a detailed discussion of arthritis is found in Chapter 101.

In the absence of obvious trauma, fever, or systemic symptoms, the next step in the approach to the differential diagnosis of a limp is to determine the focality of the findings and the degree of pain. Localized pain suggests repetitive microtrauma, bone tumor, or an acquired skeletal deformity. Repetitive microtrauma may be responsible for avascular necrosis of the foot bones in two locations: the tarsal navicular bone (Kohler's disease) in younger children and the metatarsal heads (Freiberg's disease) in adolescents. Both benign and malignant bone tumors may present with a painful limp. Benign lesions include bone cysts (unicameral or aneurysmal), fibrous dysplasia, and eosinophilic granulomas. Osteoid osteoma, caused by a painful nidus of vascular osteoid tissue, is another benign lesion unique to young people. The most common malignant pediatric bone tumors are osteogenic sarcoma and Ewing's sarcoma. Bone tumor pain may be acute or chronic, with acute pain usually related to a pathologic fracture. Examples of acquired skeletal abnormalities causing painful limp include tarsal coalition and osteochondritis dissecans. Tarsal coalition occurs as a result of gradual calcification of a congenital cartilaginous bar between tarsal bones; it presents most commonly as a painful flatfoot in school-age children. Osteochondritis dissecans is related to separation of articular cartilage from underlying bone; it most commonly affects the knees of adolescent boys.

Localized findings without pain suggest congenital or slowly developing acquired limb abnormalities. Three disorders of the hip fit into this category, each of which is characteristic of a specific age group. Developmental dysplasia of the hip includes a spectrum of abnormalities, ranging from mild dysplasia to frank dislocation. Most affected children with access to primary care are diagnosed with abnormal hip abduction on routine examination in infancy. Occasionally, the diagnosis will be missed, and the child then presents at the onset of walking with a painless short-leg limp, or waddling gait if bilateral, with weakness of the abductor musculature. Legg-Calvé-Perthes disease, an avascular necrosis of the capital femoral epiphysis, presents in young school-age children as an insidious limp with mild, activity-related pain. Slipped capital femoral epiphysis (SCFE) presents in young, typically obese, adolescents with an externally rotated limp. The amount of pain experienced is related to the rate of displacement of the epiphysis, ranging from none to severe. Legg-Calvé-Perthes disease and SCFE are more common in boys. Other acquired skeletal deformities that may cause painless limp include limb-length inequality, Blount's disease (with marked bowing of the proximal tibias), and torsional deformities. Baker's cyst of the

popliteal tendon may cause limping with minimal local discomfort.

Limping in the absence of localized limb findings suggests a systemic (or nonlimb) source such as the spine or the abdomen. A painful limp without localization or with migratory bone pain suggests a hematologic or oncologic cause, such as sickle cell disease or leukemia. Limping with bilateral leg pain localized to the muscles, especially the calves, suggests myositis. Benign acute childhood myositis is common during influenza epidemics. Recurrent diffuse aches after periods of vigorous activity, usually worse at night, suggest benign hypermobility syndrome or "growing pains." A painless, poorly localized limp may occur with metabolic bone disease (e.g., rickets). Spinal problems that can cause leg pain, weakness, or limp include dysraphism, vertebral infection, spondylolisthesis, and herniated disc. Spinal dysraphism refers to a spectrum of abnormalities in the development of the spinal cord and vertebrae ranging from obvious (myelomeningocele) to occult (tethered cord). Associated neurologic and musculoskeletal findings, including pain, atrophy, high arches, and tight heel cords, may develop in early childhood. Vertebral infection typically presents with fever and back pain. Spondylolisthesis and herniated disc are rare in young children but may be seen in adolescents who complain of back pain or radicular pain. Limp may rarely present as an early symptom of a peripheral neuropathy, either hereditary (e.g., Charcot-Marie-Tooth disease) or acquired (Guillan-Barre syndrome, vitamin- or medication-related). Intraabdominal pathology that can result in limp includes appendicitis, pelvic or psoas abscess, and renal disease. Solid tumors, most commonly neuroblastoma, can cause limp through retroperitoneal irritation or extension into the spinal canal. Likewise, a sacral teratoma may affect the nerves of the cauda equina or sacral plexus. Testicular pain may present with limping in a boy who is reluctant or embarrassed to admit the true source of his discomfort.

EVALUATION AND DECISION

The conditions that lead to a presentation of limp range from mundane (poorly fitting shoes) to life threatening (leukemia). The role of the pediatric acute care physician is to rule out the possibility of life- and limb-threatening pathologic conditions. The serious conditions include bacterial infection of the bone or joint space, malignancy, and disorders that threaten the blood supply to the bone, such as avascular necrosis and SCFE. Often, a definitive diagnosis will not be reached in the emergency department, and the patient will require follow-up with the primary care physician or specialist. Figure 42.1 provides an algorithmic approach to the child with a limp.

History

The history in a limping child should include information about the onset and duration of the limp, the family's perception of the origin of the problem, and associated symptoms such as pain, fever, and systemic illness. When pain is present, the physician should inquire about the location and severity. A history of trauma should be addressed, keeping in mind the inherent difficulty in obtaining an accurate trauma history in very young children. Conversely, obvious trauma in the absence of a consistent history raises the question of inflicted injury. In more chronic presentations, any cyclical or recurrent patterns should be noted. Stiffness and limp primarily in the morning suggest rheumatic disease, whereas evening symptoms suggest weakness or overuse injury. A history of joint or limb swelling should be investigated, with attention to the degree of swelling and any migratory or recurrent patterns.

The medical history should include birth and developmental history. Breech position is associated with developmental dysplasia of the hip, and mild cerebral palsy may present in childhood with abnormal gait. History of viral infections, streptococcal pharyngitis, medication use, and immunizations may provide clues to the cause of limping. A family history of rheumatic or autoimmune disease, neurologic disease, inflammatory bowel disease, hemoglobinopathy, or other bleeding disorders may help facilitate diagnosis. Finally, the review of systems should include questions about past trauma, infections, neoplasia, endocrine disease, metabolic disease, and congenital anomalies.

Physical Examination

The physical examination in a limping child should begin with observation of the child's gait. Ideally, the child should be observed walking in bare feet and wearing minimal clothing, preferably in a long hallway. The physician should attempt to observe the child unobtrusively to avoid gait changes caused by self-consciousness. The observer should note the symmetry of stride length, the proportion of the gait cycle spent in stance phase, hip abductor muscle strength (with abnormal strength manifested by Trendelenburg or waddling gait), in-toeing or out-toeing, and joint flexibility. Muscle strength may be tested by asking the child to run, hop, and walk on toes and heels.

After observing the child in action, the physician should perform a complete examination with attention to the musculoskeletal and neurologic systems. The musculoskeletal examination begins with inspection of the limbs and feet for swelling or deformity. Supine positioning with the leg slightly flexed, abducted, and externally rotated at the hip is suggestive of fluid in the joint capsule. The spine should be inspected for curvature, both standing and bending forward, and the soles of feet and toes should be checked for foreign bodies and calluses. The bones, muscles, and joints should be palpated for areas of tenderness; range of motion of all joints should be checked; and limb lengths (from anterior superior iliac spine to medial malleolus), as well as thigh and calf circumferences, should be measured for asymmetry. The neurologic examination should include inspection of the spine for lumbosacral hair or dimple (indicating possible spinal dysraphism), and testing of strength, sensation, and reflexes. The abdomen and external genitalia should be examined for tenderness or masses and the skin for rashes. A rectal examination may be indicated if sacral pathology is suspected. Finally, wear patterns on the child's shoes may provide clues to the nature and duration of the limp.

Laboratory and Imaging

Plain radiographs remain a mainstay of the workup of a limping child. They provide an excellent means of screening for

fracture, effusion, lytic lesions, periosteal reaction, and avascular necrosis. In a child with an obvious focus of pain, the radiographs may be obtained with views specific to that area, noting that children with knee pain may have hip pathology. The need for comparative views (of the normal extremity) depends on the experience of the physician interpreting the films. Some radiographic findings can be subtle, and comparison with the opposite side may be helpful. In a young child or a child lacking obvious focus for the limp, anteroposterior and lateral views of both lower extremities (including the feet) should be ordered as an initial screen. In toddlers lacking a focus of pain and in older children in whom hip pathology is suspected, anteroposterior and frog-leg lateral views of the pelvis are required. The frog-leg lateral view, obtained with the hips abducted and externally rotated, allows excellent visualization of the femoral heads. These radiographs should always include both hips to enable comparison of the femoral heads and width of the joint spaces. Radiographs of the spine are necessary if the child has neurologic signs or symptoms.

In children whose limp is associated with fever or systemic illness, laboratory studies, including a complete blood cell count, C-reactive protein level, and an erythrocyte sedimentation rate, are indicated. An elevated C-reactive protein level is a better independent predictor of disease than is an elevated erythrocyte sedimentation rate, and a C-reactive protein level of more than 2.0 mg per dL (20 mg per L) is strongly suggestive of bacterial infection. These studies serve as screens for infection, inflammation, malignancy, and hemoglobinopathy. Laboratory studies are also indicated in the absence of fever if the child has been limping for several days without evidence of trauma on plain films. Children with evidence of infection or inflammation with a joint effusion may require arthrocentesis for definitive diagnosis. In areas of endemic Lyme disease, a Lyme titer is a reasonable initial screening test in a patient with arthritis. A creatine phosphokinase level may be helpful if muscle inflammation is suspected.

When the initial history, physical examination, imaging, and laboratory evaluation indicate the cause of the limp, specific treatment can be initiated. Abnormalities in the initial workup without a definitive diagnosis should prompt further imaging or laboratory studies. Bone scintigraphy is more sensitive than plain radiographs for occult fracture, infection, avascular necrosis, and tumor; however, it is not specific for a given pathologic process. Computed tomography is an excellent imaging modality for cortical bone; it serves as a useful diagnostic adjunct in certain fractures, bony coalitions, and bone tumors. Ultrasound is the preferred modality for diagnosing hip effusions; it is also useful for guiding needle aspirations of the hip joint. Magnetic resonance imaging is useful in imaging the spinal cord, avascular necrosis, and bone marrow disease. Magnetic resonance imaging is becoming increasingly useful in the evaluation of infectious and oncologic musculoskeletal abnormalities as well, as an adjunct to bone scintigraphy or in place of it when the site of pathology is well localized.

If the initial workup in a limping child is completely normal, including screening radiographs and laboratory studies, the child may be followed closely as an outpatient. The child should be examined every few days until improvement is noted or a cause is determined. If the limp persists beyond 1 to 2 weeks without a diagnosis, further workup or consultation with a specialist is indicated.

CHAPTER 43 ■ LYMPHADENOPATHY

RICHARD MALLEY, MD

Lymphadenopathy is defined as swelling of the lymph nodes. Swollen lymph nodes are a common presenting sign in children, mainly because children have more pronounced lymphoid responses to inflammation than adults do, and they also have relatively more lymphoid tissue. Because the differential diagnosis of lymphadenopathy is extensive, it is helpful to distinguish localized from generalized lymphadenopathy. *Localized* or *regional adenopathy* generally occurs in response to a focal infectious process, although rarely other causes may need to be considered. Because a large number of organisms can cause localized adenopathy, it is often helpful to differentiate between acute and subacute/chronic regional adenopathy. *Generalized lymphadenopathy* is defined as enlargement of more than two noncontiguous lymph node regions. The most common causes of generalized adenopathy are systemic infections (bacterial or viral), autoimmune diseases, and neoplastic processes.

DIFFERENTIAL DIAGNOSIS

Acute Regional Adenopathy

The clinician caring for a child with acute regional adenopathy will benefit from knowledge of the anatomic distribution of nodes in the area and their drainage areas, as described in Table 43.1. The location of lymphadenopathy is often suggestive of a possible cause. For instance, in the head and neck region, swollen nodes are often a response to focal infectious processes occurring in areas that drain in the region of the nodes. Occipital nodes most commonly enlarge in response to bacterial or fungal scalp infections or chronic inflammation, such as occurs in seborrheic dermatitis. Because preauricular nodes drain the conjunctiva and lateral eyelids, these often enlarge in viral conjunctivitis. Epidemic keratoconjunctivitis caused by adenoviruses often presents with an enlarged preauricular node. The combination of conjunctivitis and ipsilateral preauricular adenopathy is called oculoglandular syndrome, or Parinaud's syndrome. Another infection that can present as Parinaud's syndrome is chlamydial conjunctivitis, also called neonatal-inclusion conjunctivitis. Chlamydial conjunctivitis, which generally presents within 5 to 7 days after birth, is diagnosed by the finding of intracytoplasmic inclusion bodies in conjunctival scrapings or, more commonly, by detection of the pathogen by immunofluorescent staining of ocular secretions. Parinaud's syndrome is also occasionally seen in cat-scratch disease, tularemia, and listeriosis. Similarly, the presence of submaxillary and submental nodes indicates the possibility of an infectious process in the oral cavity. Therefore, the physician should perform a careful oral and dental examination in these cases. Dental abscesses or gingival infections may be responsible for lymphadenopathy in these regions.

The differential diagnosis of cervical adenopathy is more extensive, mainly because the anatomy of the region is more complex. As can be seen in Table 43.1, nodes in the cervical region can be divided into three areas: the superior deep nodes below the angle of the mandible, the superficial cervical nodes found anteriorly and posteriorly along the sternocleidomastoid muscle, and the inferior deep nodes at the base of the neck. Enlargement of superior deep or superficial nodes raises the possibility of a lingual, external ear, or parotid gland process. In contrast, the inferior deep nodes have a much wider drainage area, including the head and neck, upper extremities, and the thoracic and abdominal regions. Swelling of these nodes, in particular, scalene and supraclavicular nodes, can be the first sign of occult thoracic or abdominal pathology, such as malignancy. Therefore, nodes found in these regions must be investigated carefully, with thorough physical examinations and, if necessary, radiographic examinations.

By far, the most common cause of acute cervical adenopathy is a viral upper respiratory tract infection. In these cases, lymph nodes are generally symmetrically enlarged and are soft and minimally tender, if at all. The reactive adenopathy may persist for 2 to 3 weeks beyond the resolution of the viral illness, but there should be no progression in the size or extent of the adenopathy. Bacterial cervical adenitis is also a common cause of cervical lymphadenopathy in children, particularly in preschool-age children. It is usually caused by group A β-hemolytic *Streptococcus* or *Staphylococcus aureus* (including methicillin-resistant *S. aureus*), although anaerobes (routinely penicillin-sensitive) may also be involved, particularly in oral infections. A history of a sore throat may be present in a minority of patients. Bacterial adenitis is most often unilateral and presents with firm, tender, and warm lymph nodes. In addition to the cervical area, other common sites of involvement include submaxillary, inguinal, and axillary nodes. If left untreated, these nodes may become erythematous and eventually fluctuant. Drainage of the nodes is sometimes required, even in appropriately treated cases (see Chapter 92).

Epstein-Barr virus (EBV), the agent of infectious mononucleosis, commonly causes posterior cervical lymphadenopathy in older children and adolescents. EBV infections do not always cause generalized adenopathy. The classic presentation of a child with EBV includes malaise, fever, an exudative tonsillopharyngitis, and hepatosplenomegaly. Facial edema may accompany significant EBV adenopathy, presumably reflecting obstructed lymph drainage. Younger children and infants with EBV infection may present less typically with fever alone or with symptoms suggestive of a mild upper respiratory infection. The diagnosis is made most easily with the detection of a

Popliteal	Knee joint Skin of lower leg/foot	Severe local infection	

positive heterophile-agglutinating antibody (e.g., Monospot), although it is important to remember that this test may be falsely negative in children younger than 7 years.

A rarer, but very important, cause of acute cervical lymphadenopathy is Kawasaki disease, a systemic febrile syndrome of as yet undefined cause (see Chapter 101). Kawasaki disease, also called *mucocutaneous lymph node syndrome*, occurs most often in children younger than 4 years and is rare after 8 years of age. It is important to diagnose Kawasaki disease early because prompt treatment with intravenous gamma

globulin can prevent coronary artery aneurysms, the most serious complication of this illness. The cervical lymphadenopathy in Kawasaki disease, seen in approximately 50% to 70% of patients, occurs during the early phase of the illness and may be unilateral or bilateral. The nodes are firm and mildly tender and should be at least 1.5 cm in diameter. The presence of a large node in the cervical area, in association with fever of more than 5 days' duration, bilateral conjunctival injection with limbal sparing, mucous membrane involvement, peripheral edema or erythema, and a polymorphous truncal rash, should alert the physician to the possibility of this disorder.

Axillary adenopathy is commonly present with any infection or inflammation of the upper extremities. Most commonly, injuries to the hand, such as occur after falling or with puncture wounds or bites, may present with concomitant axillary adenopathy. Similarly, epitrochlear nodes, which are not normally palpable in children, may become inflamed after infections of the third, fourth, or fifth finger; medial portion of the hand; or ulnar portion of the forearm. Most commonly, these infections are caused by pyogenic bacteria (e.g., *S. pyogenes, S. aureus*), but depending on the inciting event, other pathogens may be responsible (e.g., *S. moniliformis* and *Spirillum minus* in rat-bite fever).

Inguinal adenopathy most often results from lower-extremity infection, although sexually transmitted diseases may also be responsible. For example, acute genital infection with herpes simplex virus-2 often presents with tender inguinal adenopathy, occasionally as the only sign. Similarly, chancroid, lymphogranuloma venereum, and syphilis may present with inguinal nodal swelling and tenderness. The presence of genital lesions, which may be either painful (as in herpes simplex virus or chancroid) or painless (as in syphilis), offers clues to these diagnoses. Therefore, careful history-taking and physical examination are necessary to exclude these possibilities. Enlarged iliac nodes are palpable deeply over the inguinal ligament and become inflamed with lower-extremity infection, urinary tract infection, abdominal trauma, and appendicitis. Of note, iliac adenitis, which can present with fever, limp, and inability to fully extend the leg, may mimic the signs and symptoms of septic hip arthritis. Unlike in hip disease, however, hip motion is not limited on examination. Iliac adenitis may also be confused with appendicitis, but the pain initially occurs in the thigh and hip rather than in the periumbilical region or right lower quadrant.

Chronic Regional Adenopathy

Numerous agents can cause chronic regional lymphadenopathy. Organisms such as *Bartonella henselae* (the etiologic agent of cat-scratch disease), mycobacteria, and atypical mycobacteria are most commonly responsible for chronic adenopathy. Cat-scratch disease is a relatively common cause of chronic axillary or cervical adenopathy (see Chapter 92). Cat-scratch disease is characterized by a history of exposure to kittens (although other animals have also been implicated) and the development of a primary lesion at the site of a scratch. The primary lesion is 2 to 5 mm in size and is typically papular initially, and it may then progress to a pustule. About 2 weeks later, lymphadenopathy develops proximal to the site of the lesion. Typically, the nodes are enlarged but may or may not be inflamed. Lymphangitis does not occur in cat-scratch disease. Fever is present in only about 30% of patients. Other symptoms, such as seizures, may occur but are rare. Although histopathology may be helpful in diagnosing cat-scratch disease, the most reliable diagnostic method is serology.

Tuberculous cervical lymphadenitis, otherwise known as *scrofula*, most commonly involves the posterior cervical nodes. Scrofula has become less common in the United States, although more recent epidemiologic studies in this country have suggested that the incidence of tuberculosis is rising. A history of exposure to an individual with active tuberculosis is often elicited, and several family members may have positive results on skin tests. Pulmonary and other systemic symptoms, such as fever, fatigue, and weight loss, are often present. The affected nodes are typically bilateral, fixed, and matted. Fluctuance is a late and rare finding in tuberculous adenitis. The diagnosis of tuberculous cervical lymphadenitis is made by a combination of skin testing, chest radiographs, and if possible, culture data from the involved node.

In contrast, atypical mycobacterial adenitis usually involves children younger than 5 years and is generally unilateral. The node is rarely larger than 3 cm. Overlying skin may turn a deep purple and gradually thins, developing a parchment-paper appearance. Fluctuance and ulceration occur commonly. Infected patients generally appear well, with a notable absence of any systemic symptoms. Chest radiographs are normal. A clear history of exposure to atypical mycobacteria (e.g., acquiring the infection via a fish tank) is the exception rather than the rule. Formal diagnosis is made by culture of the infected node, although the clinical appearance of the lesion and careful physical examination will often lead the clinician to the correct diagnosis. Treatment generally involves excision of the node, although, more recently, reports of treatment with newer macrolides suggest a possible role for antimicrobial therapy of these infections.

Other less common causes of chronic adenopathy deserve mention. A prolonged heterophile-negative adenopathy unresponsive to a trial of antibiotics should raise suspicion for one of these possibilities. Cytomegalovirus infection, which is characterized by cervical adenopathy, pharyngitis, and atypical lymphocytosis, may cause prolonged adenopathy in younger children. Toxoplasmosis typically presents as a single, nontender posterior cervical node. Brucellosis, associated generally with axillary and cervical lymphadenopathy, and tularemia with cervical adenopathy, are rare infectious causes of chronic adenopathy in children.

Noninfectious etiologies may also cause chronic regional adenopathy. Various malignancies, such as Hodgkin's disease, lymphosarcoma, neuroblastoma, and rhabdomyosarcoma, may all present with chronic cervical lymphadenopathy (see Chapter 97). For example, Hodgkin's disease usually presents as a slowly growing, painless firm node in the upper third of the neck. Lymphosarcoma also presents as a firm painless node, but it occurs in children younger than those with Hodgkin's and more commonly involves extranodal sites such as the tonsils. Rhabdomyosarcoma, the most common solid tumor of the head and neck in children, often involves the nasopharynx, middle ear, mastoid, or orbit, but it can also occur as a painless mass anywhere in the head and neck.

In African American children, sarcoidosis must be entertained in a child with bilateral chronic cervical adenopathy. Scalene nodes are involved in more than 80% of cases. An abnormal chest film, with hilar adenopathy and peribronchial fibrosis, suggests sarcoidosis. Sinus histiocytosis, a benign form of histiocytosis, can present as a large painless cervical adenopathy. The clinical presentation often includes fever,

anemia, leukocytosis, and elevated erythrocyte sedimentation rate. Although the initial clinical presentation may be confused with lymphoma, the disease usually has a benign course, with resolution over a prolonged period.

Generalized Lymphadenopathy

Various systemic illnesses are associated with generalized lymphadenopathy (Table 43.2). The most common causes of generalized lymphadenopathy include bacterial or viral illnesses that disseminate systemically. As an example, the high incidence of vomiting and abdominal pain in streptococcal pharyngitis has been attributed to abdominal node inflammation and swelling, suggesting a more systemic pattern of adenopathy in streptococcal disease. Rarer bacterial causes of generalized lymphadenopathy include bacterial illnesses such as brucellosis and leptospirosis, diagnoses that may be suggested by occupational or dietary history. Common viral causes of generalized adenopathy include EBV or cytomegalovirus mononucleosis, rubella, and measles in parts of the world where the disease is endemic. Another cause of generalized adenopathy includes human immunodeficiency virus (HIV) infection. HIV infection in children can present with persistent generalized adenopathy, hepatosplenomegaly, and failure to thrive. Generalized lymphadenopathy may occasionally be the only presenting symptom in a child with vertical HIV infection.

Noninfectious systemic disease may also present with generalized adenopathy. Approximately 70% of patients with systemic lupus erythematosus or juvenile idiopathic arthritis manifest generalized adenopathy during the acute phase of illness (see Chapter 101). The lymphadenopathy of serum sickness often occurs in the presence of the exanthem but may be seen without rash. The lymphadenopathy of autoimmune hemolytic anemia coincides with each episode of hemolysis.

Neoplastic disease that causes generalized adenopathy may be primary to the lymph node as in Hodgkin's and non-Hodgkin's lymphomas, or it may be metastatic to the node with invasion of the node by extrinsic malignant cells as in leukemia or neuroblastoma (see Chapter 97). Hodgkin's disease, as discussed previously under "Regional Adenopathy", usually manifests as cervical adenopathy. In contrast, non-Hodgkin's lymphoma may present with rapidly enlarging, diffuse adenopathy, often accompanied by abdominal pain, vomiting, and diarrhea secondary to abdominal node involvement. Another neoplastic condition that can present with generalized adenopathy is leukemia. Approximately 70% of patients with acute lymphocytic leukemia and 30% of patients with acute myelogenous leukemia have generalized adenopathy (see Chapter 97). These children usually appear ill, having other systemic signs—hepatosplenomegaly, anemia, and thrombocytopenia with petechiae, purpura, and hemorrhage.

Histiocytosis presents as a spectrum of disease, ranging from a benign, isolated eosinophilic granuloma found in a long bone of an older child to the malignant multiorgan histiocytic infiltration found in infants with Letterer-Siwe disease (see Chapter 97). Lymphadenopathy often occurs in histiocytosis and can be an isolated finding; however, it usually occurs in association with other manifestations of disease.

Rarer causes of systemic adenopathy include lipid storage diseases (Gaucher's and Niemann-Pick's diseases), which can cause diffuse adenopathy, and are almost always associated with hepatosplenomegaly. Bone marrow biopsy, showing lipid-laden histiocytes, is diagnostic.

Certain drugs can be associated with generalized adenopathy. Drug-induced hypersensitivity syndrome deserves particular attention because it has been associated with rather severe

- **Drugs**
  - Aromatic antiepileptics: phenytoin, phenobarbital, carbamazepine, primidone
  - Other antiepileptic agents: lamotrigine, valproic acid, ethosuximide
  - Antibiotics: isoniazid, dapsone, sulfonamides, minocycline
  - Others
    - Allopurinol
    - Diltiazem
    - Zalcitabine
- **Miscellaneous**
  - Hyperthyroidism

presentations, some of which have been fatal. This syndrome is generally, but not always, associated with aromatic anticonvulsants such as phenytoin, phenobarbital, and carbamazepine, but newer antiepileptic and other drugs have also been reported to cause this syndrome (Table 43.2). The aromatic antiepileptic agents have a common benzene ring that is metabolized to arene oxides. It is postulated that anticonvulsant hypersensitivity syndrome occurs in patients who may have a defect in the epoxide hydrolase enzymatic pathway, which normally degrades the toxic arene oxide metabolites formed during oxidation of the antiepileptics. It is important to remember that a patient with a history of a hypersensitivity reaction to one anticonvulsant drug may be at high risk for an even more severe reaction if exposed to another anticonvulsant drug. Although this syndrome can occasionally present with lymphadenopathy alone (which may not even be generalized), the characteristic features generally progress to include fever, rash, and organ involvement (e.g., liver, bone marrow, kidney, and lungs). Beyond cessation of the drug and provision of supportive care, the optimal therapy for this condition is not established at this time, although some have proposed the use of systemic corticosteroids and/or intravenous immune globulin.

Finally, hyperthyroidism can be associated with a nonspecific lymph node hyperplasia, but one should see other signs and symptoms of the illness, such as tachycardia, hypertension, diaphoresis, weight loss, goiter, lid lag, and hyperreflexia, on physical examination.

Life-Threatening Lymphadenopathy

Several disorders associated with lymphadenopathy, primarily but not exclusively oncologic, can be life threatening (Table 43.3). The superior vena cava (SVC) syndrome is an example of life-threatening adenopathy. The SVC is a thin-walled vessel with low intravascular pressure that is approximated tightly to the right mainstem bronchus and completely encircled by the lymph nodes that drain the thoracic cavity. SVC syndrome is obstruction of the SVC, usually caused by massive adenopathy, and manifests as dilated chest wall and neck veins, facial edema, and plethora. Drowsiness or stupor, called "wet brain" syndrome, may also be seen. Superior mediastinal syndrome is a variant of the SVC syndrome, with additional respiratory symptoms caused by trachea or bronchus compression. In contrast with patients with SVC syndrome, those with superior mediastinal syndrome present in respiratory distress with coughing and wheezing.

TABLE 43.3

LIFE-THREATENING CONDITIONS ASSOCIATED WITH LYMPHADENOPATHY

Superior vena cava syndrome	Acute myelogenous leukemia
Hodgkin's disease	Neuroblastoma
Non-Hodgkin's lymphoma	Letterer-Siwe disease
Neuroblastoma	Coronary artery aneurysm
Bone marrow failure/ multiorgan infiltration	Kawasaki disease
Acute lymphocytic leukemia	Drug-induced hypersensitivity syndrome

Almost all patients with SVC or superior mediastinal syndrome have a malignant etiology (see Chapter 97). In children, Hodgkin's and non-Hodgkin's lymphomas are the most common causes, followed by metastatic neuroblastoma. Emergency physicians who treat patients with SVC syndrome must be careful to administer all intravenous therapy in the lower extremities. Poor circulation in the upper extremities and torso because of SVC obstruction results in poor drug distribution and places the patient with SVC syndrome at increased risk of thrombus formation.

EVALUATION AND DECISION

The clinician who evaluates lymphadenopathy is faced with an extensive differential diagnosis. A meticulous history and physical examination can help focus the evaluation of the patient. Historical data that need to be obtained include the time of onset, the rate of growth, and the duration of symptoms. Lymphadenopathy of more than 3 weeks' duration is considered chronic. The presence and duration of fever, history of rash or pruritus, cough, weight loss, anorexia, and nausea are important systemic symptoms. Recent illnesses must be considered, particularly because lymphadenopathy may persist for 2 to 3 weeks after the resolution of common viral illnesses. Certain medications, most notably the aromatic anticonvulsants and other drugs listed in Table 43.2, can cause generalized lymphadenopathy and must be kept in mind because of the potential severity of hypersensitivity reactions. In addition, the presence of certain risk factors, such as young cats in the home (cat-scratch disease) or other animals (e.g., dogs, rabbits, rats), exposure to patients with active tuberculosis, consumption of unpasteurized milk, or exposure to fish tanks (atypical mycobacteria), among others, needs to be ascertained. Finally, the clinician must ask whether any prior treatment, such as antibiotic therapy or attempted aspiration with cultures, has been initiated. For example, children with atypical mycobacterial adenitis may present to the emergency department after a prolonged course of antistaphylococcal antibiotic therapy failed to reduce the size of the node. Knowledge of the response to specific antimicrobial therapy can often guide the physician to exclude certain diagnoses.

The physical examination should include a careful determination of the size of the enlarged nodes and documentation of the number of nodes involved to provide an adequate baseline for follow-up. In general, lymph nodes larger than 1 cm are significant in any location. The presence of erythema, warmth, and tenderness often indicates an acute pyogenic bacterial process. In most disease processes that cause lymphadenopathy in children, the nodes will be firm, rubbery, and mobile. Lymph nodes fixed to underlying tissues or located in deeper fascial planes are rare in children, but when present, they should prompt the physician to consider early surgical evaluation. Finally, because several systemic diseases manifest a specific pattern of adenopathy, examination of all lymph node regions must be performed. Likewise, hepatosplenomegaly, rash, and other signs of systemic involvement must be sought.

The approach to the patient with lymphadenopathy focuses initially on the history and examination findings as noted, with emphasis on the distribution of enlarged nodes: regional or generalized (Fig. 43.1). Regional lymphadenopathy should be categorized as acute or subacute/chronic.

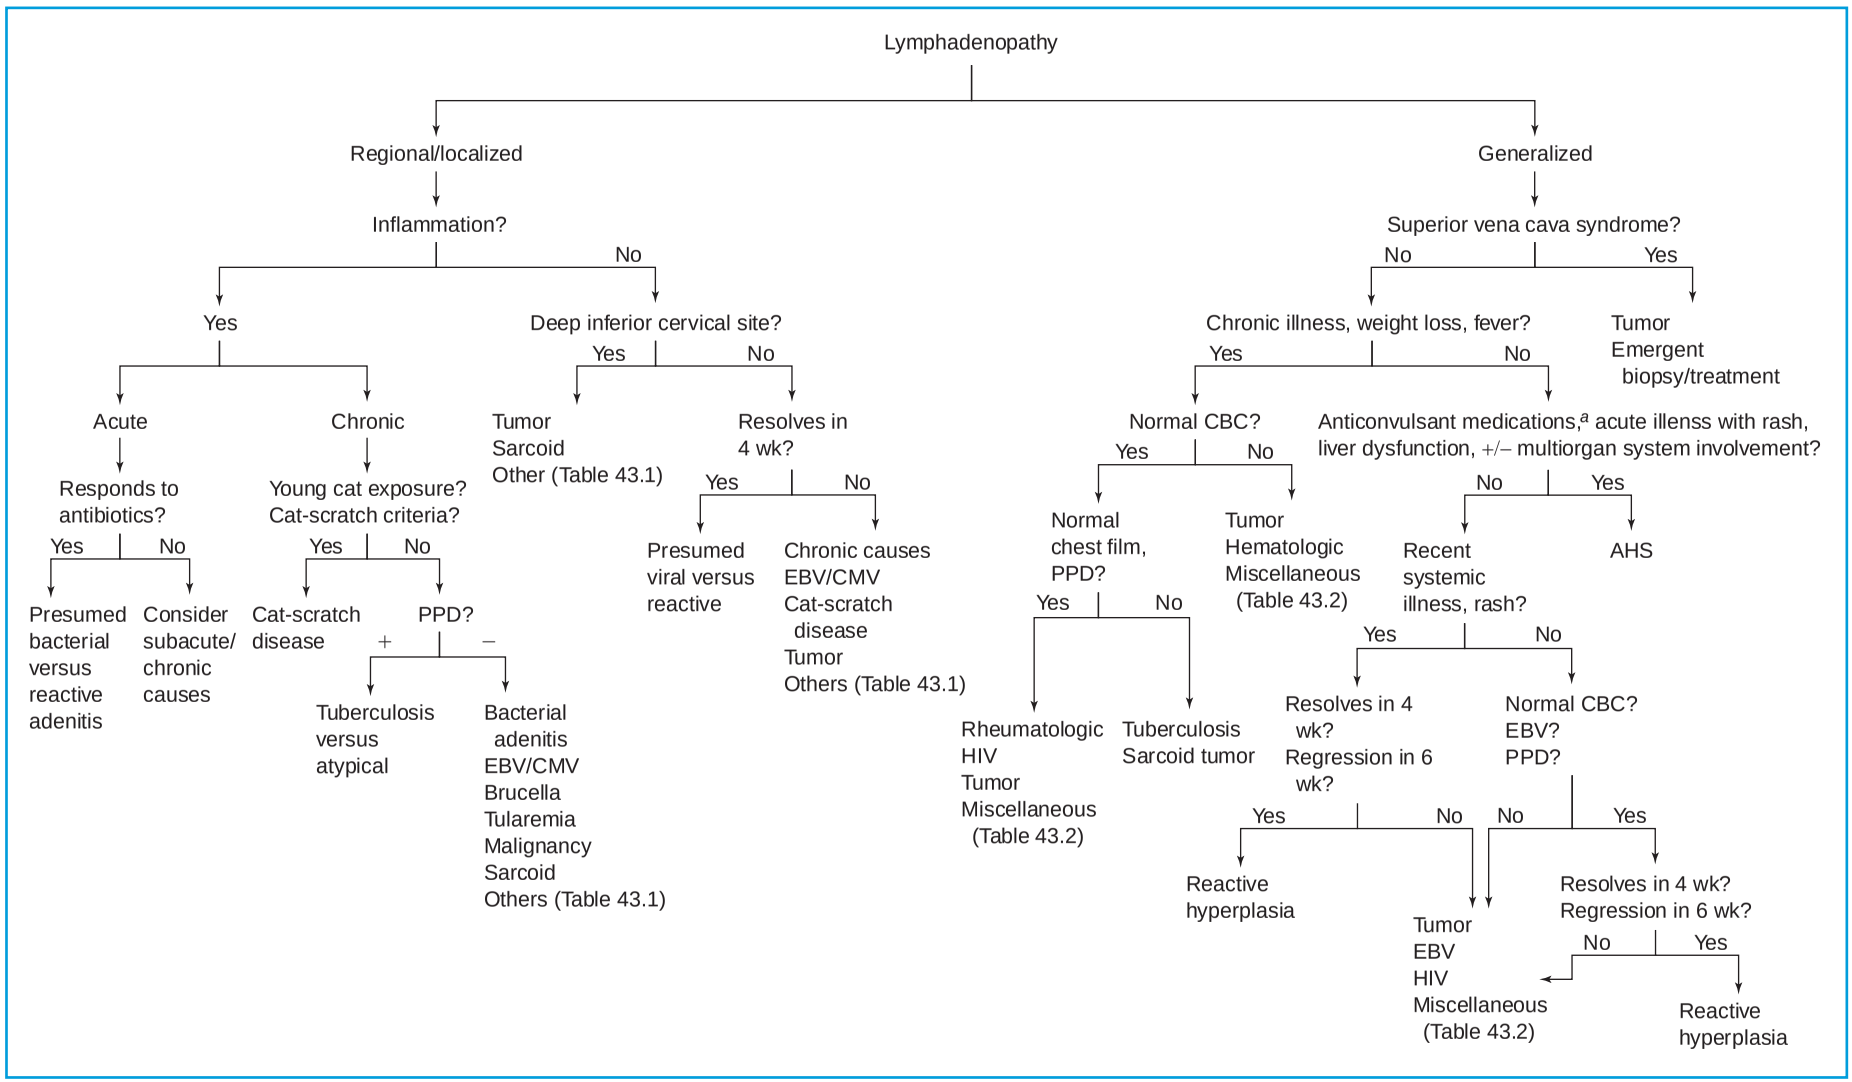

FIGURE 43.1 The diagnostic approach to the child with lymphadenopathy. [a]Rarely, other drugs may cause AHS (Table 43.2). PPD, purified protein derivative; EBV, Epstein-Barr virus; CMV, cytomegalovirus; CBC, complete blood cell count; HIV, human immunodeficiency virus; AHS, anticonvulsant hypersensitivity syndrome.

The most common causes of acute regional lymphadenopathy include reactive hyperplasia, acute bacterial adenitis, and EBV infection (infectious mononucleosis). Findings of acute inflammation, such as erythema and tenderness, indicate bacterial adenitis. The emergency physician must decide whether the patient would benefit from aspiration and drainage of the lymph node, particularly if the lesion is fluctuant and easily amenable to the procedure. Bedside ultrasonography may also help to differentiate those nodes with a purulent collection. Treatment of acute bacterial adenitis should include antistaphylococcal (including coverage of methicillin-resistant *S aureus*) and antistreptococcal antibiotics as well as careful follow-up. It is important to note and inform the patient's parents that these infections often are slow to resolve and may eventually require incision and drainage, despite adequate antimicrobial therapy (see Chapter 92).

The presence of systemic symptoms may suggest other causes of acute regional adenopathy. For example, the presence of pharyngitis, hepatosplenomegaly, and periorbital edema should suggest EBV infection. In the absence of any respiratory compromise, the treatment of EBV infection is supportive. Several days of high fever, rash, and swelling of the extremities in the presence of a large node should alert the physician to the possibility of Kawasaki disease. Early identification of these patients is essential in preventing serious sequelae of this disease. Therefore, a low index of suspicion for Kawasaki disease is prudent.

The evaluation of subacute or chronic regional adenopathy includes consideration of various infectious and noninfectious causes. Exposure to cats should alert the physician to the possibility of cat-scratch disease. The possibility of tuberculosis or atypical mycobacteria can be evaluated by placing a positive purified protein derivative test on the patient or can be elicited by a history of exposure to a patient with active tuberculosis. Malignancies and chronic systemic disorders (sarcoid) are less common causes of subacute or chronic regional adenopathy. Either the location (e.g., supraclavicular) or persistence of the node indicates a neoplastic disease or another serious process.

The evaluation of generalized lymphadenopathy involves consideration of systemic diseases that may be associated with adenopathy. The presence of systemic signs of illness, such as weight loss and fever, may be seen in subacute bacterial endocarditis, HIV, tuberculosis, brucellosis, and syphilis. A recent, brief febrile illness, at times with a rash, is characteristic of EBV, tuberculosis, mononucleosis, or acute HIV infection. Signs of toxicity suggest less commonly encountered causes (tumors, collagen vascular disease, sarcoid). In the absence of toxicity, and particularly if the adenopathy begins to resolve within 4 weeks of presentation, the diagnosis of reactive hyperplasia is most likely.

The decision to perform a biopsy on an enlarged node remains a clinical one. In general, early node biopsy should be considered in all neonates with lymphadenopathy and in older children who are ill with systemic symptoms, persistent fever, or weight loss. Deep inferior cervical or supraclavicular adenopathy with or without an abnormal chest film showing hilar adenopathy should be aggressively pursued with biopsy. Beyond this, in the face of an otherwise negative diagnostic workup that included a complete blood cell count, tuberculosis skin test, EBV heterophile, and chest film, serial measurement over a period of weeks showing progressive or rapid enlargement of the affected node raises suspicion for malignant disease and biopsy should be strongly considered. Biopsy should also be considered if an enlarged node fails to regress in size after approximately 6 weeks of observation.

CHAPTER 44 ■ NECK MASS

CARLA MARIA PRUDEN, MD, MPH, AND CONSTANCE M. MCANENEY, MD, MS

Neck masses are common in children, and the diagnosis encompasses a multitude of disorders. By definition, neck masses include any visible swelling that disturbs the normal contour of the neck between the shoulder and the angle of the jaw. The patient's age and the location of the neck mass are important in determining the differential diagnosis. In the pediatric population, the four basic classifications of neck lesions are inflammatory, congenital, traumatic, and neoplastic. Inflammatory masses are the most common and usually represent structures normally present, such as lymph nodes, that are undergoing changes from infectious causes. By far, the most common causes of neck masses in children are reactive adenopathy and adenitis. Congenital anatomic defects of the neck are often unapparent or minimally recognizable at birth, but they develop into significant cystic masses over time. Included in this category are cystic hygromas, branchial cleft cysts, hemangiomas, thyroglossal duct cysts, and dermoids. Traumatic neck masses are usually caused by hematoma surrounding vital structures and may lead to significant distress. Malignant lesions of the head and neck must be ruled out, but fortunately, they are fairly uncommon and are often caused by cancer of the lymphatic system. Therefore, an organized thorough history and examination of the head and neck, as well as a working understanding of the embryology of the neck, is important to assist in an appropriate workup to facilitate diagnosis and treatment.

True medical emergencies arise if neck masses compromise adjacent vital structures, including the airway, carotid and jugular blood vessels, and cervical spinal cord. In rare cases, the principal threat to life is from systemic toxicity. Infection that leads to septicemia, or the effects of excess hormone secretion in thyroid storm, can lead to uncompensated shock. Most large neck masses do not encroach on vital structures because their growth points outward. Embarrassment about personal appearance or a concern of malignancy may be factors, however, in the initiation of the emergency department (ED) visit.

This chapter first emphasizes recognition of masses that represent true emergencies (Table 44.1). Then, the approach to nonemergent but commonly seen lesions is described (Table 44.2). Table 44.3 lists causes of neck masses of children by origin.

EVALUATION AND DECISION

The initial history and physical examination should screen rapidly for airway or vascular compromise with consideration of integrity of the cervical spine. The presence of stridor, hoarseness, dysphagia, and drooling indicates respiratory compromise. The quality of breathing, level of consciousness, and integrity of the cervical spine should also be assessed. Appropriate resuscitative measures should be taken if respiratory or vascular compromise is evident. The cervical spine should be immobilized if there is history of trauma or if the initial evaluation leads to suspicion. Table 44.1 lists disorders that constitute true emergencies because of local pressure on vital structures or because of systemic toxicity.

Child with Neck Mass and Respiratory Distress or Systemic Toxicity

Trauma from vehicular collisions, falls from heights, or sports injuries may cause bleeding or hematoma formation near vital structures such as the carotid artery or trachea. If the trauma involves the cervical spine, a hematoma may occur over fractured vertebrae. Even mild injuries may lead to severe hemorrhage and compression of vital structures of the neck in children who have clotting factor disorders (i.e., hemophilia) or platelet disorders (i.e., idiopathic thrombocytopenic purpura). Symptomatic arteriovenous fistulas may appear weeks after neck trauma. The emergency physician should be wary of severe trauma or ecchymoses with an "insignificant history" and should consider possible child abuse or an acquired bleeding problem. The progression of a pneumomediastinum to pneumothorax can be rapid although very uncommon and requires close observation of the tachypneic child with a "crepitant" neck mass. Acutely, this may be caused by trauma to the chest and rib cage or by severe airway obstruction caused by asthma or a foreign body. In children with obstructive lung diseases, such as asthma and cystic fibrosis, high transpulmonary pressure generated in these diseases forces air through small alveolar leaks into the mediastinum or pleural space. This may produce a pneumomediastinum that dissects into the neck. Anaphylactic reaction with neck swelling may precipitate an acute emergency if the swelling compromises the airway. Severe, local reactions to bee stings or to other sensitizing allergens may cause enough tissue edema to obstruct the trachea.

Infections associated with life-threatening processes include retropharyngeal, lateral pharyngeal, and peritonsillar abscesses. Lemierre's syndrome, an uncommon parapharyngeal infection involving thrombophlebitis of the internal jugular vein with metastatic pulmonary abscesses, may manifest as respiratory distress and systemic toxicity in the adolescent with a history of pharyngitis. Rarely, epiglottitis may present with associated cervical adenitis or the appearance of submandibular mass from ballooning of the hypopharynx. These patients may have cervical adenitis and concomitant dysphagia, drooling, and stridor. Occasionally, branchial cleft cysts or cystic hygromas can become infected and progress to abscess formation or rarely to mediastinitis. Laryngoceles may become acutely infected and obstruct airflow. Massive tonsillar hypertrophy with infectious

TABLE 44.1

LIFE-THREATENING CAUSES OF NECK MASS

- Hematoma secondary to trauma
  - Cervical spine injury
  - Vascular compromise or acute bleeding
  - Late arteriovenous fistula
- Subcutaneous emphysema with associated airway or pulmonary injury
- Local hypersensitivity reaction (sting/bite) with airway edema
- Airway compromise with epiglottitis, tonsillar abscess, or infection of floor of mouth or retropharyngeal space (with adenopathy)
- Bacteremia/sepsis associated with local infection of a cyst (cystic hygroma, thyroglossal, or branchial cleft cyst)
- Non-Hodgkin's lymphoma with mediastinal mass and airway compromise
- Thyroid storm
- Mucocutaneous lymph node syndrome with coronary vasculitis
- Tumor—leukemia, lymphoma, rhabdomyosarcoma, histiocytosis X
- Lemierre's syndrome

mononucleosis can manifest with upper airway obstruction. Dental infection that spreads to the floor of the mouth (Ludwig's angina) and neck may cause neck masses and airway compression. More recently, children with human immunodeficiency virus (HIV) infection (see Chapter 93) are reported to have parotitis or generalized lymphadenopathy, particularly visible in the neck as a presenting complaint. Children may have hyperthyroid symptoms when a neck mass represents thyromegaly. Similarly, patients with the mucocutaneous lymph node syndrome (Kawasaki disease) often have cervical lymphadenopathy and, on rare occasions, have active life-threatening vasculitis of the coronary vessels.

Neck tumors in children may become large enough to encroach on vital structures. Lymphoma, an uncommon but important cause of neck mass, is suggested especially by painless enlargement (often of supraclavicular nodes) that occurs over several weeks in the older school-age child. When mediastinal nodes are involved, the patient may rapidly develop a blockage of the intrathoracic trachea that is accentuated on lying down. These children may be fine when sitting, but when supine, the anterior mediastinal masses compress the trachea, causing the airway to collapse. Cystic hygromas and hemangiomas occasionally enlarge sufficiently enough to interfere with feeding or to obstruct the airway. Other tumors, such as rhabdomyosarcoma, leukemia, neuroblastoma, and histiocytosis X, are life threatening because of local invasion and metabolic and hematologic effects.

TABLE 44.2

COMMON CAUSES OF NECK MASS

- Lymphadenopathy secondary to viral or bacterial infection
- Cervical adenitis (bacterial)
- Hematoma
- Benign tumors—lipoma, keloid
- Congenital cyst (squamous epithelial cysts)

TABLE 44.3

DIFFERENTIAL DIAGNOSIS OF NECK MASS BY ETIOLOGY

- **Congenital**
  - Squamous epithelial cyst (congenital or posttraumatic)
  - Pilomatrixoma (Malherbe's calcifying epithelioma)
  - Hemangioma and cystic hygroma (lymphangioma)
  - Branchial cleft cyst
  - Thyroglossal duct cyst
  - Laryngocele
  - Dermoid cyst
  - Cervical rib
- **Inflammatory**
  - Infection
    - Cervical adenitis—streptococcal, staphylococcal, fungal, mycobacterial, cat-scratch disease, tularemia
    - Adenopathy—secondary to local head and neck infection
    - Secondary to systemic "infection"—infectious mononucleosis, cytomegalovirus, toxoplasmosis, others
    - Retropharyngeal abscess
    - Focal myositis—inflammatory muscular pseudotumor
    - Lemierre's syndrome
  - "Antigen" mediated
    - Local hypersensitivity reaction (sting/bite)
    - Serum sickness, autoimmune disease
    - Pseudolymphoma (secondary to phenytoin)
    - Kawasaki disease
    - Sarcoidosis
    - Caffey-Silverman syndrome
- **Trauma**
  - Hematoma
  - Sternocleidomastoid tumor of infancy (fibromatosis colli)
  - Subcutaneous emphysema
  - Acute bleeding
  - Arteriovenous fistula
  - Foreign body
  - Cervical spine fracture
- **Neoplasms**
  - Benign
    - Epidermoid
    - Lipoma, fibroma, neurofibroma
    - Keloid
    - Goiter (with or without thyroid hormone disturbance)
    - Osteochondroma
    - Teratoma (may be malignant)
    - "Normal" anatomy or variant
  - Malignant
    - Lymphoma—Hodgkin's disease, non-Hodgkin's lymphoma
    - Leukemia
    - Other—rhabdomyosarcoma, neuroblastoma, histiocytosis X, nasopharyngeal squamous cell carcinoma, thyroid, or salivary gland tumor

Child with Neck Mass and No Distress

Most children in the ED with a neck mass are not in distress; the leading diagnoses are reactive adenopathy or acute lymphadenitis

from viral or bacterial infection. A common concern, however, is deciding which neck mass bears the diagnosis of malignancy and requires biopsy or further evaluation.

History

A careful evaluation of history, establishing the duration of signs and symptoms, as well as ascertaining the involvement of other organ systems (fatigue, weight loss, night sweats, adenopathy elsewhere), often suggests the diagnosis. Presence of sore throat, fever, neck pain, difficulty breathing, or "noisy breathing" (stridor, wheezing) should be elicited. Location of the mass, size and shape of the mass, duration of symptoms, and a history of injury are important. The patient's age at discovery of the lesion should be noted because those found early in infancy increase the risk of a cyst of congenital origin. Birth trauma, with bleeding into the sternocleidomastoid muscle, may cause torticollis, which presents at several weeks of age with a neck mass. It is important to note that not all congenital lesions present at birth or in the first months of life. They are brought to medical attention with acute infection or inflammation, sometimes as a recurrent unilateral neck mass in young infants. Changes in the size of the mass with time or with a child's growth, and whether there has been a change in the character of the lesion, should be noted. Presence of a dimple or sinuses, history of drainage, and other symptoms of infection may assist in making the diagnosis. History of exposure to an infectious agent, including streptococcal pharyngitis, infectious mononucleosis, or recent upper respiratory illness, should be sought. Questions regarding exposure to animal bites or scratches are important. Systemic symptoms that suggest serum sickness (fever, malaise, rash, arthralgias, nephritis) or pseudolymphoma ought to prompt an exposure history for medications (e.g., antibiotics and anticonvulsants, respectively). Figure 44.1 describes a pathway to facilitate some of the differential diagnoses by category.

Physical Examination

After assessment for critical illness is performed, the clinician should perform a thorough examination on a child with a neck mass. It is often valuable to examine the patient thoroughly and then come to examine the area of the head and neck last. Palpation of the mass, noting its location, size, shape, relationship, attachment to normal structures in the neck, and overlying skin changes, should be completed. Figure 44.2 diagrams the locations of many of the causes of neck mass. It is important to ascertain whether crepitation, a thrill, or a bruit is present and the degree to which an inflammatory mass is fluctuant. The surrounding area should be palpated for additional lesions (10% to 20% of branchial lesions are bilateral) and to evaluate normal structures of the neck such as the thyroid gland, sternocleidomastoid muscles, trachea, and cervical spine. The ability of the patient to flex and extend the neck should be ascertained. Inspection of the oral cavity should be performed, noting oral mucosa, dentition, and the orifices such as Stensen's duct (parotid gland) and other glands. The presence of movement of the mass with swallowing or with protrusion of the tongue is important. The examination of the head should be meticulous, including the scalp, ears, sinuses, and nasopharynx.

During auscultation of the chest, special attention should be paid to inspiration because extrathoracic airway obstruction from the trachea or upper airway may produce only faint stridor. Respiratory distress or wheezing that worsens in the supine position may be an early sign of an anterior mediastinal mass. The physical examination should be completed, looking for signs of systemic illness as a cause for the neck mass. The general appearance and color of the child is important, as is the presence of hepatosplenomegaly or an abdominal mass, indicating a high suspicion for a malignancy. Signs of thyroid hormone excess (tachycardia, bounding pulses, systolic hypertension, exophthalmos) or deficiency may be associated with a goiter. Rashes, generalized lymphadenopathy, and fever may indicate an inflammatory or oncologic process. Failure to thrive or weight loss may be found with a number of causes of infection or oncologic illness, including HIV disease, histiocytosis X, mycobacterium infections, and others. Finally, a close examination of the skin, not only observing the overlying skin but also noting any animal scratches or bites of the face and extremities, is imperative.

Details of chronicity, size, and progression and evidence of inflammation help distinguish between infection and neoplasm. Characteristics that some authors have found associated with malignancy include masses that are firm and larger than 3 cm in diameter, nonpainful, progressively enlarging, ulcerating, deep to fascia or fixed to tissue, or discovered in a newborn. These criteria are sensitive but not specific for cancer. Even with these characteristics, most lesions are benign congenital cysts or inflammatory masses. The duration the "node" is present is not discriminating in that, often, inflammatory nodes that are biopsied have been present for more than 2 to 3 months.

DIFFERENTIAL DIAGNOSIS

Congenital Masses

Thyroglossal duct cysts are the most common congenital cyst of the neck. They develop along the line of descent of the thyroid gland in the neck anywhere from the base of the tongue to the sternal notch in the *anterior triangle*. This will occur if the embryologic thyroglossal duct fails to obliterate before the formation of the hyoid bone. Sixty-five percent of these are found to be infrahyoid. Thyroglossal duct cysts are usually midline, adjacent to the hyoid bone, and more than half are diagnosed in children before 10 years of age. Occurrence usually is noticed after an upper respiratory infection or an episode of hemorrhage. Thyroglossal duct cysts are soft, nontender, smooth, and may move cranially when the child swallows or protrudes the tongue. If infected, they may be warm, erythematous, and drain externally. If drainage occurs by way of the foramen cecum, there may be an associated foul taste in the mouth. Antibiotics (for mouth and skin flora), warm compresses, and incision and drainage (if indicated) should be initiated for signs of infection. Complete excision is the treatment of choice after complete resolution of infection.

Cystic hygromas are cystic lymphatic malformations occurring in the *posterior triangle* of the neck. Most are identified at birth, but some may be recognized after injury or upper respiratory infection when "herniation" has occurred after crying,

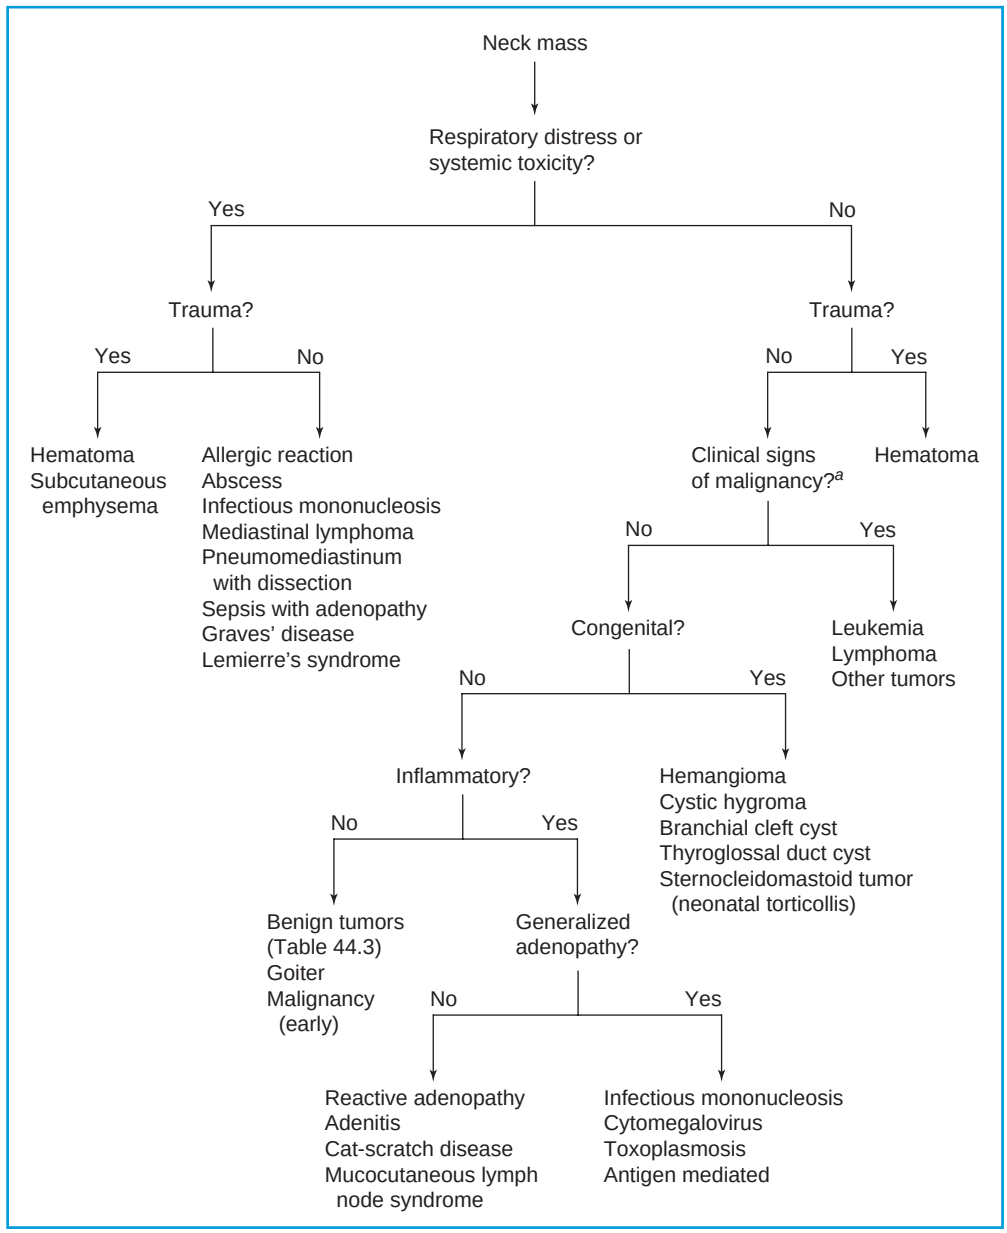

FIGURE 44.1 Evaluation of the child with a neck mass. [a]Malignancy: nontender, >3 cm diameter (and firm), enlarging mass of several weeks' duration, ulceration, location deep to superficial fascia or fixed to tissue, supraclavicular mass, systemic lymphadenopathy and bruising, superior vena cava syndrome.

coughing, or other forceful Valsalva maneuvers. Ninety percent present before the age of 2 years. Cystic hygromas appear discrete, soft, mobile, nontender, and vary greatly in size. Extension to the mediastinum can cause chylothorax or chylomediastinum, and rarely, airway compromise can occur; thus, chest radiograph is recommended. Infection is uncommon, but signs of it would be as expected. Ultrasonography is useful in establishing whether the mass is cystic. Computed tomography (CT) imaging or magnetic resonance imaging can determine the extent and involvement of surrounding structures. Spontaneous regression is rare; therefore, complete excision is the treatment of choice.

Branchial cleft anomalies are lesions most commonly occurring from defects in the development of the second branchial arch, giving rise to firm masses along the anterior border of the sternocleidomastoid muscle near the angle of the mandible in the *posterior triangle of the neck*. Branchial cleft sinuses are painless and present with drainage at the junction of the middle and lower thirds of the sternocleidomastoid muscle. Cysts that are usually fluctuant, mobile, and nontender may occur if the sinus tract becomes blocked. If the cyst becomes infected, it can be painful and warm. Probing or injecting the tract may lead to infection. Incision and drainage of a branchial lesion should be avoided because it may result in fistula formation. Ultrasonography may be useful in identifying a thin-walled, anechoic, fluid-filled cyst. Treatment with antibiotics with complete resolution of infection is necessary if the sinus or cyst is infected. Excision of the entire tract and cyst is important to prevent recurrence.

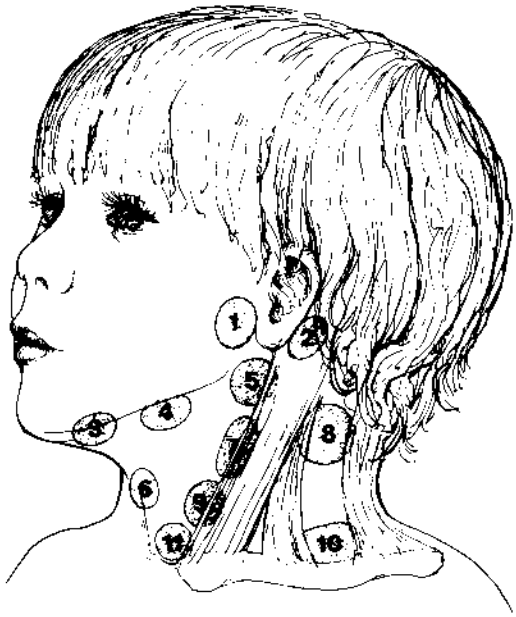

FIGURE 44.2 Differential diagnosis of neck mass by location. *Area 1. Parotid:* Cystic hygroma, hemangioma, lymphadenitis, parotitis, Sjogren's and Caffey-Silverman syndrome, lymphoma. *Area 2. Postauricular:* Lymphadenitis, branchial cleft cyst (1st), squamous epithelial cyst. *Area 3. Submental:* Lymphadenitis, cystic hygroma, sialadenitis, tumor, cystic fibrosis. *Area 4. Submandibular:* Lymphadenitis, cystic hygroma, sialadenitis, tumor, cystic fibrosis. *Area 5. Jugulodigastric:* Lymphadenitis, squamous epithelial cyst, branchial cleft cyst (1st), parotid tumor, *normal*—transverse process C2, styloid process. *Area 6. Midline neck:* Lymphadenitis, thyroglossal duct cyst, dermoid, laryngocele, *normal*—hyoid, thyroid. *Area 7. Sternocleidomastoid (anterior):* Lymphadenitis, branchial cleft cyst (2nd, 3rd), pilomatrixoma, rare tumors. *Area 8. Spinal accessory:* Lymphadenitis, lymphoma, metastasis (from nasopharynx). *Area 9. Paratracheal:* Thyroid, parathyroid, esophageal diverticulum. *Area 10. Supraclavicular:* Cystic hygroma, lipoma, lymphoma, metastasis, *normal*—fat pad, pneumatocele of upper lobe. *Area 11. Suprasternal:* Thyroid, lipoma, dermoid, thymus, mediastinal mass. From May M. Neck masses in children: diagnosis and treatment. *Clin Pediatr* 1976;5:17. Reprinted by permission.

Hemangiomas, which include capillary hemangiomas, strawberry hemangiomas, and capillary-cavernous hemangiomas, are common head and neck lesions identified in infancy and are usually noticed within the first year of life. They are three times more common in female child than in male child. Hemangiomas are soft, mobile, nontender, and bluish or reddish with increased warmth. After compressing the mass, they may refill. A thrill or bruit may be present. They tend to grow larger in the first year of life and then involute over the next several years. Rare complications include thrombocytopenia from platelet consumption, disseminated intravascular coagulation, hemorrhage, airway obstruction, congestive heart failure, ulceration, infection, and necrosis. If located in the beard distribution, these may be associated with glottic and subglottic hemangiomas, increasing the risk for airway compromise. Treatment for most hemangiomas is conservative and nonoperative because the issues are almost solely cosmetic and short term. Other treatments (corticosteroids, laser treatment, resection) are reserved for rapidly growing lesions that are impairing vision and hearing, or which are life threatening.

Neonatal torticollis, also known as *fibromatosis colli*, results from sternocleidomastoid fibrosis and shortening of the muscle. Presenting symptoms of torticollis occur in the first 3 weeks of life, with the infant holding his/her face and chin away from the affected side and the head tilted toward the fibrous mass. The mass is firm and seems attached to the muscle. Physical therapy, including massage, range-of-motion exercises, stretching exercises, and positional changes, is the preferred treatment. Facial and cranial asymmetry can develop without intervention. Surgical intervention is rarely needed.

Inflammatory Masses

Cervical lymphadenopathy is the most common reason for neck masses in children. Up to 90% of children between the ages of 4 and 8 years can have cervical adenopathy without obvious associated infection or systemic illness. Lymphadenopathy in newborns and young infants is rare and warrants investigation. Anterior cervical nodes drain the oropharynx and become enlarged with upper respiratory, oral, and pharyngeal infections. Posterior cervical lymph nodes drain the scalp and nasopharynx and become enlarged with inflammation or infection in these areas. Supraclavicular lymphadenopathy is considered pathologic and should be biopsied. Etiology for cervical adenopathy includes bacterial or viral infection [including rhinovirus, parainfluenza virus, respiratory syncytial virus, cytomegalovirus, and Epstein-Barr virus (EBV)] from local, regional, or systemic illness. With treatment of the underlying infection, cervical lymphadenopathy should resolve.

Cervical lymphadenitis occurs when acute infection is present within the lymph node (see Chapter 93). Bacteria are the most common causes and include methicillin-resistant *Staphylococcus aureus* and group A β-hemolytic streptococci, although those caused by *Haemophilus influenzae*, anaerobic bacteria, and virus have also been noted. Common presentation is usually one or more cervical lymph nodes that become acutely enlarged, tender, warm, and erythematous after an upper respiratory illness, pharyngitis, tonsillitis, or otitis media. Systemic symptoms of fever and malaise may be present. Treatment includes antibiotics and warm compresses. If the patient appears toxic, admission and treatment with intravenous (IV) antibiotics are appropriate. Without antibiotic treatment, enlargement with the development of fluctuation and regional cellulitis may progress. Most cases of acute cervical lymphadenitis resolve with oral β-lactamase–resistant antibiotics. If the patient fails to improve on this treatment, further diagnostic investigation is necessary, which may include serology, ultrasound, fine needle aspiration, and incision and drainage. Purulent fluid should be sent for Gram stain and aerobic and anaerobic cultures, with antibiotic management based on results.

Cat-scratch disease is another common cause of lymph node enlargement in children. Typically, regional lymph nodes enlarge 2 to 4 weeks after a cat scratch (usually a kitten). The lymphadenopathy can be cervical if the head or neck has been scratched (33% to 50%). Fever and malaise may have been present initially (30%), and usually, a single node is involved. The area around the lymph node is warm, tender, indurated, and erythematous. *Bartonella henselae* is the organism most

likely responsible. Indirect immunofluorescent antibody assay for detection of serum antibodies to antigens of *Bartonella* organisms is useful in diagnosis. The indirect immunofluorescent antibody test is available in commercial laboratories, state public health department laboratories, and the Centers for Disease Control and Prevention. Polymerase chain reaction assays are available in some commercial and research laboratories. Warthin-Starry silver stain of the lymph node or inoculation site will identify the organism but is not specific. Management is symptomatic with resolution in 2 to 4 months. Needle aspiration provides relief to those with tender, suppurative nodes and aids in diagnosis. Surgical excision is unnecessary and can lead to formation of a draining sinus. Antibiotics should be considered for acutely ill patients with systemic symptoms (hepatic or splenic involvement, endocarditis), the immunocompromised patient and patients with painful adenitis. Oral azithromycin, erythromycin, rifampin, trimethoprim-sulfamethoxazole, and ciprofloxacin have been shown to be effective. Parenteral gentamicin is also effective and is suggested for those patients with endocarditis.

Mycobacterial infection of the cervical lymph nodes is most often caused by the atypical strains of *Mycobacterium avium-intracellulare* and *M. scrofulaceum*. The enlarged lymph nodes are generally submandibular in location and red, rubbery, and minimally tender to palpation. If systemic manifestations are present, an immune deficiency should be considered. In contrast, clinical systemic signs of tuberculosis accompany cervical lymphadenopathy caused by *M. tuberculosis*. The supraclavicular lymph nodes are commonly involved. Children with suspected mycobacterium infection should have a purified protein derivative tuberculin skin test and chest radiograph performed. The purified protein derivative tuberculin test may be negative in atypical mycobacterium infections. An excisional biopsy may need to be performed to differentiate between tuberculous and nontuberculous mycobacteria as the offending organism. Treatment for atypical mycobacterial cervical lymphadenitis is complete surgical excision. Treatment with clarithromycin with ethambutol or rifampin may be indicated in children with recurrent disease or incomplete excision. Incision and drainage result in a draining sinus. Treatment for *M. tuberculosis* lymphadenitis is the same as for pulmonary tuberculosis–6 to 9 months of antituberculosis chemotherapy.

Cervical lymphadenitis can be the result of viral infections (rhinovirus, parainfluenza virus, respiratory syncytial virus, cytomegalovirus, and EBV), most commonly mononucleosis. Classically, the patient has diffuse lymphadenopathy with prominent posterior cervical lymphadenopathy and large, hypertrophied tonsils. *EBV* is the most common cause of mononucleosis. Systemic symptoms of fever, headache, malaise, and the presence of hepatosplenomegaly are common. Exudative pharyngitis may be present, and the throat should be cultured for group A β-hemolytic streptococci. If bacterial pharyngitis is present, the child should be treated with antibiotics. Generally, treatment for mononucleosis is supportive. Corticosteroids (prednisolone/prednisone at 1 mg per kg per day) have been found useful in reducing tonsillar inflammation in patients with airway compromise.

Kawasaki disease (*mucocutaneous lymph node syndrome;* see Chapter 101) is associated with a single enlarged cervical lymph node (>1.5 cm diameter), nonexudative conjunctival injection, erythematous mouth, cracked lips, strawberry tongue, erythematous rash, induration of the palms of hands and soles of the feet, and fever of at least 3 days' duration. Cervical lymphadenopathy is the least common of the presenting signs, however. The peak incidence is 18 to 24 months, with the vast majority of the cases occurring in children younger than 4 years. The cause is unknown but is believed to be infectious. Kawasaki disease is associated with long-term complications, such as coronary artery aneurysm; thus, immunosuppressive therapy should be started if it is suspected. An echocardiogram should be performed to rule out coronary artery aneurysms.

Retropharyngeal abscess is a potentially serious deep neck infection that can present with neck mass, fever, dysphagia, sore throat, and pain with extension and/or flexion of the neck. Retropharyngeal abscesses are a result of infections of the nasopharynx, paranasal sinuses, or middle ear, and the paramedian lymph nodes that drain those areas. Most cases of retropharyngeal abscesses occur in children younger than 6 years. The usual pathogens are group A streptococcus, anaerobes, or *S. aureus*. Airway radiographs may show an enlarged retropharyngeal space. Proper positioning is paramount to avoid false-positive radiographs seen with wider prevertebral soft tissue in nonextension films. CT scan of the neck is more accurate in determining the presence of retropharyngeal abscess. Treatment includes monitoring for signs of airway compromise and IV antibiotic treatment using clindamycin, ampicillin/sulbactam, or cefazolin. Most children will need drainage, but IV antibiotics and observation may be sufficient for those determined to have retropharyngeal cellulitis.

Lemierre's syndrome is an infection of the parapharyngeal space with septic thrombophlebitis of the internal jugular vein, leading to septic embolization to the lungs and/or central nervous system. It is seen as a complication of inadequately treated tonsillitis but can also be seen with neck abscesses. It is generally seen in adolescents and adults. Sore throat, fever, fullness to one side of the neck, neck pain, trismus, dysphagia, dyspnea, and toxic appearance can be the presenting clinical signs and symptoms. The predominant pathogen is a gram-negative bacillus *Fusobacterium necrophorum*. Treatment consists of either penicillin in combination with a β-lactamase inhibitor or a β-lactamase–resistant antibiotic in combination with a drug that is highly effective against anaerobes (clindamycin or metronidazole) for at least 6 weeks. Anticoagulation is still controversial.

Neoplasms

Fortunately, neoplasms of the head and neck in children are less commonly seen than infection or congenital lesions. It is estimated that 80% to 90% of neck masses in children are benign. Presentation is usually a painless, firm, fixed cervical mass. Systemic symptoms may not be present. Differentiating between a benign and malignant lesion can be difficult. Findings that would prompt further workup to rule out malignancy include supraclavicular lymphadenopathy, a node larger than 2 cm in diameter, enlargement of a node for more than 2 weeks, no decrease in size of a lymph node after 4 to 6 weeks, lack of inflammation, firm or rubbery consistency, ulceration, failure to respond to antibiotics, and systemic symptoms. Neoplastic etiologies for neck mass in children include

Hodgkin's and non-Hodgkin's lymphoma, rhabdomyosarcoma, neuroblastoma, thyroid carcinoma, nasopharyngeal carcinoma, and teratomas. As described in the section on evaluation, duration and characteristics of the neck mass will lead to increased likelihood of cancer. If a malignancy is suspected, a complete blood cell count, chest radiograph, and selective CT or magnetic resonance imaging should be obtained. Treatment is individualized according to specific tumor and extent of disease (see Chapter 97).

LABORATORY TESTING

The clinical impression should be used to ascertain the need for laboratory studies or radiologic imaging. Many of the common conditions are inflammatory or acute infections, and no studies need to be performed. Oxygenation may be determined by pulse oximetry. In processes for which the risk of critical airway obstruction is impending, the utility of the arterial blood gas adds little initially, and the stress may lead to worsening of the obstruction. A complete white blood cell count and differential are most helpful when an oncologic cause or mononucleosis is suspected. When bleeding from trivial trauma is being considered as a cause of neck mass, the platelet count, prothrombin time, and partial thromboplastin time should be obtained. Consider also a bleeding time when a coagulopathy is in the differential. Serum thyroid hormone and thyroid-stimulating hormone levels may be warranted for suspected thyroid masses. Throat culture for streptococcal disease (or a rapid strep screen) should be obtained when pharyngitis is found. A heterophile antibody assay or, especially in the younger child, EBV-specific serologic tests should be performed to confirm infectious mononucleosis.

Cervical spine radiographs need to be obtained for trauma patients when instability or fracture of the cervical spine is suspected. For most patients with a neck mass and concern for deeper-tissue involvement, the imaging study of choice will be CT. Facial or mandibular films may be necessary to evaluate for some lower-face trauma or oral infections. Soft-tissue lateral neck films may be helpful to evaluate for intraoral, retropharyngeal, or airway infectious problems. In the child with respiratory distress, a chest radiograph is necessary to view the mediastinum, pleura, and lung for infection, tumor, pneumothorax, or pneumomediastinum. Ultrasound may be useful in defining the mass; a cystic mass with linear septations is characteristic of a cystic hygroma. Other masses (lymphadenopathy, thyroglossal duct) and fibromatosis colli (congenital torticollis) have fairly definitive patterns. Ultrasound may also help identify adenitis with abscess formation requiring drainage. Although not specific, the finding of calcification within a mass may suggest a teratoma or neuroblastoma.

In studies in which biopsies of neck masses were obtained, several authors have found preoperative diagnoses to be correct as infrequently as 60% of the time. Biopsy of the lesion is required when the suspicion is high for malignancy. As in adults, fine needle aspiration in children is becoming more popular at some centers because it offers high sensitivity and specificity for tumors. This may reduce the need for open biopsies as often as 75% of the time by identifying inflammatory or self-limiting processes.

THERAPY

In the ED, the clinical evaluation most often reveals adenopathy that requires no acute therapy or adenitis that necessitates a course of systemic oral antibiotics and local care. Important to the approach to adenitis is the follow-up in several days to monitor clinical response and need for aspiration and drainage. When the mass is suspicious for tumor or congenital cyst, surgical consultation for biopsy or excision is indicated. Hospitalization and institution of definitive therapy are indicated for the patients with neck masses who present with systemic toxicity, airway compromise, or severe local disease.

CHAPTER 45 ■ NECK STIFFNESS

LEAH TZIMENATOS, MD, CHERYL VANCE, MD, AND NATHAN KUPPERMANN, MD, MPH

Neck stiffness is an important chief complaint in children evaluated in the emergency department. Commonly, neck stiffness is accompanied by neck pain. Certain clinical conditions, however, may lead a child to hold the neck in an abnormal posture without neck pain. The underlying causes of neck stiffness or malposition in children range from relatively benign (e.g., muscle strain, cervical adenitis) to life threatening (e.g., meningitis, fracture, or subluxation of the cervical spine).

Torticollis (meaning "twisted neck" from the Latin roots *tortus* and *collum*) is a subset of neck stiffness. With torticollis, the child holds the head tilted to one side and the chin rotated in the opposite direction, reflecting unilateral neck muscle contraction. This may result from various pathologic processes and may or may not be associated with neck pain. Torticollis is often congenital and muscular in origin; however, it can also be associated with acquired processes such as trauma, infectious or inflammatory illnesses, central nervous system neoplasms, drug reactions, and a variety of different syndromes.

This chapter reviews the differential diagnosis of neck stiffness including torticollis, both with and without neck pain, in children. The proposed algorithm at the end of the chapter helps distinguish potentially life-threatening causes from benign causes of neck stiffness, while providing a broad differential diagnosis for this important clinical finding.

DIFFERENTIAL DIAGNOSIS

Most patients presenting with neck stiffness are well appearing with benign, frequently self-limited conditions; however, the differential diagnosis of neck stiffness is broad and includes many potentially life-threatening causes. These various diagnoses must be considered and, when appropriate, excluded depending on the patient's clinical presentation and history. A history of trauma, signs or symptoms of an infectious or inflammatory process, or any evidence of spinal cord involvement may be helpful in identifying a number of specific diagnoses.

Table 45.1 lists most causes of neck stiffness in children, Table 45.2 lists the common causes, and Table 45.3 lists the life-threatening causes. The following descriptions categorize the causes of neck stiffness in children by underlying mechanism and severity.

Neck Stiffness Associated with Trauma

Potentially Life-threatening Causes

Trauma to the neck is a common cause of neck pain and stiffness in children (see Chapter 115). Fortunately, serious injuries to the cervical spine (fractures, subluxations, and spinal cord injuries) are uncommon, especially in children younger than 8 years. Because of a higher fulcrum of the cervical spine and relative weakness of the neck muscles compared to adults, these injuries generally occur in the upper cervical spine in younger children, as opposed to the lower cervical spine in adolescents and adults. Neck injuries in children most commonly result from high kinetic energy mechanisms, such as motor vehicle-related collisions, sports injuries, and falls.

Fractures of the Cervical Spine. Fractures of the cervical spine in children are very uncommon, occurring in 1% to 3% of hospitalized pediatric trauma patients. Although some children with fractures of the cervical spine are unresponsive at the time of evaluation, most are alert and verbal, limit their neck movement secondary to pain, and have no demonstrable neurological deficit. At the minimum, the cervical spine should be immobilized and multiple-view radiographs of the cervical spine should be obtained on any child with an altered level of consciousness, pain or stiffness of the neck, any neurological deficits, or distracting painful injuries after blunt trauma. Radiographs should also be obtained in those who are unable to perceive pain (as a result of alcohol or drugs) or describe their symptoms. A large prospective study of blunt trauma victims identified five criteria (posterior midline cervical tenderness, altered alertness, distracting injury, intoxication, and focal neurological signs) that correctly identified all children with cervical spine injuries; however, there were few children younger than 9 years and none younger than 2 years with cervical spine injury in this study. A multicenter attempt to retrospectively validate this decision rule among a different cohort of children (including those younger than 2 years) demonstrated a lower sensitivity, suggesting the need for refinement of these criteria before use in pediatric patients.

Subluxation of the Cervical Spine. Traumatic subluxations of the cervical spine are more common than fractures and may occasionally result from minor trauma (e.g., falls from low heights) but more commonly result from more severe trauma (see Chapter 115). The most commonly occurring of these is rotary (or "rotatory") atlantoaxial subluxation, which generally does not compromise the spinal canal because the transverse ligament of the atlas remains intact. Rotary subluxation typically causes neck pain and torticollis. Sternocleidomastoid (SCM) spasm and neck tenderness are localized to the same side as the head rotation (as the SCM attempts to "reduce" the deformity) in contrast to muscular (inflammatory and congenital) torticollis, in which the spastic, tender SCM muscle is opposite to the direction of head rotation. In addition, in rotary subluxation, there is palpable deviation of the spinous

TABLE 45.1

CAUSES OF NECK STIFFNESS OR MALPOSITION

Trauma
Fracture of the cervical spine
Subluxation of the cervical spine
Epidural hematoma of the cervical spine
Subarachnoid hemorrhage
Muscular contusions/spasm of the neck
Clavicular fracture

Infectious/inflammatory conditions
Bacterial meningitis
Retropharyngeal abscess
Infections of the spine (osteomyelitis, tuberculosis, epidural abscesses, discitis)
Minor irritation, malposition, and muscle spasm
Rotary atlantoaxial subluxation as a result of local inflammation and/or otolaryngologic procedures (Grisel's syndrome)
Primary or reactive cervical lymphadenitis/lymphadenopathy
Intervertebral disc calcification
Collagen vascular diseases (juvenile rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, and other spondyloarthropathies)
Upper lobe pneumonia
Acute suppurative thyroiditis
Otitis media and mastoiditis
Viral myositis
Pharyngotonsillitis
Upper respiratory tract infection

Tumors, vascular lesions of the central nervous system, and other space-occupying lesions
Brain tumor
Spinal cord tumor
Subarachnoid hemorrhage (aneurysm rupture)
Other tumors of the head and neck (rhabdomyosarcoma, Ewing's sarcoma, lymphoma, nasopharyngeal carcinoma, orbital tumor, acoustic neuroma, osteoblastoma, and metastatic tumors)
Other space-occupying lesions of the head and neck (Arnold-Chiari malformation)
Other space-occupying lesions of the spinal cord (neurenteric cyst, arteriovenous malformation, syringomyelia)

Congenital conditions
Congenital muscular torticollis
Skeletal malformations (Klippel-Feil syndrome, Sprengel's deformity, hemiatlas, basilar impression, occipitocervical synostosis)
Atlantoaxial instability secondary to congenital conditions (Down syndrome, Marfan syndrome, Klippel-Feil syndrome, os odontoideum, Morquio syndrome)

Miscellaneous
Ophthalmologic, neurological, and/or vestibular causes (strabismus, cranial nerve palsies, extraocular muscle palsies, refractive errors, migraine headache, myasthenia gravis, Guillain-Barré syndrome, pseudotumor cerebri)
Benign paroxysmal torticollis of infancy
Sandifer syndrome
Spontaneous pneumomediastinum
Spasmus nutans
Dystonic reaction
Psychogenic

TABLE 45.2

COMMON CAUSES OF NECK STIFFNESS OR MALPOSITION

Trauma
Minor trauma (cervical muscular contusions, strains, and spasm)
Clavicular fracture
Traumatic rotary atlantoaxial subluxation

Infectious/inflammatory conditions
Minor irritation, malposition, and muscle spasm
Cervical lymphadenitis
Pharyngotonsillitis and other upper respiratory tract infections
Viral myositis/myalgias
Bacterial meningitis
Infectious rotary atlantoaxial subluxation (Grisel's syndrome)

Congenital conditions
Congenital muscular torticollis

Miscellaneous
Dystonic reaction

process of C2 in the same direction as the head rotation. In contrast, during normal neck rotation beyond 20 degrees, the spinous process of C2 deviates to the contralateral side. With rotary atlantoaxial subluxation, an anteroposterior open-mouth radiograph typically shows the rotation of C1 on C2, with the odontoid in an eccentric position relative to C1. However, definitive diagnosis is made by dynamic computed tomography (CT) scans of the neck showing a fixed rotation between C1 and C2 that fails to resolve with attempts to

TABLE 45.3

LIFE-THREATENING CAUSES OF NECK STIFFNESS OR MALPOSITION

Trauma
Injuries to the cervical spine (fracture, subluxation, epidural hematoma)
Subarachnoid hemorrhage

Infection
Bacterial meningitis
Retropharyngeal abscess
Infections of the spine (osteomyelitis, epidural abscesses, discitis)
Atlantoaxial subluxation with anterior displacement of the atlas as a result of local inflammation

Tumors, vascular lesions of the central nervous system, and other space-occupying lesions
Brain tumor
Spinal cord tumor
Subarachnoid hemorrhage (aneurysm rupture)
Other tumors and space-occupying lesions of the head, neck, and spinal cord

Congenital conditions
Atlantoaxial instability secondary to congenital conditions

correct the torticollis. Neurological deficits are rare in patients with traumatic rotary subluxation. Most patients can be treated with a cervical collar and antiinflammatory medications. Traction and immobilization, and rarely surgery, are necessary for more severe and/or long-standing rotary subluxation or if reduction is not achieved by conservative measures. Early diagnosis and treatment are important.

Atlantoaxial subluxation with compromise of the spinal canal results when there is ligamentous laxity or rupture with resultant anterior movement of the atlas on the axis. Children with underlying conditions including Down syndrome and Marfan syndrome are more susceptible to this due to laxity of the transverse ligament of the atlas. Radiographic findings may include a widened predental space and prevertebral soft-tissue swelling. Treatment involves immobilization and cervical traction.

Epidural Hematomas of the Cervical Spine. Epidural hematomas of the cervical spine are uncommon but may occur even after apparently minor trauma. These may compress the spinal cord, leading to progressive neurological symptoms and signs as well as neck stiffness or pain. Magnetic resonance imaging (MRI) of the spinal cord clearly demonstrates this injury. Emergent neurosurgical consultation and surgical decompression are indicated.

Subarachnoid Hemorrhage. Subarachnoid hemorrhage after trauma may lead to neck stiffness but is accompanied by headache and/or other physical findings of head trauma. Rarely, subarachnoid hemorrhage may be due to nontraumatic causes such as aneurysm rupture.

Generally Non–life-threatening Causes

Traumatic Muscular Contusions of the Neck. Blunt trauma to the neck may result in neck pain as a result of muscular contusion and/or spasm. This is a diagnosis of exclusion, however, and should not be entertained until a detailed physical (including neurological) examination and radiographs of the cervical spine exclude the possibility of a more serious injury. Treatment includes a soft cervical collar and analgesic medication.

Clavicular Fracture. Fracture of the clavicle in children is common and may cause torticollis because of SCM muscle spasm. However, the diagnosis of clavicle fracture is usually clear because pain, tenderness, and swelling are noted over the fracture site. The acute symptoms associated with clavicle fractures may, on occasion, however, mask an associated rotary atlantoaxial subluxation. Clinicians caring for children should be aware of this association.

Neck Stiffness Associated with Infectious/Inflammatory Conditions

Potentially Life-threatening Causes

Bacterial Meningitis. Bacterial meningitis has become a rare childhood disease in the United States; however, it is still the most important infectious cause of neck stiffness. In the post–HiB and PCV7 vaccine era, the most common bacterial pathogens causing meningitis after infancy are *Streptococcus pneumoniae* (including non-vaccine type strains) and *Neisseria meningitidis*. Children with meningitis typically have findings of neck stiffness on physical examination, although this may not be apparent in young infants and in those children who lack an inflammatory response (i.e., meningococcal meningitis). In a study of 326 children presenting to an emergency department in the Netherlands between 1988 and 1998 with signs of fever and meningeal irritation, 30% had bacterial meningitis and 13% had viral or aseptic meningitis. Torticollis has also been reported in patients with bacterial meningitis, although far less commonly than meningismus.

Retropharyngeal Abscess. There are several other important infectious processes for which neck stiffness and fever usually are the presenting signs. Retropharyngeal abscess is an infection that occupies the potential space between the posterior pharyngeal wall and the anterior border of the cervical vertebrae. Most commonly caused by group A streptococcus, oral anaerobic organisms (*Bacteroides)*, and *Staphylococcus aureus,* these infections cause clinical toxicity, drooling, and stridor. Neck pain and/or stiffness are presenting clinical findings in approximately two-thirds of children with these infections. Limitation of neck extension and torticollis are particularly common. Lateral radiographs of the neck can be helpful in making the diagnosis and will reveal soft-tissue swelling anterior to the upper cervical vertebral bodies. These films are often limited, however, due to inadequate neck extension or failure to obtain the image during inspiration. CT imaging with intravenous contrast is currently the imaging modality of choice.

Infections of the Spine. Infectious processes involving the spine (osteomyelitis, epidural abscess, discitis) in children can involve the cervical region, although they occur most commonly in the thoracic and lumbar areas. Localized pain, fever, and elevation of inflammatory markers including erythrocyte sedimentation rate (ESR) and C-reactive protein generally accompany these infections.

Vertebral osteomyelitis occurring in the cervical spine may lead to neck stiffness. Vertebral osteomyelitis is usually bacterial in origin (most commonly caused by *S. aureus*) but may be caused by mycobacteria (tuberculous or nontuberculous) as well. If the cervical spine is involved, radiographs of this area may reveal destruction of the vertebral body, local soft-tissue swelling, or narrowing of the disc space. Technetium bone scanning or MRI will frequently reveal abnormalities of the spine before bony destruction is visible on plain radiography.

Although uncommon, spinal epidural abscesses are associated with significant morbidity and mortality. Epidural abscesses may occur in the cervical spine, although lower spine involvement is much more common. When these abscesses occur in the cervical region, severe neurological deficits may occur, and emergent neurosurgical referral is essential.

Discitis is uncommon in children and usually affects the thoracic or lumbar spine; however, cases of cervical discitis have been reported. This disease is generally seen in children younger than 3 years and is often caused by infection with *S. aureus,* although bacterial cultures are commonly negative, and the cause has been debated. When evaluating for this

condition, technetium bone scanning or MRI may be necessary if conventional radiography is nondiagnostic.

Generally Non–life-threatening Causes

Torticollis Due to Minor Irritation, Malposition, and Muscle Spasm. Most well-appearing children with sudden onset of mild torticollis without a history of trauma, fever, or neurological abnormalities do not have serious underlying pathology as a cause of their symptoms. Commonly, the patient awakens with mild neck pain, stiffness, and malposition. On evaluation, there is no history of trauma, fever, preceding illness, pharyngotonsillitis or any additional physical examination abnormality. The examination reveals a well-appearing child with mild torticollis, whose limitation of motion is primarily when he or she attempts correction of the malposition. Such muscular torticollis may be due to SCM spasm from awkward sleeping position or other mild irritation. In cases with this type of benign presentation, history, and examination, nothing more than careful clinical assessment, analgesic/antiinflammatory medication, consideration of soft cervical collar, and close follow-up may be necessary.

Atlantoaxial Subluxation as a Result of Local Inflammation and/or Otolaryngologic Procedures (Grisel's Syndrome). Rotary atlantoaxial subluxation rarely may occur as a result of inflammatory processes in the head and neck region (e.g., rheumatoid arthritis, systemic lupus erythematosus, tonsillitis, pharyngitis, otitis media, retropharyngeal abscess) or after otolaryngologic procedures (e.g., tonsillectomy, adenoidectomy). This condition, also called *Grisel's syndrome*, is believed to occur as a result of ligamentous laxity after an infectious or inflammatory process. The subluxation may or may not be associated with displacement of the atlas, depending on the degree of involvement of the transverse ligament of the atlas. Most children with Grisel's syndrome have torticollis and neck pain, often localized to the ipsilateral SCM muscle. Fever and dysphagia are also common. The child's head is tilted to one side and rotated to the side opposite of the facet dislocation. As with rotary atlantoaxial subluxation from traumatic causes, radiographs may demonstrate abnormality, but dynamic CT scan is diagnostic (see previous discussion). In the uncommon likelihood of severe disease (and certainly in the rare likelihood of spinal cord compression), neurosurgical consultation should be obtained because cervical traction and immobilization are needed. Most commonly, the condition is mild and there is no anterior displacement of the axis. If mild, the condition usually responds to analgesic medication, physical therapy, and a soft cervical collar. In addition to treating the subluxation, antibiotics to treat an underlying bacterial infection, if present, are needed.

Cervical Lymphadenitis. Cervical lymphadenitis, either acute or chronic, is a common cause of neck pain and stiffness. The child with this condition typically has tender swelling over the lateral aspect of the neck, with or without fever. Most cases of cervical lymphadenitis are caused by *S. aureus* or group A streptococcus; however, other bacteria, mycobacteria, and other infectious conditions may be involved (including *Bartonella henselae,* the cause of cat-scratch disease). A purified protein derivative skin test to screen for tuberculosis if any risk factors are present and empirical antibiotics to treat the most common bacterial pathogens are usually sufficient therapy. Cervical adenitis may also occur in response to an infection in a juxtaposing site (i.e., site of lymphatic drainage to the cervical nodes), such as the scalp.

Intervertebral Disc Calcification. Intervertebral disc calcification (IDC) in children is an uncommon, generally self-limited condition in which the nucleus pulposus of one or more intervertebral discs calcifies. Both the underlying cause of the condition and the cause of acute symptoms are unknown. Children typically present with 24 to 48 hours of neck pain associated with neck stiffness or torticollis; fever is often present as well. The ESR is usually elevated in IDC, and leukocytosis occurs in one-third of patients. Radiographs of the spine usually show the disc calcification, and CT scans help localize the calcification within the nucleus pulposus. The calcification resorbs spontaneously, and the disease is generally benign and self-limited, although disc protrusion and cord compression may uncommonly occur. However, one must distinguish infections of the spine and meningitis (see previous discussions) from IDC.

Collagen Vascular Disease. Collagen vascular disease (see Chapter 101) in children may involve the cervical spine and lead to neck stiffness and/or pain. Children with juvenile rheumatoid arthritis may have either insidious or acute onset of symptoms, which commonly include neck stiffness. Although isolated cervical disease is unusual, neck stiffness or torticollis may be the presenting sign of juvenile rheumatoid arthritis. Cervical involvement in ankylosing spondylitis is a late finding as it is in other spondyloarthropathies. Girls with psoriatic arthritis, however, may have cervical involvement preceding sacroiliac and lumbar involvement.

Other Infectious/Inflammatory Conditions. Pharyngotonsillitis, upper respiratory tract infections, otitis media, and mastoiditis may be associated with neck pain. Torticollis may occasionally be seen as these conditions may be accompanied by Grisel's syndrome as well. It is important to remember that if the neck pain is posterior in location and accompanied by fever, a lumbar puncture should be strongly considered to exclude the possibility of meningitis. Similarly, the diagnosis of viral myositis involving the neck can be made only after excluding the possibility of meningitis in a child with neck pain and fever. Upper lobe pneumonia may cause pain referred to the neck with or without associated stiffness. Although rare, acute suppurative thyroiditis is another infectious cause of neck pain and stiffness and is associated with fever and a palpable neck mass (i.e., swelling of the thyroid).

Neck Stiffness Associated with Tumors, Vascular Lesions of the Central Nervous System or Other Space-occupying Lesions

Potentially Life-threatening Causes

Space-occupying lesions of the brain and spinal cord may lead to neck stiffness, malposition, and/or pain. Even if the histology of these lesions is benign, they are potentially life threatening because of the complications of intracranial pressure

elevation and the potential for brain and spinal cord compression. Ruptured aneurysms may cause subarachnoid hemorrhage with associated neck stiffness.

Brain Tumors. Children with tumors of the posterior fossa, the most common location for pediatric brain tumors, may present with head tilt, neck stiffness, or torticollis. Posterior fossa tumors may cause any of a number of other symptoms and signs (e.g., vomiting, headache, ataxia, disturbances in vision including diplopia, papilledema, cranial nerve deficits, corticospinal or corticobulbar signs). Head tilt may result from attempts to compensate for diplopia. However, neck stiffness is believed to result from irritation of the accessory nerve by the cerebellar tonsils trapped in the occipital foramen or by tonsillar herniation.

Spinal Cord Tumors. Tumors of the spinal cord are uncommon in children and account for a small fraction of all central nervous system tumors in childhood. The most common spinal cord tumor is an astrocytoma. Typically, spinal cord tumors cause pain at the site of the tumor and neurological defects (sensory and motor defects, impaired bowel and bladder function), but symptoms may be very slow to develop, often leading to delays in diagnosis. Spinal cord tumors may also cause torticollis. Patients with these tumors may also hold their heads in a forward flexed position (hanging head sign). An MRI of the a spine should be obtained on any child with symptoms and signs suggestive of a spinal cord tumor, and emergency neurosurgical consultation should be obtained.

Vascular Anomalies. Congenital berry aneurysms and acquired cerebral aneurysms may rupture spontaneously and result in life-threatening subarachnoid hemorrhage. This can present with abrupt onset of severe headache, meningismus, nausea and vomiting, photophobia, and possibly fever, thus mimicking meningitis.

Other Space-occupying Lesions of the Head and Neck. Head and neck tumors are uncommon in children, and diagnosis requires a high index of suspicion. Presenting signs and symptoms may include neck pain, stiffness, and/or torticollis. Rhabdomyosarcomas, Ewing's sarcomas, and lymphomas account for most of the tumors of the neck but other tumors occurring in this region include nasopharyngeal carcinoma, orbital tumors, acoustic neuromas, osteoblastomas, and metastatic tumors. Arnold-Chiari malformations of the brain may also cause neck pain and stiffness.

Other Space-occupying Lesions of the Spinal Cord. Other uncommon space-occupying lesions of the cervical spine such as neurenteric cysts, arteriovenous malformations, spontaneous spinal epidural hematomas, and syringomyelia may also cause neck pain and stiffness, generally accompanied by neurological findings. Early diagnosis by MRI is essential.

Generally Non–life-threatening Causes

Benign Tumors of the Head and Neck. Osteoid osteoma is a benign bone tumor that typically affects older children and adolescents. Pain is the typical presenting symptom, often worse at night. If the osteoma is in the cervical spine, neck pain and/or stiffness result. Plain radiography is usually diagnostic (showing a well-demarcated radiolucent lesion surrounded by sclerotic bone). Treatment may be conservative medical management, radiofrequency ablation, or surgical. Eosinophilic granulomas and bone cysts are other benign (and rare) lesions of the spine that may cause neck pain and stiffness.

Congenital Causes of Neck Stiffness

Neck stiffness and/or torticollis from congenital abnormalities are usually not life threatening. These congenital causes are usually muscular or skeletal in origin.

Congenital Muscular Torticollis

Congenital muscular torticollis is the most common cause of torticollis in infancy. The etiology of this condition is unclear but is believed to be related to birth trauma, causing an injury to the SCM muscle with hematoma formation, followed by fibrous contracture of the muscle. Other theories include those suggesting intrauterine malposition, infection, neurogenic causes, and intrauterine compartment syndrome of the SCM muscle. On examination, a palpable mass can often be detected in the inferior aspect of the SCM. The mass is generally not present at birth but appears in the neonatal period. The head is held in the characteristic position, with the patient's chin pointing away from the affected, contracted SCM muscle. Craniofacial asymmetry is commonly found to some degree in these patients, typically with contralateral flattening of the occiput and ipsilateral depression of the malar prominence. Radiographs of the cervical spine may be necessary to exclude other causes of torticollis. Treatment is conservative with active positioning and manual stretching of the involved muscle. If the deformity persists after 6 to 12 months, surgical release of the SCM is required (approximately 5% of cases).

Skeletal Malformations

Klippel-Feil syndrome is characterized by congenital fusion of a variable number of cervical vertebrae, which may result in atlantoaxial instability. The cause of this syndrome is unknown. It is often associated with many other bony abnormalities, and significant scoliosis develops in more than 50% of affected children. Limitation in range of motion of the neck is the most common physical sign. In addition to limited neck motion, the classic triad also includes a low hairline and a short neck; this triad, however, is seen in fewer than half of patients.

Sprengel's deformity is characterized by congenital failure of the scapula to descend to its correct position. The scapula rests in a high position relative to the neck and thorax. In its most severe form, the scapula may be connected by bone to the cervical spine and limit neck movement.

Hemiatlas is a malformation of the first cervical vertebra, which may cause severe, progressive torticollis. In time, the deformity becomes fixed; therefore, posterior fusion is recommended.

Basilar impression is a condition resulting from anomalies at the base of the skull and vertebrae, which lead to a short neck, headache, neck pain, and cranial nerve palsies due to compression of the cranial nerves. Many congenital conditions, including Klippel-Feil syndrome, achondroplasia, and

neurofibromatosis, may cause basilar impression. Commonly associated with basilar impression is occipitocervical synostosis, a condition in which fibrous or bony connections between the base of the skull and the atlas cause neck pain, torticollis, high scapula, and several neurological symptoms.

Atlantoaxial Instability

Several congenital conditions may be associated with atlantoaxial instability and may predispose the patient to cervical subluxation. In addition to Down, Marfan, and Klippel-Feil syndromes, these include other skeletal dysplasias and os odontoideum (aplasia or hypoplasia of the odontoid). Children with these conditions should be screened for atlantoaxial instability. Morquio syndrome is a mucopolysaccharidosis resulting in flattening of the vertebrae and multiple skeletal dysplasias. In this syndrome, the odontoid process of the axis is underdeveloped and may lead to atlantoaxial subluxation.

Miscellaneous Causes of Neck Stiffness

Head tilt, neck stiffness, and/or torticollis have been reported in several other conditions, some of which are life threatening and others generally benign.

Ophthalmologic, Neurological, and/or Vestibular Causes

Head tilt or neck malposition may result from abnormalities of vision (strabismus, cranial nerve palsies, extraocular muscle palsies, refractive errors) or the vestibular apparatus. The child attempts to correct for the disturbance through changes in neck position. Careful ophthalmologic and neurological examinations of the child with head tilt are necessary to exclude these possibilities. Torticollis has also been reported in patients with migraine headaches.

Myasthenia Gravis

Patients with myasthenia gravis may develop torticollis, although ptosis, impairment of extraocular muscular movement, and other cranial nerve palsies are generally earlier signs.

Guillain-Barré Syndrome

Neck stiffness has been reported in children with Guillain-Barré syndrome. Neck stiffness in this condition, however, is seen in association with the generalized motor weakness and areflexia.

Pseudotumor Cerebri

Stiff neck and torticollis have also been reported in children with pseudotumor cerebri. In fact, these neck symptoms may be the presenting signs of the condition. Of course, the more usual clinical presentation of pseudotumor is characterized by headache, vomiting, and papilledema. Lumbar puncture and removal of cerebrospinal fluid may quickly resolve the cervical symptoms and signs. This association serves as a reminder to the clinician to inspect the optic discs of children with neck stiffness and/or torticollis.

Benign Paroxysmal Torticollis of Infancy

Benign paroxysmal torticollis of infancy presents as recurrent episodes of head tilt sometimes accompanied by pallor, agitation, and vomiting. Typical onset is between 2 and 8 months of age, and the condition tends to remit by 2 to 3 years. Episodes subside spontaneously within a few hours or days. The etiology is unknown, and there is no effective treatment

Sandifer Syndrome

Sandifer syndrome is the constellation of torticollis, gastroesophageal reflux, and hiatal hernia. Children with this syndrome may have recurrent vomiting and failure to thrive.

Spontaneous Pneumomediastinum

Spontaneous pneumomediastinum may present with neck pain and torticollis. A history of severe coughing and/or retching is usually elicited. Crepitus is generally palpated along the neck.

Spasmus Nutans

Spasmus nutans is an acquired condition of childhood, characterized by nystagmus, head nodding, and torticollis. Children with these findings typically become symptomatic in the first 2 years of life. The condition is generally benign and self-limited. However, some children with the symptoms of spasmus nutans have underlying brain tumors. Therefore, imaging of the brain is necessary to exclude this possibility.

Dystonic Reaction

Certain drugs can cause acute dystonic reactions with torticollis. These include many antipsychotic and antiemetic agents (most commonly haloperidol, prochlorperazine, and metoclopramide), as well as some benzodiazepines, antihistamines, and other agents. Treatment with 1 to 2 mg per kg of diphenhydramine may be diagnostic and therapeutic.

Psychogenic

Hysterical patients may present with torticollis. This diagnosis can be made only after excluding other more serious causes.

EVALUATION AND DECISION

The evaluation of, and treatment plan for, neck stiffness is best organized around several important historical/clinical questions and physical examination findings: (i) Is there evidence of spinal cord involvement? (ii) Is there a history of trauma? (iii) Is there evidence of an infectious or inflammatory process (e.g., history or presence of fever)? (iv) Is a cervical mass present? (v) Are the symptoms acute or chronic?

The approach to the child with a stiff or malpositioned neck should focus initially on whether there is spinal cord involvement, as detailed in Fig. 45.1. The studies included in the figure represent potential diagnostic modalities to be considered for a child with those signs/symptoms; however, these studies are not required. Decisions regarding specific diagnostic modalities will depend on each patient's individual presentation, history, and examination.

For any child with neck stiffness or pain, a history of weakness or paresthesias of the extremities or of functional abnormalities of the bowel or bladder should be sought. In addition,

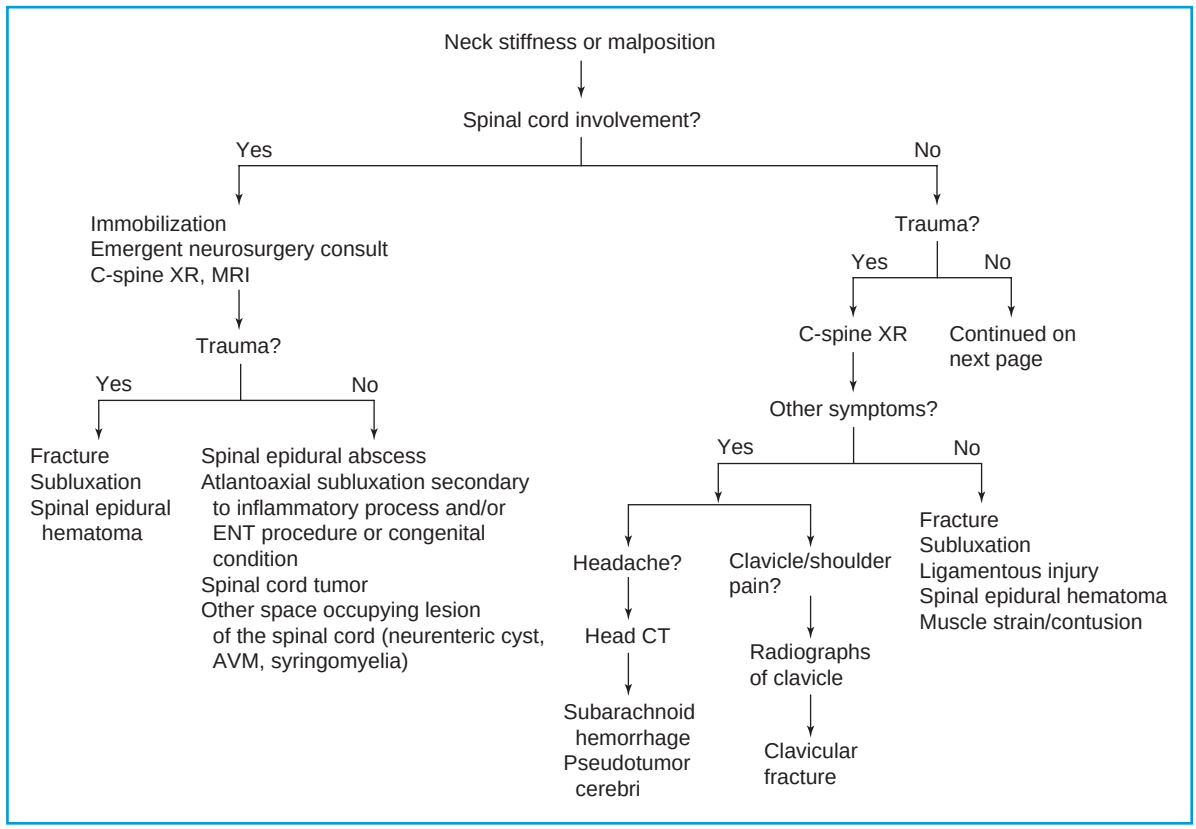

FIGURE 45.1 Approach to the child with stiff or malpositioned neck. Diagnostic studies included in this approach are intended to be *considerations* that may assist with making a diagnosis depending on the specific clinical scenario. C-spine XR, cervical spine radiograph; MRI, magnetic resonance imaging; ENT, ear, nose, and throat; AVM, arteriovenous malformation; CT, computed tomography; CBC, complete blood count; ESR, erythrocyte sedimentation rate; CRP, C-reactive protein; PPD, purified protein derivative; TB, tuberculosis; SCM, sternocleidomastoid; CXR, chest radiograph. (*continued*)

a complete ophthalmologic and neurological examination should be performed, with the latter focusing on spinal cord function. Included in this examination should be an assessment of muscle strength, sensation, deep tendon reflexes, the Babinski reflex, and anal tone. Extra vigilance must be used if the patient is too young or incapacitated to provide an accurate history.

If *spinal cord involvement* is detected, immobilization, neurosurgical consultation, and imaging of the cervical spine (radiographs and MRI of the cervical spine) are necessary. Conditions causing cervical spinal cord compromise may rapidly lead to permanent disability or death if not immediately addressed. If secondary to trauma, one should suspect cervical spine fracture, subluxation, or spinal epidural hematoma. In the setting of fever, a spinal epidural abscess should be considered. Atlantoaxial subluxation with instability secondary to otolaryngologic diseases or procedures should be considered in children with spinal cord involvement and consistent histories. Finally, spinal cord tumors and other space-occupying lesions should be considered if the development of symptoms is gradual and not associated with trauma or fever.

The next issue to be considered is whether the neck stiffness is the result of an *acute traumatic event*. If acute trauma is the cause of the neck stiffness, the cervical spine should be properly immobilized (see Chapter 115) and multiple radiographic views of the cervical spine obtained. Fractures and subluxations/dislocations will generally be identified on plain radiography of the cervical spine. Other modalities (e.g., flexion-extension views, CT, MRI) may be useful to detect ligamentous injury, rotary subluxation, or spinal epidural hematomas. Cervical muscle strain and/or contusion are diagnoses of exclusion in the setting of trauma, and neck stiffness after the possibility of more serious conditions is excluded. If other symptoms in addition to the neck stiffness are present, appropriate studies should be obtained. For example, the patient with neck stiffness and headache may have a subarachnoid hemorrhage for which a head CT scan would be indicated. The patient with clavicle fracture may have spasm of the SCM muscle and torticollis. However, tenderness is noted over the injured clavicle, and radiographs will confirm the diagnosis. On occasion, rotary atlantoaxial subluxation may be associated with clavicle fracture.

Fever in the setting of neck stiffness suggests the presence of an infectious, inflammatory, or neoplastic process. The presence of meningitis must be excluded either clinically or with a lumbar puncture (see Chapter 92). On examination, the finding of meningismus should be sought. A lumbar puncture

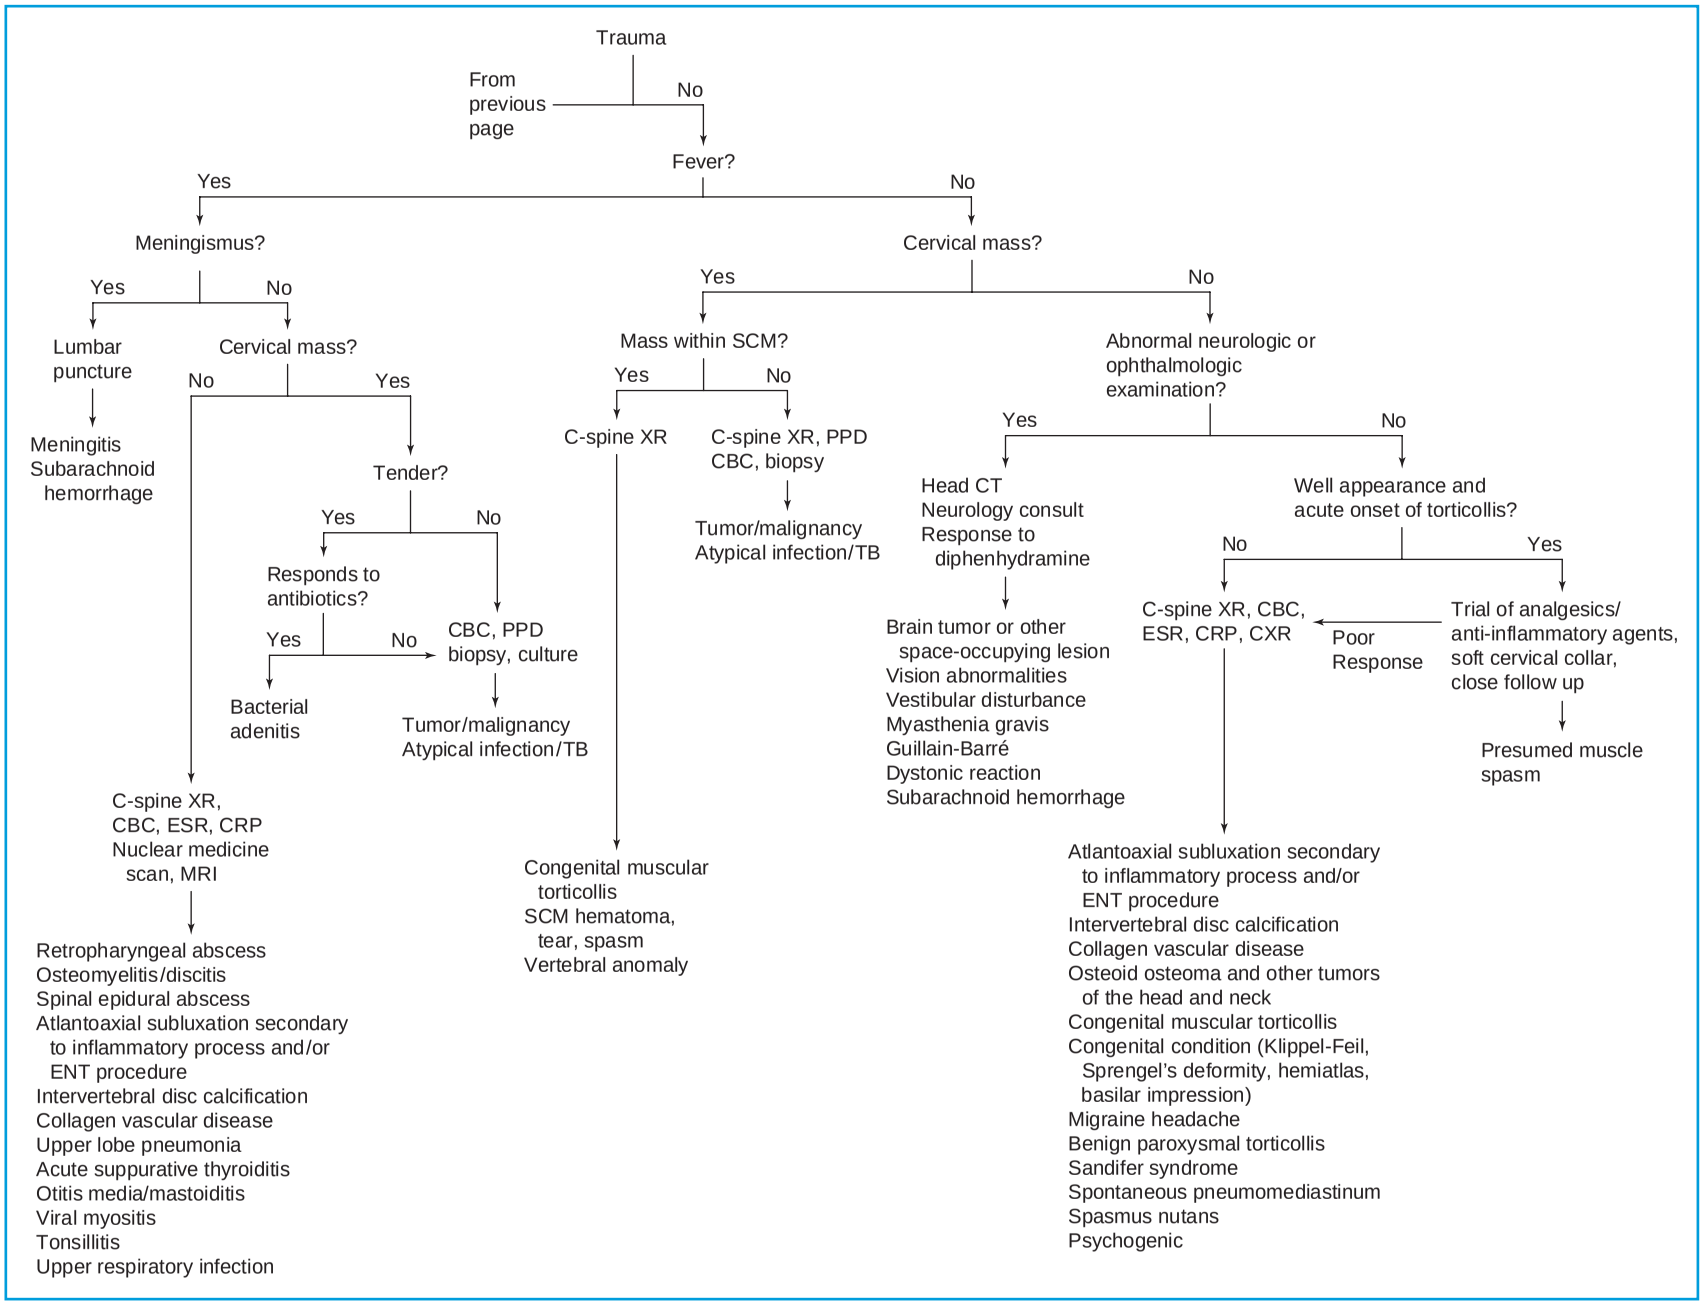

FIGURE 45.1 (*Continued*)

should be seriously considered in the presence of fever and neck stiffness of any type because meningitis may present with fever and atypical neck signs. Helpful supporting signs include Brudzinski's sign (flexing the neck, eliciting flexion of the knee and hip) and Kernig's sign (with the hip flexed, pain with extension of the leg). Other conditions (e.g., subarachnoid hemorrhage) may also present with fever and meningismus, and a lumbar puncture is helpful in evaluating these conditions as well.

After the presence of meningitis has been excluded in the febrile patient with neck stiffness, the examination should focus on the *presence or absence of a cervical mass*. If a cervical mass is identified, a history of head or neck infections, contact with cats suggestive of *Bartonella*, or constitutional symptoms suggestive of malignancy should be elicited. If the cervical mass is tender, a trial of antibiotics directed at the most common bacterial pathogens and the placement of a purified protein derivative skin test to screen for tuberculosis if risk factors are present may be all that is necessary. If the cervical mass does not respond to an appropriate trial of antibiotics, cat-scratch disease, atypical mycobacterial infection, or malignancy may be the cause.

If no palpable cervical mass is present in the febrile child with neck pain and/or stiffness, a more in-depth evaluation may be necessary, based on the history and physical examination of the child. Radiographs of the neck may suggest retropharyngeal abscess in the child with stridor, drooling, and neck stiffness, and radiographs of the cervical spine may detect atlantoaxial subluxation in the child with otolaryngologic disease or in the child who has recently had an otolaryngologic procedure. Plain radiographs may also be useful in detecting other diseases involving the cervical spine, including vertebral osteomyelitis, discitis, IDC, and neck stiffness from collagen vascular disease. Although nonspecific, white blood cell count, ESR, or C-reactive protein level will be elevated in most children with these conditions, as well as those with spinal epidural abscesses and infections of the head and neck (e.g., tonsillitis, mastoiditis). If plain radiography is not diagnostic, technetium scans or MRI will identify vertebral osteomyelitis or discitis. CT or MRI of the spine will also identify spinal epidural abscesses and can be helpful if routine radiographs are equivocal in several of the previously described conditions. Finally, an upper lobe pneumonia identified on chest film may be the cause of neck stiffness in the febrile child.

In the *afebrile* child with neck stiffness, the presence of a cervical mass within the SCM suggests congenital muscular torticollis (in an infant) or a SCM hematoma or tear. Radiographs of the cervical spine should be obtained to exclude more serious conditions. If the cervical mass is not within the SCM, a malignancy or atypical infection may be the cause, and a complete blood cell count and biopsy of the mass should be considered.

For the afebrile child with neck stiffness and/or malposition of the neck and no cervical mass, the possibility of a brain tumor, other space-occupying lesions of the brain, visual disturbances, and vestibular disturbance causing the abnormal neck posture should be considered. At times, the patient does not have primary neck pain or stiffness but is attempting to correct for these disturbances through changes in head position. In addition to careful neurological and ophthalmologic examinations, a head CT scan is necessary to exclude the possibility of a space-occupying lesion of the brain, including a brain tumor. The child with myasthenia gravis generally has ptosis and weakness of extraocular muscles and may develop torticollis. In such cases, a neurologist should be consulted. A trial of intravenous edrophonium chloride (Tensilon) is diagnostic because symptoms will improve immediately; however, edrophonium chloride should not be given to young infants, who are especially prone to this agent's ability to cause cardiac arrhythmias. Children with torticollis after receiving neuroleptic or antiemetic medications (dystonic reaction) will usually respond to intravenous diphenhydramine.

The child with neck stiffness without fever, cervical mass, or abnormal ophthalmologic or neurological examination may have any of a number of conditions. *Timing of the symptoms (i.e., acute or chronic)* may be an important factor in determining the appropriate evaluation. Chronic symptoms may suggest a congenital syndrome, collagen vascular disease, or a neoplastic process, but children with these conditions may also present with acute onset of symptoms. Many of the disorders mentioned as typically being associated with fever are commonly seen without fever as well (e.g. atlantoaxial subluxation in the child with otolaryngologic diseases or after otolaryngologic procedures, IDC, collagen vascular disease). Furthermore, infants with congenital muscular torticollis may not have SCM masses that are detectable on physical examination. Some children with neck stiffness may have dysmorphic features, suggesting specific skeletal malformation syndromes or cervical subluxation in a child with Down syndrome. Plain radiographs of the head, cervical spine, or chest may help detect additional diagnoses such as osteoid osteoma and other benign tumors of the head and neck or an upper lobe pneumonia or spontaneous pneumomediastinum, the latter usually in association with a history of severe coughing and/or retching. Finally, if no cause can be identified after a complete history, detailed examination, and careful radiographic and laboratory evaluation, muscle spasm or hysteria may be the cause of torticollis.

For the well-appearing child with sudden onset of mild torticollis without a history of trauma, fever, or neurological abnormalities (e.g., the child who awakens with mild torticollis after sleeping in an unusual position), nothing more than careful clinical assessment, analgesic/anti-inflammatory medication, consideration of soft cervical collar, and close follow-up may be necessary. For others with more severe findings or suggestive histories, however, diagnostic imaging, laboratory testing, or both are likely indicated.

In conclusion, neck stiffness and/or malposition may indicate a wide array of medical and traumatic conditions, both life-threatening and relatively benign. A careful examination must be performed to exclude the presence of spinal cord involvement. Trauma and infection are the most important causes of neck stiffness in children, and a history of trauma or fever will help guide the evaluation and decision making. Cervical spine fracture, subluxation/dislocation, and meningitis remain the most important diagnoses to exclude.

CHAPTER 46 ■ ODOR—UNUSUAL

ALISON BRENT, MD

The human nose is able to discriminate approximately 4,000 odors! Occasionally, parents bring an infant or child to the emergency department (ED) complaining of an unusual smell. Adolescents are more likely to note a new or unusual odor themselves and present to the ED with specific complaints.

Unfortunately, olfaction is a sense that most medical professionals are not trained to use, quantify, or describe. Before the development of sophisticated laboratory tests, clinicians relied heavily on the sense of smell. Even today, early diagnostic clues that can lead the clinician to a more selective workup, rapid diagnosis, and prompt therapeutic intervention may be obtained. In some situations, a prompt diagnosis can be lifesaving or can improve the quality of life.

PATHOPHYSIOLOGY

The olfactory area extends from the roof of the nasal cavity approximately 10 mm down the septum and superior turbinates bilaterally. The exact mechanism of stimulation of the olfactory receptors is unknown. Smell is more acute in the darkness and is believed to be linked to blood cortisol levels.

The unique odor emitted by a person is produced by a combination of body secretions and excretions, particularly those from the oropharynx and nasopharynx and the respiratory tract, plus aromas from the skin and cutaneous lesions, urine, feces, and flatus. The most significant components of odor in healthy humans are the apocrine glands. These secretions are initially odorless, but bacterial breakdown that results in fatty acid production can cause an offensive odor. Body odor is altered by hygiene, metabolism, toxins, infections, and systemic diseases.

When a child is unable to detect odor, anosmia should be considered. When a child complains of strange odors, especially if no one else is able to identify them, temporal lobe epilepsy should be contemplated.

DIFFERENTIAL DIAGNOSIS

A number of conditions, including metabolic disorders, dermatologic conditions, intoxications, infections, foreign bodies, various abnormalities of the body orifices, and a variety of systemic diseases, may result in an abnormal body odor (Table 46.1).

Metabolic Disorders

The most common metabolic disorder that has a characteristic odor is diabetic ketoacidosis (Table 46.2). The characteristic breath odor is caused by acetone and is described as sweet or fruity. It is important to note that any condition that results in a marked metabolic acidosis and ketosis will result in the characteristic sweet or fruity breath.

Inborn errors of metabolism that result in altered body, breath, or skin odors are unusual individually, but as a composite, they reflect a significant percentage of life-threatening illnesses of infancy (see Chapter 94). Although definitive diagnosis depends on specific identification of serum and urine amino and organic acid levels, many such conditions are associated with a positive ferric chloride test, which when performed in the ED can yield presumptive diagnosis.

Phenylketonuria is a disorder of amino acid metabolism associated with a deficiency of phenylalanine dehydroxylase and dihydropteridine reductase, which forces use of minor metabolic pathways of phenylalanine, resulting in the buildup of phenylacetic acid. It is the buildup of phenylacetic acid in the sweat and urine that causes a musty, mousy, horsey, wolflike, or barny odor. Clinical features of untreated phenylketonuria include white-blond hair, blue eyes, fair complexion, eczema, microcephaly, hypertonicity, increased risk for pyloric stenosis, seizures, and progressive mental deterioration. Although neonatal screening detects most of these cases, the observation of a characteristic odor in an infant should prompt appropriate laboratory studies, which may include a ferric chloride test in the ED. Prompt diagnosis and dietary restriction of phenylalanine promote a normal outcome.

Maple syrup urine disease is caused by a metabolic defect in the decarboxylation of the ketoacids of the branch-chain amino acids (leucine, isoleucine, and valine), which results in their accumulation in the blood. It is apparently a metabolite of isoleucine in the urine that results in the characteristic odor of maple syrup, caramelized sugar, or boiled Chinese herbal medicine. Children with this disorder can have variable clinical manifestations, ranging from decreased appetite, vomiting, and ataxia to progressive acidosis, seizures, coma, and death. Prompt diagnosis and limitation of dietary branched-chain amino acids promotes normal development.

Oasthouse urine disease, or methionine malabsorption syndrome, is caused by defective transport of methionine and, to a lesser extent, leucine, isoleucine, valine, tyrosine, and phenylalanine by the intestines and kidneys. The unabsorbed methionine in the gut is broken down by colonic bacteria to α-hydroxybutyric acid, which causes the characteristic odor described as yeast, celery, malt, or a brewery. Clinical presentation includes fair hair and skin, hyperpnea, extensor spasms, fever, edema, and mental retardation. Successful treatment consists of a methionine-restricted diet.

The odor of sweaty feet syndrome, or isovaleric acidemia, is caused by a defect in the catabolism of leucine. The characteristic

Nasal foreign body	Foul, putrid	*Metabolic diseases*	*Metabolic disease odors*
		Maple syrup urine disease	Maple syrup, caramel, boiled Chinese herbal medicine
		Infectious diseases	*Infectious disease odors*
		Pseudomonas	Foul
		Foreign body	*Foreign body odors*
		Otic foreign body	Foul, putrid

odor described as sweaty feet or socks or ripe cheese comes from the buildup of isovaleric acid. Clinically, children experience vomiting, dehydration, acidosis, and slowly progressive mental deterioration. Treatment consists of restriction of leucine in the diet.

In the odor of cat's urine syndrome, the enzymatic defects are in the biotin-dependent enzymes β-methylcrotonyl-CoA carboxylase, pyruvate carboxylase, and propionyl-CoA carboxylase. The cause of the distinctive aroma of cat urine is unknown. Clinically, children have failure to thrive, ketoacidosis, and neurologic symptoms similar to Werdnig-Hoffmann's disease. Treatment consists of a low-leucine diet and the addition of biotin.

Fish odor syndrome, trimethylaminuria, results from an unidentified defect that possibly relates to choline metabolism. The dead fish odor in the urine results from buildup of

TABLE 46.2

METABOLIC DISEASE ASSOCIATED WITH UNUSUAL ODORS

Disease	Odor	Odor source	Enzyme defect	Clinical features	Treatment	Rapid emergency department diagnosis
Diabetic ketoacidosis	Sweet or fruity	Breath	Lack of insulin or insulin activity	Polyuria, polydipsia, polyphagia, weight loss, coma, acidosis	Insulin administration	1 mL urine + 10% ferric chloride—red-brown color
Phenylketonuria	Musty, mousy, horsey, wolflike, barny	Urine and body	Phenylalanine hydroxylase	Progressive mental retardation, eczema, decreased pigmentation, seizures, spasticity, white-blond hair, blue eyes, pyloric stenosis, microcephaly	Diet low in phenylalanine	1 mL urine + 10% ferric chloride—green color
Maple syrup urine disease (branched-chain ketonuria)	Maple syrup, caramel, boiled Chinese herbal medicine	Urine	Branched-chain ketoacid decarboxylase	Marked acidosis, seizures, vomiting, ataxia, decreased appetite, coma leading to death in first year or two of life or mental subnormality without acidosis or intermittent acidosis without mental retardation	Diet low in branched-chain amino acid; protein restriction and/or thiamine in large doses	1 mL urine + 10% ferric chloride—blue, yellow, or blue-green color
Oasthouse urine disease (methionine malabsorption)	Yeast, celery, malt, brewery	Urine	Defective transport of methionine, branched-chain amino acids, tyrosine, and phenylalanine	Mental retardation, spasticity, hyperpnea, fever, edema, fair hair and skin0	Restrict methionine in diet	1 mL urine + 10% ferric chloride—purpleor red-brown color
Odor of sweaty feet syndrome (isovaleric acidemia)	Sweaty feet or socks, ripe cheese	Urine, body, breath, all body fluids	Isovaleryl-CoA dehydrogenase	Recurrent bouts of acidosis, vomiting, dehydration, coma, aversion to protein foods, lethargy, hypotension	Restrict leucine in diet	N/A
Odor of cat's urine syndrome (biotin-responsive multiple carboxylase deficiency)	Tomcat urine	Urine	β-Methylcrotonyl-CoA carboxylase, pyruvate carboxylase, propionyl-CoA carboxylase	Neurologic disorder resembling Werdnig-Hoffmann's disease, ketoacidosis, failure to thrive	Leucine restriction? Biotin administration	N/A
Fish odor syndrome (trimethylaminuria)	Dead fish	Urine	Unknown defect in choline metabolism	Stigmata of Turner syndrome, neutropenia, recurrent infections, anemia, splenomegaly	Unknown	N/A
Odor of rancid butter syndrome (tyrosinosis)	Rancid butter, rotten cabbage, fishy, musty	Urine	Unknown	Poor feeding, irritability, progressive neurologic deterioration, seizures, hepatic dysfunction, death	Response to decreased phenylalanine and tyrosine intake?	1 mL urine + 10% ferric chloride—transient blue-green color

N/A, not applicable.

trimethylamine. Clinical presentation includes stigmata of Turner syndrome, normal complement of chromosomes, neutropenia, recurrent pulmonary infections, and abnormal platelet function.

The odor of rancid butter syndrome, tyrosinosis, results from an unidentified defect in metabolism. It is hypothesized that a buildup of α-ketogammame-thiolbutyric acid in the urine results in the characteristic smell of rancid butter. Clinical presentation includes poor feeding, irritability, seizures, coma, progressive neurologic deterioration, and early death secondary to infection and liver failure. In some cases, restriction of dietary phenylalanine and tyrosine has been helpful.

Dermatological Conditions

Many dermatologic diseases (Table 46.1) are associated with specific odors. Any cause of hyperhidrosis results in an offensive body odor. Hidradenitis has a characteristic pungent odor, whereas Darier's disease is noted to have a pervasive aroma of burned tissue. An abscess or cellulitis is identified by the characteristic odors of the responsible microorganisms.

In burn patients, there is the typical odor of charred flesh, which when infected with *Pseudomonas aeruginosa,* takes on a characteristic sweet, grapelike odor.

Toxicologic Considerations

Recognition of a characteristic odor is vital for rapid, accurate diagnosis and treatment of some potentially lethal ingestions before laboratory identification (Table 46.1) (see Chapter 102).

Penicillins give off an ammoniacal scent, whereas cephalosporins are noted to have a musty odor. Topical benzoyl peroxide, applied in large quantities, emits a pungent, pervasive aroma.

A strong garlic odor is typical of arsenic, arsine gas, phosphorus, tellurium, parathion, malathion, selenium, dimethyl sulfoxide, and thallium. The odor of bitter almonds or peach pits is indicative of cyanide poisoning, in which the degree of excretion of the odor parallels toxicity (although the ability to detect this odor is genetically determined and may only be present in up to 40% of persons).

Diagnostic odors are found in several sedative-hypnotic medications that primarily have central nervous system manifestations. Ethchlorvynol (Placidyl) is a volatile agent that has an aromatic plastic or vinyl-like breath odor. Ingestion results in coma, hypothermia, respiratory depression, hypotension, and bradycardia. An overdose of chloral hydrate can result in central nervous system depression ranging from slurred speech, ataxia, and incoordination to deep coma, gastritis, and cardiac arrhythmias. It may be seen in children or as an intentional overdose in adults, and it imparts a fruity, pearlike scent. Disulfiram (Antabuse) gives the breath a rotten egg odor because of the sulfide metabolites. The pleasant smell of oil of wintergreen indicates methyl salicylate poisoning.

Infectious Diseases

Many microorganisms produce characteristic odors that suggest the diagnosis of their respective infectious diseases by olfaction alone (Table 46.1) (see also Chapter 92). Omphalitis in the newborn can be life threatening. It presents with a foul or putrid odor associated with a draining, erythematous umbilical area. Less common infections that have been historically associated with characteristic odors include typhoid's aroma of freshly baked bread, yellow fever's butcher shop smell, smallpox's menagerie odor, scrofula's odor of stale beer, diphtheria's sweet smell, and rubella's scent of freshly plucked feathers.

Foreign Bodies

Foreign bodies are capable of producing a foul odor that results from secondary bacterial colonization or infection. Foreign body odors can be localized to a particular orifice, or they may pervade a patient's clothing, body, and surrounding environment. Foul-smelling, fetid, or feculent odors indicate anaerobic infections, whereas a sickly sweet odor is associated with *Escherichia coli,* and *Clostridia* is associated with a mousy odor.

Orifice Odors

Specific orifice odors can be diagnostic of infectious disease processes.

Oropharynx

A healthy mouth does not give off an offensive odor. Halitosis, or bad breath, is the result of a release of volatile sulfur compounds formed when the oral flora metabolizes amino acids from compounds in the saliva that adhere to the tongue, teeth, and gums. Halitosis is increased in states of diminished solid and liquid intake. Tonsillitis (see Chapters 71 and 92) has an offensive odor, and group A β-hemolytic streptococcus gives off a characteristic "strep breath" smell. Dental abscesses (see Chapter 122) and acute ulcerative gingivitis (Vincent's angina or trench mouth) are associated with a penetrating, offensive odor. The oropharynx is also the portal of exit for deeper infections. Lung abscesses, empyema, bronchitis, and bronchiectasis result in foul breath and sputum. Nasal foreign bodies in toddlers are usually associated with an odor identified by parents as bad breath.

Nose

Nasal drainage can be clear and odorless or mucopurulent and odiferous. Nasal drainage and bleeding can reflect local infections, foreign bodies, irritations of the nasal passage, and sinus drainage.

Ear

Sterile inner ear fluid is odorless but gives off a rank smell when infected. Acute otitis externa is usually associated with a mucoid drainage, whereas chronic otitis externa produces a purulent, discolored drainage with a foul odor, usually secondary to *Pseudomonas aeruginosa* or *Staphylococcus aureus*.

Genitalia

Vaginal secretions are combinations of vulvar secretions from sebaceous, sweat, Bartholin's and Skene's glands, transudate through the vaginal wall, exfoliated cells, cervical mucus, endometrial and oviductal fluids, plus vaginal microorganisms

and menstrual blood. These secretions are hormonally mediated and vary with the menstrual cycle. Odors are exacerbated by the presence of retained foreign bodies, including tampons and diaphragms.

Bacterial vaginosis (nonspecific vaginitis, *Gardnerella* vaginitis, *Corynebacterium* vaginitis, *Haemophilus* vaginitis, nonspecific vaginosis, and anaerobic vaginosis) is caused by an increase in anaerobic bacteria and a decrease in lactobacilli (see Chapter 90). The anaerobic bacteria act synergistically with *Gardnerella vaginosa*, to produce enzymes and aminopeptidases that degrade protein, and decarboxylases that convert amino acids and other compounds to amines. The amines produce the characteristic "fishy" odor, which is best detected by alkalinization by using 10% potassium hydroxide placed directly on a vaginal swab and smelling immediately. This odor also can be indicative of sexual abuse in children. Vaginal infection with *Trichomonas* often is associated with a fishy odor, whereas *Candida* vaginitis is notably free of odor (see Chapter 94).

A male counterpart, balanoposthitis, is associated with a urethral discharge that produces a fishy odor when alkalinized because of the same process and organisms as occur in bacterial vaginosis.

Urethral Meatus

A urinary tract infection caused by urea-splitting bacteria will emit an ammoniacal odor.

Rectum

Stool odors vary with diet, medications, and microbiologic flora. Various malabsorptive syndromes, such as sprue, cystic fibrosis (see Chapter 99), and Whipple's disease, are associated with foul-smelling stool. The presence of blood in the stool has a distinctive, pungent odor, as does pus. *Shigella* and *Salmonella* (see Chapter 92) have distinctive rank odors.

Systemic Diseases

Several nutritional syndromes (Table 46.1), such as pellagra's stench of sour or musty butter and the putrid or fetid smell of scurvy and gout, have unique odors. Schizophrenia has a characteristic body odor described as heavy, unpleasant, and pungent. The odor-producing substance is *trans*-3-methyl-2-hexanoic acid, which is produced in the sweat. Uremic breath is produced by secondary and tertiary amines, dimethylamines, and trimethylamines that produce a fishy odor. Malignancy—especially when associated with an expanding external mass, bleeding, and necrosis—gives off a trenchant odor because of tissue and cellular breakdown plus gas formation. Hepatic failure gives an odor of "fetor hepaticus" (described as musty, rotten eggs, or garlic) and is noted in the breath or urine. In Crohn's disease (see Chapter 89), the development of gastric fistulae is often heralded by a feculent odor.

A physiologic odor that often heralds the onset of puberty is that emanating from the underarms. This is usually the earliest sign of puberty and precedes all other physical changes. Age of onset is around 6 to 8 years and reflects the onset of adrenarche. Dehydroepiandrosterone sulfate is the androgen believed to be responsible for the pungent aroma of underarm body odor and can be measured for confirmation. Although the adrenal and hypothalamic-pituitary-gonadal axes are separate systems involved with the onset of puberty, they often become active nearly simultaneously.

EVALUATION AND DECISION

The evaluation of a child who presents to the ED should incorporate all the senses, including smell (Fig. 46.1). Both presence and absence of odors can be diagnostic. Each person has a unique odor, ranging from pleasant to offensive. Using the sense of smell should be done in stages; an initial evaluation of the prevailing odor of the examination room, followed by attention to overall body odor and identification of odors from individual orifices and body fluids. Body fluids such as ocular, ear, nasal, sinus tract, or umbilical drainage; vomitus; sputum; genital discharge; stool; ulcers; and superinfection of the dermis have unique identifiable odors.

Good or poor hygiene is readily detected in a closed examination room. When an unusual odor is detected, the history should include information about medications (topical, oral, or rectal), onset and duration of odor, methods used to alter odor, unusual drainage from body orifices, suspicion of foreign body, fever, and other pertinent symptoms.

In the evaluation of the significance of odors, attention must be paid to the child's age and developmental level. At birth, infant odors are a conglomeration of their own and their mother's physical environment. After birth, a well-cared-for, healthy infant should have a very pleasing aroma and odorless breath. Offensive body odor in a newborn suggests an inborn error of metabolism, a localized infection such as omphalitis, or neglect. During infancy, inborn errors of metabolism are relatively common (Table 46.3) and are potentially life-threatening causes of unusual odor (Table 46.4). Infection localized to the umbilicus, omphalitis, produces a foul odor and is easily diagnosed on the basis of erythema, induration, and discharge. Other sources found in older children (foreign bodies, ingestions, and pharyngitis) are unusual in the infant.

In an older child, the physician should determine a child's history and whether clinical signs of chronic systemic diseases, such as diabetes, liver failure, or uremia, are present. The child with ketoacidosis usually appears dehydrated and manifests deep, rapid (Kussmaul) respirations; the breath may smell of ketones. Uremia develops in patients with renal failure who may have short stature, edema, hypertension, and a characteristic fishy odor of their breath. With liver failure, the patient may have jaundice, ascites, lethargy, or mental status changes, as well as breath and urine that takes on the odor of rotten eggs or garlic.

Body odors change with puberty through hormonally induced metabolic changes. The most significant change is the development of axillary odor related to apocrine secretions that are retained or spread by axillary hair. Normal quantities of sweat have a barely perceptible odor, whereas increasing quantities of sweat production cause increasingly noticeable and offensive odor.

Early on, the physician should determine the potential risk of ingestion of a toxic substance. In the adolescent, the risk of a significant ingestion increases and can be life threatening (Table 46.4). Next, the physician should ascertain whether the odor emanates from a particular body orifice such as the ear,

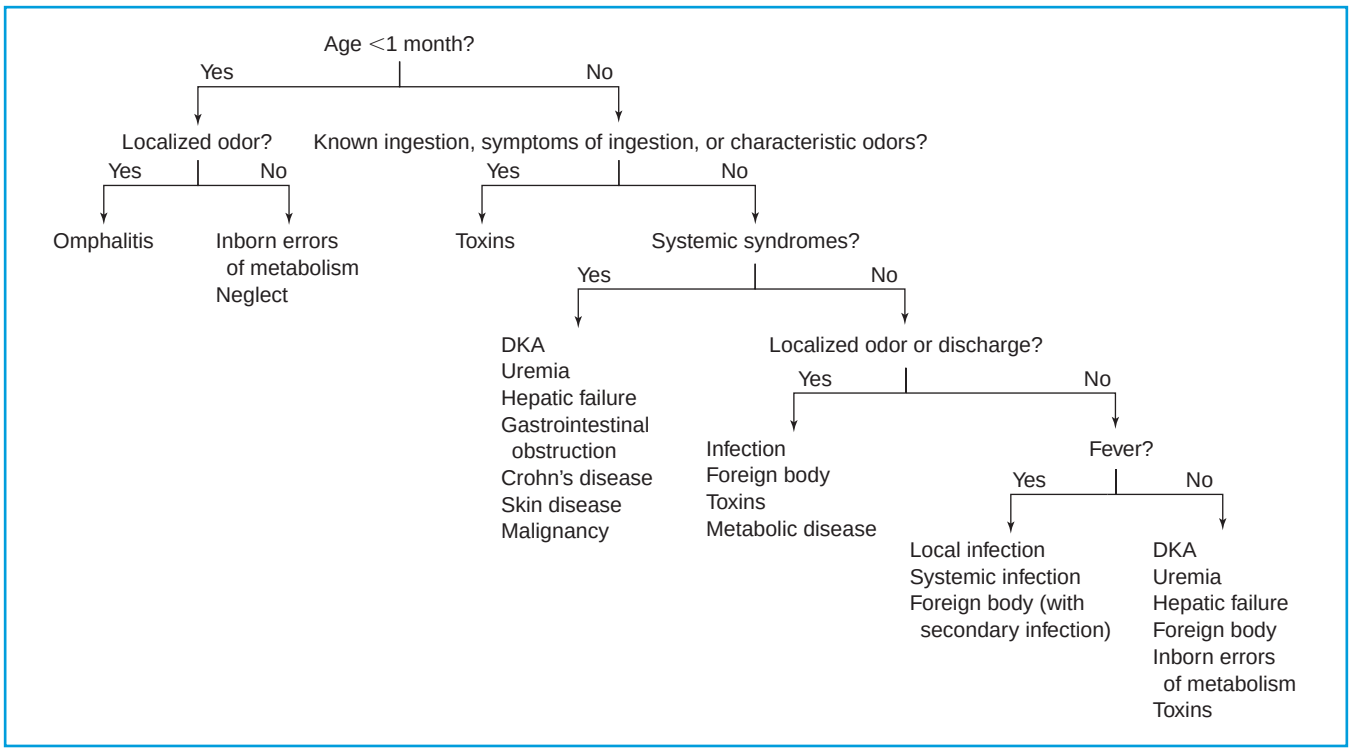

FIGURE 46.1 Evaluation and decision for unusual odors. DKA, diabetic ketoacidosis.

nose, pharynx, vagina, urethra, or rectum. Nasal foreign bodies are particularly common in children between the ages of 1 and 5 years. They may remain hidden for weeks, long beyond the child's memory of placing the object, and eventually, they produce a secondary infection that leads to a foul discharge. In some cases of foreign body, the odor may be so strong that it appears to be generalized. Thus, a careful examination of the various orifices, with particular attention to the nares, is always advisable. The presence or absence of fever is another crucial variable in the evaluation of odor. Fever suggests an infectious cause, either systemic or localized. Pharyngitis and tonsillitis characteristically cause foul odor to the breath, much like a lung abscess. Occasionally, parents state that their child smells as if he or she had a "strep throat." Although

foreign bodies occasionally produce obstruction and a secondary infection of severity sufficient enough to evoke a febrile response, in most cases, the inflammation is localized and the child is afebrile.

In the absence of a known history or obvious findings of chronic systemic disease, a visible foreign body, known ingestion, or fever, the clinician should perform a careful physical examination and a urinalysis. Diabetic ketoacidosis always causes glucosuria and ketonuria, but hepatic or renal failure may be less obvious. In addition, inborn errors of metabolism may first manifest well beyond the newborn period. Foreign bodies may defy routine attempts at visualization and, based on a high index of suspicion, require endoscopy or imaging procedures. Therefore, persistence or an unusual odor or concern for chronic toxicity merits further laboratory evaluation. In cases in which an explanation of the odor is not uncovered, a follow-up evaluation in 2 to 3 days is prudent.

In patients who have died in the ED, a faint fecal odor is usually noted, possibly related to the release of intestinal contents to the atmosphere. Unique identifiable odors detected at the time of death or autopsy can direct laboratory evaluation toward possible causes of death.

CHAPTER 47 ■ OLIGOMENORRHEA

JAN E. PARADISE, MD

In this chapter, possible causes of oligomenorrhea and secondary amenorrhea are reviewed. *Oligomenorrhea* means infrequent menstruation and can be defined for the pediatric emergency physician as an interval of more than 6 weeks between two menstrual periods. If menstrual cycles do not resume within 3 to 6 months, the term *secondary amenorrhea* is applied. Some patients with anovulatory menstrual cycles have oligomenorrhea punctuated by episodes of excessive bleeding. An approach to the evaluation of abnormal vaginal bleeding is presented in Chapter 76.

Oligomenorrhea should be distinguished from hypomenorrhea, a nonpathologic pattern of light but regular menstrual periods. This chapter does not include a consideration of primary amenorrhea—that is, failure to menstruate by a specified age, often 16 years. However, some of the disorders discussed here can produce primary rather than secondary amenorrhea as part of an overall delay in pubertal development.

The differential diagnosis of oligomenorrhea is given in Table 47.1.

EVALUATION AND DECISION

Diagnosis of Pregnancy

"Is she pregnant?" is always the first question to answer in evaluating an adolescent with one or several missed menstrual periods (Fig. 47.1). If the patient is not pregnant, her evaluation can proceed at a more deliberate pace. If she is pregnant, however, prompt diagnosis and referral are important for the teenager who intends to seek a therapeutic abortion, as well as for the one who plans to continue her pregnancy. Early and regular prenatal care is associated with reduced morbidity and mortality among pregnant teenagers and their offspring. Early diagnosis also affords the pregnant adolescent more time to decide on and to arrange for a therapeutic abortion if that is her choice. As of 2009, before a minor can have an abortion, 35 states require consent by or notification of a parent (both parents in Minnesota, Mississippi, and North Dakota) or a hearing by a judge, and 25 states require counseling followed by a 24-hour waiting period. The time needed to comply with these requirements can push the procedure into the second trimester, resulting in higher morbidity and higher cost.

Early pregnancy is not always easy to recognize. Symptoms of fatigue, nausea, vomiting (not necessarily in the morning), urinary frequency, and breast growth or tenderness are common but by no means universal or specific. On pelvic examination, the first indications of pregnancy are softening of the lower uterine segment (Hegar's sign) and of the cervix (Goodell's sign) at 4 to 6 weeks after the last menstrual period. By 6 weeks' gestation, the uterus changes from pear-shaped to globular and by about 8 weeks, the vagina and cervix acquire a bluish hue (Chadwick's sign). These changes occur in ectopic as well as in intrauterine pregnancies. A serviceable rule is that the pregnant uterus grows to about the size of a tennis ball at 8 weeks after the last menstrual period, becomes baseball-sized at 10 weeks, and softball-sized at 12 weeks. When the uterus is retroflexed, its size is more difficult to assess and rectovaginal palpation should be done. After 12 weeks, the uterine fundus is palpable above the symphysis pubis on abdominal examination. Fetal movement can be discerned after about 16 weeks. The fundus reaches the level of the umbilicus at 20 weeks' gestation.

Some patients may report the result of a home pregnancy test. However, because of variability in patients' timing of ovulation and of blastocyst implantation, and because of variability in the test's sensitivity for detecting urinary human chorionic gonadotropin (hCG), home pregnancy test kits commonly give falsely negative results. False-positive results can also occur. Accordingly, the emergency physician should not rely on the reported result of a home pregnancy test to make or to exclude the diagnosis of pregnancy.

Qualitative urine and serum pregnancy tests performed in medical settings generally detect the β-subunit of hCG (β-hCG) at levels above 25 mIU per mL. Quantitative serum tests for β-hCG generally have a sensitivity of around 5 mIU per mL. These sensitivities will permit the detection of a normal pregnancy within about 10 days after conception and, in most but not all cases, by the time an expected menstrual period is missed. Ectopic pregnancies often produce abnormally low levels of β-hCG. The emergency physician should know the detection level of the quantitative and qualitative β-hCG tests used by his or her laboratory.

If a patient with one or several missed menstrual periods also complains of abdominal pain or abnormal vaginal bleeding, the diagnosis of *ectopic pregnancy* must be entertained. (The diagnosis of ectopic pregnancy is discussed at greater length in Chapter 76.) Ectopic pregnancies are less common among adolescents than among older women. Although more than half of women with ectopic pregnancy have no risk factors, prior chlamydial and gonococcal cervicitis and prior pelvic inflammatory disease all increase the likelihood that a subsequent pregnancy will be ectopic.

Pseudocyesis is a rare cause of amenorrhea in women who believe they are pregnant and who exhibit many presumptive symptoms and signs of pregnancy, including nausea, vomiting, hyperpigmented areolae, galactorrhea, and abdominal

distension. The diagnosis is made when a patient who insists that she is pregnant nevertheless has no true uterine enlargement, no demonstrable fetal parts or heart sounds, and a negative pregnancy test result. Psychiatric consultation should be obtained for such patients.

Evaluation of Nonpregnant Patients

If the physician can answer "no" to our original question—"Is she pregnant?"—the evaluation of an adolescent with

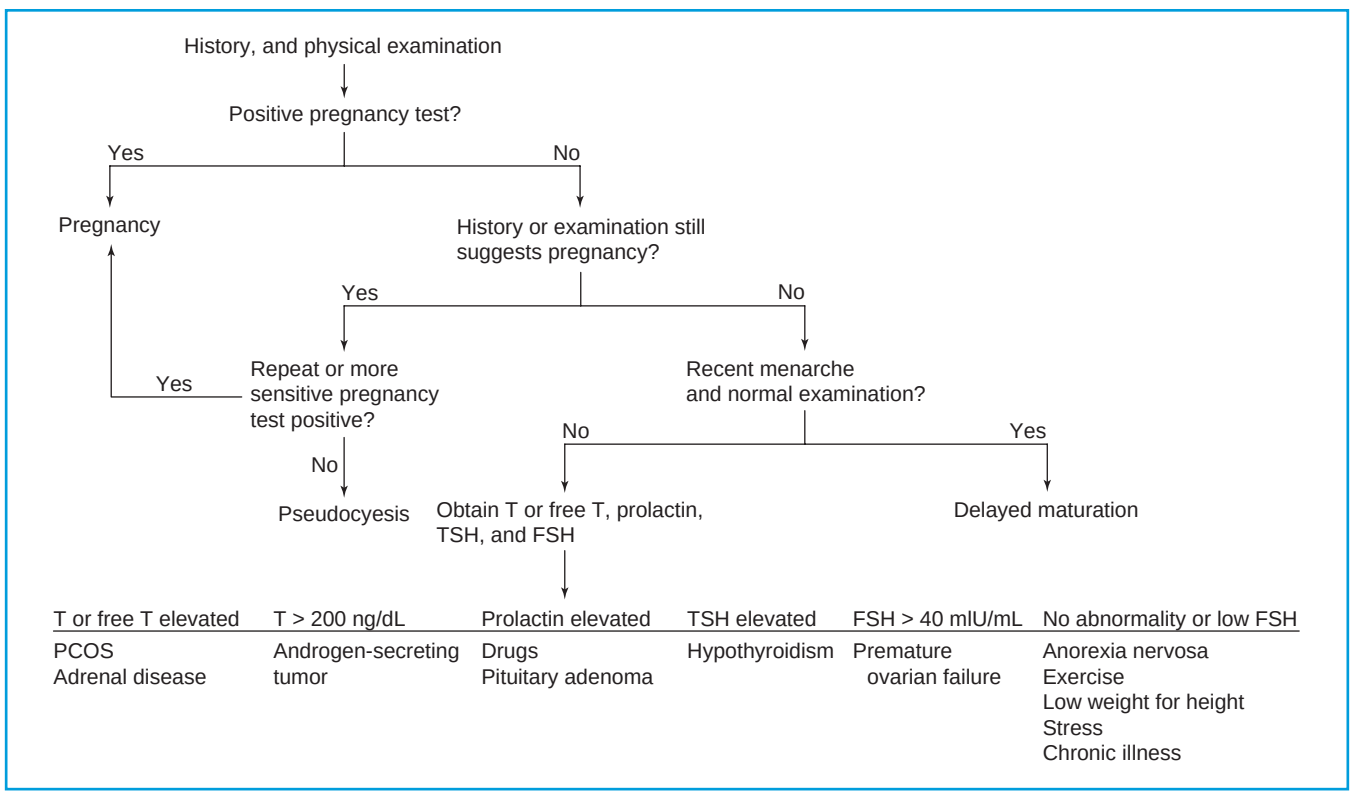

FIGURE 47.1 Strategy for initial diagnostic evaluation of the patient with oligomenorrhea. T, testosterone; TSH, thyroid-stimulating hormone; FSH, follicle-stimulating hormone; PCOS, polycystic ovary syndrome.

oligomenorrhea can proceed at a deliberate pace (Fig. 47.1). During the first 2 years after menarche, it is not unusual for girls to have an occasional menstrual cycle that lasts less than 25 days or more than 40 days. As a rule, if an adolescent complains of only one or two prolonged menstrual cycles, is fewer than 2 years past menarche, and is not sexually active, further investigation in the emergency department (ED) is not warranted. However, the ED physician should be aware that, among adolescents who report oligomenorrhea at baseline (defined as an average cycle length of 42 to 180 days), the prognosis for developing regular cycles is guarded. After 3 years of follow-up, more than half will continue to have abnormally long cycles.

Adolescents with oligomenorrhea that has persisted for longer than 2 years after menarche or that involves three or more cycles longer than 42 days during the past year are candidates for further diagnostic evaluation, although ordinarily this ought to be accomplished in an outpatient setting rather than in an ED. In the interview, historical details about the patient's menstrual pattern, growth, endocrine and central nervous systems, psychological status, and medications should be sought specifically. On physical examination, the patient's height and weight, skin, breasts, and pelvis should be checked. Because galactorrhea is not always spontaneous, the examiner should try to express fluid manually from the patient's breasts. The completed examination will separate the majority of patients who have no notable abnormalities from a minority with the important findings of hirsutism, obesity, galactorrhea, and marked thinness.

Hirsute or Obese Patients

Classically, hirsutism, obesity, ovarian enlargement, and amenorrhea or infertility constitute the clinical features of *polycystic ovary syndrome* (PCOS, previously the Stein-Leventhal syndrome). However, patients with PCOS are a heterogeneous group with varying combinations of these features. In one sample of women with polycystic ovaries diagnosed by ultrasound, 71% had oligoamenorrhea, 4% had menometrorrhagia, 61% were hirsute, and 35% were obese. Few adolescents with clinical and biochemical evidence of PCOS have palpably enlarged ovaries and their hyperandrogenism is typically mild. Table 47.2 provides the Androgen Excess Society's 2006 criteria for the diagnosis of PCOS.

The pathophysiologic basis for PCOS is incompletely understood. However, the principal endocrinologic abnormalities involved are chronic anovulation, ovarian hyperandrogenism, and, in many affected patients, insulin resistance. Perhaps as a result of a disturbance in the hypothalamic-pituitary-ovarian feedback system that may occur during puberty or even earlier, patients with PCOS have increases in both the amplitude and the frequency of luteinizing hormone (LH) pulses. In response to stimulation by LH, ovarian theca cells produce increased amounts of androstenedione and testosterone. The local excess of androgens inhibits the normal development of ovarian follicles. The tonic levels of ovarian estradiol, in turn, probably suppress the mid-cycle surge of follicle-stimulating hormone (FSH) needed for normal ovulation.

A substantial number of patients with PCOS have insulin resistance, and the proportion of women who do have it increases with age. This is independent of obesity: the insulin resistance in both lean and obese women with PCOS is disproportionately greater than in women of the same habitus who ovulate regularly. In synergy with LH, insulin promotes ovarian androgen production. Hyperinsulinemia also inhibits hepatic production of sex hormone–binding globulin (SHBG). The resulting higher proportion of testosterone unbound to SHBG in patients with PCOS can stimulate excessive hair growth, even in patients whose total serum testosterone level is normal or only minimally elevated. The conversion of androstenedione to estrone in adipose tissue and the reduced levels of SHBG also produce relatively high circulating levels of free estradiol. Persistent, rather than cyclical, levels of estrogen promote continuing secretion of LH and maintain the state of chronic anovulation.

The goals of treatment of adolescent patients with PCOS are to restore monthly menstrual cycles, to minimize hirsutism, to prevent the development of endometrial hyperplasia, and, it is hoped, to reduce the long-term risks of relative infertility, glucose intolerance, endometrial adenocarcinoma, and cardiovascular morbidity. Weight reduction can ameliorate the endocrinologic derangements and promote ovulation and regular menstruation in obese teens with PCOS, but few adolescents are able to achieve or to maintain substantial weight loss. The appropriate treatment of adolescents who do not desire pregnancy is a combined estrogen-progestin birth control pill to suppress ovarian or adrenal androgen production and to produce monthly menstrual bleeding. In adults, metformin has been used to treat PCOS because it increases peripheral tissue sensitivity to insulin. However, metformin often restores fertility (increasing the risk of unwanted pregnancy in adolescents). Studies to date of metformin use in adolescents have been limited by small numbers of subjects, lack of control groups, and short follow-up intervals.

TABLE 47.2

ANDROGEN EXCESS SOCIETY CRITERIA FOR THE DIAGNOSIS OF POLYCYSTIC OVARY SYNDROME (2006)

Diagnostic criteria	Comment
1. Hirsutism and/or hyperandrogenemia	Hirsutism present in about 60% of patients; elevated free or total testosterone or DHEAS in 60%–80% of patients
2. Oligoanovulation and/or polycystic ovaries	Oligoamenorrhea present in 70%–100% of patients; ovarian morphology (by transvaginal ultrasound) not required for diagnosis
3. Other potential disorders excluded	Especially nonclassic congenital adrenal hyperplasia and androgen-secreting tumors

DHEAS, dehydroepiandrosterone sulfate.
Adapted from Azziz R, Carmina E, Dewailly D, et al. Position Statement: criteria for defining polycystic ovary syndrome as a predominantly hyperandrogenic syndrome: an Androgen Excess Society guideline. *J Clin Endocrinol Metab* 2006;91:4237–4245.

Nonclassic *congenital adrenal hyperplasia* is a rare cause of oligomenorrhea associated with hyperandrogenism. It is usually indistinguishable clinically from PCOS and can be excluded by a normal 17-hydroxyprogesterone level in the morning during the follicular phase of the menstrual cycle. Other rare causes of oligomenorrhea, including *Cushing's disease* and *ovarian and adrenal tumors*, should be suspected in patients with hirsutism accompanied by signs of glucocorticoid excess, or with rapidly developing, more severe virilization (male-pattern baldness, deepening of the voice, clitoromegaly), and in those with testosterone levels above 200 ng per dL.

Galactorrhea

Hyperprolactinemia occurs in approximately 25% of adult women with secondary amenorrhea but is a much less common cause of oligomenorrhea in adolescents. Nevertheless, the possibility of hyperprolactinemia must be considered in all adolescents with oligomenorrhea because only 40% to 50% of hyperprolactinemic patients have spontaneous or expressible galactorrhea. The constellation of oligomenorrhea, galactorrhea, and hyperprolactinemia can be produced by many drugs (Table 47.3), especially antipsychotic agents; by the discontinuation of birth control pills; rarely by cutaneous or neurogenic stimulation of the breasts; and by excessive secretion of prolactin itself (e.g., primary hypothyroidism, pituitary adenoma). Drugs produce hyperprolactinemia by blocking pituitary dopamine receptors or interfering in other ways with dopaminergic or serotoninergic central nervous system pathways. Rarely, in hypothyroid patients, hypothalamic thyroid-releasing hormone acts as a prolactin-releasing factor, resulting in galactorrhea. Breastfeeding is an obvious physiologic cause of prolactin secretion and oligomenorrhea. The occasional patient with galactorrhea but with a normal prolactin level should be reevaluated periodically in an effort to identify a treatable cause of the problem.

Thin Patients

In patients who have eating disorders or malnutrition, and in those who participate in sports that emphasize thinness, recent research indicates that *caloric intake insufficient to meet energy expenditures* or an "energy drain" is probably the cause of oligomenorrhea. Leptin levels fluctuate in relation to body fat stores, are positively correlated with body mass index, and are lowered during fasting. The normal diurnal pattern of leptin concentration is absent in amenorrheic women. Hypothalamic neurons involved in controlling the gonadotropin-releasing hormone pulse generator have leptin receptors. Levels of the hormone ghrelin are elevated in amenorrheic women with either anorexia nervosa or high levels of exercise. Thus, leptin and possibly ghrelin appear to serve as signals to the hypothalamic-pituitary system concerning overall energy balance.

Accordingly, in assessing the nonpregnant adolescent with oligomenorrhea whose body mass index is low, one should inquire routinely about recent weight loss, chronic illness or other causes of negative energy balance, behavior characteristic of anorexia nervosa (Table 47.4), a restrictive eating pattern, and *strenuous exercise* (especially sports that put a premium on low body weight such as long-distance running, dance, and gymnastics). Many amenorrheic women who are athletes restrict their food intake; amenorrhea, eating disorders, and osteoporosis together are termed "the female athletic triad."

All Other Patients

Among adolescents who do not have hirsutism, obesity, galactorrhea, obesity, or excessive thinness, suppression of the hypothalamic-pituitary axis is the most common cause of oligomenorrhea that occurs more or persists for at least 2 years after menarche. Although oligomenorrhea in otherwise normal-appearing adolescents has historically been ascribed to psychosocial stressors (family disruption, moving, depression), many patients with apparently psychogenic menstrual irregularity prove on careful evaluation to have disordered eating patterns or nutritional deficits.

TABLE 47.3

PARTIAL LIST OF DRUGS THAT CAN CAUSE HYPERPROLACTINEMIA AND/OR GALACTORRHEA

1. *Antipsychotic and antidepressant agents*
   Phenothiazines [e.g., chlorpromazine (Thorazine), clomipramine (Anafranil), fluphenazine (Prolixin), prochlorperazine (Compazine), thioridazine (Mellaril)]
   Haloperidol (Haldol)
   Pimozide (Orap)
   Risperidone (Risperdal)
   Thiothixene (Navane)
2. *Drugs used to treat gastrointestinal disorders*
   Cimetidine (Tagamet)
   Metoclopramide (Reglan)
3. *Antihypertensive Agents*
   Methyldopa (Aldomet)
   Reserpine (Hydromox, Serpasil, others)
   Verapamil (Calan, Isoptin)
4. *Opiates*
   Codeine
   Morphine

TABLE 47.4

DSM-IV-TR CRITERIA FOR THE DIAGNOSIS OF ANOREXIA NERVOSA

1. Refusal to maintain body weight at or above a minimally normal weight for age and height (i.e., weight loss or failure to gain weight leading to body weight <85% of that expected for age and height).
2. Intense fear of gaining weight or becoming fat, even though underweight.
3. Disturbed experience of one's body weight or shape, undue influence of weight or shape on self-evaluation, or denial of the seriousness of the current low body weight.
4. In postmenarcheal females, amenorrhea (i.e., absence of at least three or more consecutive anticipated cycles). Menstruation induced by hormonal treatment is excluded.

Adapted from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision*. Washington, DC: American Psychiatric Association, 2000.

Other diagnostic possibilities for oligomenorrheic patients with no abnormal physical findings include a wide variety of conditions. About half of women using contraceptive *medroxyprogesterone* injections for 12 months have amenorrhea; after 2 years of use, the proportion with amenorrhea is 68%. Amenorrhea also occurs in about 2% of menstrual cycles among patients taking *birth control pills* that contain 50 μg or less of estrogen. However, amenorrhea persisting 12 months after the last injection of medroxyprogesterone or 6 months after birth control pills have been stopped should be evaluated in the standard fashion.

Hypothyroidism and *hyperthyroidism* can both produce menstrual irregularities. Although hypothyroidism has classically been associated with metrorrhagia, recent data indicate that oligomenorrhea is more common than metrorrhagia among women with hypothyroidism.

Many patients with hyperprolactinemia and oligomenorrhea do not have concomitant galactorrhea that would otherwise prompt a medical investigation. Similarly, although hirsutism and obesity are classic features of PCOS, many adolescent patients with oligomenorrhea and the endocrinologic abnormalities of PCOS lack one or both of these signs. A history of hot flashes, antineoplastic chemotherapy, pelvic irradiation, or autoimmune disease suggests the diagnosis of *premature ovarian failure*. *Endometrial destruction* that results from overly vigorous curettage or pelvic tuberculosis is an exceedingly rare cause of oligomenorrhea.

Approach to Diagnosis

Patients with oligomenorrhea but few other symptoms or signs of disease require laboratory evaluation to differentiate among the many potential causes of oligomenorrhea after pregnancy has been excluded. Figure 47.1 outlines a strategy for initial diagnostic evaluation. Determinations of serum levels of FSH, testosterone (T), and/or free testosterone (free T), prolactin, and thyroid-stimulating hormone (TSH) are needed either to corroborate the suspected diagnosis or to categorize the patient whose history and physical examination have provided few diagnostic clues. Other laboratory tests should be performed as warranted by the clinical situation. The finding of a mildly elevated total or free T level constitutes strong evidence for a diagnosis of PCOS. A testosterone level of more than 200 ng per dL suggests an ovarian or adrenal tumor. An elevated prolactin level indicates a pituitary microadenoma in patients who are not taking any of the drugs known to cause hyperprolactinemia and galactorrhea (Table 47.3). An elevated TSH level points to hypothyroidism either as the cause of oligomenorrhea or as a concomitant condition. FSH values of more than 40 mIU per mL confirm ovarian failure as the source of difficulty. If the laboratory evaluation discloses no abnormalities or only a low FSH level, the patient probably has one of the many conditions that cause hypothalamic-pituitary suppression. For definitive diagnosis, which may require additional laboratory testing, and for ongoing clinical management, all patients with oligomenorrhea should be referred to their primary care providers.

The administration of exogenous progestin is often advocated as an in vivo test of ovarian and endometrial function for oligomenorrheic patients. If the hypothalamic-pituitary axis is producing some gonadotropin, the ovaries are responding with some estradiol production, and the uterine endometrium is growing appropriately, then the addition of exogenous progestin (medroxyprogesterone acetate 10 mg per day for 7 days) will be followed by at least scanty menstrual bleeding within 7 days after the treatment is completed. This "withdrawal" flow, if it appears, provides the patient and her physician with tangible evidence of the basic integrity of these organs and indicates that anovulation is the source of the amenorrhea. For diagnosis in adolescents, however, laboratory investigation is much preferable to progestin administration. Nearly all nonpregnant adolescents with oligomenorrhea do have anovulation and will have a withdrawal bleed. Interposing this step merely postpones the laboratory evaluation that the clinician must still conduct to arrive at a diagnosis and to select an appropriate treatment.

CHAPTER 48 ■ ORAL LESIONS

MARK G. ROBACK, MD

Children of all ages, from birth forward, experience oral lesions, which may represent a wide range of illnesses. Oral lesions may be associated with benign conditions that completely resolve without intervention or may be representative of life-threatening diseases. The differential diagnosis includes a large number of localized congenital and acquired causes; however, lesions associated with systemic disease must also be considered (Fig. 48.1 and Table 48.1). Most often, patients with isolated complaints (e.g., a mouth sore or mass, drooling, pain, fever) represent common, self-limited conditions (Table 48.2). However, a complete history and physical examination is essential for all patients with oral lesions to rule out systemic and potentially life-threatening diseases (Table 48.3) that may present initially with only isolated mouth findings.

PATHOPHYSIOLOGY

Oral lesions may result from localized or systemic pathophysiologic processes. Localized causes include congenital masses and cysts, infectious diseases, and oral tumors. Systemic illnesses with prominent oral involvement include a number of infectious and other inflammatory or toxin-mediated conditions. Given the broad spectrum of illnesses presenting with oral lesions, it is convenient to discuss individual causes under specific headings within the differential diagnosis. Several conditions with typical oral lesions exist that do not comfortably fit under any of these headings and are discussed in the section on miscellaneous oral lesions.

DIFFERENTIAL DIAGNOSIS

Congenital Oral Lesions

Most oral lesions present at birth or early infancy represent benign findings. Patients are largely asymptomatic, and the lesions resolve spontaneously.

Epstein's pearls occur in more than 60% of newborns as small, white milia in the midline of the hard palate. These epithelial inclusion cysts are often found in clusters and resolve over the first few months of life. Epithelial pearls are similar to Epstein's pearls and appear as shiny, small, white, self-limited lesions that occur on the gums.

Bohn's nodules are also self-limited cysts that appear on the mandibular or maxillary dental ridges. Dental lamina cysts occur on the alveolar ridge of newborns and represent trapped remnants of the dental lamina.

Natal teeth are the premature eruption of primary teeth and are found at birth (natal) or within the first month of life (neonatal). These teeth are either supernumerary or true deciduous teeth and are usually found in the lower incisor region. Natal teeth may lead to ulcerations of the underside of the tongue, called Riga-Fede disease.

Patients with ankyloglossia may be referred to as "tongue tied" because of congenital shortening of the lingual frenum, which limits their ability to fully extend the tongue. Surgical correction is considered for patients when speech is affected.

Epulis is a congenital, fibrous, sarcomatous tumor that arises from the periosteum of the mandible or maxilla. The mass is firm and pedunculated and may regress spontaneously. Excision is required if the epulis interferes with feeding or breathing, or for cosmetic reasons.

Lymphangioma is a benign congenital tumor of lymphatic vessels appearing on the tongue, lips, or buccal mucosa at birth or in early infancy. Hemangiomas are benign vascular malformations present at birth that may become more apparent as the patient grows. Oral hemangiomas are typically accompanied by vascular lesions elsewhere in the body, especially on the skin.

Infectious Oral Lesions

Infectious oral lesions are typically manifestations of viral infections but may be caused by bacterial or fungal infections as well (see Chapter 92).

Candidiasis, or thrush, is white plaque on the buccal mucosa, gingivae, and palate that will not "rub off" with a tongue blade. Caused by *Candida albicans*, thrush is common in neonates and infants. When thrush occurs after infancy, the immune status of the patient must be considered. Oral candidiasis most commonly occurs in patients infected with human immunodeficiency virus (HIV).

The typical lesions of herpes simplex virus (HSV) are groups of vesicles on an erythematous base that may become unroofed and appear as erosions in and around the mouth. Infections may be primary or recurrent. Herpes gingivostomatitis, most commonly caused by HSV type 1 (HSV-1), represents primary infection that typically occurs in young children and infants. These patients have pain, fever, and drooling. Herpes labialis manifests as recurrent painful lesions that occur on the lips, most often the lower lip. Herpes labialis, or "cold sores," may be accompanied by an acute febrile illness, extensive sun exposure, or stress.

Hand-foot-mouth disease is characterized by discrete shallow erosions in the mouth, especially on the soft palate, accompanied by erythematous papulovesicular lesions on the hands and feet. High fever may be associated with this enteroviral,

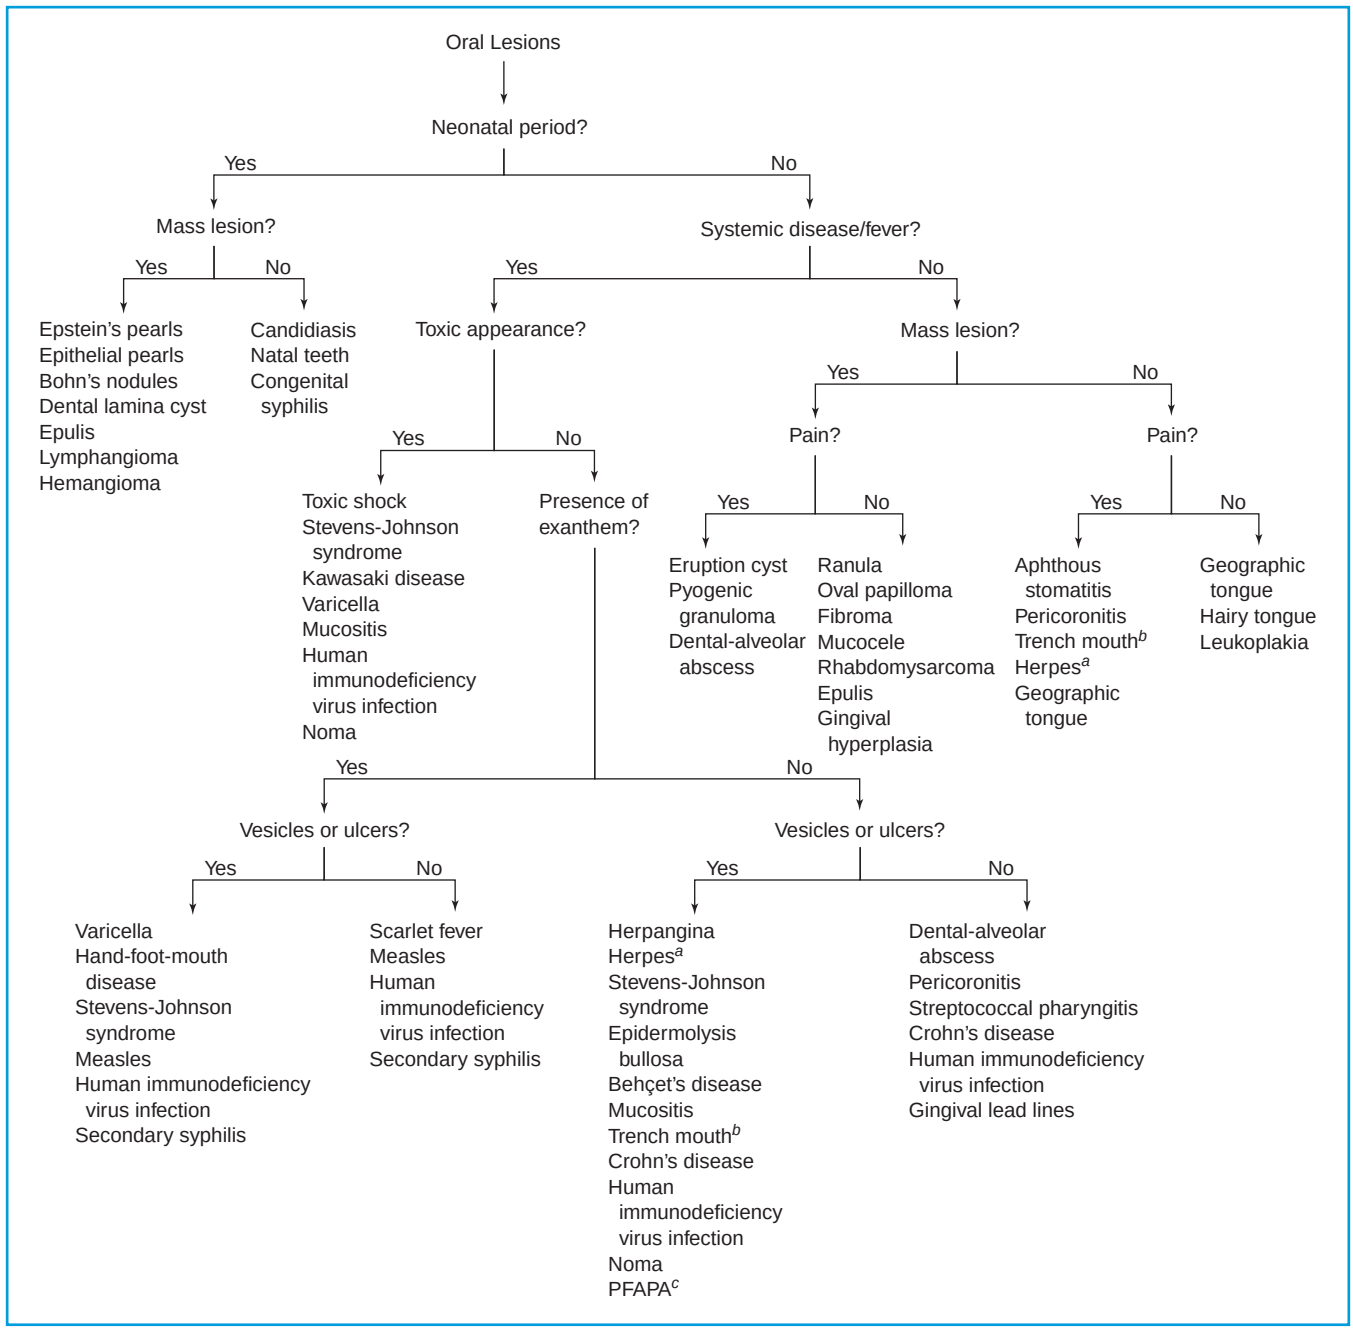

FIGURE 48.1 Oral lesions. [a]Herpes gingivostomatitis or labialis. [b]Trench mouth, acute necrotizing ulcerative gingivitis. [c]PFAPA, *p*eriodic *f*ever, *a*phthous stomatitis, *p*haryngitis, and cervical *a*denitis syndrome.

typically coxsackievirus, mediated disease that is self-limited in nature. Supportive treatment, specifically antipyretics/analgesics and adequate oral hydration, is usually sufficient therapy.

Herpangina is also a group A coxsackievirus infection that is characterized by vesicles or ulcers on the pharynx of patients with fever, muscle aches, and malaise. Similar to hand-foot-mouth disease, the treatment of herpangina is largely supportive in nature.

The characteristic "strawberry tongue" seen in streptococcal scarlet fever is the result of hypertrophic red papillae on a thick white coat. Palatal petechiae are often present, as is the typical "sandpaper" papular rash on an erythematous base that blanches on palpation, involving the trunk and back. Streptococcal pharyngitis without exanthem often presents with strawberry tongue and palatal petechiae.

Koplik's spots—pinpoint white macules on markedly erythematous mucous membranes—occur during the prodrome

TABLE 48.1

DIFFERENTIAL DIAGNOSIS OF ORAL LESIONS

Congenital oral lesions
Epstein's pearls
Epithelial pearls
Bohn's nodules
Dental lamina cysts
Natal teeth
Ankyloglossia
Epulis (gum boil)
Lymphangioma
Hemangioma

Infectious oral lesions
Candidiasis
Herpes simplex
  Gingivostomatitis—primary
  Labialis—recurrent (cold sores)
Hand-foot-mouth disease
Herpangina
Scarlet fever
Streptococcal pharyngitis
Measles
Varicella
Human immunodeficiency virus infection
Dental-alveolar abscess
Pericoronitis
Acute necrotizing ulcerative gingivitis (trench mouth)
Noma
Syphilis
  Acquired (secondary)
  Congenital
Hairy tongue

Tumorous oral lesions
Eruption cyst
Oral papilloma
Fibroma
Mucocele
Ranula
Pyogenic granuloma
Rhabdomyosarcoma

Oral lesions associated with systemic disease
Stevens-Johnson syndrome
Toxic shock syndrome
Mucositis
Kawasaki disease
Crohn's disease
Behçet's syndrome
Epidermolysis bullosa
Gingival lead lines

Miscellaneous oral lesions
Aphthous stomatitis
Geographic tongue
Gingival hyperplasia
Leukoplakia

PFAPA, periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis.

TABLE 48.2

COMMON CAUSES OF ORAL LESIONS

Candidiasis
Aphthous stomatitis
Herpes simplex
  Gingivostomatitis—primary
  Labialis—recurrent
Hand-foot-mouth disease
Herpangina

of measles, which includes cough, coryza, conjunctivitis, and fever. By the time the characteristic rash occurs, Koplik's spots have typically resolved.

Varicella lesions occurring in the mouth result in painful vesicles, which may become unroofed, on an erythematous base. Patients may be reluctant to swallow because of pain. Unless secondary bacterial infection occurs, these lesions are self-limited.

Oral lesions will be the initial presenting sign in approximately half of children with perinatally acquired HIV infection. Oral candidiasis, parotid enlargement, herpes simplex, hairy leukoplakia, aphthous ulcers, and necrotizing ulcerative gingivitis occur commonly in children infected with HIV. Blue, purple, or red macules, papules, or nodules on the palate suggest oral Kaposi's sarcoma, whereas diffuse swelling, discrete nodules, or ulcers of any oral mucosal surface may indicate non–Hodgkin's lymphoma. The prevalence of oral lesions appears to decrease with highly active antiviral therapy and increase in children with low CD4 percentage and may signal advancing disease.

The pain, erythema, and swelling of the gingiva seen with dental-alveolar abscesses may be associated with fever and loosening or extrusion of the associated tooth. Significant lymphadenopathy and facial cellulitis may develop. Causative organisms are streptococci and anaerobes. Antibiotic therapy with penicillin is secondary in importance to drainage of the abscess.

Pericoronitis is the local infection of the gingiva surrounding an erupting tooth. Although penicillin therapy may be required, good oral hygiene is essential. Lymphadenopathy and facial swelling may accompany pericoronitis.

Acute necrotizing ulcerative gingivitis (ANUG), also called trench mouth or Vincent's angina, is a spirochetal infection of the gingiva that occurs in adolescents. Patients report tender, bleeding gums and breath that has a fetid odor. Gums are hyperemic and appear "punched out" secondary

TABLE 48.3

LIFE-THREATENING CAUSES OF ORAL LESIONS

Stevens-Johnson syndrome
Kawasaki disease
Toxic shock syndrome
Human immunodeficiency virus infection
Noma

to tissue loss between the teeth. Treatment involves attention to oral hygiene, mouth rinses with a dilute hydrogen peroxide solution, oral penicillin, and debridement of necrotic tissue.

Noma, or cancrum oris, is a potentially fatal, gangrenous anaerobic infection of the oral cavity that may rapidly spread outward to involve large areas of the face. It typically begins as an oral mucosal ulcer or as ANUG, particularly after a bout of measles or other intercurrent illness in malnourished or immunocompromised patients. Currently, it is being recognized increasingly in HIV-infected and/or otherwise malnourished children in sub-Saharan Africa.

Although infection is present at birth, the oral lesions of congenital syphilis may not become obvious until several months of age. Erythematous papules are seen in the mouth and other mucocutaneous sites. *Hutchinson's teeth*, peg-shaped, superior, central incisors, are not present until later in life. The secondary stage of acquired syphilis is characterized by patches of ulcers or raised lesions in the mouth and is seen in association with generalized rash, fever, malaise, and adenopathy.

Patients receiving long-term antibiotic therapy may develop elongation of filiform papillae of the dorsum of the tongue and a "hairy" appearance from fungal overgrowth called hairy tongue. Hairy leukoplakia of the lateral aspects of the tongue is found in HIV-infected patients in association with intraepithelial proliferation of Epstein-Barr virus infection.

Tumorous Oral Lesions

The vast majority of tumorous oral lesions in children are self-limited and benign in nature. Congenital oral tumors such as hemangioma, lymphangioma, and epulis have been considered previously.

Eruption cysts are associated with the eruption of teeth, appear on the alveolar ridge, and may contain blood.

Oral papillomas are fingerlike extensions from the epithelium of the tongue, gums, lips, or buccal mucosa. They are typically benign, although a small percentage of papillomas may become malignant.

A fibroma is a benign, smooth mass with a sessile base that frequently develops secondary to soft-tissue injury from minor trauma. The tongue, lips, buccal mucosa, and palate are common sites for the development of fibromas.

Mucoceles are soft, well-demarcated masses that arise secondary to obstruction of salivary glands. Patients are generally otherwise asymptomatic; however, excision or marsupialization is typically required.

Ranula is a retention cyst or mucocele of the submaxillary or sublingual duct. Ranulas are typically seen on the underside of the tongue or on either side of the frenulum on the floor of the mouth. Initial management of pediatric oral cavity ranulas consists of observation for spontaneous resolution. If the lesion does not resolve or recurs repeatedly, surgical treatment is recommended.

Pyogenic granuloma represents granulation tissue that develops in response to an irritant such as a trauma or a foreign body. Most commonly found on the gingiva, pyogenic granulomas are also found on the tongue, lips, and buccal mucosa. Treatment involves incision and drainage. Recurrence is common, especially when a foreign body is present.

Although 35% to 40% of cases will present in the head and neck region, rhabdomyosarcoma is a rare malignant tumor of the oral cavity. These lesions are ulcerative in nature, characterized by rapid growth, and may present with bleeding. Associated signs and symptoms are usually attributed to the mass lesion or obstructive sequelae. Other malignant oral tumors such as fibrosarcoma, carcinoma of the parotid, and osteosarcoma occur but are even more rare than rhabdomyosarcoma.

Oral Lesions Associated with Systemic Disease

Stevens-Johnson syndrome, a severe form of erythema multiforme, consists of an inflammatory process that typically involves mucous membranes in addition to the skin. Oral lesions are erythematous plaques on the mucosa of the oral cavity and lips that develop into vesicles or bullae and may become hemorrhagic. This potentially life-threatening disorder is believed to be secondary to a drug reaction or to follow infections.

Toxic shock syndrome may manifest erythema of the oropharynx and a strawberry tongue in patients with a diffuse erythematous macular exanthem, hyperemic mucous membranes, fever, and signs of shock. This toxin-mediated disease is caused by *Staphylococcus aureus* and may be associated with tampon use or nasal carriage of this organism. Toxin-mediated disease associated with streptococci also presents with diffuse erythema of the skin and oropharynx and may progress to septic shock.

Mucositis presents as ulcers, exudate, and pseudomembranes on the gingivae and buccal mucosa of patients, with neutropenia often secondary to chemotherapy. Lesions are extremely painful, and the breath becomes fetid.

Kawasaki disease is a potentially life-threatening disorder that typically presents with an array of findings, including prolonged fever, rash, lymphadenopathy, nonpurulent conjunctivitis, and edema of the hands and feet. Oral changes of Kawasaki disease include red, dry, cracked lips, erythematous oropharynx, and strawberry tongue. Therapy is directed toward the prevention of coronary aneurysm development.

The inflammatory lesions of Crohn's disease may occur in any portion of the gastrointestinal tract. Oral lesions, seen most often in adolescents and young adults, consist of ulcers, polypoid papulous hyperplastic mucosa, and edema found on the lips, gingiva, vestibular sulci, and buccal mucosa. Immunosuppressive therapy with steroids and azathioprine has yielded mixed results.

Chronic, recurrent ulcers surrounded by erythema and gray exudate are found anywhere in the oral cavity in patients with Behçet's syndrome. Similar lesions occur on the skin, and the genitourinary tract may also be involved. Behçet's syndrome is rare, affecting older children and adolescents, usually boys.

More than 15 types of hereditary epidermolysis bullosa have been described. This rare, vesiculobullous condition

affects mucous membranes and teeth, as well as the skin. Scarring may lead to restriction of mouth opening.

Bluish purple "lead lines" on the gingivae have been described, primarily in adults, with chronic lead toxicity and poor oral hygiene.

Miscellaneous Oral Lesions

Aphthous stomatitis is the ulceration of the oral epidermis of unknown cause. These recurrent lesions typically present as 5- to 10-mm ulcerations with a rim of erythema on the buccal mucosa, lips, and lateral aspect of the tongue. The lesions are painful, but patients do not experience fever. The lesions resolve spontaneously after 7 to 10 days.

Less commonly, aphthous stomatitis also occurs with a constellation of symptoms seen in the syndrome of PFAPA (*p*eriodic *f*ever, *a*phthous stomatitis, *p*haryngitis, and cervical *a*denitis). Children, usually between 2 and 6 years of age, experience the acute onset of periodic fever with temperature more than 39°C, which usually lasts 4 or 5 days in association with aphthous stomatitis, pharyngitis, and cervical adenitis. The fevers and associated symptoms recur every 2 to 8 weeks. Although the episodes resolve spontaneously, the use of glucocorticoids has been reported to be effective in arresting the symptoms of PFAPA. Affected children grow normally without associated disease or long-term sequelae. Tonsillectomy has been reported to prevent recurrence. There is no known etiology of PFAPA.

Geographic tongue represents a benign inflammatory disorder that results in migratory smooth annular patches on the tongue. Although typically asymptomatic, patients may complain of pain. Geographic tongue is typically seen in children younger than 4 years. No treatment is required.

Gingival hyperplasia seen in patients receiving long-term anticonvulsant therapy with phenytoin is irreversible. However, gingival overgrowth that occurs in association with the medications cyclosporine and nifedipine is reversible with discontinuation of the drugs. Poor dental hygiene appears to play a role in the cause. The gingivae undergo fibrous enlargement but are not inflamed or painful. Gingival fibromatosis is an inherited form of gingival hyperplasia.

Leukoplakia of the oral mucosa develops secondary to long-term smokeless tobacco use. These painless, leathery, white patches or plaques occur in areas of greatest tobacco exposure, typically on the mucosa of the buccal sulcus. Significant exposure to tobacco may result in dysplasia or carcinoma.

EVALUATION AND DECISION

When evaluating patients with complaints of oral lesions, it is important to consider a myriad of associated signs and symptoms while taking a complete history and performing the physical examination. The patient's age, general health and appearance, presence of an exanthem or fever, and whether the lesions are painful must be considered. Once the lesions are identified, they should be further characterized by color, type, and location and considered in the context of any additional physical findings.

Neonates with oral lesions can be divided into two groups on the basis of the morphology of the lesions. Discrete masses usually represent congenital disorders, most of which are self-limited. Candidiasis, which involves the oral cavity more diffusely, is also common.

Among older children, toxic-appearing patients require immediate evaluation for potentially life-threatening disease. Patients with conditions listed in Table 48.3 have associated findings such as diffuse cutaneous rash, hyperemia of other mucous membranes, or poor perfusion indicative of shock. However, Stevens-Johnson syndrome may cause isolated oral lesions initially and then rapidly progress to systemic involvement.

Once life-threatening causes have been considered, careful history and physical examination may lead to the diagnosis of other systemic diseases. Weight loss, abdominal pain, and diarrhea with or without blood loss suggest Crohn's disease, whereas genital ulceration in an adolescent boy points to Behçet's syndrome or secondary syphilis.

The presence of rash and fever makes disorders of infectious etiology more likely. Measles, varicella, scarlet fever, and hand-foot-mouth disease are generally diagnosed by history and physical examination alone. Laboratory evaluation might include a throat culture for streptococci and serologic testing for measles or HIV when these infections are suspected.

Infectious causes of oral lesions without exanthem may display obvious findings such as cachexia and alopecia in the neutropenic patient with mucositis, or they may be relatively localized to the oropharynx as in herpangina, herpes gingivostomatitis or labialis, and dental infections, which may or may not cause fever and lymphadenopathy.

Oral lesions without overt signs of systemic disease are mostly congenital or tumorous in nature. Lesions found in the newborn and during infancy are largely self-limited and most will resolve spontaneously. A few, including lymphangioma, hemangioma, and congenital epulis, may require intervention.

Children and adolescents experience an array of oral lesions not associated with obvious signs of systemic disease that are typically further delineated by considering the type of lesion (i.e., mass, vesicle, ulcer) and whether they are painful. Most of these processes require little or no therapy. Rhabdomyosarcoma is an obvious exception to this observation.

CHAPTER 49 ■ PAIN—ABDOMEN

MARK I. NEUMAN, MD, MPH

Abdominal pain is a common complaint of children who seek care in the emergency department (ED). Although most children with acute abdominal pain have self-limiting conditions, the pain may herald a serious medical or surgical emergency. The diverse etiologies include acute surgical diseases (e.g., appendicitis, intussusception, strangulated hernia, trauma to solid or hollow organ), intraabdominal medical ailments [e.g., gastroenteritis, urinary tract infection (UTI), gastric ulcer disease, gastroesophageal reflux disease], extraabdominal conditions (e.g., pneumonia, pharyngitis, contusions of the abdominal musculature or soft tissue), systemic illnesses (e.g., "viral syndrome," leukemia, diabetic ketoacidosis, vasoocclusive crisis from sickle cell anemia), and, commonly, functional abdominal pain. Making a timely diagnosis of an acute abdomen, such as appendicitis or volvulus, early enough to reduce the rate of complications, particularly in infants and young children, often proves challenging.

PATHOPHYSIOLOGY

Abdominal pain can be stimulated by at least three neural pathways: visceral, somatic, and referred. Visceral pain generally is a dull, aching sensation primarily in the midabdominal, epigastric, or lower abdominal regions. Distension of a viscus stimulates nerves locally, initiating an impulse that travels through autonomic afferent fibers to the spinal tract and central nervous system. The nerve fibers from different abdominal organs overlap and are bilateral, accounting for the lack of specificity to the discomfort. Children perceive the sensation of visceral pain generally in one of three areas: the epigastric, periumbilical, or suprapubic region. Somatic pain usually is well localized and intense (often sharp) in character. It is carried by somatic nerves in the parietal peritoneum, muscle, or skin unilaterally to the spinal cord level from T6 to L1. An intraabdominal process will manifest somatic pain if the affected viscus introduces an inflammatory process that touches the innervated organ. Referred pain is felt at a location distant from the diseased organ and can be either a sharp, localized sensation or a vague ache. Afferent nerves from different sites, such as the parietal pleura of the lung and the abdominal wall, share pathways centrally. All three types of pain may be modified by the child's level of tolerance. Multiple psychogenic and environmental factors augment or inhibit the "sensation" to varying degrees in different persons. Individual variation exists such that some children with an appendiceal abscess will appear to have minimal pain, whereas other children with a functional etiology of their abdominal pain will appear quite distressed.

A number of illnesses cannot be readily explained neurophysiologically as the triggers of abdominal pain, including conditions such as tonsillitis with high fever, viral syndromes, and streptococcal pharyngitis. However, diagnostic tools such as ultrasound may support that the presence of mesenteric lymphadenitis explains such pain in some cases. Other systemic or local conditions may present with abdominal pain as a primary manifestation. Despite the appearance of localized abdominal pain, clinicians need to perform a thorough physical examination that should include the assessment of the oropharynx, lung, skin, and genitourinary system. The principal causes of abdominal pain in children and adolescents are summarized in Table 49.1. Table 49.2 highlights those disorders that are life threatening.

DIFFERENTIAL DIAGNOSIS

Intraabdominal injuries can be life threatening (such as hemorrhage from solid organ laceration or fluid loss and infection from perforated hollow viscus) and rarely may occur after minor trauma. An accurate history may not always be provided and, thus, clinicians must specifically inquire about a history of trauma in a child presenting with acute abdominal pain. Typical mechanisms include motor vehicle crashes, falls, and child abuse.

Bowel obstruction may occur as a result of adhesions in a child with previous abdominal surgery. Malrotation with volvulus, and necrotizing enterocolitis, should be considered in neonates with bilious emesis. Intussusception (invagination of a part of the intestine into itself, causing obstruction) usually occurs among children 2 months to 2 years of age. Colicky abdominal pain is a typical feature of intussusception. The presence of blood in the stool, or "currant jelly stool," is a relatively late finding among children with intussusception.

Among children of all ages, appendicitis can cause peritoneal irritation and focal tenderness. It occurs most commonly in children older than 5 years. The classic history of diffuse abdominal pain that later migrates to the right lower abdomen is not always elicited. The diagnosis of appendicitis in younger children can be more difficult and is often made later in the course of disease; as such, the rate of perforation in younger children in high. Primary bacterial peritonitis (usually as a complication of nephrotic syndrome) is an uncommon cause of abdominal pain among children.

Common conditions that are associated with acute abdominal pain include viral gastroenteritis, systemic viral illness, streptococcal pharyngitis, lobar pneumonia, and UTIs. Frequent causes of chronic or recurrent abdominal pain include colic (among neonates) and constipation. Other gastrointestinal (GI) conditions that may present with abdominal pain include

TABLE 49.1

CAUSES OF ACUTE ABDOMINAL PAIN

<2 yr	2–5 yr	6–12 yr	>12 yr
Common			
Colic (age <3 mo)	Acute gastroenteritis	Acute gastroenteritis	Acute gastroenteritis
GERD	UTI	Trauma	Gastritis
	Trauma		
Acute gastroenteritis	Appendicitis	Appendicitis	Colitis
"Viral syndromes"	Pneumonia, asthma	UTI	GERD
	Sickling syndromes	Functional abdominal pain	Trauma
	"Viral syndromes"	Sickling syndromes	Constipation
	Constipation	Constipation	Appendicitis
		"Viral syndromes"	Pelvic inflammatory disease
			UTI
			Pneumonia, asthma
			"Viral syndromes"
			Dysmenorrhea
			Epididymitis
			Lactose intolerance
			Sickling syndromes
			Mittelschmerz
Less common			
Trauma (possible child abuse)	Meckel's diverticulum	Pneumonia, asthma, cystic fibrosis	Ectopic pregnancy
Intussusception	Henoch-Schönlein purpura	Inflammatory bowel disease	Testicular torsion
		Peptic ulcer disease	Ovarian torsion
Incarcerated hernia	Toxin	Cholecystitis, pancreatic disease	Renal calculi
Sickling syndromes	Cystic fibrosis	Diabetes mellitus	Peptic ulcer disease
Milk protein allergy	Intussusception	Collagen vascular disease	Hepatitis
	Nephrotic syndrome	Testicular torsion	Cholecystitis or pancreatic disease
			Meconium ileus (cystic fibrosis)
			Collagen vascular disease
			Inflammatory bowel disease
			Toxin
Very uncommon or rare			
Appendicitis	Incarcerated hernia	Rheumatic fever	Rheumatic fever
Volvulus	Neoplasm	Toxin	Tumor
Tumors (e.g., Wilms' tumor)	Hemolytic uremic syndrome	Renal calculi	Abdominal abscess
Toxin (heavy metal—Pb)	Rheumatic fever, myocarditis, pericarditis	Tumor	
Malabsorptive syndromes	Hepatitis	Ovarian torsion	
	Inflammatory bowel disease	Meconium ileus (cystic fibrosis)	
	Choledochal cyst	Intussusception	
	Hemolytic anemia		
	Diabetes mellitus		
	Porphyria		

GERD, gastroesophageal reflux disease; UTI, urinary tract infection.
